Absolute Penalty Estimation

Ejaz S. Ahmed[1], Enayetur Raheem[2], Shakhawat Hossain[2]
[1]Professor and Department Head of Mathematics and Statistics
University of Windsor, Windsor, ON, Canada
[2]University of Windsor, Windsor, ON, Canada

In statistics, the technique of ▶least squares is used for estimating the unknown parameters in a linear regression model (see ▶Linear Regression Models). This method minimizes the sum of squared distances between the observed responses in a set of data, and the fitted responses from the regression model. Suppose we observe a collection of data $\{y_i, \boldsymbol{x}_i\}_{i=1}^n$ on n units, where y_is are responses and $\boldsymbol{x}_i = (x_{i1}, x_{i2}, \ldots, x_{ip})^T$ is a vector of predictors. It is convenient to write the model in matrix notation, as,

$$\boldsymbol{y} = \boldsymbol{X}\boldsymbol{\beta} + \varepsilon, \tag{1}$$

where $\boldsymbol{y}$ is $n \times 1$ vector of responses, $\boldsymbol{X}$ is $n \times p$ matrix, known as the design matrix, $\boldsymbol{\beta} = (\beta_1, \beta_2, \ldots, \beta_p)^T$ is the unknown parameter vector and ε is the vector of random errors. In ordinary least squares (OLS) regression, we estimate $\boldsymbol{\beta}$ by minimizing the residual sum of squares, $RSS = (\boldsymbol{y} - \boldsymbol{X}\boldsymbol{\beta})^T(\boldsymbol{y} - \boldsymbol{X}\boldsymbol{\beta})$, giving $\hat{\boldsymbol{\beta}}_{\text{OLS}} = (\boldsymbol{X}^T\boldsymbol{X})^{-1}\boldsymbol{X}^T\boldsymbol{y}$. This estimator is simple and has some good statistical properties. However, the estimator suffers from lack of uniqueness if the design matrix $\boldsymbol{X}$ is less than full rank, and if the columns of $\boldsymbol{X}$ are (nearly) collinear. To achieve better prediction and to alleviate ill conditioning problem of $\boldsymbol{X}^T\boldsymbol{X}$, Hoerl and Kernard (1970) introduced ridge regression (see ▶Ridge and Surrogate Ridge Regressions), which minimizes the RSS subject to a constraint, $\sum \beta_j^2 \le t$, in other words

$$\hat{\boldsymbol{\beta}}^{\text{ridge}} = \underset{\boldsymbol{\beta}}{\text{argmin}} \left\{ \sum_{i=1}^{N} (y_i - \beta_0 - \sum_{j=1}^{p} x_{ij}\beta_j)^2 + \lambda \sum_{j=1}^{p} \beta_j^2 \right\}, \tag{2}$$

where $\lambda \ge 0$ is known as the complexity parameter that controls the amount of shrinkage. The larger the value of λ, the greater the amount of shrinkage. The quadratic penalty term makes $\hat{\boldsymbol{\beta}}^{\text{ridge}}$ a linear function of $\boldsymbol{y}$. Frank and Friedman (1993) introduced bridge regression, a generalized version of penalty (or absolute penalty type) estimation, which includes ridge regression when $\gamma = 2$. For a given penalty function $\pi(\cdot)$ and regularization parameter λ, the general form can be written as

$$\phi(\boldsymbol{\beta}) = (\boldsymbol{y} - \boldsymbol{X}\boldsymbol{\beta})^T(\boldsymbol{y} - \boldsymbol{X}\boldsymbol{\beta}) + \lambda\pi(\boldsymbol{\beta}),$$

where the penalty function is of the form

$$\pi(\beta) = \sum_{j=1}^{p} |\beta_j|^\gamma, \ \gamma > 0. \tag{3}$$

The penalty function in (3) bounds the L_γ norm of the parameters in the given model as $\sum_{j=1}^{m} |\beta_j|^\gamma \le t$, where t is the tuning parameter that controls the amount of shrinkage. We see that for $\gamma = 2$, we obtain ridge regression. However, if $\gamma \ne 2$, the penalty function will not be rotationally invariant. Interestingly, for $\gamma < 2$, it shrinks the coefficient toward zero, and depending on the value of λ, it sets some of them to be exactly zero. Thus, the procedure combines variable selection and shrinkage of coefficients of penalized regression. An important member of the penalized least squares (PLS) family is the L_1 penalized least squares estimator or the *lasso* [*least absolute shrinkage and selection operator*, Tibshirani (1996)]. In other words, the *absolute penalty estimator* (APE) arises when the absolute value of penalty term is considered, i.e., $\gamma = 1$ in (3). Similar to the ridge regression, the lasso estimates are obtained as

$$\hat{\boldsymbol{\beta}}^{\text{lasso}} = \underset{\beta}{\text{argmin}} \left\{ \sum_{i=1}^{n} (y_i - \beta_0 - \sum_{j=1}^{p} x_{ij}\beta_j)^2 + \lambda \sum_{j=1}^{p} |\beta_j| \right\}. \tag{4}$$

The lasso shrinks the OLS estimator toward zero and depending on the value of λ, it sets some coefficients to exactly zero. Tibshirani (1996) used a quadratic programming method to solve (4) for $\hat{\boldsymbol{\beta}}^{\text{lasso}}$. Later, Efron et al. (2004) proposed least angle regression (LAR), a type of stepwise regression, with which the

Miodrag Lovric (ed.), *International Encyclopedia of Statistical Science*, DOI 10.1007/978-3-642-04898-2,

lasso estimates can be obtained at the same computational cost as that of an ordinary least squares estimation Hastie et al. (2009). Further, the lasso estimator remains numerically feasible for dimensions m that are much higher than the sample size n. Zou and Hastie (2005) introduced a hybrid PLS regression with the so called *elastic net penalty* defined as $\lambda \sum_{j=1}^{p} (\alpha \beta_j^2 + (1-\alpha)\,|\beta_j|)$. Here the penalty function is a linear combination of the ridge regression penalty function and lasso penalty function. A different type of PLS, called *garotte* is due to Breiman (1993). Further, PLS estimation provides a generalization of both nonparametric least squares and weighted projection estimators, and a popular version of the PLS is given by Tikhonov regularization (Tikhonov 1963). Generally speaking, the ridge regression is highly efficient and stable when there are many small coefficients. The performance of lasso is superior when there are a small-to-medium number of moderate-sized coefficients. On the other hand, shrinkage estimators perform well when there are large known zero coefficients.

Ahmed et al. (2007) proposed an APE for partially linear models. Further, they reappraised the properties of shrinkage estimators based on Stein-rule estimation. There exists a whole family of estimators that are better than OLS estimators in regression models when the number of predictors is large. A partially linear regression model is defined as

$$y_i = \boldsymbol{x}_i^T \boldsymbol{\beta} + g(t_i) + \varepsilon_i, \quad i = 1, \ldots, n, \tag{5}$$

where $t_i \in [0,1]$ are design points, $g(\cdot)$ is an unknown real-valued function defined on $[0,1]$, and y_i, $\boldsymbol{x}$, $\boldsymbol{\beta}$, and ε_i's are as defined in the context of (1). We consider experiments where the vector of coefficients $\boldsymbol{\beta}$ in the linear part of (5) can be partitioned as $(\boldsymbol{\beta}_1^T, \boldsymbol{\beta}_2^T)^T$, where $\boldsymbol{\beta}_1$ is the coefficient vector of order $p_1 \times 1$ for main effects (e.g., treatment effects, genetic effects) and $\boldsymbol{\beta}_2$ is a vector of order $p_2 \times 1$ for "nuisance" effects (e.g., age, laboratory). Our relevant hypothesis is $H_0 : \boldsymbol{\beta}_2 = \mathbf{0}$. Let $\hat{\boldsymbol{\beta}}_1$ be a semiparametric least squares estimator of $\boldsymbol{\beta}_1$, and we let $\tilde{\boldsymbol{\beta}}_1$ denote the restricted semiparametric least squares estimator of $\boldsymbol{\beta}_1$. Then the semiparametric Stein-type estimator (see ►James-Stein Estimator and Semiparametric Regression Models), $\hat{\boldsymbol{\beta}}_1^S$, of $\boldsymbol{\beta}_1$ is

$$\hat{\boldsymbol{\beta}}_1^S = \tilde{\boldsymbol{\beta}}_1 + \{1 - (p_2 - 2)T^{-1}\}(\hat{\boldsymbol{\beta}}_1 - \tilde{\boldsymbol{\beta}}_1), \quad p_2 \geq 3 \tag{6}$$

where T is an appropriate test statistic for the H_0. A positive-rule shrinkage estimator (PSE) $\hat{\boldsymbol{\beta}}_1^{S+}$ is defined as

$$\hat{\boldsymbol{\beta}}_1^{S+} = \tilde{\boldsymbol{\beta}}_1 + \{1 - (p_2 - 2)T^{-1}\}^+(\hat{\boldsymbol{\beta}}_1 - \tilde{\boldsymbol{\beta}}_1), \quad p_2 \geq 3 \tag{7}$$

where $z^+ = max(0, z)$. The PSE is particularly important to control the over-shrinking inherent in $\hat{\boldsymbol{\beta}}_1^S$. The shrinkage estimators can be viewed as a competitor to the APE approach. Ahmed et al. (2007) finds that, when p_2 is relatively small with respect to p, APE performs better than the shrinkage method. On the other hand, the shrinkage method performs better when p_2 is large, which is consistent with the performance of the APE in linear models. Importantly, the shrinkage approach is free from any tuning parameters, easy to compute and calculations are not iterative. The shrinkage estimation strategy can be extended in various directions to more complex problems. It may be worth mentioning that this is one of the two areas Bradley Efron predicted for the early twenty-first century (RSS News, January 1995). Shrinkage and likelihood-based methods continue to be extremely useful tools for efficient estimation.

Accelerated Lifetime Testing

Francisco Louzada-Neto
Associate Professor
Universidade Federal de São Carlos, Sao Paulo, Brazil

Accelerated life tests (ALT) are efficient industrial experiments for obtaining measures of a device reliability under the usual working conditions.

A practical problem for industries of different areas is to obtain measures of a device reliability under its usual working conditions. Typically, the time and cost of such experimentation are long and expensive. The ALT are efficient for handling such situation, since the information on the device performance under the usual working conditions are obtained by considering a time and cost-reduced experimental scheme. The ALT are performed by testing items at higher stress covariate levels than the usual working conditions, such as temperature, pressure and voltage.

There is a large literature on ALT and interested readers can refer to Mann et al. (1974), Nelson (1990), Meeker and Escobar (1998) which are excellent sources for ALT. Nelson (2005a, b) provides a brief background on accelerated testing and test plans and surveys the related literature point out more than 150 related references.

A simple ALT scenario is characterized by putting k groups of n_i items each under constant and fixed stress covariate levels, X_i (hereafter stress level), for $i = 1, \ldots, k$, where $i = 1$ generally denotes the usual stress level, that is, the usual working conditions. The experiment ends after a certain pre-fixed number $r_i < n_i$ of failures, $t_{i1}, t_{i2}, \ldots, t_{ir_i}$, at each stress level, characterizing a type II censoring scheme (Lawless 2003; see also ▶Censoring Methodology). Other stress schemes, such as step (see ▶Step-Stress Accelerated Life Tests) and progressive ones, are also common in practice but will not be considered here. Examples of those more sophisticated stress schemes can be found in Nelson (1990).

The ALT models are composed by two components. One is a probabilistic component, which is represented by a lifetime distribution, such as exponential, Weibull, log-normal, log-logistic, among others. The other is a stress-response relationship (SRR), which relates the mean lifetime (or a function of this parameter) with the stress levels. Common SRRs are the power law, Eyring and Arrhenius models (Meeker and Escobar 1998) or even a general log-linear or log-non-linear SRR which encompass the formers. For sake of illustration, we shall assume an exponential distribution as the lifetime model and a general log-linear SRR. Here, the mean lifetime under the usual working conditions shall represent our device reliability measure of interesting.

Let $T > 0$ be the lifetime random variable with an exponential density

$$f(t, \lambda_i) = \lambda_i \exp\{-\lambda_i t\}, \tag{1}$$

where $\lambda_i > 0$ is an unknown parameter representing the constant failure rate for $i = 1, \ldots, k$ (number of stress levels). The mean lifetime is given by $\theta_i = 1/\lambda_i$.

The likelihood function for λ_i, under the i-th stress level X_i, is given by

$$L_i(\lambda_i) = \left(\prod_{j=1}^{r_i} f(t_{ij}, \lambda_i)\right) (S(t_{ir_i}, \lambda_i))^{n_i - r_i} = \lambda_i^{r_i} \exp\{-\lambda_i A_i\},$$

where $S(t_{ir_i}, \lambda_i)$ is the survival function at t_{ir_i} and $A_i = \sum_{j=1}^{r_i} t_{ij} + (n_i - r_i) t_{ir_i}$ denotes the total time on test for the i-th stress level.

Considering data under the k random stress levels, the likelihood function for the parameter vector $\lambda = (\lambda_1, \lambda_2, \ldots, \lambda_k)$ is given by

$$L(\lambda) = \prod_{i=1}^{k} \lambda_i^{r_i} \exp\{-\lambda_i A_i\}. \tag{2}$$

We consider a general log-linear SRR defined as

$$\lambda_i = \exp(-Z_i - \beta_0 - \beta_1 X_i), \tag{3}$$

where X is the covariate, $Z = g(X)$ and β_0 and β_1 are unknown parameters such that $-\infty < \beta_0, \beta_1 < \infty$.

The SRR (3) has several models as particular cases. The Arrhenius model is obtained if $Z_i = 0$, $Xi = 1/Vi$, $\beta_0 = -\alpha_1$ and $\beta_1 = \alpha_2$, where Vi denotes a level of the temperature variable. If $Z_i = 0$, $Xi = -log(Vi)$, $\beta_0 = log(\alpha)$ and $\beta_1 = \alpha_2$, where Vi denotes a level of the voltage variable we obtain the power model. Following Louzada-Neto and Pardo-Fernandéz (2001), the Eyring model is obtained if $Z_i = -\log V_i$, $Xi = 1/Vi$, $\beta_0 = -\alpha_1$ and $\beta_1 = \alpha_2$, where Vi denotes a level of the temperature variable. Interested readers can refer to Meeker and Escobar (1998) for more information about the physical models considered here.

From (2) and (3), the likelihood function for β_0 and β_1 is given by

$$L(\beta_0, \beta_1) = \prod_{i=1}^{k} \{\exp(-Z_i - \beta_0 - \beta_1 X_i)^{r_i} \exp(-\exp(-Z_i - \beta_0 - \beta_1 X_i) A_i)\}. \quad (4)$$

The maximum likelihood estimates (MLEs) of β_0 and β_1 can be obtained by direct maximization of (4), or by solving the system of nonlinear equations, $\partial \log L / \partial \theta = 0$, where $\theta' = (\beta_0, \beta_1)$. Obtaining the score function is conceptually simple and the expressions are not given explicitly. The MLEs of θ_i can be obtained, in principle, straightforwardly by considering the invariance property of the MLEs.

Large-sample inference for the parameters can be based on the MLEs and their estimated variances, obtained by inverting the expected information matrix (Cox and Hinkley 1974). For small or moderate-sized samples however we may consider simulation approaches, such as the bootstrap confidence intervals (see ►Bootstrap Methods) that are based on the empirical evidence and are therefore preferred (Davison and Hinkley 1997). Formal goodness-of-fit tests are also feasible since, from (3), we can use the likelihood ratio statistics (LRS) for testing goodness-of-fit of hypotheses such as $H_0 : \beta_1 = 0$.

Although we considered only an exponential distribution as our lifetime model, more general lifetime distributions, such as the Weibull (see ►Weibull Distribution and Generalized Weibull Distributions), log-normal, log-logistic, among others, could be considered in principle. However, the degree of difficulty in the calculations increase considerably. Also we considered only one stress covariate, however this is not critical for the overall approach to hold and the multiple covariate case can be handle straightforwardly.

A study on the effect of different reparametrizations on the accuracy of inferences for ALT is discussed in Louzada-Neto and Pardo-Fernandéz 2001). Modeling ALT with a log-non-linear SRR can be found in Perdoná et al. (2004). Modeling ALT with a threshold stress, below which the lifetime of a product can be considered to be infinity or much higher than that for which it has been developed is proposed by Tojeiro et al. (2004).

We only considered ALT in presence of constant stress loading, however non-constant stress loading, such as step stress and linearly increasing stress are provided by Miller and Nelson (1983) and Bai, Cha and Chung (1992), respectively. A comparison between constant and step stress tests is provided by Khamis (1997). A log-logistic step stress model is provided by Srivastava and Shukla (2008).

Two types of software for ALT are provided by Meeker and Escobar (2002) and ReliaSoft Corporation (2004).

Acceptance Sampling

M. Ivette Gomes
Professor
Universidade de Lisboa, DEIO and CEAUL, Lisboa, Portugal

Introduction

Acceptance sampling (AS) is one of the oldest statistical techniques in the area of ▶statistical quality control. It is performed out of the line production, most commonly before it, for deciding on incoming batches, but also after it, for evaluating the final product (see Duncan 1986; Stephens 2001; Pandey 2007; Montgomery 2009; and Schilling and Neubauer 2009, among others). Accepted batches go into the production line or are sold to consumers; the rejected ones are usually submitted to a *rectification process*. A *sampling plan* is defined by the *size of the sample* (samples) taken from the batch and by the associated *acceptance–rejection* criterion. The most widely used plans are given by the Military Standard tables, developed during the *World War* II, and first issued in 1950. We mention MIL STD 105E (1989) and the civil version ANSI/ASQC Z1.9 (1993) of the *American National Standards Institution* and the *American Society for Quality Control*.

At the beginning, all items and products were inspected for the identification of nonconformities. At the late 20s, Dodge and Romig (see Dodge and Romig 1959), in the Bell Laboratories, developed the area of AS, as an alternative to 100% inspection. The aim of AS is to lead producers to a decision (acceptance or rejection of a batch) and not to the estimation or improvement of the quality of a batch. Consequently, AS does not provide a direct form of *quality control*, but its indirect effects in *quality* are important: if a batch is rejected, either the supplier tries improving its production methods or the consumer (producer) looks for a better supplier, indirectly increasing quality.

Regarding the decision on the batches, we distinguish three different approaches: (1) *acceptance without inspection*, applied when the supplier is highly reliable; (2) 100% *inspection*, which is expensive and can lead to a sloppy attitude towards quality; (3) *an intermediate decision*, i.e., an *acceptance sampling program*. This increases the interest on quality and leads to the lemma: *make things right in the first place*. The type of inspection that should be applied depends on the quality of the last batches inspected. At the beginning of inspection, a so-called *normal inspection* is used, but there are two other types of inspection, a *tightened inspection* (for a history of low quality), and a *reduced inspection* (for a history of high quality). There are special and empirical switching rules between the three types of inspection, as well as for discontinuation of inspection.

Factors for Classifications of Sampling Plans

Sampling plans by attributes versus sampling plans by variables. If the item inspection leads to a binary result (conforming or nonconforming), we are dealing with *sampling by attributes*, detailed later on. If the item inspection leads to a continuous measurement X, we are *sampling by variables*. Then, we generally use sampling plans based on the sample mean and standard deviation, the so-called *variable sampling plans*. If X is normal, it is easy to compute the number of items to be collected and the criteria that leads to the rejection of the batch, with chosen risks α and β. For different *sampling plans by variables*, see Duncan (1986), among others.

Incoming versus outgoing inspection. If the batches are inspected before the product is sent to the consumer, it is called *outgoing inspection*. If the inspection is done by the consumer (producer), after they were received from the supplier, it is called *incoming inspection*.

Rectifying versus non-rectifying sampling plans. All depends on what is done with nonconforming items that were found during the inspection. When the cost of replacing faulty items with new ones, or reworking them is accounted for, the sampling plan is rectifying.

Single, double, multiple and sequential sampling plans.

- **Single sampling**. This is the most common sampling plan: we draw a random sample of n items from the batch, and count the number of nonconforming items (or the number of nonconformities, if more than one nonconformity is possible on a single item). Such a

plan is defined by n and by an associated *acceptance-rejection* criterion, usually a value c, the so-called *acceptance number*, the number of nonconforming items that cannot be exceeded. If the number of nonconforming items is greater than c, the batch is rejected; otherwise, the batch is accepted. The number r, defined as the minimum number of nonconforming items leading to the rejection of the batch, is the so-called *rejection number*. In the most simple case, as above, $r = c + 1$, but we can have $r > c + 1$.

- **Double sampling**. A *double sampling plan* is characterized by four parameters: $n_1 << n$, the size of the first sample, c_1 the acceptance number for the first sample, n_2 the size of the second sample and c_2 ($> c_1$) the acceptance number for the joint sample. The main advantage of a double sampling plan is the reduction of the total inspection and associated cost, particularly if we proceed to a *curtailment* in the second sample, i.e. we stop the inspection whenever c_2 is exceeded. Another (psychological) advantage of these plans is the way they give a second opportunity to the batch.
- **Multiple sampling**. In the *multiple plans* a predetermined number of samples are drawn before taking a decision.
- ►**Sequential sampling**. The *sequential plans* are a generalization of multiple plans. The main difference is that the number of samples is not pre-determined. If, at each step, we draw a sample of size *one*, the plan, based on Wald's test, is called *sequential item-to-item*; otherwise, it is *sequential by groups*. For a full study of multiple and sequential plans see, for instance, Duncan (1986) (see also the entry ►Sequential Sampling).

Special sampling plans. Among the great variety of special plans, we distinguish:

- **Chain sampling**. When the inspection procedures are destructive or very expensive, a small n is recommendable. We are then led to acceptance numbers equal to zero. This is dangerous for the supplier and if rectifying inspection is used, it is expensive for the consumer. In 1955, Dodge suggested a procedure alternative to this type of plans, which uses also the information of preceding batches, the so-called *chain sampling method* (see Dogdge and Romig 1959).
- **Continuous sampling plans** (CSP). There are continuous production processes, where the raw material is not naturally provided in batches. For this type of production it is common to alternate sequences of sampling inspection with 100% inspection – they are in a certain sense rectifying plans. The simplest plan of this type, the CSP-1, was suggested in 1943 by Dodge. It begins with a 100% inspection. When a pre-specified number i of consecutive nonconforming items is achieved, the plan changes into sampling inspection, with the inspection of f items, randomly selected, along the continuous production. If *one* nonconforming item is detected (the reason for the terminology CSP-1), 100% inspection comes again, and the nonconforming item is replaced. For properties of this plan and its generalizations see Duncan (1986).

A Few Characteristics of a Sampling Plan

OCC. The *operational characteristic curve* (OCC) is $P_a \equiv P_a(p) = \mathbb{P}(\text{acceptance of the batch} \mid p)$, where p is the probability of a nonconforming item in the batch.

AQL and LTPD (or RQL). The sampling plans are built taken into account the wishes of both the supplier and the consumer, defining two quality levels for the judgment of the batches: the *acceptance quality level* (AQL), the worst operating quality of the process which leads to a high probability of acceptance of the batch, usually 95% – for the protection of the supplier regarding high quality batches, and the *lot tolerance percent defective* (LTPD) or *rejectable quality level* (RQL), the quality level below which an item cannot be considered acceptable. This leads to a small acceptance of the batch, usually 10% – for the protection of the consumer against low quality batches. There exist two types of decision, acceptance or rejection of the batch, and two types of risks, to reject a "good" (high quality) batch, and to accept a "bad" (low quality) batch. The probabilities of occurrence of these risks are the so-called *supplier risk* and *consumer risk*, respectively. In a *single sampling plan*, the *supplier risk* is $\alpha = 1 - P_a(\text{AQL})$ and the *consumer risk* is $\beta = P_a(\text{LTPD})$. The sampling plans should take into account the specifications AQL and LTPD, i.e. we are supposed to find a single plan with an OCC that passes through the points (AQL, 1-α) and (LTPD, β). The construction of double plans which protect both the supplier and the consumer are much more difficult, and it is no longer sufficient to provide indication on two points of the OCC. There exist the so-called *Grubbs' tables* (see Montgomery 2009) providing (c_1, c_2, n_1, n_2), for $n_2 = 2n_1$, as an example, $\alpha = 0.05$, $\beta = 0.10$ and several rates RQL/AQL.

AOQ, AOQL and ATI. If there is a *rectifying inspection program* – a corrective program, based on a 100% inspection and replacement of nonconforming by conforming items, after the rejection of a batch by an AS plan –, the most relevant *characteristics* are the *average outgoing quality* (AOQ), $\text{AOQ}(p) = p\,(1 - n/N)\,P_a$, which attains

a maximum at the so-called *average output quality limit* (AOQL), the worst average quality of a product after a rectifying inspection program, as well as the *average total inspection* (ATI), the amount of items subject to inspection, equal to n if there is no rectification, but given by $\mathrm{ATI}(p) = nP_a + N(1 - P_a)$, otherwise.

Actuarial Methods

Vassiliy Simchera
Director
Rosstat's Statistical Research Institute, Moscow, Russia

A specific (and relatively new) type of financial calculations are actuarial operations, which represent a special (in majority of countries they are usually licensed) sphere of activity related to identifications of risks outcomes and market assessment of future (temporary) borrowed current assets and liabilities costs for their redemption.

The broad range of existing and applicable actuarial calculations require use of various methods and inevitably predetermines a necessity of their alteration depending on concrete cases of comparison analysis and selection of most efficient of them.

The condition of success is a typology of actuarial calculations methods, based on existing typology fields and objects of their applications, as well as knowledge of rule for selection of most efficient methods, which would provide selection of target results with minimum costs or high accuracy.

Regarding the continuous character of financial transactions, the actuarial calculations are carried out permanently. The aim of actuarial calculations in every particular case is probabilistic determination of profit sharing (transaction return) either in the form of financial liabilities (interest, margin, agio, etc.) or as commission charges (such as royalty).

The subject of actuarial calculations can be distinguished in the narrow and in the broad senses.

The given subject in the broad sense covers financial and actuarial accounts, budgeting, balance, audit, assessment of financial conditions and financial provision for all categories and types of borrowing institutions, basis for their preferential financial decisions and transactions, conditions and results of work for different financial and credit institutions; financial management of cash flows, resources, indicators, mechanisms, instruments, as well as financial analysis and audit of financial activity of companies, countries, nations their groups and unions, including national system of financial account, financial control, engineering, and forecast. In other words, the subject of actuarial calculations is a process of determination of any expenditures and incomes from any type of transactions in the shortest way.

In the narrow sense it is a process of determination, in the same way, of future liabilities and their comparison with present assets in order to estimate their sufficiency, deficit of surplus.

We can define general and efficient actuarial calculations, the principals of which are given below.

Efficient actuarial calculations imply calculations of any derivative indicators, which are carried out through conjugation (comparison) of two or more dissimilar initial indicators, the results of which are presented as different relative numbers (coefficients, norms, percents, shares, indices, rates, tariffs, etc.), characterizing differential (effect) of anticipatory increment of one indicator in comparison with another one.

In some cases similar values are called gradients, derivatives (of different orders), elasticity coefficients, or

anticipatory coefficients and can be determined by reference to more complex statistical and mathematical methods including geometrical, differential, integral, and correlation and regression multivariate calculations.

Herewith in case of application of nominal comparison scales for two or more simple values (so called scale of simple interests, which are calculated and represented in terms of current prices) they are determined and operated as it was mentioned by current nominal financial indicators, but in case of real scales application, i.e. scales of so called compound interests, they are calculated and represented in terms of future or current prices, that is real efficient financial indicators.

In case of insurance scheme the calculation of efficient financial indicators signify the special type of financial calculations i.e. actuarial calculations, which imply additional profit (discounts) or demanding compensation of loss (loss, damage or loss of profit) in connection with occurrence of contingency and risks (risk of legislation alteration, exchange rates, devaluation or revaluation, inflation or deflation, changes in efficiency coefficients).

Actuarial calculations represent special branch of activity (usually licensed activity) dealing with market assessment of compliance of current assets of insurance, joint-stock, investment, pension, credit and other financial companies (i.e. companies engaged in credit relations) with future liabilities to the repayment of credit in order to prevent insolvency of a debtor and to provide efficient protection for investors-creditors.

Actuarial calculations assume the comparison of assets (ways of use or allocation of obtained funds) with liabilities (sources of gained funds) for borrowing companies of all types and forms, which are carried out in aggregate by particular items of their expenses under circumstances of mutual risks in order to expose the degree of compliance or incompliance (surplus or deficit) of borrowed assets with future liabilities in term of repayment, in other words to check the solvency of borrowing companies.

Borrowing companies – insurance, stock, broker and auditor firms, banks, mutual, pension, and other specialized investment funds whose accounts payable two or more times exceeds their own assets and appear to be a source of high risk, which in turn affects interests of broad groups of business society as well as population – are considered as companies that are subjects to obligatory insurance and actuarial assessment.

Actuarial calculations assume the construction of balances for future assets and liabilities, probabilistic assessment of future liabilities repayment (debts) at the expense of disposable assets with regard to risks of changes of their amount on hand and market prices. The procedures of documentary adoption, which include construction of actuarial balances and preparation of actuarial reports and conclusions, are called actuarial estimation; the organizations that are carrying out such procedures are called actuarial organizations.

Hence, there is a necessity to learn the organization and technique of actuarial methods (estimations) in aggregate; as well as to introduce the knowledge of actuarial subjects to any expert who is involved in direct actuarial estimations of future assets and liabilities costs of various funds, credit, insurance, and similarly financial companies. This is true for assets and liabilities of any country.

The knowledge of these actuarial assessments and practical use is a significant reserve for increasing not only efficiency but (more important today) legitimate, transparent, and protected futures for both borrowing and lending companies.

Key Terms

Actuary (actuarius – Latin) – profession, appraiser of risks, certified expert on assessment of documentary insurance (and wider – financial) risks; in insurance – insurer; in realty agencies – appraiser; in accounting – auditor; in financial markets – broker (or bookmaker); in the past registrar and holder of insurance documents; in England – adjuster or underwriter.

Actuarial transactions – special field of activity related to determination of insurance outcomes in circumstances of uncertainty that require knowledge of probability theory and actuarial statistics methods and mathematics, including modern computer programs.

Actuarial assessment – type of practical activity, licensed in the majority of countries, related to preparation of actuarial balances, market assessment of current and future costs of assets and liabilities of insurer (in case of pension insurance assets and liabilities of non-governmental pension funds, insurances companies and specialized mutual trust funds); completed with preparation of actuarial report according to standard methodologies and procedures approved, as a rule in conventional (sometimes in legislative) order.

Actuarial estimations – documentary estimations of chance outcomes (betting) of any risk (gambling) actions (games) with participation of two or more parties with fixed (registered) rates of repayment of insurance premium and compensations premium for possible losses. They differ by criteria of complexity – that is elementary (simple or initial) and complex. The most widespread cases of elementary actuarial estimations are bookmaker estimations of profit and loss from different types of gambling including playing cards, lottery, and casinos, as well as risk

taking on modern stock exchange, foreign exchange markets, commodity exchanges, etc. The complex estimations assume determination of profit from second and consequent derived risks (outcomes over outcomes, insurance over insurance, repayment on repayment, transactions with derivatives, etc.). All of these estimations are carried out with the help of various method of high mathematics (first of all, numeric methods of probability theory and mathematical statistics). They are also often represented as methods of high actuarial estimations.

Generally due to ignorance about such estimations, current world debt (in 2008 approximately 700 trillion USD, including 300 trillion USD in the USA) has drastically exceeded real assets, which account for about 65 trillion USD, which is actually causing the enormous financial crisis everywhere in the world.

Usually such estimations are being undertaken towards future insurance operations, profits and losses, and that is why they are classified as strictly approximate and represented in categories of probabilistic expectations.

The fundamental methods of actuarial estimations are the following: methods for valuing investments, selecting portfolios, pricing insurance contracts, estimating reserves, valuing portfolios, controlling pension scheme, finances, asset management, time delays and underwriting cycle, stochastic approach to life insurance mathematics, pension funding and feed back, multiple state and disability insurance, and methods of actuarial balances.

The most popular range of application for actuarial methods are: 1) investments, (actuarial estimations) of investments assets and liabilities, internal and external, real and portfolio types their mathematical methods and models, investments risks and management; 2) life insurance (various types and methods, insurance bonuses, insurance companies and risks, role of the actuarial methods in management of insurance companies and reduction of insurance risks); 3) general insurance (insurance schemes, premium rating, reinsurance, reserving); 4) actuarial provision of pension insurance (pension investments – investment policy, actuarial databases, meeting the cost, actuarial researches).

Scientist who have greatly contributed to actuarial practices: William Morgan, Jacob Bernoulli, A. A. Markov, V. Y. Bunyakovsky, M. E. Atkinson, M. H. Amsler, B. Benjamin, G. Clark, C. Haberman, S. M. Hoem, W. F. Scott, and H. R. Watson.

World's famous actuary's schools and institutes: The Institute of Actuaries in London, Faculty of Actuaries in Edinburgh (on 25 May 2010, following a ballot of Fellows of both institutions, it was announced that the Institute and Faculty would merge to form one body – the "Institute and Faculty of Actuaries"), Charted Insurance Institute, International Association of Actuaries, International Forum of Actuaries Associations, International Congress of Actuaries, and Groupe Consultatif Actuariel Européen.

About the Author

Professor Vassiliy M. Simchera received his PhD at the age of 24 and his Doctor's degree when he was 35. He has been Vice-president of the Russian Academy of Economical Sciences (RAES), Chairman of the Academic Council and Counsel of PhDs dissertations of RAES, Director of Russian State Scientific and Research Statistical Institute of Rosstat (Moscow, from 2000). He was also Head of Chair of statistics in the All-Russian Distant Financial and Statistical Institute (1983–2000), Director of Computer Statistics Department in the State Committee on statistics and techniques of the USSR (1973–1983), and Head of Section of Statistical Researches in the Science Academy of the USSR (1965–1973). He has supervised 8 Doctors and over 50 PhD's. He has (co-) authored over 50 books and 350 articles, including the following books: *Encyclopedia of Statistical Publications* (2001, 991 p., in co-authorship), *Financial and Actuarial Calculations* (2002), *Organization of State Statistics in Russian Federation* (2004) and *Development of Russia's Economy for 100 Years*, 1900–2005 (2006). Professor Simchera was founder and executive director (1987–1991) of Russian Statistical Association, member of various domestic and foreign academies, as well as scientific councils and societies. He has received numerous honors and awards for his work, including Honored Scientist of Russian Federation (2001) (Decree of the President of the Russian Federation) and Saint Nicolay Chudotvoretz honor of III degree (2006). He is a full member of the International Statistical Institute (from 2001).

Adaptive Linear Regression

Jana Jurečková
Professor
Charles University in Prague, Prague, Czech Republic

Consider a set of data consisting of n observations of a response variable Y and of vector of p explanatory variables $\mathbf{X} = (X_1, X_2, \ldots, X_p)^\top$. Their relationship is described by the *linear regression model* (see ►Linear Regression Models)

$$Y = \beta_1 X_1 + \beta_2 X_2 + \ldots + \beta_p X_p + e.$$

In terms of the observed data, the model is

$$Y_i = \beta_1 x_{i1} + \beta_2 x_{i2} + \ldots + \beta_p x_{ip} + e_i, \quad i = 1, 2, \ldots, n.$$

The variables $e_1, \ldots, e_n$ are unobservable model errors, which are assumed being independent and identically distributed random variables with a distribution function F and density f. The density is unknown, we only assume that it is symmetric around 0. The vector $\boldsymbol{\beta} = (\beta_1, \beta_2, \ldots, \beta_p)^\top$ is an unknown parameter, and the problem of interest is to estimate $\boldsymbol{\beta}$ based on observations $Y_1, \ldots, Y_n$ and $\mathbf{x}_i = (x_{i1}, \ldots, x_{ip})^\top$, $i = 1, \ldots, n$.

Besides the classical ►least squares estimator, there exists a big variety of *robust estimators* of $\boldsymbol{\beta}$. Some are distributionally robust (less sensitive to deviations from the assumed shape of f), others are resistant to the leverage points in the design matrix and have a high breakdown point [introduced originally by Hampel (1968), the finite sample version is studied in Donoho and Huber (1983)].

The last 40 years brought a host of statistical procedures, many of them enjoying excellent properties and being equipped with a computational software (see ►Computational Statistics and ►Statistical Software: An Overview). On the other hand, this progress has put an applied statistician into a difficult situation: If one needs to fit the data with a regression hyperplane, he (she) is hesitating which procedure to use. If there is more information on the model, then the estimation procedure can be chosen accordingly. If the data are automatically collected by a computer and the statistician is not able to make any diagnostics, then he (she) might use one of the high breakdown-point estimators. However, many decline this idea due to the difficult computation. Then, at the end, the statistician can prefer the simplicity to the optimality and uses either the classical least squares (LS), LAD-method or other reasonably simple method.

Instead of to fix ourselves on one fixed method, one can try to combine two convenient estimation methods, and in this way diminish eventual shortages of both. Taylor (1973) suggested to combine the LAD (minimizing the L_1 norm) and the least squares (minimizing the L_2 norm) methods. Arthanari and Dodge (1981) considered a convex combination of LAD- and LS-methods. Simulation study by Dodge and Lindstrom (1981) showed that this procedure is robust to small deviations from the normal distribution (see ►Normal Distribution, Univariate). Dodge (1984) extended this method to a convex combination of LAD and Huber's M-estimation methods (see ►Robust Statistics and Robust Statistical Methods). Dodge and Jurečková (1987) observed that the convex combination of two methods could be adapted in such a way that the resulted estimator has the minimal asymptotic variance in the class of estimators of a similar kind, no matter what is the unknown distribution. The first numerical study of this procedure was made by Dodge et al. (1991). Dodge and Jurečková (1988, 1991) then extended the adaptive procedure to the combinations of LAD- with M-estimation and with the trimmed least squares estimation. The results and examples are summarized in monograph of Dodge and Jurečková (2000), where are many references added.

Let us describe the general idea, leading to a construction of an adaptive convex combination of two estimation methods: We consider a family of symmetric densities indexed by an suitable measure of scale s :

$$\mathcal{F} = \left\{ f : f(z) = s^{-1} f_0(z/s),\ s > 0 \right\}.$$

The shape of f_0 is generally unknown; it only satisfies some regularity conditions and the unit element $f_0 \in \mathcal{F}$ has the scale $s_0 = 1$. We take $s = 1/f(0)$ when we combine L_1-estimator with other class of estimators.

The scale characteristic s is estimated by a consistent estimator $\hat{s}_n$ based on $Y_1, \ldots, Y_n$, which is regression-invariant and scale-equivariant, i.e.,

(a) $\hat{s}_n(\mathbf{Y}) \xrightarrow{p} s$ as $n \to \infty$
(b) $\hat{s}_n(\mathbf{Y} + \mathbf{Xb}) = \hat{s}_n(\mathbf{Y})$ for any $\mathbf{b} \in \mathbb{R}^p$ (regression-invariance)
(c) $\hat{s}_n(c\mathbf{Y}) = c\hat{s}_n(\mathbf{Y})$ for $c > 0$ (scale-equivariance).

Such estimator based on the regression quantiles was constructed e.g., by Dodge and Jurečková (1995). Other estimators are described in the monograph by Koenker (2005).

The adaptive estimator $\mathbf{T}_n(\delta)$ of $\boldsymbol{\beta}$ is defined as a solution of the minimization problem

$$\sum_{i=1}^{n} \rho\left(\frac{Y_i - \mathbf{x}_i^\top \mathbf{t}}{\hat{s}_n}\right) := \min$$

with respect to $\mathbf{t} \in \mathbb{R}^p$, where

$$\rho(z) = \delta\rho_1(z) + (1-\delta)\rho_2(z) \tag{1}$$

with a suitable fixed δ, $0 \le \delta \le 1$, where $\rho_1(z)$ and $\rho_2(z)$ are symmetric (convex) discrepancy functions defining the respective estimators. For instance, $\rho_1(z) = |z|$ and $\rho_2(z) = z^2$ if we want to combine LAD and LS estimators. Then $\sqrt{n}(\mathbf{T}_n(\delta) - \boldsymbol{\beta})$ has an asymptotically normal distribution (see ►Asymptotic Normality) $\mathcal{N}_p(\mathbf{0}, \mathbf{Q}^{-1}\sigma^2(\delta,\rho,f))$ with the variance dependent on δ, ρ and f, where

$$\mathbf{Q} = \lim_{n\to\infty} \mathbf{Q}_n, \quad \mathbf{Q}_n = \frac{1}{n}\sum_{i=1}^{n} \mathbf{x}_i\mathbf{x}_i^\top.$$

Using $\delta = \delta_0$ which minimizes $\sigma^2(\delta,\rho,f)$ with respect to δ, $0 \le \delta \le 1$, we get an estimator $\mathbf{T}_n(\delta_0)$ minimizing the asymptotic variance for a fixed distribution shape. Typically, $\sigma^2(\delta,\rho,f)$ depends on f only through two moments of f_0. However, these moments should be estimated on the data.

Let us illustrate the procedure on the combination of the least squares and the L_1 procedures. Set

$$\sigma^2 = \int z^2 f(z)dz, \quad \sigma_0^2 = \int z^2 f_0(z)dz \tag{2}$$
$$E_1^0 = \int |z| f_0(z)dz, \quad E_1 = \int |z| f(z)dz.$$

Then

$$\sigma^2 = \int z^2 f(z)dz = s^2\sigma_0^2, \qquad E_1 = \int |z| f(z)dz = sE_1^0$$

and the corresponding asymptotic variance of $\mathbf{T}_n(\delta)$ is

$$\sigma^2(\delta,f,s) = \frac{s^2}{4}\{4(1-\delta)^2\sigma_0^2 + 4\delta(1-\delta)E_1^0 + \delta^2\}. \tag{3}$$

If we know all moments in (2), we minimize the variance (3) with respect to δ, under the restriction $0 \le \delta \le 1$. It is minimized for $\delta = \delta_0$ where

$$\delta_0 = \begin{cases} 0 & \text{if } 2\sigma_0^2 \le E_1^0 < 1/2 \\ \dfrac{4\sigma_0^2 - 2E_1^0}{4\sigma_0^2 - 4E_1^0 + 1} & \text{if } E_1^0 < 1/2 \text{ and } E_1^0 < 2\sigma_0^2 \\ 1 & \text{if } 1/2 \le E_1^0 < 2\sigma_0^2. \end{cases}$$

The estimator $\mathbf{T}_n(\delta_0)$ of $\boldsymbol{\beta}$ is a solution of the minimization

$$\sum_{i=1}^{n} \rho((Y_i - \mathbf{x}_i^\top \mathbf{t})/\hat{s}_n) := \min, \quad \mathbf{t} \in \mathbb{R}^p,$$
$$\rho(z) = (1-\delta_0)z^2 + \delta_0|z|, \; z \in \mathbb{R}^1. \tag{4}$$

But δ_0 is unknown, because the entities in (2) depend on the unknown distribution f. Hence, we should replace δ_0 by an appropriate estimator based on $\mathbf{Y}$. We shall proceed in the following way:

First estimate $E_1^0 = E_1/s = f(0)\int_{\mathbb{R}} |z| f(z)dz$ by

$$\widehat{E}_1^0 = \hat{s}_n^{-1}(n-p)^{-1}\sum_{i=1}^{n}\left|Y_i - \mathbf{x}_i'\widehat{\boldsymbol{\beta}}_n\left(\frac{1}{2}\right)\right| \tag{5}$$

where $\widehat{\boldsymbol{\beta}}_n(1/2)$ is the LAD-estimator of $\boldsymbol{\beta}$. The choice of optimal $\widehat{\delta}_{0n}$ is then based on the following decision procedure (Table 1).

It can be proved that $\widehat{\delta}_{0n} \xrightarrow{p} \delta_0$ as $n \to \infty$ and $\mathbf{T}_n(\widehat{\delta}_{0n})$ is a consistent estimator of $\boldsymbol{\beta}$ and is asymptotically normally distributed with the minimum possible variance.

Adaptive Linear Regression. Table 1 Decision procedure

Compute $\widehat{E}_1^0$ as in (5).

(1) If $\widehat{E}_{1n}^0 < 1/2$, calculate

$$\widehat{\sigma}_{0n}^2 = \frac{1}{\hat{s}_n^2(n-p)}\sum_{i=1}^{n}\left(Y_i - \mathbf{x}_i^\top\widehat{\boldsymbol{\beta}}(1/2)\right)^2$$

and go to (2). If not, go to (4).

(2) If $\widehat{E}_{1n}^0 \ge 2\widehat{\sigma}_{0n}^2$, put $\widehat{\delta}_{0n} = 0$. Then $\mathbf{T}_n$ is the ordinary LS estimator of $\boldsymbol{\beta}$. If not, go to (3).

(3) If $\widehat{E}_{1n}^0 < 2\widehat{\sigma}_{0n}^2$, calculate

$$\widehat{\delta}_{0n} = \frac{4\widehat{\sigma}_{0n}^2 - 2\widehat{E}_{1n}^0}{4\widehat{\sigma}_{0n}^2 - 4\widehat{E}_{1n}^0 + 1}$$

and perform the minimization (4) with the function ρ equal to

$$(1-\widehat{\delta}_{0n})\sum_{i=1}^{n}\left(\frac{Y_i - \mathbf{x}_i'\mathbf{t}}{\hat{s}_n}\right)^2 + \widehat{\delta}_{0n}\sum_{i=1}^{n}\left|\frac{Y_i - \mathbf{x}_i^\top\mathbf{t}}{\hat{s}_n}\right|.$$

(4) Put $\widehat{\delta}_{0n} = 1$; then $\mathbf{T}_n$ is the LAD-estimate of $\boldsymbol{\beta}$.

Many numerical examp les based on real data can be find in the monograph Dodge and Jurečková (2000).

Adaptive Methods

Saïd El Melhaoui
Professor Assistant
Université Mohammed Premier, Oujda, Morocco

Introduction

Statistical procedures, the efficiencies of which are optimal and invariant with regard to the knowledge or not of certain features of the data, are called adaptive statistical methods.

Such procedures should be used when one suspects that the usual inference assumptions, for example, the normality of the error's distribution, may not be met. Indeed, traditional methods have a serious defect. If the distribution of the error is non-normal, the power of classical tests, as *pseudo-Gaussian tests*, can be much less than the optimal power. So, the variance of the classical least squares estimator is much bigger than the smallest possible variance.

What Is Adaptivity?

The adaptive methods deal with the problem of estimating and testing hypotheses about a parameter of interest θ in the presence of nuisance parameter ν. The fact that ν remains unspecified induces, in general, a loss of efficiency

with the situation where v is exactly specified. *Adaptivity* occurs when the loss of efficiency is null, i.e., when we can estimate (testing hypotheses about) θ as when not knowing v as well as when knowing v. The method used in this respect is called *adaptive*.

Adaptivity is a property of the model under study, the best known of which is undoubtedly the symmetric location model; see Stone (1975). However, under a totally unspecified density, possibly non-symmetric, the mean can not be adaptively estimated.

Approaches to Adaptive Inference

Approaches to adaptive inference mainly belong to one of two types: either to estimate the unknown parameters v in some way, or to use the data itself to determine which statistical procedure is the most appropriate to these data. These two approaches are the starting points of two rather distinct strands of the statistical literature. *Nonparametric adaptive inference*, on one hand, where v is estimated from the sample, and on the other hand, *data-driven methods*, where the shape of v is identified via a selection statistic to distinguish the effective statistical procedure suitable at the current data.

Nonparametric Methods

The first approach is often used for the *semiparametric model*, where θ is a Euclidean parameter and the nuisance parameter is an infinite dimensional parameter f - often, the unspecified density of some white noise underlying the data generating process.

Stein (1956) introduced the notion of adaptation and gave a simple necessary condition for adaptation in semiparametric models. A comprehensive account of adaptive inference can be found in the monograph by Bickel et al. (1993) for semiparametric models with independent observations. Adaptive inference for dependent data have been studied in a series of papers, e.g., Kreiss (1987), Drost et al. (1997), and Koul and Schick (1997). The current state of the art is summarized in Grenwood et al. (2004).

The basic idea in this literature is to estimate the underlying f using a portion of the sample, and to reduce locally and asymptotically the semiparametric problem to a simpler parametric one, through the so-called "*least favorable parametric submodel*" argument. In general, the resulting computations are non-trivial.

An alternative technique is the use of *adaptive rank based statistics*. Hallin and Werker (2003) proposed a sufficient condition for adaptivity; that is, adaptivity occurs if a parametrically efficient method based on rank statistics can be derived. Then, it suffices, to substitute f in the rank statistics by an estimate $\hat{f}$ measurable on the ►*order statistics*. Some results in this direction have been obtained by Hájek (1962), Beran (1974), and Allal and El Melhaoui (2006).

Finally, these nonparametric adaptive methods, when they exist, are robust in efficiency: they cannot be outperformed by any non-adaptive method. However, these methods have not been widely used in practice, because the estimation of density, typically, requires a large number of observations.

Data-Driven Methods

The second strand of literature addresses the same problem of constructing adaptive inference, and consists of the use of the data to determine which statistical procedure should be used and then using the data again to carry out the procedure.

The was first proposed by Randles and Hogg (1973). Hogg et al. (1975) used the measure of symmetry and tailweight as selection statistics in and adaptive two-sample test. If the selection fell into one of the regions defined by the adaptive procedure, then a certain set of rank scores was selected, whereas if the selection statistic fell into a different region, then different rank scores would be used in the test. Hogg and Lenth (1984) proposed an adaptive estimator of the mean of symmetric distribution. They used selection statistics to determine if a mean, a 25% trimmed mean, or median should be used as an estimate of the mean of population. O'Gorman (2002) proposed an adaptive procedure that performs the commonly used tests of significance, including the two-sample test, a test for a slope in linear regression, and a test for interaction in two-way factorial design. A comprehensive account of this approach can be found in the monograph by O'Gorman (2004).

The advantage of the data-driven methods is that if an adaptive method is properly constructed, it automatically downweight outliers and could easily be applied in practice. However, and contrary to the nonparametric approach, the adaptive data-driven method is the best among the existing procedures, but not the best that can be built. As a consequence, the method so built is not definitively optimal.

Adaptive Sampling

George A. F. Seber[1], Mohammad Salehi M.[2]
[1]Emeritus Professor of Statistics
Auckland University, Auckland, New Zealand
[2]Professor
Isfahan University of Technology, Isfahan, Iran

Adaptive sampling is particularly useful for sampling populations that are sparse but clustered. For example, fish can form large, widely scattered schools with few fish in between. Applying standard sampling methods such as simple random sampling (SRS, see ▶Simple Random Sample) to get a sample of plots from such a population could yield little information, with most of the plots being empty. The idea can be simply described follows. We go fishing in a lake using a boat and, assuming complete ignorance about the population, we select a location at random and fish. If we don't catch anything we select another location at random and try again. If we do catch something we fish in a specific neighborhood of that location and keep expanding the neighborhood until we catch no more fish. We then move on to a second location. This process continues until we have, for example, fished at a fixed number of locations or until our total catch has exceeded a certain number of fish. This kind of technique where the sampling is adapted to what turns up at each stage has been applied to a variety of diverse populations such as marine life, birds, mineral deposits, animal habitats, forests, and rare infectious diseases, and to pollution studies.

We now break down this process into components and introduce some general notation. Our initial focus will be on adaptive ▶cluster sampling, the most popular of the adaptive methods developed by Steven Thompson in the 1990s. Suppose we have a population of N plots and let y_i be a variable that we measure on the ith plot ($i = 1, 2, \ldots, N$). This variable can be continuous (e.g., level of pollution or biomass), discrete (e.g., number of animals or plants), or even just an indicator variable taking the value 1 for presence and zero for absence. Our aim is to estimate some function of the population y values such as, for example, the population total $\tau = \sum_{i=1}^{N} y_i$, the population mean $\mu = \tau/N$, or the population density $D = \tau/A$, where A is the population area.

The next step is to determine the nature of the neighborhood of each initially chosen plot. For example, we could choose all the adjacent units with a common boundary which, together with unit i, form a "cross" Neighborhoods can be defined to have a variety of patterns and the units in a neighborhood do not have to be contiguous (next to each other). We then specify a condition C such as $y_i > c$ which determines when we sample the neighborhood of the ith plot; typically $c = 0$ if y is a count. If C for the ith plot or unit is satisfied, we sample all the units in the neighborhood and if the rule is satisfied for any of those units we sample their neighborhoods as well, and so on, thus leading to a cluster of units. This cluster has the property that all the units on its "boundary" (called "edge units") do not satisfy C. Because of a dual role played by the edge units, the underlying theory is based on the concept of a network, which is a cluster minus its edge units.

It should be noted that if the initial unit selected is any one of the units in the cluster except an edge unit, then

all the units in the cluster end up being sampled. Clearly, if the unit is chosen at random, the probability of selecting the cluster will depend on the size of the cluster. For this reason adaptive cluster sampling can be described as unequal probability cluster sampling – a form of biased sampling.

The final step is to decide how we choose both the size and the method of selecting the initial sample size. Focusing on the second of these for the moment, one simple approach would be to use SRS to get a sample of size n_1, say. If a unit selected in the initial sample does not satisfy C, then there is no augmentation and we have a cluster of size one. We note that even if the units in the initial sample are distinct, as in SRS, repeats can occur in the final sample as clusters may overlap on their edge units or even coincide. For example, if two non-edge units in the same cluster are selected in the initial sample, then that whole cluster occurs twice in the final sample. The final sample then consists of n_1 (not necessarily distinct) clusters, one for each unit selected in the initial sample. We finally end up with a total of n units, which is random, and some units may be repeated.

There are many modifications of the above scheme depending on the nature of the population and we mention just a few. For example, the initial sample may be selected by sampling with replacement, or by using a form of systematic sampling (with a random start) or by using unequal probability sampling, as in sampling a tree with probability proportional to its basal area. Larger initial sampling units other than single plots can be used, for example a strip transect (primary unit) commonly used in both aerial and ship surveys of animals and marine mammals. Other shaped primary units can also be used and units in the primary unit need not be contiguous. If the population is divided into strata, then adaptive cluster sampling can be applied within each stratum, and the individual estimates combined. How they are combined depends on whether clusters are allowed to cross stratum boundaries or not. If instead of strata, we simply have a number of same-size primary units and choose a sample of primary units at random, and then apply the adaptive sampling within each of the chosen primary units, we have two-stage sampling with its appropriate theory.

In some situations, the choice of c in condition C is problematical as, with a wrong choice, we may end up with a feast or famine of plots. Thompson suggested using the data themselves, in fact the ►order statistics for the y_i values in the initial sample. Sometimes animals are not always detected and the theory has been modified to allow for incomplete detectability. If we replace y_i by a vector, then the scheme can be modified to allow for multivariate data.

We now turn our attention to sample sizes. Several ways of controlling sample sizes have been developed. For example, to avoid duplication we can remove a network once it has been selected by sampling networks without replacement. Sequential methods can also be used, such as selecting the initial sample sequentially until n exceeds some value. In fact Salehi, in collaboration with various other authors has developed a number of methods using both inverse and sequential schemes. One critical question remains: How can we use a pilot survey to design an experiment with a given efficiency or expected cost? One solution has been provided using the two-stage sampling method mentioned above (Salehi and Seber 1997).

We have not said anything about actual estimates as this would take several pages. However, a number of estimates associated with the authors Horvitz-Thompson (see ►Horvitz–Thompson Estimator), Hansen-Hurwitz, and Murthy have all been adapted to provide unbiased estimates for virtually all the above schemes and modifications. Salehi (1999) has also used the famous ►Rao-Blackwell theorem to provide more efficient unbiased estimates in a number of cases. The mentioned estimators based on small samples under adaptive cluster sampling often have highly skewed distributions. In such situations, confidence intervals (see ►Confidence Interval) based on traditional normal approximation can lead to unsatisfactory results, with poor coverage properties; for another solution see Salehi et al. (2009a).

As you can see, the topic is rich in applications and modifications and we have only told part of the story! For example, there is a related topic called adaptive allocation that has been used in fisheries; for a short review of adaptive allocation designs see Salehi et al. (2009b). Extensive references to the above are Thompson and Seber (1996) and Seber and Salehi (2004).

About the Author

Professor Seber was appointed to the foundation Chair in Statistics and Head of a newly created Statistics Unit within the Mathematics Department at the University of Auckland in 1973. He was involved in forming a separate Department of Statistics in 1994. He was awarded the Hector Medal by the Royal Society of New Zealand for fundamental contributions to statistical theory, for the development of the statistics profession in New Zealand, and for the advancement of statistics education through his teaching and writing (1999). He has authored or coauthored ten books as well as several second editions, and numerous research papers. However, despite the breadth of his contribution from linear models, multivariate statistics, linear regression, non-linear models, to adaptive sampling, he is perhaps still best known internationally for his research

on the estimation of animal abundance. He is the author of the internationally recognized text *Estimation of Animal Abundance and Related Parameters* (Wiley, 2nd edit., 1994; paperback reprint, Blackburn, 2002). The third conference on Statistics in Ecology and Environmental Monitoring was held in Dunedin (1999) "to mark and recapture the contribution of Professor George Seber to Statistical Ecology."

Advantages of Bayesian Structuring: Estimating Ranks and Histograms

Thomas A. Louis
Professsor
Johns Hopkins Bloomberg School of Public Health, Baltimore, MD, USA

Introduction

Methods developed using the Bayesian formalism can be very effective in addressing both Bayesian and frequentist goals. These advantages are conferred by full probability modeling are most apparent in the context of ►nonlinear models or in addressing non-standard goals. Once the likelihood and the prior have been specified and data observed, ►Bayes' Theorem maps the prior distribution into the posterior. Then, inferences are computed from the posterior, possibly guided by a ►loss function. This last step allows proper processing for complicated, non-intuitive goals. In this context, we show how the Bayesian approach is effective in estimating ►ranks and CDFs (histograms). We give the basic ideas; see Lin et al. (2006, 2008); Paddock et al. (2006) and the references thereof for full details and generalizations.

Importantly, as Carlin and Louis (2009) and many authors caution, the Bayesian approach is not a panacea. Indeed, the requirements for an effective procedure are more demanding than those for a frequentist approach. However, the benefits are many and generally worth the effort, especially now that ►Markov Chain Monte Carlo (MCMC) and other computing innovations are available.

A Basic Hierarchical Model

Consider a basic, compound sampling model with parameters of interest $\boldsymbol{\theta} = (\theta_1, \ldots, \theta_K)$ and data $\mathbf{Y} = (Y_1, \ldots, Y_K)$. The θ_k are *iid* and conditional on the θs, the Y_k are independent.

$$\begin{aligned} \theta_k &\overset{iid}{\sim} G(\cdot) \\ Y_k|\theta_k &\overset{indep}{\sim} f_k(Y_k|\theta_k) \end{aligned} \tag{1}$$

in practice, the θ_k might be the true differential expression of the *kth* gene, the true standardized mortality ratio for the *kth* dialysis clinic, or the true, underlying region-specific disease rate. Generalizations of (1) include adding a third stage to represent uncertainty in the prior, a regression model in the prior, or a priori association among the θs.

Assume that the θ_k and $\boldsymbol{\eta}$ are continuous random variables. Then, their posterior distribution is,

$$g(\boldsymbol{\theta} \mid \mathbf{Y}) = \prod_1^K g(\theta_k \mid Y_k) \tag{2}$$

$$g(\theta_k \mid Y_k) = \frac{f_k(Y_k \mid \theta_k) g(\theta_k)}{\int f_k(Y_k \mid s) g(s) ds} = \frac{f_k(Y_k \mid \theta_k) g(\theta_k)}{f_G(Y_k)}$$

Ranking

The ranking goal nicely shows the beauty of Bayesian structuring. Following Shen and Louis (1998), if the θ_k were directly observed, then their ranks (R_k) and percentiles (P_k) are:

$$R_k(\boldsymbol{\theta}) = \text{rank}(\theta_k) = \sum_{j=1}^K I_{\{\theta_k \geq \theta_j\}}; \; P_k(\boldsymbol{\theta}) = R_k(\boldsymbol{\theta})/(K+1). \tag{3}$$

The smallest θ has rank 1 and the largest has rank K. Note that the ranks are monotone transform invariant (e.g., ranking the logs of parameters produces the original ranks) and estimated ranks should preserve this invariance. In practice, we don't get to observe the θ_k, but can use their posterior distribution (2) to make inferences. For example, minimizing posterior squared-error loss *for the ranks* produces,

$$\bar{R}_k(\mathbf{Y}) = E_{\boldsymbol{\theta}|\mathbf{Y}}[R_k(\boldsymbol{\theta}) \mid \mathbf{Y}] = \sum_{j=1}^{K} \text{pr}(\theta_k \geq \theta_j \mid \mathbf{Y}). \qquad (4)$$

The $\bar{R}_k$ are shrunk towards the mid-rank, $(K+1)/2$, and generally are not integers. Optimal integer ranks result from ranking the $\bar{R}_k$, producing,

$$\hat{R}_k(\mathbf{Y}) = \text{rank}(\bar{R}_k(\mathbf{Y})); \; \hat{P}_k = \hat{R}_k/(K+1). \qquad (5)$$

Unless the posterior distributions of the θ_k are stochastically ordered, ranks based on maximum likelihood estimates or those based on hypothesis test statistics perform poorly. For example, if all θ_k are equal, MLEs with relatively high variance will tend to be ranked at the extremes; if Z-scores testing the hypothesis that a θ_k is equal to the typical value are used, then the units with relatively small variance will tend to be at the extremes. Optimal ranks compromise between these two extremes, a compromise best structured by minimizing posterior expected loss in the Bayesian context.

Example: The basic Gaussian-Gaussian model

We specialize (1) to the model with a Gaussian prior and Gaussian sampling distributions, with possibly different sampling variances. Without loss of generality assume that the prior mean is $\mu = 0$ and the prior variance is $\tau^2 = 1$. We have,

$$\begin{aligned} \theta_k \; &iid \; N(0,1), \\ Y_k|\theta_k &\sim N(\theta_k, \sigma_k^2) \\ \theta_k \mid Y_k \; &ind \; N\left(\theta_k^{pm}, (1-B_k)\sigma_k^2\right) \\ \theta_k^{pm} &= (1-B_k)Y_k; \; B_k = \sigma_k^2/(\sigma_k^2+1). \end{aligned}$$

The σ_k^2 are an ordered, geometric sequence with ratio of the largest σ^2 to the smallest $rls = \sigma_K^2/\sigma_1^2$ and ▶geometric mean $gmv = GM(\sigma_1^2, \ldots, \sigma_K^2)$. When $rls = 1$, the σ_k^2 are all equal. The quantity gmv measures the typical sampling variance and here we consider only $gmv = 1$.

Table 1 documents *SEL* performance for $\hat{P}_k$ (the optimal approach), Y_k (the MLE), ranked θ_k^{pm} and ranked $\exp\left\{\theta_k^{pm} + \frac{(1-B_k)\sigma_k^2}{2}\right\}$ (the posterior mean of e^{θ_k}). We present this last to assess performance for a monotone, non-linear transform of the target parameters. For $rls = 1$, the posterior distributions are stochastically ordered and the four sets of percentiles are identical, as is their performance. As rls increases, performance of Y_k-derived percentiles degrades, those based on the θ_k^{pm} are quite competitive with $\hat{P}_k$, but performance for percentiles based on the posterior mean of e^{θ_k} degrades as rls increases. Results show that though the posterior mean can perform well, in general it is not competitive with the optimal approach.

Advantages of Bayesian Structuring: Estimating Ranks and Histograms. Table 1 Simulated preposterior 10,000 × *SEL* for $gmv = 1$. As a baseline for comparison, if the data provided no information on the θ_k ($gmv = \infty$), all entries would be 833. If the data provided perfect information ($gmv = 0$), all entries would be 0

	Percentiles based on			
rls	$\hat{P}_k$	θ_k^{pm}	$\exp\left\{\theta_k^{pm} + \frac{(1-B_k)\sigma_k^2}{2}\right\}$	Y_k
1	516	516	516	516
25	517	517	534	582
100	522	525	547	644

Estimating the CDF or Histogram

Similar advantages of the Bayesian approach apply to estimating the empirical distribution function (EDF) of the θ_k,

$$G_K(t \mid \boldsymbol{\theta}) = K^{-1} \sum I_{\{\theta_k \leq t\}}.$$

As shown by Shen and Louis (1998), The optimal SEL estimate is

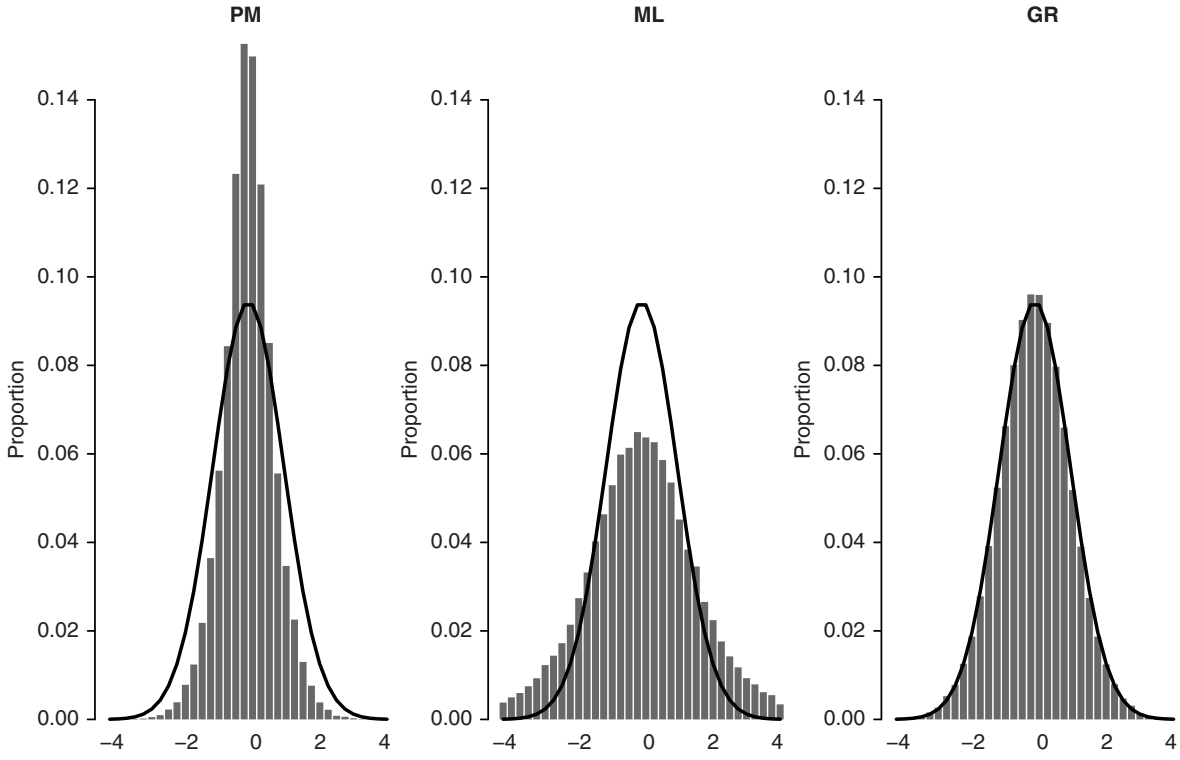
$$\bar{G}_K(t|\mathbf{Y}) = E[G_K(t \mid \boldsymbol{\theta})|\mathbf{Y}] = K^{-1} \sum Pr(\theta_k \leq t|\mathbf{Y}).$$

The optimal discrete distribution estimate with at most K mass points is $\hat{G}_K$, with mass K^{-1} at

$$\hat{U}_j = \bar{G}_K^{-1}\left(\frac{2j-1}{2K}\middle|\mathbf{Y}\right), \qquad j = 1, \ldots, K$$

The EDF is easy to compute from MCMC sampling. After burn-in, pool all θs, order them and set U_j equal to the $(2j-1)th$ order statistic.

Bayesian structuring to estimate G_K pays big dividends. As shown in Fig. 1, for the basic Gaussian model it produces the correct spread, whereas the histogram of the θ_k^{pm} (the posterior means) is under-dispersed and that of the Y_k (the MLEs) is over dispersed. More generally, when the true EDF is asymmetric or multi-modal,



Advantages of Bayesian Structuring: Estimating Ranks and Histograms. Fig. 1 Histogram estimates using θ^{pm}, ML, and $\bar{G}_K$ for the basic Gaussian/Gaussian model. $GM(\{\sigma_k^2\}) = 1$, $rls = 100$

the Bayesian approach also produces the correct shape Paddock et al. (2006).

Discussion

The foregoing are but two examples of the effectiveness of Bayesian structuring. Many more are available in the cited references and in other literature. In closing, we reiterate that the Bayesian approach needs to be used with care; there is nothing automatic about realizing its benefits.

African Population Censuses

James P. M. Ntozi
Professor of Demographic Statistics
Makerere University, Kampala, Uganda

Definition

A Population ►census is the total process of collecting, compiling, evaluating, analyzing and disseminating demographic, economic and social data related to a specified time, to all persons in a country or a well defined part of a country.

History of Population Censuses

Population censuses are as old as human history. There are records of census enumerations as early as in 4000 BC in Babylonia, in 3000 BC in China and in 2500 BC in Egypt. The Roman Empire conducted population censuses and one of the most remembered censuses was the one held around AD 1 when Jesus Christ was born as his parents had moved from Nazareth to Bethlehem for the purpose of being counted. However, modern censuses did not start taking place until one was held in Quebec, Canada in 1666. This was followed by one in Sweden in 1749, USA in 1790, UK in 1801 and India 1871.

African Population Censuses

In the absence of complete civil registration systems in Africa, population censuses provide one of the best sources of socioeconomic and demographic information for the continent. Like in other parts of the world, censuses in Africa started as headcounts and assemblies until after the Second World War. The British were the first to introduce modern censuses in their colonial territories in west, east and southern Africa. For example in East Africa, the first modern census was conducted in 1948 in what was being referred to as British East Africa consisting of Kenya and Uganda. This was followed by censuses in 1957 in Tanzania, in 1959 in Uganda and 1962 in Kenya to prepare the countries for their political independence in 1961, 1962 and 1963, respectively. Other censuses have followed in these three countries. Similarly, the British West African countries of Ghana, Gambia, Nigeria and Sierra Leone were held in 1950s, 1960s and 1970s. In Southern Africa, similar censuses were held in Botswana, Lesotho, Malawi, Swaziland, Zambia and Zimbabwe in 1960s and 1970s, long before the Francophone and Lusophone countries did so. It was not until in 1970s and 1980s that the Francophone and Lusophone African countries started doing censuses instead of sample surveys which they preferred.

To help African countries do population censuses, United Nations set up an African census programme in late 1960s. Out of 41 countries, 22 participated in the programme. This programme closed in 1977 and was succeeded by the Regional Advisory Services in the demographic statistics set up as a section of Statistics Division at the United Nations Economic Commission for Africa. This section supported many African countries in conducting the 1980 and 1990 rounds of censuses. The section was superseded by the UNFPA sub-regional country support teams stationed in Addis Ababa, Cairo, Dakar and Harare. Each of these teams had census experts to give advisory services to countries in the 2000 round of censuses. These teams have now been reduced to three teams stationed in Pretoria, Cairo and Dakar and are currently supporting the African countries in population censuses.

There were working group committees on census on each round of censuses to work on the content of census ►questionnaire. For instance, in the 1980 round of censuses the working group recommended that the census questionnaire should have geographic characteristics, demographic characteristics, economic characteristics, community level variables and housing characteristics. In 1990 round of censuses, questions on the disabled persons were recommended to be added to the 1980 round questions. Later in the 2000 round of censuses, questions on economic establishments, agricultural sector and deaths in households were added. In the current round of 2010 censuses, the questions on disability were sharpened to capture the data better. New questions being asked include those on child labour, age at first marriage, ownership of mobile phone, ownership of email address, access to internet, distance to police post, access to salt in household, most commonly spoken language in household and cause of death in household.

In the 1960 and 1970s round of censuses, Post enumeration surveys (PES) to check on the quality of the censuses were attempted in Ghana. However, the experience with and results from PES were not encouraging, which discouraged most of the African countries from conducting them. Recently, the Post enumeration surveys have been revived and conducted in several African

countries like South Africa, Tanzania and Uganda. The challenges of PES have included: poor cartographic work, neglecting operational independence, inadequate funding, fatigue after the census, matching alternative names, lack of qualified personnel, useless questions in PES, probability sample design and selection, field reconciliation, lack of unique physical addresses in Africa and neglect of pretest of PES.

The achievements of the African censuses include supplying the needed sub-national data to the decentralized units for decision making processes, generating data for monitoring poverty reduction programmes, providing information for measuring indicators of most MDGs, using the data for measuring the achievement of indicators of International Conference on Population and Development (ICP), meeting the demand for data for emerging issues of socioeconomic concerns, accumulating experience in the region of census operations and capacity building at census and national statistical offices.

However, there are still several limitations associated with the African censuses. These have included inadequate participation of the population of the region; only 57% of the African population was counted in the 2000 round of censuses, which was much below to what happened in other regions: Oceania – 100%, Europe and North America – 99%, Asia – 97%, South America – 80% and the world – 91%. Other shortcomings were weak organizational and managerial skills, inadequate funding, non-conducive political environment, civil conflicts, weak technical expertise at NSOs and lack of data for gender indicators.

About the Author

Dr. James P. M. Ntozi is a Professor of demographic statistics at the Institute of Statistics, Makerere University, Kampala, Uganda. He is a founder and Past president of Uganda Statistical Society and Population Association of Uganda. He was a Council member of the International Statistical Institute and Union for African Population Studies, currently a Fellow and Chartered Statistician of the Royal Statistical Society and Council member of the Uganda National Academy of Sciences. He has authored, coauthored, and presented over 100 scientific papers as well as 6 books on fertility and censuses in Africa. He was an Editor of *African Population Studies*, co-edited 4 books, and is currently on the editorial board of *African Statistical Journal* and the *Journal of African Health Sciences*. He has received awards from Population Association of America, Uganda Statistical Society, Makerere University, Bishop Stuart University, Uganda and Ankole Diocese, Church of Uganda. James has been involved in planning and implementation of past Uganda censuses of population and housing of 1980, 1991, and 2002. He is currently helping the Liberian Statistical office to analyze the 2008 census data. Professor Ntozi is a past Director of the Institute of Statistics and Applied Economics, a regional statistical training center based at Makerere University, Uganda, and responsible for training many leaders in statistics and demography in sub-Saharan Africa for over 40 years. His other professional achievements have been research and consultancies in fertility, HIV/AIDS, Human Development Reports, and strategic planning.

Aggregation Schemes

Devendra Chhetry
President of the Nepal Statistical Association (NEPSA),
Professor and Head
Tribhuvan University, Kathmandu, Nepal

Given a data vector $\mathbf{x} = (x_1, x_2, \ldots, x_n)$ and a weight vector $\mathbf{w} = (w_1, w_2, \ldots, w_n)$, there exist three aggregation schemes in the area of statistics that, under certain assumptions, generate three well-known measures of location: arithmetic mean (*AM*), ►geometric mean (*GM*), and ►harmonic mean (*HM*), where it is implicitly understood that the data vector $\mathbf{x}$ contains values of a single variable. Among all these three measures, *AM* is more frequently used in statistics for some theoretical reasons. It is well known that $AM \geq GM \geq HM$ where equality holds only when all components of $\mathbf{x}$ are equal.

In recent years, some of these three and a new aggregation scheme are being practiced in the aggregation of development or deprivation indicators by extending the definition of data vector to a vector of indicators, in the sense that it contains measurements of development or deprivation of several sub-population groups or measurements of several dimensions of development or deprivation. The measurements of development or deprivation are either available in the form of percentages or need to be transformed in the form of unit free indices. Physical Quality of Life Index (Morris 1979), Human Development Index (UNDP 1991), Gender-related Development Index (UNDP 1995), Gender Empowerment Measure (UNDP 1995), and Human Poverty Index (UNDP 1997) are some of the aggregated indices of several dimensions of development or deprivation.

In developing countries, aggregation of development or deprivation indicators is a challenging task, mainly due to two reasons. First, indicators usually display large variations or inequalities in the achievement of development or in the reduction of deprivation across the sub-populations or across the dimensions of development or deprivation within a region. Second, during the process of aggregation it is desired to incorporate the public aversion to social inequalities or, equivalently, public preference for social equalities. Public aversion to social inequalities is essential for development workers or planners of developing countries for bringing marginalized sub-populations into the mainstream by monitoring and evaluation of the development works. Motivated by this problem, Anand and Sen (UNDP 1995) introduced the notion of the gender-equality sensitive indicator (GESI).

In societies of equal proportion of female and male population, for example, the AM of 60 and 30 percent of male and female literacy rate is the same as that of 50 and 40 percent, showing that AM fails to incorporate the public aversion to gender inequality due to the *AM's built-in problem of perfect substitutability*, in the sense that a 10 percentage point decrease in female literacy rate in the former society as compared to the latter one is substituted by the 10 percentage point increase in male literacy rate. The *GM* or *HM*, however, incorporates the public aversion to gender inequality because they do not posses the perfect substitutability property. Instead of *AM*, Anand and Sen used *HM* in the construction of GESI.

In the above example consider that society perceives the social problem from the perspective of deprivation; that is, instead of gender-disaggregated literacy rates society considers gender-disaggregated illiteracy rates. Arguing as before, it immediately follows that *AM* fails to incorporate the public aversion to gender inequality. It also follows that neither *GM* nor *HM* incorporates the public aversion to gender inequality. A new aggregation scheme is required for aggregating indicators of deprivation.

So far, currently practiced aggregation schemes are accommodated within a slightly modified version of the following single mathematical function due to Hardy et al. (1952) under the assumption that components of $\mathbf{x}$ and $\mathbf{w}$ are positive and the sum of the components of $\mathbf{w}$ is unity.

$$\mu(\mathbf{x}, \mathbf{w}, r) = \begin{cases} \left(\sum_{i=1}^{n} w_i {x_i}^r \right)^{1/r} & \text{if } r \neq 0, \\ \prod_{i=1}^{n} {x_i}^{w_i} & \text{if } r = 0. \end{cases} \tag{1}$$

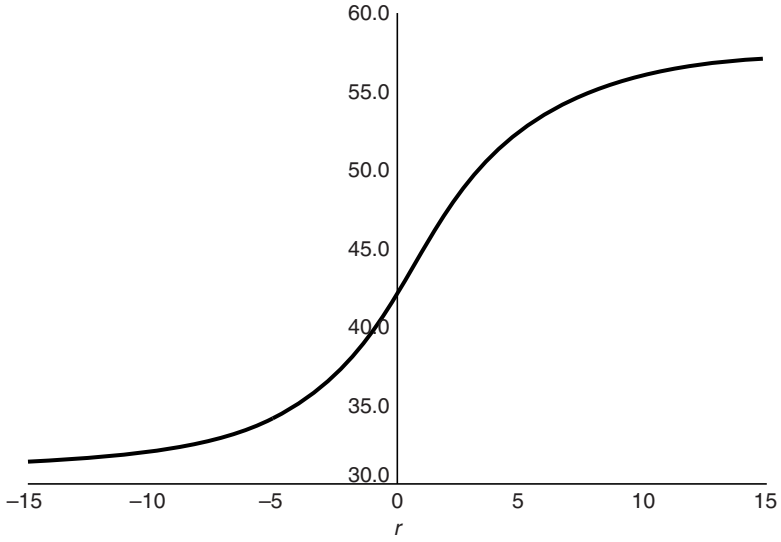
For fixed $\mathbf{x}$ and $\mathbf{w}$, the function (1) is defined for all real numbers, implying that the function (1) yields an infinite number of aggregation schemes. In particular, it yields *AM* when $r = 1$, *HM* when $r = -1$, and obviously *GM* when $r = 0$, and a new aggregation scheme suggested by Anand and Sen in constructing Human Poverty Index when $n = 3$, $w_1 = w_2 = w_3 = 1/3$ and $r = 3$ (UNDP 1997). It is well known that the values of the function are bounded between $x_{(1)}$ and $x_{(n)}$, where $x_{(1)} = \min\{x_1, x_2, \ldots, x_n\}$ and $x_{(n)} = \max\{x_1, x_2, \ldots, x_n\}$, and the function is strictly increasing with respect to r if all the components of data vector are not equal (see Fig. 1 when $w_1 = w_2 = 0.5$, $x_1 = 60\%$ and $x_2 = 30\%$).

The first two partial derivatives of the function with respect to the k^{th} component of the vector $\mathbf{x}$ yield the following results where $g(\mathbf{x}, \mathbf{w})$ is *GM*.

$$\frac{\partial \mu(\mathbf{x}, \mathbf{w}, r)}{\partial x_k} = \begin{cases} w_k \left(\frac{x_k}{\mu(\mathbf{x}, \mathbf{w}, r)} \right)^{r-1} & \text{if } r \neq 0, \\ w_k \, g(\mathbf{x}, \mathbf{w}) x_k^{-1} & \text{if } r = 0. \end{cases} \tag{2}$$

$$\frac{\partial^2 \mu(\mathbf{x}, \mathbf{w}, r)}{\partial x_k^2} = \begin{cases} (r-1) w_k \left[\frac{x_k}{\mu(\mathbf{x}, \mathbf{w}, r)} \right]^{r-2} \sum_{i \neq k} \mathbf{w_i} \mathbf{x_i^r} & \text{if } r \neq 0, \\ w_k \, (w_k - 1) g(\mathbf{x}, \mathbf{w}) x_k{}^{-}2 & \text{if } r = 0. \end{cases} \tag{3}$$

For fixed $\begin{pmatrix} r < 1 \\ r > 1 \end{pmatrix}$ and $\mathbf{w}$, (2) and (3) imply that the function (1) is increasing and $\begin{pmatrix} \text{concave} \\ \text{convex} \end{pmatrix}$ with



Aggregation Schemes. Fig. 1 Nature of the function in a particular case

respect to each x_k, implying that the aggregated value increases at $\begin{pmatrix}\text{decreasing}\\\text{increasing}\end{pmatrix}$ rate with respect to each component of **x**. These properties are desirable for aggregating the $\begin{pmatrix}\text{development}\\\text{deprivation}\end{pmatrix}$ indicators, since the aggregated value of $\begin{pmatrix}\text{development}\\\text{deprivation}\end{pmatrix}$ is expected to $\begin{pmatrix}\text{rise}\\\text{fall}\end{pmatrix}$ from the $\begin{pmatrix}\text{floor to the ceiling value}\\\text{ceiling to the floor value}\end{pmatrix}$ at decreasing rate with respect to each component of **x**. For given **x** and **w**, the function (1) with any value of r, $\begin{pmatrix}r<1\\r>1\end{pmatrix}$, could be used to aggregate the $\begin{pmatrix}\text{development}\\\text{deprivation}\end{pmatrix}$ indicators if the public aversion to social inequalities should be incorporated.

What value of r should one use in practice? There is no simple answer to this question, since the answer depends upon the society's degree of preference for social equality. If a society has no preference for social equality, then one can use $r = 1$ in aggregating development or deprivation indicators, which is still a common practice in developing countries, even though the public efforts for bringing marginalized sub-populations into the mainstream has become a major agenda of development.

If a society has preference for social equality, then subjective judgment in the choice of r seems to be unavoidable. For the purpose of monitoring and evaluation, such judgment does not seem to be a serious issue as long as a fixed value of r is decided upon. In this context, Anand and Sen suggested using $r = -1$ for aggregating the indicators of development when $n = 2$ (UNDP 1995), and $r = 3$ for aggregating the indicators of deprivation when $n = 3$ (UNDP 1997). A lot of research work still needs to be done in this area for producing social-equality sensitive indicators of development or deprivation.

Agriculture, Statistics in

Gavin J. S. Ross
Rothamsted Research, Harpenden, UK

The need to collect information on agricultural production has been with us since the dawn of civilization. Agriculture was the main economic activity, supplying both food for growing populations and the basis for taxation. The Sumerians of Mesopotamia before 3000 BC developed writing systems in order to record crop yields and livestock numbers. The Ancient Egyptians recorded the extent and productivity of arable land on the banks of the Nile. Later conquerors surveyed their new possessions, as in the Norman conquest of England which resulted in the Domesday Book of 1086, recording the agricultural potential of each district in great detail.

The pioneers of scientific agriculture, such as J.B. Lawes and J.H.Gilbert at Rothamsted, England, from 1843 onwards, insisted on accurate measurement and recording as the first requirement for a better understanding of the processes of agricultural production. The Royal Statistical Society (RSS) was founded in 1834 with its symbol of a sheaf of corn, implying that the duty of statisticians was to gather numerical information, but for others to interpret the data. Lawes published numerous papers on the variability of crop yields from year to year, and later joined the Council of the RSS. By 1900 agricultural experiments were conducted in several countries, including Germany, the Netherlands and Ireland, where W.S. Gosset, publishing under the name of "Student," conducted trials of barley varieties for the brewing industry.

In 1919 R.A. Fisher was appointed to analyze the accumulated results of 70 years of field experimentation at Rothamsted, initiating a revolution in statistical theory and practice. Fisher had already published the theoretical explanation of Student's t-distribution and the sampling distribution of the correlation coefficient, and challenged Karl Pearson's position that statistical analysis was only possible with large samples. His first task was to study the relationship between rainfall and crop yields on the long-term experiments, for which he demanded a powerful mechanical calculator, the "Millionaire." Introducing orthogonal polynomials to fit the yearly weather patterns and to eliminate the long-term trend in crop yield, he performed multiple regressions on the rainfall components, and developed the variance ratio test (later the F-distribution) to justify which terms to include using what became the ►analysis of variance. If the results were of minor interest to farmers, the methods used were of enormous importance in establishing the new methodology of curve fitting, regression analysis and the analysis of variance.

Fisher's work with agricultural scientists brought him a whole range of statistical challenges. Working with small samples he saw the role of the statistician as one who extracts the information in a sample as efficiently as possible. Working with non-normally distributed data he proposed the concept of likelihood, and the method of maximum likelihood to estimate parameters in a model. The early field experiments at Rothamsted contained the accepted notion of comparison of treatments with controls at the same location, and some plots included factorial combinations of fertilizer sources. Fisher saw that in order to apply statistical methods to assess the significance of observed effects it was necessary to introduce ►randomization and replication. Local control on land of varying fertility could be improved by blocking, and for trends in two directions he introduced Latin Square designs. The analysis of factorial experiments could be expressed in terms of main effects and interaction effects, with the components of interaction between blocks and treatments regarded as the basic residual error variance.

Fisher's ideas rapidly gained attention and his ideas and methods were extended to many fields beyond agricultural science. George Snedecor in Iowa, Mahalanobis and C.R. Rao in India, were early disciples, and his assistants included L.H.C. Tippett, J. Wishart and H. Hotelling. He was visited in 1926 by J. Neyman, who was working with agricultural scientists in Poland. In 1930 he was joined by Frank Yates who had experience of ►least squares methods as a surveyor in West Africa. Fisher left Rothamsted in 1933 to pursue his interests in genetics, but continued to collaborate with Yates. They introduced Balanced Incomplete Blocks and Lattice designs, and Split Plot designs with more than one component of error variance. Their *Statistical Tables*, first published in 1938, were widely used for many decades later.

Yates expanded his department to provide statistical analysis and consulting to agricultural departments and institutes in Britain and the British Empire. Field experimentation spread to South America with W.L Stevens, and his assistants W.G. Cochran, D.J. Finney and O. Kempthorne became well-known statistical innovators in many applications. During World War II Yates persuaded the government of the value of sample surveys to provide information about farm productivity, pests and diseases and fertilizer use. He later advised Indian statisticians on

the design and analysis of experiments in which small farmers in a particular area might be responsible for one plot each.

In 1954 Yates saw the potential of the electronic computer in statistical research, and was able to acquire the first computer devoted to civilian research, the Elliott 401. On this computer the first statistical programs were written for the analysis of field experiments and surveys, for bioassay and ►probit analysis, for multiple regression and multivariate analysis, and for model fitting by maximum likelihood. All the programs were in response to the needs of agricultural scientists, at field or laboratory level, including those working in animal science. Animal experiments typically had unequal numbers of units with different treatments, and iterative methods were needed to fit parameters by least squares or maximum likelihood. Animal breeding data required lengthy computing to obtain components of variance from which to estimate heritabilities and selection indices. The needs of researcher workers in fruit tree research, forestry, glasshouse crops and agricultural engineering all posed different challenges to the statistical profession.

In 1968 J.A. Nelder came to Rothamsted as head of the Statistics Department, having been previously at the National Vegetable Research Station at Wellesbourne, where he had explored the used of systematic designs for vegetable trials, and had developed the well-used Simplex Algorithm with R. Mead to fit ►nonlinear models. With more powerful computers it was now possible to combine many analyses into one system, and he invited G.N. Wilkinson from Adelaide to include his general algorithm for the analysis of variance in a more comprehensive system that would allow the whole range of nested and crossed experimental designs to be handled, along with facilities for regression and multivariate analysis. The program GENSTAT is now used world-wide in agricultural and other research settings.

Nelder worked with R.M. Wedderburn to show how the methodology of Probit Analysis (fitting binomial data to a transformed regression line) could be generalized to a whole class of ►Generalized Linear Models. These methods were particularly useful for the analysis of multiway contingency tables, using logit transformations for binomial data and log transformations for positive data with long-tailed distributions. The applications may have been originally in agriculture but found many uses elsewhere, such as in medical and pharmaceutical research.

The needs of soil scientists brought new classes of statistical problems. The classification of soils was complicated by the fact that overlapping horizons with different properties did not occur at the same depth, although samples were essential similar but displaced. The method of Kriging, first used by South African mining engineers, was found to be useful in describing the spatial variability of agricultural land, with its allowance for differing trends and sharp boundaries.

The need to model responses to fertilizer applications, the growth of plants and animals, and the spread of weeds, pests and diseases led to developments in fitting non-linear models. While improvements in the efficiency of numerical optimization algorithms were important, attention to the parameters to be optimized helped to show the relationship between the model and the data, and which observations contributed most to the parameters of interest. The limitations of agricultural data, with many unknown or unmeasurable factors present, makes it necessary to limit the complexity of the models being fitted, or to fit common parameters to several related samples.

Interest in spatial statistics, and in the use of models with more than one source of error, has led to developments such as the powerful REML algorithm. The use of intercropping to make better use of productive land has led to appropriate developments in experimental design and analysis.

With the increase in power of computers it became possible to construct large, complex models, incorporating where possible known relationships between growing crops and all the natural and artificial influences affecting their growth over the whole cycle from planting to harvest. These models have been valuable in understanding the processes involved, but have not been very useful in predicting final yields. The statistical ideas developed by Fisher and his successors have concentrated on the choices which farmers can make in the light of information available at the time, rather than to provide the best outcomes for speculators in crop futures. Modeling on its own is no substitute for continued experimentation.

The challenge for the 21st century will be to ensure sustainable agriculture for the future, taking account of climate change, resistance to pesticides and herbicides, soil degradation and water and energy shortages. Statistical methods will always be needed to evaluate new techniques of plant and animal breeding, alternative food sources and environmental effects.

About the Author

Gavin J.S. Ross has worked in the Statistics Department at Rothamsted Experimental Station since 1961, now as a retired visiting worker. He served under Frank Yates,

John Nelder and John Gower, advising agricultural workers, and creating statistical software for nonlinear modelling and for cluster analysis and multivariate analysis, contributing to the GENSTAT program as well as producing the specialist programs MLP and CLASP for his major research interests. His textbook *Nonlinear Estimation* (Springer 1990) describes the use of stable parameter transformations to fit and interpret nonlinear models. He served as President of the British Classification Society.

Akaike's Information Criterion

Hirotugu Akaike†
Former Director General of the Institute of Statistical Mathematics and a Kyoto Prize Winner
Tokyo, Japan

The Information Criterion $I(g:f)$ that measures the deviation of a model specified by the probability distribution f from the true distribution g is defined by the formula

$$I(g:f) = E\log g(X) - E\log f(X).$$

Here E denotes the expectation with respect to the true distribution g of X. The criterion is a measure of the deviation of the model f from the true model g, or the best possible model for the handling of the present problem.

The following relation illustrates the significant characteristic of the log likelihood:

$$I(g:f_1) - I(g:f_2) = -E(\log f_1(X) - \log f_2(X)).$$

This formula shows that for an observation x of X the log likelihood $\log f(x)$ provides a relative measure of the closeness of the model f to the truth, or the goodness of the model. This measure is useful even when the true structure g is unknown.

For a model $f(X/\mathbf{a})$ with unknown parameter $\mathbf{a}$ the maximum likelihood estimate $\mathbf{a}(x)$ is defined as the value of $\mathbf{a}$ that maximizes the likelihood $f(x/\mathbf{a})$ for a given observation x. Due to this process the value of $\log f(x/\mathbf{a}(x))$ shows an upward bias as an estimate of $\log f(X/\mathbf{a})$. Thus to use $\log f(x/\mathbf{a}(x))$ as the measure of the goodness of the model $f(X/\mathbf{a})$, it must be corrected for the expected bias.

In typical application of the method of maximum likelihood this expected bias is equal the dimension, or the number of components, of the unknown parameter $\mathbf{a}$. Thus the relative goodness of a model determined by the maximum likelihood estimate is given by

AIC = −2 (log maximum likelihood − (number of parameters)).

Here log denotes natural logarithm. The coefficient −2 is used to make the quantity similar to the familiar chi-square statistic in the test of dimensionality of the parameter.

AIC is the abbreviation of An Information Criterion.

About the Author

Professor Akaike died of pneumonia in Tokyo on 4th August 2009, aged 81. He was the Founding Head of the first Department of Statistical Science in Japan. "Now that he has left us forever, the world has lost one of its most innovative statisticians, the Japanese people have lost the finest statistician in their history and many of us a most noble friend" (Professor Howell Tong, from "The Obituary of Professor Hirotugu Akaike." *Journal of the Royal Statistical Society, Series A,* March, 2010). Professor Akaike had sent his Encyclopedia entry on May 14 2009, adding the following sentence in his email: "This is all that I could do under the present physical condition."

Introduction

The ▶Akaike Information Criterion, AIC, was introduced by Hirotogu Akaike in his seminal 1973 paper "Information Theory and an Extension of the Maximum Likelihood Principle." AIC was the first model selection criterion to gain widespread attention in the statistical community. Today, AIC continues to be the most widely known and used model selection tool among practitioners.

The traditional maximum likelihood paradigm, as applied to statistical modeling, provides a mechanism for estimating the unknown parameters of a model having a specified dimension and structure. Akaike extended this paradigm by considering a framework in which the model dimension is also unknown, and must therefore be determined from the data. Thus, Akaike proposed a framework wherein both model estimation and selection could be simultaneously accomplished.

For a parametric candidate model of interest, the likelihood function reflects the conformity of the model to the observed data. As the complexity of the model is increased, the model becomes more capable of adapting to the characteristics of the data. Thus, selecting the fitted model that maximizes the empirical likelihood will invariably lead one to choose the most complex model in the candidate collection. ▶Model selection based on the likelihood principle, therefore, requires an extension of the traditional likelihood paradigm.

Background

To formally introduce AIC, consider the following model selection framework. Suppose we endeavor to find a suitable model to describe a collection of response measurements y. We will assume that y has been generated according to an unknown density $g(y)$. We refer to $g(y)$ as the *true* or *generating model*.

A model formulated by the investigator to describe the data y is called a *candidate* or *approximating model*. We will assume that any candidate model structurally corresponds to a parametric class of distributions. Specifically, for a certain candidate model, we assume there exists a k-dimensional parametric class of density functions

$$\mathcal{F}(k) = \{f(y|\,\theta_k) \mid \theta_k \in \Theta(k)\},$$

a class in which the parameter space $\Theta(k)$ consists of k-dimensional vectors whose components are functionally independent.

Let $L(\theta_k\,|\,y)$ denote the likelihood corresponding to the density $f(y|\,\theta_k)$, i.e., $L(\theta_k\,|\,y) = f(y|\,\theta_k)$. Let $\hat{\theta}_k$ denote a vector of estimates obtained by maximizing $L(\theta_k\,|\,y)$ over $\Theta(k)$.

Suppose we formulate a collection of candidate models of various dimensions k. These models may be based on different subsets of explanatory variables, different mean and variance/covariance structures, and even different specifications for the type of distribution for the response variable. Our objective is to search among this collection for the fitted model that "best" approximates $g(y)$.

In the development of AIC, optimal approximation is defined in terms of a well-known measure that can be used to gauge the similarity between the true model $g(y)$ and a candidate model $f(y|\,\theta_k)$: the *Kullback–Leibler information* (Kullback and Leibler 1951; Kullback 1968). The Kullback–Leibler information between $g(y)$ and $f(y|\,\theta_k)$ with respect to $g(y)$ is defined as

$$I(\theta_k) = \mathrm{E}\left\{\log\frac{g(y)}{f(y|\,\theta_k)}\right\},$$

where $\mathrm{E}(\cdot)$ denotes the expectation under $g(y)$. It can be shown that $I(\theta_k) \geq 0$ with equality if and only if $f(y|\,\theta_k)$ is the same density as $g(y)$. $I(\theta_k)$ is not a formal metric, yet we view the measure in a similar manner to a distance: i.e., as the disparity between $f(y|\,\theta_k)$ and $g(y)$ grows, the magnitude of $I(\theta_k)$ will generally increase to reflect this separation.

Next, define

$$d(\theta_k) = \mathrm{E}\{-2\log f(y|\,\theta_k)\}.$$

We can then write

$$2I(\theta_k) = d(\theta_k) - \mathrm{E}\{-2\log g(y)\}.$$

Since $\mathrm{E}\{-2\log g(y)\}$ does not depend on θ_k, any ranking of a set of candidate models corresponding to values of $I(\theta_k)$ would be identical to a ranking corresponding to values of $d(\theta_k)$. Hence, for the purpose of discriminating among various candidate models, $d(\theta_k)$ serves as a valid substitute for $I(\theta_k)$. We will refer to $d(\theta_k)$ as the *Kullback discrepancy*.

To measure the separation between between a fitted candidate model $f(y|\,\hat{\theta}_k)$ and the generating model

$g(y)$, we consider the Kullback discrepancy evaluated at $\hat{\theta}_k$:

$$d(\hat{\theta}_k) = \mathrm{E}\{-2\log f(y|\,\theta_k)\}|_{\theta_k=\hat{\theta}_k}.$$

Obviously, $d(\hat{\theta}_k)$ would provide an attractive means for comparing various fitted models for the purpose of discerning which model is closest to the truth. Yet evaluating $d(\hat{\theta}_k)$ is not possible, since doing so requires knowledge of the true distribution $g(\cdot)$. The work of Akaike (1973, 1974), however, suggests that $-2\log f(y|\,\hat{\theta}_k)$ serves as a biased estimator of $d(\hat{\theta}_k)$, and that the bias adjustment

$$\mathrm{E}\{d(\hat{\theta}_k)\} - \mathrm{E}\{-2\log f(y|\,\hat{\theta}_k)\} \tag{1}$$

can often be asymptotically estimated by twice the dimension of θ_k.

Since k denotes the dimension of θ_k, under appropriate conditions, the expected value of

$$\mathrm{AIC} = -2\log f(y|\,\hat{\theta}_k) + 2k$$

will asymptotically approach the expected value of $d(\hat{\theta}_k)$, say

$$\Delta(k) = \mathrm{E}\{d(\hat{\theta}_k)\}.$$

Specifically, we will establish that

$$\mathrm{E}\{\mathrm{AIC}\} + o(1) = \Delta(k). \tag{2}$$

AIC therefore provides an asymptotically unbiased estimator of $\Delta(k)$. $\Delta(k)$ is often called the *expected Kullback discrepancy*.

In AIC, the empirical log-likelihood term $-2\log f(y|\,\hat{\theta}_k)$ is called the *goodness-of-fit term*. The bias correction $2k$ is called the *penalty term*. Intuitively, models which are too simplistic to adequately accommodate the data at hand will be characterized by large goodness-of-fit terms yet small penalty terms. On the other hand, models that conform well to the data, yet do so at the expense of containing unnecessary parameters, will be characterized by small goodness-of-fit terms yet large penalty terms. Models that provide a desirable balance between fidelity to the data and parsimony should correspond to small AIC values, with the sum of the two AIC components reflecting this balance.

Derivation

To justify AIC as an asymptotically unbiased estimator of $\Delta(k)$, we will focus on a particular candidate class $\mathcal{F}(k)$. For notational simplicity, we will suppress the dimension index k on the parameter vector θ_k and its estimator $\hat{\theta}_k$.

The justification of (2) requires the strong assumption that the true density $g(y)$ is a member of the candidate class $\mathcal{F}(k)$. Under this assumption, we may define a parameter vector θ_o having the same size as θ, and write $g(y)$ using the parametric form $f(y|\,\theta_o)$. The assumption that $f(y|\,\theta_o) \in \mathcal{F}(k)$ implies that the fitted model is either correctly specified or overfit.

To justify (2), consider writing $\Delta(k)$ as indicated:

$$\begin{aligned}
&\Delta(k)\\
&= \mathrm{E}\{d(\hat{\theta})\}\\
&= \mathrm{E}\{-2\log f(y|\,\hat{\theta})\}\\
&\quad + \left[\mathrm{E}\{-2\log f(y|\,\theta_o)\} - \mathrm{E}\{-2\log f(y|\,\hat{\theta})\}\right] \qquad (3)\\
&\quad + \left[\mathrm{E}\{d(\hat{\theta})\} - \mathrm{E}\{-2\log f(y|\,\theta_o)\}\right]. \qquad (4)
\end{aligned}$$

The following lemma asserts that (3) and (4) are both within $o(1)$ of k.

We assume the necessary regularity conditions required to ensure the consistency and ▸asymptotic normality of the maximum likelihood vector $\hat{\theta}$.

Lemma

$$\mathrm{E}\{-2\log f(y|\,\theta_o)\} - \mathrm{E}\{-2\log f(y|\,\hat{\theta})\} = k + o(1), \tag{5}$$

$$\mathrm{E}\{d(\hat{\theta})\} - \mathrm{E}\{-2\log f(y|\,\theta_o)\} = k + o(1). \tag{6}$$

Proof

Define

$$\mathrm{I}(\theta) = \mathrm{E}\left[-\frac{\partial^2 \log f(y|\,\theta)}{\partial\theta\partial\theta'}\right]$$

$$\text{and } \mathcal{I}(\theta, y) = \left[-\frac{\partial^2 \log f(y|\,\theta)}{\partial\theta\partial\theta'}\right].$$

$\mathrm{I}(\theta)$ denotes the *expected Fisher information matrix* and $\mathcal{I}(\theta, y)$ denotes the *observed Fisher information matrix*.

First, consider taking a second-order expansion of $-2\log f(y|\,\theta_o)$ about $\hat{\theta}$, and evaluating the expectation of the result. Since $-2\log f(y|\,\theta)$ is minimized at $\theta = \hat{\theta}$, the first-order term disappears, and we obtain

$$\begin{aligned}
\mathrm{E}\{-2\log f(y|\,\theta_o)\} &= \mathrm{E}\{-2\log f(y|\,\hat{\theta})\}\\
&\quad + \mathrm{E}\left\{(\hat{\theta} - \theta_o)'\{\mathcal{I}(\hat{\theta}, y)\}(\hat{\theta} - \theta_o)\right\}\\
&\quad + o(1).
\end{aligned}$$

Thus,

$$\begin{aligned}
&\mathrm{E}\{-2\log f(y|\,\theta_o)\} - \mathrm{E}\{-2\log f(y|\,\hat{\theta})\}\\
&\quad = \mathrm{E}\left\{(\hat{\theta} - \theta_o)'\{\mathcal{I}(\hat{\theta}, y)\}(\hat{\theta} - \theta_o)\right\} + o(1). \qquad (7)
\end{aligned}$$

Next, consider taking a second-order expansion of $d(\hat{\theta})$ about θ_o, again evaluating the expectation of the

result. Since $d(\theta)$ is minimized at $\theta = \theta_o$, the first-order term disappears, and we obtain

$$\begin{aligned}\mathrm{E}\{d(\hat{\theta})\} &= \mathrm{E}\{-2\log f(y|\,\theta_o)\} \\ &\quad + \mathrm{E}\left\{(\hat{\theta}-\theta_o)'\{\mathrm{I}(\theta_o)\}(\hat{\theta}-\theta_o)\right\} \\ &\quad + o(1).\end{aligned}$$

Thus,

$$\begin{aligned}&\mathrm{E}\{d(\hat{\theta})\} - \mathrm{E}\{-2\log f(y|\,\theta_o)\} \\ &\quad = \mathrm{E}\left\{(\hat{\theta}-\theta_o)'\{\mathrm{I}(\theta_o)\}(\hat{\theta}-\theta_o)\right\} + o(1). \qquad (8)\end{aligned}$$

Recall that by assumption, $\theta_o \in \Theta(k)$. Therefore, the quadratic forms

$$(\hat{\theta}-\theta_o)'\{\mathcal{I}(\hat{\theta},y)\}(\hat{\theta}-\theta_o) \text{ and } (\hat{\theta}-\theta_o)'\{\mathrm{I}(\theta_o)\}(\hat{\theta}-\theta_o)$$

both converge to centrally distributed chi-square random variables with k degrees of freedom. Thus, the expectations of both quadratic forms are within $o(1)$ of k. This fact along with (7) and (8) establishes (5) and (6). □

Properties

The previous lemma establishes that AIC provides an asymptotically unbiased estimator of $\Delta(k)$ for fitted candidate models that are correctly specified or overfit. From a practical perspective, AIC estimates $\Delta(k)$ with negligible bias in settings where n is large and k is comparatively small. In settings where n is small and k is comparatively large (e.g., $k \approx n/2$), $2k$ is often much smaller than the bias adjustment, making AIC substantially negatively biased as an estimator of $\Delta(k)$.

If AIC severely underestimates $\Delta(k)$ for higher dimensional fitted models in the candidate collection, the criterion may favor the higher dimensional models even when the expected discrepancy between these models and the generating model is rather large. Examples illustrating this phenomenon appear in Linhart and Zucchini (1986, 86–88), who comment (p. 78) that "in some cases the criterion simply continues to decrease as the number of parameters in the approximating model is increased."

AIC is *asymptotically efficient* in the sense of Shibata (1980, 1981), yet it is not *consistent*. Suppose that the generating model is of a finite dimension, and that this model is represented in the candidate collection under consideration. A consistent criterion will asymptotically select the fitted candidate model having the correct structure with probability one. On the other hand, suppose that the generating model is of an infinite dimension, and therefore lies outside of the candidate collection under consideration. An asymptotically efficient criterion will asymptotically select the fitted candidate model which minimizes the mean squared error of prediction.

From a theoretical standpoint, asymptotic efficiency is arguably the strongest optimality property of AIC. The property is somewhat surprising, however, since demonstrating the asymptotic unbiasedness of AIC as an estimator of the expected Kullback discrepancy requires the assumption that the candidate model of interest subsumes the true model.

Refinements

A number of AIC variants have been developed and proposed since the introduction of the criterion. In general, these variants have been designed to achieve either or both of two objectives: (1) to relax the assumptions or expand the setting under which the criterion can be applied, (2) to improve the small-sample performance of the criterion.

In the Gaussian linear regression framework, Sugiura (1978) established that the bias adjustment (1) can be exactly evaluated for correctly specified or overfit models. The resulting criterion, with a refined penalty term, is known as "corrected" AIC, or AICc. Hurvich and Tsai (1989) extended AICc to the frameworks of Gaussian nonlinear regression models and time series autoregressive models. Subsequent work has extended AICc to other modeling frameworks, such as autoregressive moving average models, vector autoregressive models, and certain ►generalized linear models and ►linear mixed models.

The Takeuchi (1976) information criterion, TIC, was derived by obtaining a general, large-sample approximation to each of (3) and (4) that does not rely on the assumption that the true density $g(y)$ is a member of the candidate class $\mathcal{F}(k)$. The resulting approximation is given by the trace of the product of two matrices: an information matrix based on the score vector, and the inverse of an information matrix based on the Hessian of the log likelihood. Under the assumption that $g(y) \in \mathcal{F}(k)$, the information matrices are equivalent. Thus, the trace reduces to k, and the penalty term of TIC reduces to that of AIC.

Bozdogon (1987) proposed a variant of AIC that corrects for its lack of consistency. The variant, called CAIC, has a penalty term that involves the log of the determinant of an information matrix. The contribution of this term leads to an overall complexity penalization that increases with the sample size at a rate sufficient to ensure consistency.

Pan (2001) introduced a variant of AIC for applications in the framework of generalized linear models fitted

using generalized estimating equations. The criterion is called QIC, since the goodness-of-fit term is based on the empirical quasi-likelihood.

Konishi and Kitagawa (1996) extended the setting in which AIC has been developed to a general framework where (1) the method used to fit the candidate model is not necessarily maximum likelihood, and (2) the true density $g(y)$ is not necessarily a member of the candidate class $\mathcal{F}(k)$. Their resulting criterion is called the generalized information criterion, GIC. The penalty term of GIC reduces to that of TIC when the fitting method is maximum likelihood.

AIC variants based on computationally intensive methods have also been proposed, including cross-validation (Stone 1977; Davies et al. 2005), bootstrapping (Ishiguro et al. 1997; Cavanaugh and Shumway 1997; Shibata 1997), and Monte Carlo simulation (Hurvich et al. 1990; Bengtsson and Cavanaugh 2006). These variants tend to perform well in settings where the sample size is small relative to the complexity of the models in the candidate collection.

About the Authors

Joseph E. Cavanaugh is Professor of Biostatistics and Professor of Statistics and Actuarial Science at The University of Iowa. He is an associate editor of the *Journal of the American Statistical Association* (2005–present) and the *Journal of Forecasting* (1999–present). He has published over 60 refereed articles.

Andrew Neath is a Professor of Mathematics and Statistics at Southern Illinois University Edwardsville. He has been recognized for his work in science education. He is an author on numerous papers, merging Bayesian views with model selection ideas. He wishes to thank Professor Miodrag Lovric for the honor of an invitation to contribute to a collection containing the works of so many notable statisticians.

Algebraic Statistics

Sonja Petrović[1], Aleksandra B. Slavković[2]

[2]Associate Professor
The Pennsylvania State University, University Park, PA, USA

Algebraic statistics applies concepts from algebraic geometry, commutative algebra, and geometric combinatorics to better understand the structure of statistical models, to

improve statistical inference, and to explore new classes of models. Modern algebraic geometry was introduced to the field of statistics in the mid 1990s. Pistone and Wynn (1996) used Gröbner bases to address the issue of confounding in design of experiments, and Diaconis and Sturmfels (1998) used them to perform exact conditional tests. The term *algebraic statistics* was coined in the book by Pistone et al. (2001), which primarily addresses experimental design. The current algebraic statistics literature includes work on contingency tables, sampling methods, graphical and latent class models, and applications in areas such as statistical disclosure limitation (e.g., Dobra et al. (2009)), and computational biology and phylogenetics (e.g., Pachter and Sturmfels (2005)).

Algebraic Geometry of Statistical Models

Algebraic geometry is a broad subject that has seen an immense growth over the past century. It is concerned with the study of algebraic varieties, defined to be (closures of) solution sets of systems of polynomial equations. For an introduction to computational algebraic geometry and commutative algebra, see Cox et al. (2007).

Algebraic statistics studies statistical models whose parameter spaces correspond to real positive parts of algebraic varieties. To demonstrate how this correspondence works, consider the following simple example of the independence model of two binary random variables, X and Y, such that joint probabilities are arranged in a 2×2 matrix $p := [p_{ij}]$. The model postulates that the joint probabilities factor as a product of marginal distributions: $p_{ij} = p_{i+}p_{+j}$, where $i, j \in \{1, 2\}$. This is referred to as an *explicit* algebraic statistical model. Equivalently, the matrix p is of rank 1, that is, its 2×2 determinant is zero: $p_{11}p_{22} - p_{12}p_{21} = 0$. This is referred to as an *implicit* description of the independence model. In algebraic geometry, the set of rank-1 matrices, where we allow p_{ij} to be arbitrary complex numbers, is a classical object called a *Segre variety*. Thus, the independence model is the real positive part of the Segre variety. Exponential family models, in general, correspond to *toric varieties*, whose implicit description is given by a set of binomials. For a broad, general definition of algebraic statistical models, see Drton and Sullivant (2007).

By saying that "we understand the algebraic geometry of a model," we mean that we understand some basic information about the corresponding variety, such as: degree, dimension and codimension (i.e., degrees of freedom); the defining equations (i.e., the implicit description of the model); the singularities (i.e., degeneracy in the model). The current algebraic statistics literature demonstrates that understanding the geometry of a model can be useful for statistical inference (e.g., exact conditional inference, goodness-of-fit testing, parameter identifiability, and maximum likelihood estimation). Furthermore, many relevant questions of interest in statistics relate to classical open problems in algebraic geometry.

Algebraic Statistics for Contingency Tables

A paper by Diaconis and Sturmfels (1998) on algebraic methods for discrete probability distributions stimulated much of the work in algebraic statistics on contingency tables, and has led to two general classes of problems: (1) algebraic representation of a statistical model, and (2) conditional inference. The algebraic representation of the independence model given above generalizes to any k-way table and its corresponding hierarchical log-linear models (e.g., see Dobra et al. (2009)). A standard reference on log-linear models is Bishop et al. (1975).

Most of the algebraic work for contingency tables has focused on geometric characterizations of log-linear models and estimation of cell probabilities under those models. Algebraic geometry naturally provides an explicit description of the closure of the parameter space. This feature has been utilized, for example, by Eriksson et al. (2006) to describe polyhedral conditions for the nonexistence of the MLE for log-linear models. More recently, Petrović et al. (2010) provide the first study of algebraic geometry of the p_1 random graph model of Holland and Leinhardt (1981).

Conditional inference relies on the fact that data-dependent objects are a convex bounded set, $P_t = \{\mathbf{x} : x_i \in \mathbb{R}_{\geq 0}, \mathbf{t} = \mathbf{A}\mathbf{x}\}$, where x is a table, A is a design matrix, and $\mathbf{t}$ a vector of constraints, typically margins, that is, sufficient statistics of a log-linear model. The set of all integer points inside P_t is referred to as a *fiber*, which is the support of the conditional distribution of tables given $\mathbf{t}$, or the so-called *exact distribution*. Characterization of the fiber is crucial for three statistical tasks: counting, sampling and optimization. Diaconis and Sturmfels (1998) provide one of the fundamental results in algebraic statistics regarding sampling from exact distributions. They define a Markov basis, a set of integer valued vectors in the kernel of A, which is a smallest set of moves needed to perform a ▶random walk over the space of tables and to guarantee connectivity of the chain. In Hara et al. (2010), for example, the authors use Markov bases for exact tests in a multiple logistic regression. The earliest application of Markov bases, counting and optimization was in the area of statistical disclosure limitation for exploring issues of confidentiality with the release of contingency table data; for an overview,

see Dobra et al. (2009), and for other related topics, see Chen et al. (2006), Onn (2006), and Slavković and Lee (2009).

Graphical and Mixture Models

Graphical models (e.g., Lauritzen (1996)) are an active research topic in algebraic statistics. Non-trivial problems, for example, include complete characterization of Markov bases for these models, and counting the number of solutions of their likelihood equations. Geiger et al. (2006) give a remarkable result in this direction: *decomposable* graphical models are precisely those whose Markov bases consist of squarefree quadrics, or, equivalently, those graphical models whose maximum likelihood degree is 1. More recently, Feliz et al. (2010) made a contribution to the mathematical finance literature by proposing a new model for analyzing default correlation.

►Mixture models, including latent class models, appear frequently in statistics, however, standard asymptotics theory often does not apply due to the presence of singularities (e.g., see Watanabe (2009)). Singularities are created by marginalizing (smooth) models; geometrically, this is a projection of the corresponding variety. Algebraically, mixture models correspond to *secant varieties*. The complexity of such models presents many interesting problems for algebraic statistics; e.g., see Fienberg et al. (2009) for the problems of maximum likelihood estimation and parameter identifiability in latent class models. A further proliferation of algebraic statistics has been supported by studying mixture models in phylogenetics (e.g., see Allman et al. (2010)), but many questions about the geometry of these models still remain open.

Further Reading

There are many facets of algebraic statistics, including generalizations of classes of models discussed above: experimental design, continuous multivariate problems, and new connections between algebraic statistics and information geometry. For more details see Putinar and Sullivant (2008), Drton et al. (2009), Gibilisco et al. (2009), and references given therein. Furthermore, there are many freely available algebraic software packages (e.g., 4ti2 (4ti2 team), CoCoA (CoCoATeam)) that can be used for relevant computations alone, or in combination with standard statistical packages.

Almost Sure Convergence of Random Variables

Herold Dehling
Professor
Ruhr-Universität Bochum, Bochum, Germany

Definition and Relationship to Other Modes of Convergence

Almost sure convergence is one of the most fundamental concepts of convergence in probability and statistics. A sequence of random variables $(X_n)_{n\geq 1}$, defined on a common probability space $(\Omega, \mathcal{F}, P)$, is said to converge almost surely to the random variable X, if

$$P(\{\omega : \lim_{n\to\infty} X_n(\omega) = X(\omega)\}) = 1.$$

Commonly used notations are $X_n \xrightarrow{a.s.} X$ or $\lim_{n\to\infty} X_n = X\,(a.s.)$. Conceptually, almost sure convergence is a very natural and easily understood mode of convergence; we simply require that the sequence of numbers $(X_n(\omega))_{n\geq 1}$ converges to $X(\omega)$ for almost all $\omega \in \Omega$. At the same time, proofs of almost sure convergence are usually quite subtle.

There are rich connections of almost sure convergence with other classical modes of convergence, such as convergence in probability, defined by $\lim_{n\to\infty} P(|X_n - X| \geq \epsilon) = 0$ for all $\epsilon > 0$, convergence in distribution, defined by $\lim_{n\to\infty} Ef(X_n) = Ef(X)$ for all real-valued bounded, continuous functions f, and convergence in L_p, defined by $\lim_{n\to\infty} E|X_n - X|^p = 0$. Almost sure convergence implies convergence in probability, which again implies convergence in distribution, but not vice versa. Almost sure convergence neither implies nor is it implied by convergence in L_p. A standard counterexample, defined on the probability space $[0,1]$, equipped with the Borel σ-field and Lebesgue measure, is the sequence $X_n(\omega) = 1_{[\frac{j}{2^k}, \frac{j+1}{2^k}]}(\omega)$, if $n = 2^k + j$, $k \geq 0$, $0 \leq j < 2^k$. The sequence $(X_n)_{n\geq 1}$ converges to zero in probability and in L_p, but not almost surely. On the same probability space, the sequence defined by $X_n = n^{1/p} 1_{[0,\frac{1}{n}]}$ provides an example that converges to zero almost surely, but not in L_p.

Although convergence in probability does not imply almost sure convergence, there is a partial result in this direction. If $(X_n)_{n\geq 1}$ converges in probabilty to X, one can find a subsequence $(n_k)_{k\geq 1}$ such that $X_{n_k} \xrightarrow{a.s.} X$.

Skorohod's almost sure representation theorem is a partial converse to the fact that almost sure convergence implies convergence in distribution. If $(X_n)_{n\geq 1}$ converges in distribution to X, one can find a sequence of random variables $(Y_n)_{n\geq 1}$ and a random variable Y such that X_n and Y_n have the same distribution, for each n, X and Y have the same distribution, and $\lim_{n\to\infty} Y_n = Y$ almost surely. Originally proved by Skorohod (1956) for random variables with values in a separable metric space, this representation theorem has been extended by Dudley (1968) to noncomplete spaces and later by Wichura (1970) to nonseparable spaces.

By some standard arguments, one can show that almost sure convergence of $(X_n)_{n\geq 1}$ to X is equivalent to

$$\lim_{n\to\infty} P(\sup_{k\geq n} |X_k - X| \geq \epsilon) = 0, \quad \text{for all } \epsilon > 0.$$

Thus almost sure convergence holds, if the series $\sum_{k\geq 1} P(|X_k - X| \geq \epsilon)$ converges. In this case, the sequence $(X_n)_{n\geq 1}$ is said to *converge completely* to X.

Important Almost Sure Convergence Theorems

Historically the earliest and also the best known almost sure convergence theorem is the *Strong Law of Large Numbers*, established originally by Borel (1909). Given an i.i.d. sequence $(X_k)_{k\geq 1}$ of random variables that are uniformly distributed on $[0,1]$, Borel showed that

$$\frac{1}{n} S_n \xrightarrow{a.s.} E(X_1),$$

where $S_n := \sum_{k=1}^n X_k$ denotes the partial sum. Later, this was generalized to sequences with arbitrary distributions. Finally, Kolmogorov (1930) could show that the existence of first moments is a necessary and sufficient condition for the strong law of large numbers for i.i.d. random variables.

Hsu and Robbins (1947) showed complete convergence in the law of large numbers, provided the random variables have finite second moments; Baum and Katz (1965) showed that this condition is also necessary.

Birkhoff (1931) proved the *Ergodic Theorem*, i.e., the validity of the strong law of large numbers for stationary ergodic sequences $(X_k)_{k\geq 1}$ with finite first moments. Kingman (1968) generalized this to the *Subadditive Ergodic Theorem*, valid for doubly indexed subadditive process $(X_{s,t})$ satisfying a certain moment condition. Doob (1953) established the *Martingale Convergence Theorem*, which states that every L_1-bounded submartingale converges almost surely.

The *Marcinkiewicz-Zygmund Strong Law of Large Numbers* (1937) is a sharpening of the law of large numbers for partial sums of i.i.d. random variables, stating that for $1 \leq p < 2$ we have

$$\lim_{n\to\infty} \frac{1}{n^{1/p}} \sum_{k=1}^{n} (X_k - E(X_k)) = 0 \text{ a.s.},$$

if and only if the random variables have finite p-th moments. Note that for $p = 2$ this result is false as it would contradict the central limit theorem (see ▶Central Limit Theorems).

For i.i.d. random variables with finite variance $\sigma^2 \neq 0$, Hartman and Wintner (1941) proved the *Law of the Iterated Logarithm*, stating that

$$\limsup_{n\to\infty} \frac{1}{\sqrt{2\sigma^2 n \log\log n}} \sum_{k=1}^{n} (X_i - E(X_1)) = 1 \text{ a.s.},$$

and that the corresponding lim inf equals −1. In the special case of a symmetric ▶random walk, this theorem had been established earlier by Khintchin (1924). The law of the iterated logarithm gives a very precise information about the behavior of the centered partial sum.

Strassen (1964) proved the *Functional Law of the Iterated Logarithm*, which concerns the normalized partial sum process, defined by

$$f_n(\frac{k}{n}) := \frac{1}{\sqrt{2\sigma^2 n \log\log n}} \sum_{i=1}^{k} (X_i - E(X_i)), 0 \leq k \leq n,$$

and linearly interpolated in between. The random sequence of functions $(f_n)_{n\geq 1}$ is almost surely relatively compact and has the following set of limit points

$$K = \{x \in C[0,1] : x \text{ is absolutely continuous and } \int_0^1 (x'(t))^2 dt \leq 1\}.$$

The functional law of the iterated logarithm gives a remarkably sharp information about the behavior of the partial sum process.

The *Almost Sure Invariance Principle*, originally established by Strassen (1964) is an important technical tool in many limit thorems. Strassen's theorem states that for i.i.d. random variables with finite variance, one can define a standard Brownian motion (see ▶Brownian Motion and Diffusions) $W(k)$ satisfying

$$\sum_{k=1}^{n} (X_k - E(X_1)) - \sigma W(n) = o(\sqrt{n \log\log n}), \text{a.s.}.$$

Komlos et al. (1975) gave a remarkable sharperning of the error term in the almost sure invariance principle, showing that for $p > 2$ one can find a standard Brownian motion $(W_t)_{t\geq 0}$ satisfying

$$\sum_{k=1}^{n} (X_k - E(X_1)) - \sigma W(n) = o(n^{1/p}), \text{a.s.}.$$

if and only if the random variables have finite p-th moments. In this way, results that hold for Brownian motion can be carried over to the partial sum process. E.g., many limit theorems in the statistical analysis of change-points are proved by a suitable application of strong approximations.

In the 1980s, Brosamler, Fisher and Schatte independently discovered the *Almost Sure Central Limit Theorem*, stating that for partial sums $S_k := \sum_{i=1}^{k} X_i$ of an i.i.d. sequence $(X_i)_{i\geq 1}$ with mean zero and variance σ^2

$$\lim_{n\to\infty} \frac{1}{\log n} \sum_{k=1}^{n} \frac{1}{k} 1_{\{S_k/\sigma\sqrt{k} \leq x\}} = \Phi(x),$$

where $\Phi(x) = \int_{-\infty}^{x} \frac{1}{\sqrt{2\pi}} e^{-t^2/2} dt$ denotes the standard normal distribution function. The remarkable feature of this theorem is that one can observe the central limit theorem, which in principle is a distributional limit theorem, along a single realization of the process.

In 1933, Glivenko and Cantelli independently discovered a result that is now known as the *Glivenko–Cantelli Theorem* (see ▶Glivenko-Cantelli Theorems). Given a sequence $(X_k)_{k\geq 1}$ of i.i.d random variables with distribution function $F(x) := P(X \leq x)$, we define the empirical distribution function $F_n(x) = \frac{1}{n} \sum_{k=1}^{n} 1_{\{X_k \leq x\}}$. The Glivenko–Cantelli theorem states that

$$\sup_{x\in\mathbb{R}} |F_n(x) - F(x)| \xrightarrow{a.s.} 0.$$

This theorem is sometimes called the fundamental theorem of statistics, as it shows that it is possible to recover the

distribution of a random variable from a sequence of observations.

Almost sure convergence has been established for U-statistics, a class of sample statistics of great importance in mathematical statistics. Given a symmetric kernel $h(x, y)$, we define the bivariate U-statistic

$$U_n := \binom{n}{2}^{-1} \sum_{1 \le i < j \le n} h(X_i, X_j).$$

Hoeffding (1961) proved the *U-Statistic Strong Law of Large Numbers*, stating that for any integrable kernel and i.i.d. random variables $(X_i)_{i \ge 1}$,

$$U_n \xrightarrow{a.s.} Eh(X_1, X_2).$$

Aaronson et al. (1996) established the corresponding *U-Statistic Ergodic Theorem*, albeit under extra conditions. The *U-statistic Law of the Iterated Logarithm*, in the case of i.i.d. data (X_i) was established by Sen (1972). In the case of degenerate kernels, i.e., kernels satisfying $Eh(x, X_1) = 0$, for all x, this was sharpened by Dehling et al. (1985) and Dehling (1989). Their *Degenerate U-Statistic Law of the Iterated Logarithm* states that

$$\limsup_{n \to \infty} \frac{1}{n \log \log n} \sum_{1 \le i < j \le n} h(X_i, X_j) = c_h, \quad \text{a.s.},$$

where c_h is the largest eigenvalue (see ►Eigenvalue, Eigenvector and Eigenspace) of the integral operator with kernel $h(x, y)$. A functional version as well as an almost sure invariance principle were established by the same authors.

Proofs of Almost Sure Convergence

In most situations, especially in applications in Statistics, almost sure convergence is proved by identifying a given sequence as a a continuous function of a sequence of a type studied in one of the basic theorems on almost sure convergence.

The proofs of the basic almost sure convergence theorems are quite subtle and require a variety of technical tools, such as exponential inequalities, maximal inequalities, truncation techniques and the Borel-Cantelli lemma (see ►Borel–Cantelli Lemma and Its Generalizations).

About the Author

Herold Dehling (born 1954 in Westrhauderfehn, Germany) is Professor of Mathematics at the Ruhr-Universität Bochum, Germany. From 1988 to 2000, he was on the faculty of the University of Groningen, The Netherlands. Prior to that he held postdoc positions at Boston University and at the University of Göttingen. Herold Dehling studied Mathematics at the University of Göttingen and the University of Illinois at Urbana-Champaign. He obtained his Ph.D. in 1981 at Göttingen. Herold Dehling is an elected member of the International Statistical Institute. In 2005 he was awarded the Prix Gay-Lussac–Humboldt of the Republic of France. Herold Dehling conducts research in the area of asymptotic methods in probability and statistics, with special emphasis on dependent processes. He has published more than 75 research papers in probability and statistics. Herold Dehling is co-author of three books, *Kansrekening* (Epsilon Uitgaven, Utrecht 2005, with J. N. Kalma), *Einführung in die Wahrscheinlichkeitsrechnung und Statistik* (Springer, Heidelberg 2004, with B. Haupt) and *Stochastic modelling in process technology* (Elsevier Amsterdam 2007, with T. Gottschalk and A. C. Hoffmann). Moreover, he is coeditor of the books *Empirical Process Techniques for Dependent Data* (Birkhäuser, Boston 2002, with T. Mikosch and M. Sorensen) and *Weak Dependence in Probability, Analysis and Number Theory* (Kendrick Press, Utah 2010, with I. Berkes, R. Bradley, M. Peligrad and R. Tichy).

[2]Professor
University of Klagenfurt, Klagenfurt, Austria

Areal Data

Areal data y_i are data that are assigned to spatial regions A_i, $i = 1, 2, \ldots, n$. Such data and spatial areas naturally arise at different levels of spatial aggregation, like data assigned to countries, counties, townships, political districts, constituencies or other spatial regions that are featured by more or less natural boundaries. Examples for data y_i might be the number of persons having a certain chronic illness, number of enterprises startups, average income, population density, number of working persons, area of cultivated land, air pollution, etc. Like all spatial data, also areal data are marked by the fact that they exert spatial correlation to the data from neighboring areas. Tobler (1970) expresses this in his first law of geography: "everything is related to everything else, but near things are more related than distant things." It is this spatial correlation which is investigated, modeled and taken into account in the analysis of areal data.

Spatial proximity matrix. A mathematical tool that is common to almost all areal analysis methods is the so-called $(n \times n)$ spatial proximity matrix $\mathbf{W}$, each of whose elements, w_{ij}, represents a measure of spatial proximity of area A_i and area A_j. According to Bailey and Gatrell (1995) some possible criteria might be:

- $w_{ij} = 1$ if A_j shares a common boundary with A_i and $w_{ij} = 0$ else.
- $w_{ij} = 1$ if the centroid of A_j is one of the k nearest centroids to that of A_i and $w_{ij} = 0$ else.
- $w_{ij} = d_{ij}^{\gamma}$ if the inter-centroid distance $d_{ij} < \delta$ $(\delta > 0, \gamma < 0)$; and $w_{ij} = 0$ else.
- $w_{ij} = \frac{l_{ij}}{l_i}$, where l_{ij} is the length of common boundary between A_i and A_j and l_i is the perimeter of A_i.

All diagonal elements w_{ii} are set to 0. The spatial proximity matrix $\mathbf{W}$ must not be symmetric. For instance, case 2 and case 4 above lead to asymmetric proximity matrices. For more proximity measures we refer to Bailey and Gatrell (1995) and any other textbook on areal spatial analysis like Anselin (1988).

Spatial Correlation Measures

Global measures of spatial correlation. The global Moran index I, first derived by Moran (1950), is a measure for spatial correlation of areal data having proximity matrix $\mathbf{W}$. Defining $S_0 = \sum_{i=1}^{n} \sum_{j=1}^{n} w_{ij}$ and $\bar{y}$, the mean of the data y_i, $i = 1, 2, \ldots, n$, the global Moran index may be written

$$I = \frac{n}{S_0} \frac{\sum_{i=1}^{n} \sum_{j=1}^{n} w_{ij}(y_i - \bar{y})(y_j - \bar{y})}{\sum_{i=1}^{n} (y_i - \bar{y})^2}. \qquad (1)$$

Thus the global Moran index may be be interpreted as measuring correlation between $\mathbf{y} = (y_1, y_2, \ldots, y_n)^T$ and the spatial lag-variable $\mathbf{Wy}$. But the Moran index does not necessarily take values between -1 and 1. Its expectation for independent data y_i is $\mathrm{E}[I] = -\frac{1}{n-1}$. Values of the Moran index larger than this value thus are an indication of

positive global spatial correlation; values smaller than this value indicate negative spatial correlation.

A global correlation measure similar to the variogram known from classical geostatistics is the Geary-index (Geary's c, Geary 1954):

$$c = \frac{n-1}{2S_0} \frac{\sum_{i=1}^{n} \sum_{j=1}^{n} w_{ij}(y_i - y_j)^2}{\sum_{i=1}^{n} (y_i - \bar{y})^2} \tag{2}$$

Under the independence assumption for the $\mathbf{y_i}$ its expectation is $\mathrm{E}[c] = 1$. Values of c larger than 1 indicate negative correlation and values smaller than 1 positive correlation.

The significance for Moran's I and Geary's c may be tested by means of building all $n!$ permutations of the y_i, $i = 1, 2, \ldots, n$, assigning them to the the different areas A_j, $j = 1, 2, \ldots, n$, calculating for each permutation Moran's I or Geary's c and then considering the distributions of these permuted spatial correlation statistics. True correlation statistics at the lower or upper end of these distributions are an indication of significance of the global correlation measures.

A map often useful for detecting spatial clusters of high or low values is the so-called LISA map. It may be shown that Moran's I is exactly the upward slope of the regression line between the regressors $(\mathbf{y} - \mathbf{1_n}\bar{y})$ and the spatial lag-variables $\mathbf{W}(\mathbf{y} - \mathbf{1_n}\bar{y})$ as responses, where the matrix $\mathbf{W}$ is here standardized to have rows which sum up to one. The corresponding scatterplot has four quadrants PP, NN, PN and NP, with P and N indicating positive and negative values for the regressors and responses. If one codes these four classes into which the pairs $[y_i - \bar{y}, \sum_{j=1}^{n} w_{ij}(y_j - \bar{y})]$ may fall with colors and visualizes these colors in a map of the areas one can easily detect clusters of areas that are surrounded by low or high neighboring values.

Both statistics, the Moran I and Geary's c make a global assumption of second order stationarity, meaning that the y_i, $i = 1, 2, \ldots, n$ all have the same constant mean and variance. If one doubts that this condition is fully met one has to rely on local measures of spatial correlation, for local versions of Moran's I and Geary's c see Anselin (1995).

Spatial Linear Regression

A problem frequently occuring in areal data analysis is the regression problem. Response variables y_i and corresponding explanatory vectors $\mathbf{x_i}$ are observed in spatial areas A_i, $i = 1, 2, \ldots, n$ and one is interested in the linear regression relationship $y_i \approx \mathbf{x_i}^T\boldsymbol{\beta}$, where $\boldsymbol{\beta}$ is an unknown regression parameter vector to be estimated. Subsuming all row vectors $\mathbf{x_i}^T$ in the $(n \times p)$ design matrix $\mathbf{X}$ and writing $\mathbf{y} = (y_1, y_2, \ldots, y_n)^T$ the ordinary ▶least squares solution to this regression problem, which does not take account of spatial correlation, is known to be $\hat{\boldsymbol{\beta}} = (\mathbf{X}^T\mathbf{X})^{-1}\mathbf{X}^T\mathbf{y}$. If the data in $\mathbf{y}$ are known to be correlated the above ordinary least squares estimator is known to be inefficient and statistical significance tests in this regression model are known to be misleading. Problems may be resolved by considering the generalized least squares estimator $\hat{\boldsymbol{\beta}} = (\mathbf{X}^T\Sigma^{-1}\mathbf{X})^{-1}\mathbf{X}^T\Sigma^{-1}\mathbf{y}$, where the covariance matrix Σ is measuring the correlation between the data in $\mathbf{y}$. All regression procedures used in areal data analysis deal more or less with the modeling and estimation of this covariance structure Σ and the estimation of β. In all subsequent sections we will assume that the spatial proximity matrix $\mathbf{W}$ is standardized such that its rows sum up to one.

Simultaneous autoregressive model (SAR). The SAR model is given as follows:

$$\mathbf{y} = \mathbf{X}\boldsymbol{\beta} + \mathbf{u},\ \mathbf{u} = \lambda\mathbf{W}\mathbf{u} + \boldsymbol{\epsilon}. \tag{3}$$

Here λ is an unknown parameter, $-1 < \lambda < 1$, measuring spatial correlation; the parameters λ and $\boldsymbol{\beta}$ are to be estimated. The error vector $\boldsymbol{\epsilon}$ has uncorrelated components with constant unknown variances σ^2, like $\mathbf{u}$ it has expectation zero. The two equations may be combined to get

$$\mathbf{y} = \lambda\mathbf{W}\mathbf{y} + \mathbf{X}\boldsymbol{\beta} - \lambda\mathbf{W}\mathbf{X}\boldsymbol{\beta} + \boldsymbol{\epsilon}$$

Obviously $\mathbf{y}$ is modeled as being influenced also by the spatial lag-variables $\mathbf{W}\mathbf{y}$ and the spatial lag-regression $\mathbf{W}\mathbf{X}\boldsymbol{\beta}$. The coefficient λ is measuring the strength of this influence. The covariance matrix of $\mathbf{u}$ may be shown to be $\mathrm{cov}[\mathbf{u}] = \sigma^2((\mathbf{I_n} - \lambda\mathbf{W})^T(\mathbf{I_n} - \lambda\mathbf{W}))^{-1}$. An estimation procedure for the SAR model is implemented in the R-package spdep, Bivand (2006). It is based on the Gaussian assumption for $\mathbf{y}$ and iteratively calculates maximum (profile) likelihood estimates for σ^2 and λ and generalized least squares estimates for $\boldsymbol{\beta}$ based on the covariance matrix $\mathrm{cov}[\mathbf{u}]$ and the estimates for σ^2 and λ calculated a step before.

Spatial lag model. The so-called spatial lag model may be written

$$\mathbf{y} = \lambda\mathbf{W}\mathbf{y} + \mathbf{X}\boldsymbol{\beta} + \boldsymbol{\epsilon}. \tag{4}$$

It is simpler in structure than the SAR model because the lag-regression term $-\lambda\mathbf{W}\mathbf{X}\boldsymbol{\beta}$ is missing. For its estimation, again, an iterative profile likelihood procedure similar to the SAR procedure may be used.

Spatial Durbin model. The spatial Durbin model is a generalization of the SAR model and given as

$$\mathbf{y} = \lambda\mathbf{W}\mathbf{y} + \mathbf{X}\boldsymbol{\beta} + \mathbf{W}\mathbf{X}\boldsymbol{\gamma} + \boldsymbol{\epsilon}, \tag{5}$$

with $\mathbf{W}\mathbf{X}\boldsymbol{\gamma}$ having its own regression parameter vector $\boldsymbol{\gamma}$. By means of the restriction $\boldsymbol{\gamma} = -\lambda\boldsymbol{\beta}$ the Durbin model

becomes equivalent to a SAR model. The so-called common factor test (Florax and de Graaf 2004), a likelihood ratio test, can be used to decide between the two hypotheses, - SAR-model and spatial Durbin model. As an alternative to the above models one may also use a SAR model with a lag-error component

$$\mathbf{y} = \mathbf{X}\boldsymbol{\beta} + \lambda \mathbf{W}\boldsymbol{\epsilon} + \boldsymbol{\epsilon}. \tag{6}$$

Deciding between models. For the investigation whether a SAR model, a spatial lag model or ordinary least squares give the best fit to the data one may adopt Lagrange multiplier tests as described in Florax and de Graaf (2004). Interestingly, these tests are based on ordinary least squares residuals and for this reason are easily calculable. Breitenecker (2009) gives a nice overview on all the possibilities related to testing models.

Geographically weighted regression. Fotheringham et al. (2002) propose, as an alternative to the above mentioned regression models, geographically weighted regression. The proposed methodology is particularly useful when the assumption of stationarity for the response and explanatory variables is not met and the regression relationship changes spatially. Denoting by (u_i, v_i) the centroids of the spatial areas A_i, $i = 1, 2, \ldots, n$, where the responses y_i and explanatory vectors $\mathbf{x_i}$ are observed, the model for geographically weighted regression may be written

$$y_i = \mathbf{x_i}^T \boldsymbol{\beta}(u_i, v_i) + \epsilon_i, i = 1, 2, \ldots, n. \tag{7}$$

The regression vector $\boldsymbol{\beta}(u_i, v_i)$ is thus dependent on the spatial location (u_i, v_i) and is estimated by means of a weighted least squares estimator that is locally dependent on a diagonal weight matrix $\mathbf{C_i}$:

$$\hat{\boldsymbol{\beta}}(u_i, v_i) = (\mathbf{X}^T \mathbf{C_i} \mathbf{X})^{-1} \mathbf{X}^T \mathbf{C_i} \mathbf{y}$$

The diagonal elements $c_{jj}^{(i)}$ of $\mathbf{C_i}$ are defined by means of a kernel function, e.g. $c_{jj}^{(i)} = \exp(-d_{ij}/h)$. Here d_{ij} is a value representing the distance beetween A_i and A_j; d_{ij} may either be Euclidean distance or any other metric measuring distance between areas. Further, h is the bandwidth measuring how related areas are and can be determined by means of crossvalidating the residuals from the regression or based on the ▶Akaike's information criterion (Brunsdon et al. 1998). Selecting the bandwidth h too large results in oversmoothing of the data. On the other hand a bandwidth too small allows for too less data during estimation.

All areal analysis methods discussed so far are implemented in the R-packages spdep and spgwr, (Bivand 2006, 2009). Methods for counting data, as they frequently appear in epidemiology, and Bayesian methods are not dealt with here; for those methods the interested reader is referred to Lawson (2009).

Spatial Interaction Data

This is a further category of spatial data which is related to modeling the "flow" of people and/or objects between a set of origins and a set of destinations. In contrast with areal (and geostatistical) data, which are located at points or in areas, spatial interaction data are related to pairs of points, or pairs of areas. Typical examples arise in health services (e.g., flow to hospitals), transport of freight goods, population migration and journeys-to-work. Good introductory material on spatial interaction models can be found in Haynes and Fotheringham (1984).

The primary objective is to model *aggregate* spatial interaction, i.e. the volume of flows, not the flows at an individual level. Having m origins and n destinations with associated flow data considered as random variables Y_{ij} $(i = 1, \ldots, m;\ j = 1, \ldots, n)$, the general spatial interaction model is of the form

$$Y_{ij} = \mu_{ij} + \varepsilon_{ij};\ i = 1, \ldots, m;\ j = 1, \ldots, n \tag{8}$$

where $E(Y_{ij}) = \mu_{ij}$ and ε_{ij} are error terms with $E(\varepsilon_{ij}) = 0$. The goal is then to find suitable models for μ_{ij} involving flow propensity parameters of the origins i, attractiveness parameters of the destinations j, and the effects of the "distances" d_{ij} between them. Here, the quantities d_{ij} may be real (Euclidean) distances, travel times, costs of travel or any other measure of the separation between origins and destinations. One of the most widely used classes of models for μ_{ij} is the so-called *gravity model*

$$\mu_{ij} = \alpha_i \beta_j \exp(\gamma\, d_{ij}) \tag{9}$$

involving origin parameters α_i, destination parameters β_j and a scaling parameter γ. Under the assumption that the Y_{ij} are independent Poisson random variables with mean μ_{ij}, this model can be treated simply as a particular case of a generalised linear model with a logarithmic link. Model fitting can then proceed by deriving maximum likelihood estimates of the parameters using iteratively weighted least squares (IRLS) techniques. The above gravity models can be further enhanced when replacing the parameters β_j by some function of observed covariates $\boldsymbol{x}_j = (x_{j1}, \ldots, x_{jk})^T$ characterising the attractiveness of each of the destinations $j = 1, \ldots, n$. Again, this is usually done in a log-linear way, and the model becomes

$$\mu_{ij} = \alpha_i \exp(g(\boldsymbol{x}_j, \boldsymbol{\theta}) + \gamma\, d_{ij}) \tag{10}$$

where g is some function (usually linear) of the vector of destination covariates and a vector of associated parameters $\boldsymbol{\theta}$. Contrary to (9), which reproduces both the total flows from any origin and the total observed flows to each destination, the new model (10) is only *origin-constrained*. The obvious counterpart to (10) is one which is *destination-constrained*:

$$\mu_{ij} = \beta_j \exp(h(\boldsymbol{z}_i, \boldsymbol{\omega}) + \gamma\, d_{ij})$$

where h is some function of origin characteristics $\boldsymbol{z}_i$ and a vector of associated parameters $\boldsymbol{\omega}$. Finally, when modeling both α_i and β_j as functions of observed characteristics at origins and destinations, we arrive at the *unconstrained model*

$$\log \mu_{ij} = h(\boldsymbol{z}_i, \boldsymbol{\omega}) + g(\boldsymbol{x}_j, \boldsymbol{\theta}) + \gamma\, d_{ij} \qquad (11)$$

In population migration one often uses a particular form of (11), where $\boldsymbol{z}_i$ and $\boldsymbol{x}_j$ are taken to be univariate variables meaning the logarithms of the population P_i and P_j at origin i and destination j, respectively. Adding an overall scaling parameter τ to reflect the general tendency for migration, the following simple model results:

$$Y_{ij} = \tau P_i^{\omega} P_j^{\theta} \exp(\gamma\, d_{ij}) + \varepsilon_{ij} \qquad (12)$$

Likewise, in all the above models one can introduce more complex distance functions than $\exp(\gamma\, d_{ij})$. Also, as mentioned before, d_{ij} could be replaced by a general separation term s_{ij} embracing travel time, actual distance and costs of overcoming distance.

The interaction models considered so far are only models for μ_{ij}, the mean flow from i to j. Thus, they are only first order models, no second order effects are included and the maximum likelihood methods for estimating the parameters of the gravity models rest on the explicit assumption that fluctuations about the mean are independent. Up to now, there has been only little work done on taking account of spatially correlated errors in interaction modeling. To address such problems, pseudo-likelihood-methods are in order. Good references for further reading on spatial interaction models are Upton and Fingleton (1989), Bailey and Gatrell (1995) and Anselin and Rey (2010).

Spatial interaction models have found broad attention among (economic) geographers and within the GIS community, but have received only little attention in the spatial statistics community. The book by Anselin and Rey (2010) forms a bridge between the two different worlds. It contains a reprint of the original paper by Getis (1991), who first suggested that the family of spatial interaction models is a special case of a general model of spatial autocorrelation. Fischer et al. (2010) present a generalization of the Getis-Ord statistic which enables to detect local non-stationarity and extend the log-additive model of spatial interaction to a general class of spatial econometric origin-destination flow models, with an error structure that reflects origin and/or destination autoregressive spatial dependence. They finally arrive at the general spatial econometric model (3), where the design matrix $\boldsymbol{X}$ includes the observed explanatory variables as well as the origin, destination and separation variables, and $\boldsymbol{W}$ is a row-standardized spatial weights matrix.

Introduction

The Analysis of Covariance (generally known as ANCOVA) is a statistical methodology for incorporating quantitatively measured independent observed (not controlled) variables in a designed experiment. Such a quantitatively measured independent observed variable is generally referred to as a covariate (hence the name of the methodology – analysis of covariance). Covariates are also referred to as concomitant variables or control variables.

If we denote the general linear model (GLM) associated with a completely randomized design as

$$Y_{ij} = \mu + \tau_j + \varepsilon_{ij},\ i = 1, \ldots, n_j,\ j = 1, \ldots, m$$

where
Y_{ij} = the ith observed value of the response variable at the jth treatment level
μ = a constant common to all observations
τ_j = the effect of the jth treatment level
ε_{ij} = the random variation attributable to all uncontrolled influences on the ith observed value of the response variable at the jth treatment level

For this model the within group variance is considered to be the experimental error, and this implies that the treatments have similar effects on all experimental units. However, in some experiments the effect of the treatments on the experimental units varies systematically with some characteristic that varies across the experimental units. For example, one may test for a difference in the efficacy of a new medical treatment and an existing treatment protocol by randomly assigning the treatments to patients (experimental units) and testing for a difference in the outcomes. However, if the ▶randomization results in the placement of a disproportionate number of young patients in the group that receives the new treatment and/or placement of a disproportionate number of elderly patients in the group that receives the existing treatment, the results will be biased if the treatment is more (or less) effective on young patients than it is on elderly patients. Under such conditions one could collect additional information on the patients' ages and include this variable in the model. The resulting general linear model

$$Y_{ij} = \mu + \tau_j + \beta X_{ij} + \varepsilon_{ij},\ i = 1, \ldots, n_j,\ j = 1, \ldots, m.$$

where
X_{ij} = the ith observed value of the covariate at the jth treatment level,
β = the estimated change in the response that corresponds to a one unit increase in the value of the covariate at a fixed level of the treatment

is said to be a completely randomized design ANCOVA model and describes an experimental design GLM one factor experiment with a single covariate.

Note that the addition of covariate(s) can accompany many treatment and design structures. This article focuses on the simple one way treatment structure in a completely randomized design for the sake of simplicity and brevity.

Purpose of ANCOVA

There are three primary purposes for including a covariate in the ▶analysis of variance of an experiment:

1. To increase the precision of estimates of treatment means and inferences on differences in the response between treatment levels by accounting for concomitant variation on quantitative but uncontrollable variables. In this respect covariates are the quantitative analogies to blocks (which are qualitative/categorical) in that they are (1) not controlled and (2) used to remove a systematic source of variation from the experimental error. Note that while the inclusion of a covariate will result in a decrease in the experimental error, it will also reduce the degrees of freedom associated with the experimental error, and so inclusion of a covariate in an experimental model will not always result in greater precision and power.

2. To allow for the assessment of the nature of the relationship between the covariate(s) and the response variable after taking into consideration the treatment effects. In this respect covariates are analogous to independent variables in linear regression, and their associated slopes can provide important insight into the nature of the relationship between the response and the covariate.
3. To statistically adjust comparisons of the response between groups for imbalances in quantitative but uncontrollable variables. In this respect covariates are analogous to stratification and are of particular importance in situations where stratification on the covariate is impractical or infeasible.

Applications of ANCOVA

Typical applications of analysis of covariance include:

- Clinical trials in which quantitative but uncontrollable variables such as the weight, height, and age of the patients may influence the effectiveness of a treatment protocol.
- Marketing research in which quantitative but uncontrollable variables such as the pretest rating of a product given by a respondent may influence the respondent's posttest rating (i.e., after exposure to the test condition) of the product.
- Education experiments in which quantitative but uncontrollable variables such as the age, intelligence (if this can be measured), and prior scholastic performance of the students may influence the effectiveness of a pedagogical approach.
- Agricultural experiments in which quantitative but uncontrollable variables such as rainfall and historical yield of fruit bearing trees may influence the yield during an experiment.

Comparing Treatments in ANCOVA

Least squares means (or *LS* means) are generally used to compare treatment effects in experiments that include one or more covariates. *LS* means (which are sometimes referred to as marginal means, estimated marginal means, or adjusted treatment means) are the group means when the covariate is set equal to its grand mean $\overline{X}_m$ (mean of the covariate over all observations across all treatments). These are easily calculated by substituting the grand mean of the covariate into the estimated general linear model, i.e.,

$$\hat{Y}_j = \mu + \tau_j + \beta\overline{X}_m,\ j = 1, \ldots, m$$

Standard errors for *LS* means are typically calculated and used (in conjunction with the ▶asymptotic normality of *LS* means) to conduct inference on individual *LS* means and contrasts based on the *LS* means.

Assumptions of ANCOVA

In addition to the standard ANOVA assumptions:

- Independence of error terms
- Homogeneity of variance of the error terms across treatments
- Normality of the error terms across treatments

One must also consider the *regression assumptions* when performing statistical inference with ANCOVA. The regression assumptions include:

- A linear relationship exists between the covariate and the response variable.

  If no relationship exists between the covariate and response, there is no reason to include the covariate in the experiment or resulting model. If the relationship between the covariate and the response variable is nonlinear, the inclusion of a covariate in the model will not remove all variation in the observed values of the response that can potentially be accounted for by the covariate. The nature of the relationship between the covariate and the response can be assessed with scatter plots of these two variables by treatment. If a nonlinear relationship exists between the covariate and the response, one can utilize a polynomial ANCOVA model.
- Homogeneity of the regression slopes associated with the covariate (i.e., parallel regression lines across treatments).

  The calculations of the *LS* means are predicated on the lack of existence of a response by covariate interaction. If this assumption is violated, the adjustment to the response variable for a common value of the covariate is misleading. This assumption can be assessed through either scatter plots of the covariate and the response by treatment or through the inclusion of a treatment-covariate interaction in the model.

If the sample results suggest that any of these assumptions are not satisfied, inference based on the model may not be valid.

Alternatives to ANCOVA

Bonate (2000) provides a good discussion of alternatives to ANCOVA in pretest-posttest designs; he considers the relative merits of difference scores, relative change functions, various blocking methods, and repeated-measures analysis. Several authors have suggested more general nonparametric alternatives to ANCOVA based on an analysis

of covariance of the ranks of the response and covariance. Some notable examples of these approaches have been suggested by Quade (1967, 1982), Puri and Sen (1969), McSweeney and Porter (1971), Burnett and Barr (1977), Shirley (1981), Conover and Iman (1982), Chang (1993), Lesaffre and Senn (2003), and Tsangari and Akritas (2004).

Analysis of Multivariate Agricultural Data

Asghar Ali
Professor and Chairman
Bahauddin Zakariya University, Multan, Pakistan

Agricultural research is most oftenly based on observational studies and experimentation resulting in multi-response variables. The selection of appropriate variety to grow; amount and types of fertilizers, insecticides and pesticides to apply; the irrigation system to use; the plant sowing technology to apply and to assess the soil fertility through chemical analysis of macro and micro nutrients available in the soil are the major areas of interest for the researcher to work on for the improvement of the agricultural productivity in terms of quality and quantity. The role of Statistics in planning agricultural research, designing experiments, data collection, analysis, modeling and interpretation of agricultural results is very well established. The basic principles and theoretical development of experimental designs pioneered by R. A. Fisher are the result of collaborative work of agricultural scientists and statisticians. In the process of experimentation and observational studies, the researcher is keen to have as many data information as possible so that nothing is left unattended related to the phenomenon under study as there will be no chance to repeat the experiment till the next season of the crop and it will not be less than a miracle if data from one year of the crop is consistent with the results of second year, no matter how much care is taken to keep the experimental conditions identical.

Agricultural data obtained through experimentation is initially analyzed using ►analysis of variance technique and then depending on the nature of treatments/factors applied, either the approach of multiple comparisons or ►response surface methodology is used to explore further the hidden features of the data. For example, the experimenter might be interested to compare different varieties of a particular crop such that there are two local varieties (V_1, V_2) in practice; three varieties are imported (V_3, V_4, V_5) and two new varieties (V_6, V_7) are developed by a local agricultural institute. If results obtained from analysis of variance conclude that performance of the varieties is significantly different from each other then obvious questions arise are to test the difference between the following variety comparisons: $[V_1$ and $V_2]$; $[V_6$ and $V_7]$; $[(V_1, V_2)$ and $(V_6, V_7)]$; $[(V_1, V_2, V_6, V_7)$ and $(V_3, V_4, V_5)]$; and if V_4 is a hybrid variety, then one has two more comparisons to test i.e., $[V_4$ with $(V_3, V_5)]$

and $[V_3$ with $V_5]$. These contrasts are orthogonal to each other but it will not always be the case, other techniques of multiple comparisons will have to be used then, which are available in almost all the books on experimental designs. On the other hand, if multifactor experiments are conducted to determine the appropriate levels of the applied factors on which optimum response is achieved. For this purpose data sets are modeled in adequate functional forms and the researcher is intended to fit simple functional form. Ordinary polynomials are the most popular functional forms which are used to model experimental data from many fields of scientific research. If first order polynomial is fitted, the researcher very simply states that the concerned factor has linear effect and the interpretation is made accordingly that with increase of levels of factor will result in increase (or decrease) in the response. The second order polynomials are used with the expectation that it will be possible to identify the levels of the applied factors to get the optimum response. A number of response functions that have been widely used by the agricultural and biological researchers have been discussed by Mead and Pike (1975). It should not be taken as granted that one response function considered applicable to one sort of situation will also be applicable to other similar situations; it is advisable that graphical approach be used to guess the appropriate functional form of the response under consideration. An extremely useful concept that is revealed by Nelder (1966) is known as Inverse Polynomial Response Functions (IPRF). It emphasizes that in agricultural research the effect of increasing a factor indefinitely is either to produce a saturation effect, in which case the response does not exceed a finite amount, or to produce a toxic effect, in which case the response eventually fall to zero and the response curve has no build-in-symmetry.

Nelder (1966) and Pike (1977) advocated these surfaces as giving responses that are nonnegative and bounded if regression coefficients are constrained to be positive and it is further assumed that $Var(Y) \propto [E(Y)]^2$. Extension in the ideas has been developed by Nelder and Wedderburn (1972) and McCullagh and Nelder (1989) for the response variables that may not be normal and that the expected response may be a function of the linear predictors rather than just the linear predictors itself. Ali (1983) and Ali et al. (1986) have objected on placing constrains on the parameters as it will violate all the properties of good estimators and will no longer follow the distributional structure required for valid inferences. Their experience of examining many sets of data leads them not to expect all regression coefficients to be positive. Taking into account the error structure and functional form used for IPRF, Ali (1983) proposed the form of a response function called as Log Linear Response Functions (LLRF) based on the logarithmic transformation of the response variable and assuming that $\log Y \sim N(E(\log Y), \sigma^2)$. The estimation of regression coefficients achieved by carrying out a multiple regression of $\log Y$ on the terms required fitting the data adequately; the resulting estimators are therefore Minimum Variance Linear Unbiased Estimators. It is simple to estimate the variance-covariance matrix of these estimators and to test hypotheses concerning parameters by the usual linear regression methods. On the theoretical grounds the LLRF model therefore has much to commend it. The assumption that $\log Y_i$ follows the normal distribution may not always be true; in such cases it is recommended that Box-Cox family of transformation may be used under the same structure of the response function as has been used for LLRF and IPRF.

In order to produce an adequate prediction the researcher is usually uncertain as to which of the large number of terms should be included in the final model. The main point to bear in mind is that it should have as many terms as necessary so that maximum variation of the data is explained and as few terms as possible so that it can easily be interpreted. Ali (1983) argued that for summarizing the data from agricultural experiments the terms in the final model are required to be selected in a conforming order by preferring main effect terms over the interactions and lower order terms over the higher. It is further to remember that the inverse terms describe the rising ridge of the surfaces, the linear terms describe the optimum region and the higher degree terms contribute in explaining the falling portion of the surfaces. It is therefore recommended that for building the appropriate model one should concentrate on selection the inverse and linear terms along with their associated interaction terms. One who is not convinced with such types of model building method has the option to use the approach established by Nelder (1977).

The methods used for selection of final model are mainly based on the Minimum Mean Square Error criterion. It is possible to find more than one models which fulfills this criterion. In such cases one should select the one which has reasonable shape of the response surface, capable to determine the values of quantitative factors at which the response is an optimum, statistically significant regression coefficients and simple functional form.

There is no ambiguity to recognize the agricultural research as multifactor and multi-response and that these responses are measured at different stages of the maturity of the crop and that these are interrelated with one another. The univariate analyses of these variables therefore have partial impact on the true findings of research. Multivariate analyses are therefore natural and essential to consider the

data by giving due weight to the interrelationships among the variables under study. One possible approach which is widely used by the researchers is to study the correlation matrix of the variables. This approach only facilitates to assess the relationship among the pairs of variables and it can be extended to triplets of variables by considering the partial correlations and the multiple correlations among those. As a result there would be $\frac{1}{6}p(p^2 + 1)$ pairs and triplets to consider and it will certainly be confusing if the number p of variables under consideration is large.

To overcome this difficulty, Principal Component Analysis (PCA) can be used. It is a multivariate technique that has its aim the explanation of relationships among several difficult-to-interpret, correlated variables in terms of a few conceptually meaningful components which are uncorrelated with each other and are capable of accounting for nearly all the variation present in the observed data. PCA therefore finds a linear transformation of original variables into a new set of variables called as principal components which are uncorrelated with each other; are capable of accounting for the variation of the obtained data and are derived in such a way that the first few of them can often provide enough information about the data and so the dimensionality of the problem can considerably be reduced. The variables with higher component loadings in a particular principal component are considered to be the important ones and it is assumed that the principal component is the representative of these variables; hence it is interpreted only in terms of these variables. This approach of interpretation of principal components is acceptable if principal components are extracted using the correlation matrix R. The variance–covariance matrix Σ is as well used to derive principal components; since the principal component technique is scale dependent, the principal component loadings with this approach will therefore be much influenced by the unit of the measurements of the variables under consideration, hence, the interpretation of principal components just based on the magnitude of the loading may become questionable and misleading. Ali et al. (1985) suggested using the correlation between the original variables and the principal component for selection of representative variables in a particular principal component instead of using principal component loadings.

PCA is extremely useful technique when interest lies in investigating the interrelationship within a set of variables; when the relationship of two sets of variables, within and among the sets is of interest, the PCA is not a valid technique. The agricultural researchers always encounter with such types of problems where the assessment of relationship among and within the twosets is essential e.g. the interdependence of nutritional status and vegetative related characteristics with the crop yield related characteristics is pivotal. For such cases, ►Canonical Correlation Analysis (CCA) technique developed by Hotelling (1936) is of great benefit. It has certain maximal properties similar to those of PCA and in a way is an extension of the multiple regression analysis. The object of this approach is to find the linear functions of the variables for each of the sets such that the correlation between these linear functions is as high as possible. After locating such a pair of linear functions which are maximally correlated with each other, we look for other pairs of linear functions which are maximally correlated subject to the restriction that the new pair of linear functions must be uncorrelated with all other previously located functions. For the purpose of interpretation of the results, it is proposed to use correlation between the canonical variates and the original variables instead of canonical weights as has been already proposed for interpretation of PCA results. Details of PCA and CCA may be found in Mardia et al. (1979) and Jolliffe (2002).

About the Author

Asghar Ali holding M.Sc and D.Phil in Statistics from Sussex University and Post Doctorate from University of Kent at Canterbury, UK is Professor of Statistics at Bahauddin Zakariya University (BZU) Multan, Pakistan. Since 1975, he is serving BZU in various capacities: Presently, he is Chairman, Department of Statistics and also for a period of three years, he held the position of chairmanship, Department of Computer Science. Especially commendable have been his period as Principal, College of Agriculture, BZU. He has been publishing regularly related to data analysis in the field of agricultural sciences which is now being cited in related text books.

Analysis of Variance

Gudmund R. Iversen
Professor Emeritus
Swarthmore College, Swarthmore, PA, USA

Analysis of variance is the name given to a collection of statistical methods originally used to analyze data obtained from experiments. The experiments make us of a quantitative dependent variable, also known as a metric variable or an interval or ratio variable, and one or more qualitative independent variables, also known as categorical or nominal variables. These analysis methods grew out of agricultural experiments in the beginning of the twentieth century, and the great English statistician Sir Ronald Fisher developed many of these methods. As an example, the dependent variable could be the yield in kilos of wheat from different plots of land and the independent variable could by types of fertilizers used on the plots of land.

Experimental Design

The way an experiment is run affects the particular analysis of variance method used for the analysis of the data. Experiments are designed according to different plans, and the choice of the design of the experiment affects which analysis of variance method being used. Without going into details about designs of experiments, an experiment could follow a factorial design, a randomized block design, a Latin square design, etc. There exist too many designs of experiments and accompanying analysis of variance methods for the analysis of the resulting data to cover all of them in this short presentation. But it is possible to present the underlying features of all analysis of variance methods.

Analysis of Variance and Multiple Regression

But first it is worth noting that analysis of variance is closely related to regression analysis. Indeed, it is possible to see both analyses as special cases of the so-called general linear model. In particular, using ▶dummy variables for the independent variables in analysis of variance, the analysis quickly turns into a regression analysis. The main difference is that when data are collected through a properly designed experiment, it is possible to conclude that there is a causal effect of the independent variable(s) on the dependent variable. When data are collected through observational, studies there may be a causal effect of the independent variable(s) or not.

Statistical Software

Much of the early work on analysis of variance consisted of finding efficient ways of making the necessary computations with the use of simple calculators. With the introduction of modern statistical software for electronic computers, this line of work is now less important. Instead, statisticians have worked on showing the similarities of the computations needed for both analysis of variance and multiple regression, and the old distinction between the two approaches to data analysis is no longer of any importance. However, statistical software packages still make a distinction between the two, and the output from the two methods often look very different.

One-Way Analysis of Variance

This name is given to the design where there is one independent nominal variable with several categories and a quantitative dependent variable with a unit of measurement and often a meaningful zero. An example of an experiment could be where students are randomly assigned to two different groups and the students in one group were taught using a new method of teaching while the students in the second group, as a control group, were taught using the old method. The random assignment to the different groups means that the effects of all other variables, for

example gender, is canceled out, and any observed difference between the two groups is causally due to the teaching method being used. In this simple case, the statistical method is the same as the *t*-test for the difference between two groups. From a regression point of view we could use a dummy variable and assign the value 0 to all the students in the control group and the value 1 to all the students in the experiment group. In this case, the intercept of the regression line would equal the mean of the dependent variable for the control group and the slope of the line would equal the difference between the means of the two groups. Thus, the *t*-test for the null hypothesis that the population regression line has zero slop becomes the same as the *t*-test for the difference between the two means.

The fundamental question in an analysis of variance is whether the population means for different groups are equal or not. But the methods for analysis of variance use variances to answer the question about means, thus the name analysis of variance. The analysis is based on identifying two factors that determine the values of the dependent variable. One such factor is the net effect of all factors except the independent variable, known as the residual variable, and the other factor is the independent variable.

The Residual Sum of Squares

If the residual variable had no effect, then all the values of the dependent variable for the control group would be equal to each other, and all the values of the dependent variable for the experimental group would be equal to each other. The best estimates of these two values would be the mean of the dependent variable for the group. To the extent that the values within each group are not equal, is due to the residual variable. Thus, the effect of the residual variable for a single observation can be seen as the difference between the observed value and the group mean. For each observation we now have such a difference. One way to summarize the values of these differences for a group is to square each difference and add all these squares. We then have a sum of squares for each of the two groups, and by adding these two sums we have a measure of the overall effect of the residual variable. If the dependent variable is known as Y and y_{ij} is the ith observation in the jth group and $\bar{y}_j$ is the mean in the jth group, then the residual sum of squares RSS can be written

$$RSS = \sum \sum (y_{ij} - \bar{y}_j)^2.$$

Note that there are many other ways we could combine these differences. For example, we could have taken the absolute value of each difference and added those differences instead of using squares. Thus, the final conclusion from the analysis should include a statement that the conclusion is based on squares and not some other mathematical operation. Even though nobody does include such a warning, it should be made clear that the analysis is based on squares.

The Treatment Sum of Squares

We also need a measure of how different the two groups are from each other. One way to do that is find how different the group means are from the overall mean. If the treatment variable has no effect, then the two group means would be equal and equal to the overall mean. One way to measure how different the group means are from the overall mean is to take each group mean and subtract the overall mean. By squaring each difference and weighing each square by the number of observations in the group n_j, then the treatment sum of squares between the groups GSS can be written

$$GSS = \sum \sum n_j (\bar{y}_j - \bar{y})^2.$$

The *F*-Test

The residual sum of squares is also known as the within group sum of squares and the group sum of squares is sometimes known as the between group squares. The final step consists of making a comparison between the two sums of squares. If the residual sum of squares is large in comparison with the group sum of squares, then it seems that the difference between the group means is not statistically significant. For this comparison we take into how many groups we have, here 2 and in general k groups, and how many observations n there are all together. A mathematical development shows that we should compute the ratio

$$F = \frac{GSS/(k-1)}{RSS/(n-k)}$$

This is known as the F-ratio and is named in honor of Ronald Fisher. It gives rise to the F-distribution, and the distribution has been extensively tabulated. The two numbers $(k-1)$ and $(n-k)$ are the so-called degrees of freedom, and they are used to take into account how many groups there are in the experiment and how many observations there are in the experiment. For example, for a 5% significance level with $k = 2$ groups and $n = 30$ observations, the critical value of F on 1 and 28 degrees of freedom equals 4.20. Thus, for any observed value of F larger than 4.20, we conclude that there is a statistically significant difference between the two groups. In this case, had we done a *t*-test

for the difference between the special case of two group means, the critical value of t becomes $\sqrt{4.20} = 2.05$.

Other Analyses

It is possible to generalize to an experiment with more than just two groups. The null hypothesis of equal group means is tested the same way as with two groups, and the computations follow the same plan as above. With two or more independent variables the analysis becomes more extensive. We can still represent the independent variables by dummy variables and do a regression analysis. But that way it is easy to overlook the possible interaction effect of the two independent variables. This means we could have an effect of the independent variables together over and beyond their separate effects. Finally, in analysis of variance we distinguish between using all values of the independent variables (Model I) and only using a sample of possible values (Model II).

About the Author

Dr. Gudmund Iversen is Professor Emeritus of Statistics at Swarthmore College, Swarthmore PA 19081. He chaired the Department of Mathematics and Statistics at three different intervals and directed the College's Center for Social and Policy Studies for several years. Prior to Swarthmore he taught statistics at the University of Michigan and also directed the Summer Training Program, Inter-university Consortium for Political and Social Research. He was a visiting lecturer in the American Statistical Association visiting lecture program. He has been a visiting professor at Zentrum für Umfragen, Methoden und Analysen (ZUMA), Mannheim, West Germany 1986, at Department of Political Science, University of Oslo, Norway (1978–1979), at The Graduate School of Social Work and Social Research, Bryn Mawr College, spring 1990, fall 2000, and at School of Social Policy and Practice at the University of Pennsylvania 1999. He was a member of the joint committee of Mathematical Association of America and American Statistical Association on the statistics curriculum (1991–1997). He was Associate book review editor, *Journal of American Statistical Association* (1986–1989), and Associate editor, *Journal of Statistics Education* (1993–2000). He has published 22 articles and 10 books on statistics and statistical education.

Introduction

Every statistical model has its own underlying "assumptions" that must be verified to validate the results. In some situations, violations of these assumptions will not change substantive research conclusions, while in others,

violation of assumptions can be critical to meaningful research. For a meaningful and conclusive data analysis by ►Analysis of Variance (ANOVA), the following assumptions are needed:

(a) Errors be normally distributed
(b) Errors have same variances (homogeneity of variances)
(c) Errors be independently distributed

However, the question arising is What would be the effects of any departure from the assumptions of the model on the inferences made? The answer is simple: It may either influence the probability of making Type I error (i.e., incorrectly rejecting null hypothesis) or a Type II error (i.e., failing to reject a null hypothesis when it is false). For a thorough discussion of the topic, the reader is referred to Scheffé (1959), Miller (1986), Snedecor and Cochran (1989), Sahai and Ojeda (2005), and Sahai and Ageel (2000). Some of the main findings are discussed in the following section.

Effects of Departures from Assumptions

Departures from Normality

For fixed effects model, due to the central limit theorem (see ►Central Limit Theorems) the lack of normality causes no problems in large samples, as long as the assumptions hold. In general, when true ►randomization occurs the violations of normality is acceptable. Also, heterogeneity of variances can result in nonnormality, so ensuring homogeneity of variances may also result in normality. Only highly skewed distributions would have a marked effect either on the level of significance or the power of the F test. However, it is worth mentioning that kurtosis of the error distribution (either more or less peaked than a normal distribution) is more important than skewness of the distribution in terms of the effects on inferences. Both analytical results (see, e.g., Scheffé 1959:345–351) and the empirical studies by Pearson (1931), Geary (1947), Gayen (1950), Box and Anderson (1955), Boneau (1960, 1962), Srivastava (1959), Bradley (1964), Tiku (1964, 1971), and Donaldson (1968) attest to the conclusion that lack of normality would have little effect of F test either in terms of level of significance or power. Hence, the F test is generally robust against departures from normality (in skewness and/or kurtosis) if sample sizes are large or even if moderately large. For instance, the specified level of significance might be 0.05, whereas the actual level for a nonnormal error distribution might vary from 0.044 to 0.052 depending on the sample size and the magnitude of the kurtosis. Generally, the actual level of significance in the presence of positive kurtosis (platykurtic) is slightly higher than the specified one and the real power of the test for positive kurtosis is slightly higher than the normal one. If the underlying population has negative kurtosis (leptokurtic), the actual power of the test will be slightly lower than the normal one (Glass et al. 1972). Single interval estimates of the factor level means and contrasts and some of the multiple comparison methods are also not much affected by the lack of normality provided the sample sizes are not too small. The robustness of multiple comparison tests in general has not been as thoroughly studied. Among few studies in this area is that of Brown (1974). Some other studies have investigated the robustness of several multiple comparison procedures, including Tukey and Scheffé, for exponential and chi-square distributions and found little effect on both α and power (see, e.g., Petrinovich and Hardyck 1969; Keselman and Rogan 1978). Dunnett (1982) reported that Tukey is conservative both with respect to α and power for long-tailed distributions and to ►outliers. Similarly, Ringland (1983) found that Scheffé was conservative for distributions with influence to outliers.

Lange and Ryan (1989) gave several examples that show that nonnormality of random effects is, indeed, encountered in practice. For random effects model, the lack of normality has more serious implications than fixed effects model. The estimates of the variance components are still unbiased, but the actual confidence coefficients for interval estimates of σ_e^2, σ_α^2, $\sigma_\alpha^2/\sigma_e^2$ may be substantially different from the specified one (Singhal and Sahai 1992). Moreover, when testing the null hypothesis, if the variance of a random effect is some specified value different from zero, the test is not robust to the assumption of normality. For some numerical results of this, the reader is referred to Arvesen and Schmitz (1970) and Arvesen and Layard (1975). However, if one is concerned only with a test of hypothesis $\sigma_\alpha^2 = 0$, then slight departures from normality have only minor consequences for the conclusions reached when the sample size is reasonably large (see, e.g., Tan and Wong 1980; Singhal et al. 1988).

Departures from Equal Variances

Both the analytical derivations by Box (1954) and the empirical studies indicate that if the variances are unequal, the F test for the equality of means under fixed effects model is only slightly affected provided there is no remarkable difference in sample sizes and the parent populations are approximately normally distributed. When the variances are unequal, an approximate test similar to the approximate t test when two group variances are unequal may be used (Welch 1956). Generally, unequal error variances increase the actual level of significance slightly

higher than the specified level and result in a slight elevation of the power function to a degree related to the magnitude of differences among variances. If larger variances are associated with larger sample sizes, the level of significance will be slightly less than the nominal value, and if they are associated with smaller sample sizes, the level of significance will be slightly greater than the nominal value (Horsnell 1953; Kohr and Games 1974). Similarly, the Scheffé's multiple comparison procedure based on the ►*F* distribution is not affected to any appreciable degree by unequal variances if the sample sizes are approximately equal. Thus, the *F* test and the related analyses are robust against unequal variances if the sample sizes are nearly equal.

On the other hand, when different number of cases appear in various samples, violation of the assumption of homogeneous variances can have serious effects in the validity of the final inference (see, e.g., Scheffé 1959; Welch 1956; James 1951; Box 1954; Brown and Forsythe 1974; Bishop and Dudewicz 1978; Tan and Tabatabai 1986). Krutchkoff (1988) made an extensive simulation study to determine the size and power of several analysis of variance procedures, including the *F* test, Kruskal–Wallis test, and a new procedure called the *K* test. It was found that both the *F* test and the Kruskal–Wallis test are highly sensitive whereas the *K* test is relatively insensitive to the heterogeneity of variances. Kruskal–Wallis test, however, is not as sensitive to the unequal error variances as the *F* test and was found to be more robust to nonnormality (when the error variances are equal) than either the *F* test or the *K* test. Thus, whenever possible, the experimenter should try to achieve the same number of cases in each factor level unless the assumption of equal population variances can reasonably be assured in the experimental context. The use of equal sample sizes for all factor levels not only tends to minimize the effects of unequal variances using the *F* test, but also simplifies the computational procedure.

For random effects model, however, the lack of homoscedasticity or unequal error variances can have serious effects on inferences about the variance components, even when all factor levels contain equal sample sizes. Boneau (1960) has shown that when variances are different in the various groups and sample sizes are small and different, ANOVA can produce highly misleading results.

Departures from Independence of Error Terms

Lack of independence can result from biased measurements or possibly from a poor allocation of treatments to experimental units. Nonindependence of the error terms can have important effects on inferences for both fixed and random effects models. If this assumption is not met, the *F* ratio may be strongly affected severely in serious errors in inferences (Scheffé 1959). The direction of the effect depends on the nature of the dependence of the error terms. In most cases encountered in practice, the dependence tends to make the value of the ratio too large and consequently the significance level will be smaller than it should be (although the opposite can also be true). Since the remedy of violation of this assumption is often difficult, every possible effort should be made to obtain independent random samples. The use of randomization in various stages of the study can be most important protection against independence of error terms. In general, great care should be taken to ensure that the data are based on independent observations, both between and within groups, i.e., each observation is in no way related to any of the other observations. Although, dependency among the error terms creates a special problem in any analysis of variance, it is not necessary that the observations themselves must be completely independent for applying the random effects model.

In summary, ANOVA is very robust to violations of the assumptions, as long as only one assumption is violated. If two or more assumptions are severely violated the results are not to be trusted. Further if the data are:

(a) Not normally distributed, but satisfies the homogeneity of variance and independent assumptions, the findings may still be valid.
(b) Normally distributed and are independent samples, but does not satisfy the homogeneity of variance assumption, the findings may still be valid.

The above review and discussion are restricted to the one-way analysis of variance. A similar finding for two-way classification without and with interaction can be found in Sahai and Ageel (2000).

Tests for Departures from Assumptions

As we have seen in the preceding section, the analysis of variance procedure is robust and can tolerate certain departures from the specified assumptions. It is, nevertheless, recommended that whenever a departure is suspected it should be checked out. In this section, we shall briefly state the tests for normality and homoscedasticity.

Tests for Normality

A relatively simple technique to determine the appropriateness of the assumption of normality is to graph the data points on a normal probability paper. If a straight line can be drawn through the plotted points, the assumption of normality is considered to be reasonable. Some formal tests for normality are the chi-square goodness of fit test, and the

tests for skewness and kurtosis that are often used as supplements to the chi-square test (see ▶Chi-Square Tests). For a detailed discussion of these tests refer to Sahai and Ageel (2000).

The tests mentioned above are some of the classical tests of normality. Over the years, a large number of other techniques have been developed for testing for departures from normality. Some powerful omnibus tests proposed for the problem are Shapiro–Wilk's test (Shapiro and Wilk 1965), Shapiro–Francia's test (Shapiro and Francia 1972), and D'Agostino's test (D'Agostino 1971).

For a discussion of tests especially designed for detecting outliers see Barnett and Lewis (1994). Robust estimation procedures have also been employed in detecting extreme observations. The procedures give less weight to data values that are extreme in comparison to the rest of the data. Robust estimation techniques have been reviewed by Hampel et al. (1986).

Tests for Homoscedasticity

If there are just two populations, the equality of two population variances can be tested by using the usual F test. However, more than two population, rather than making all pairwise F tests, we want a single test that can be used to verify the assumption of equality of population variances. There are several tests available for this purpose. The three most commonly used tests are the Bartlett's, Hartley's, and Cochran's tests. The ▶Bartlett's test (Bartlett 1937a, b) compares the weighted arithmetic and geometric means of the sample variances. The Hartley's test (Hartley 1950) compares the ratio of the largest to the smallest variance. The Cochran's test (Cochran 1941) compares the largest sample variance with the average of all the sample variances. For a full description of these procedures and illustration of their applications with examples see Sahai and Ageel (2000). These tests, however, have lower power than is desired for most applications and are adversely affected by nonnormality. Detailed practical comments on Bartlett's, Hartley's, and Cochran's tests are also given by Sahai and Ageel. In recent years, there have appeared a number of tests in the literature that are less sensitive to normality in the data and are found to have a good power for a variety of population distributions see Levene (1960). Following Levene (1960), a number of other robust procedures have been proposed, which are essentially based on techniques of applying ANOVA to transformed scores. For example, Brown and Forsythe (1974a) proposed applying an ANOVA to the absolute deviations from the mean. A somewhat different approach known as ▶jackknife was proposed by Miller (1968) where the original scores in each group are replaced by the contribution of that observation to the group variance. O'Brien (1979, 1981) proposed a procedure, which is a blend of Levene's squared deviation scores and the jackknife. In recent years, there have been a number of studies investigating the robustness of these procedures. For a further discussion and details, the reader is referred to Conover et al. (1981), Olejnik and Algina (1987), and Ramsey (1994).

Corrections for Departures from Assumptions of the Model

Departure from independence could arise in an experiment in which experimental units or plots are laid out in a field so that adjacent plots give similar yields. Lack of independence can also result from correlation in time rather than in space. If the data set in a given problem violates the assumptions of the analysis of variance model, a choice of possible corrective measures is available. One approach is to modify the model. However, this approach has the disadvantage that more often than not the modified model involves fairly complex analysis. Another approach may be to consider using some nonparametric tests. A third approach to be discussed in this section is to use transformations on the data. Sometimes it is possible to make an algebraic transformation of the data to make them appear more nearly normally distributed, or to make the variances of the error terms constant. Conclusions derived from the statistical analyses performed on the transformed data are also applicable to the original data. In this section, we briefly discuss some commonly used transformations to correct for the lack of normality and homoscedasticity. An extremely thorough and detailed monograph on transformation methodology has been prepared by Thöni (1967). An excellent and thorough introduction and a bibliography of the topic can be found in a review paper by Hoyle (1973). For a more recent bibliography of articles on transformations see Draper and Smith (1981:683–684).

Transformations to Correct Lack of Normality

Some transformations to correct for the departures from normality are logarithmic transformation, square-root transformation, and arcsine transformation.

Transformations to Correct Lack of Homoscedasticity

There are several types of data in which the variances of the error terms are not constant. If there is evidence of some systematic relationship between treatment mean and variance, homogeneity of the error variance may be achieved through an appropriate transformation of the data. Bartlett (1936) has given a formula for deriving such transformations provided the relationship between μ_i and σ_e^2 is known. In many cases where the nature of the relationship is not clear, the experimenter can, through trial

and error, find a transformation that will stabilize the variance. We give some commonly employed transformations to stabilize the variance. These are logarithmic transformation, square-root transformation, reciprocal transformation, arcsine transformation, and power transformation. For a detailed discussion of these transformations and their applicability refer to Sahai and Ageel (2000).

These are some of the more commonly used transformations. Still other transformations can be found applicable for various other relationships between the means and the variances. Further, the transformations to stabilize the variance also often make the population distribution nearly normal. For equal sample sizes, however, these transformations may not usually be necessary. Moreover, the use of such transformations may often result in different group means. It is possible that the means of the original scores are equal but the means of the transformed scores are not, and vice versa. Further, the means of transformed scores are often changed in ways that are not intuitively meaningful or are difficult to interpret.

Acknowledgment

We are grateful to Professor Miodrag Lovric, editor-in chief, for his nice editorial efforts and for his valuable suggestions and comments that led to the improvement in the contribution.

About the Authors

Dr. Hardeo Sahai held Professorial and visiting Professorial positions at the University of Puerto Rico, Mayaguez and San Juan, University of Ceara, Brazil, University of Granada, Spain, University of Veracruzana, Mexico, University of Nacional de Colombia, University of Nacional de Trujillo, Peru. He has received the University of Kentuky Outstanding Alumnus award, Medal of honor University of Granada (Spain), Plaque of honor University of Nacional de Trujillo (Peru). He has published over 150 papers in the statistical (bio)medical and epidemiological literature and is coauthor of the several books which include: *Statistics in Epidemiology: Methods, Techniques and Applications* (with Anwer Khurshid, CRC Press, Boca Raton, Florida, 1996), and *Analysis of Variance for Random Models, Vol. 1: Balanced Data and Vol. 2: Unbalanced Data* (with Mario M. Ojeda, Birkhäuser 2004). Professor Sahai is a Fellow of the American Statistical Association, Royal Statistical Society and Elected Member of the International Statistical Institute.

Dr. Mohammed Ibrahim Ali Ageel was a Full Professor and Chairman of Mathematics, Department of Mathematics, King Saud University (KSU), Saudi Arabia, and later the Chairman of Mathematics Department, King Khalid University (KKU), Saudi Arabia. He was the Dean of Graduate School, King Khalid University, Saudi Arabia. Professor Ageel was also a Full Professor of Mathematics and Dean of Engineering, Najran University (NU), Saudi Arabia. Ageel is currently a Full Professor of Mathematics, Jazan University, Jazan, Saudi Arabia. He is a Founder and President of Saudi Association of Statistical Sciences (SASS). He is an Elected member of the International Statistical Institute, and was elected as a Fellow of the Royal Statistical Society. He has published more than 50 research papers and articles in both theoretical and applied areas. Professor Ageel is a coauthor of the book *The Analysis of Variance: Fixed, Random and Mixed Models* (with Hardeo Sahai, Birkhäuser, Boston 2000).

Anwer Khurshid is a Professor at the Department of Statistics, University of Karachi, Pakistan. During 2004–2010 he had a faculty position at the Sultan Qaboos University, Oman and University of Nizwa, Oman. He is author or coauthor of more than 70 papers and two books (both with Professor Hardeo Sahai). In recognition of his teaching and research contributions Professor Khurshid was awarded a certificate of appreciation in 1997 by the Chancellor, University of Karachi, Pakistan.

Anderson–Darling Tests of Goodness-of-Fit

Theodore W. Anderson
Professor of Statistics and Economics, Emeritus
Stanford University, Stanford, CA, USA

Introduction

A "goodness-of-fit" test is a procedure for determining whether a sample of n observations, $x_1, \ldots, x_n$, can be considered as a sample from a given specified distribution. For example, the distribution might be a normal distribution with mean 0 and variance 1. More generally, the specified distribution is defined as

$$F(x) = \int_{-\infty}^{x} f(y)dy, \quad -\infty < x < \infty, \tag{1}$$

where $f(y)$ is a specified density. This density might be suggested by a theory, or it might be determined by a previous study of similar data.

When X is a random variable with distribution function $F(x) = \Pr\{X \le x\}$, then $U = F(X)$ is a random variable with distribution function

$$\Pr\{U \le u\} = \Pr\{F(X) \le u\} = u, \quad 0 \le u \le 1. \tag{2}$$

The model specifies $u_1 = F(x_1), \ldots, u_n = F(x_n)$ as a sample from the distribution (2), that is, the standard uniform distribution (see ▶Uniform Distribution in Statistics) on the unit interval $[0,1]$ written $U(0,1)$.

A test of the hypothesis that $x_1, \ldots, x_n$ is a sample from a specified distribution, say $F^0(x)$, is equivalent to a test that $u_1 = F^0(x_1), \ldots, u_n = F^0(x_n)$ is a sample from $U(0,1)$. Define the *empirical distribution function* as

$$F_n(x) = \frac{k}{n}, \quad -\infty < x < \infty, \tag{3}$$

if k of $(x_1, \ldots, x_n)$ are $\le x$. A goodness-of-fit test is a comparison of $F_n(x)$ with $F^0(x)$. The hypothesis $H_0 : F(x) = F^0(x)$, $-\infty < x < \infty$, is rejected if $F_n(x)$ is very different from $F^0(x)$. "Very different" is defined here as

$$W_n^2 = n\int_{-\infty}^{\infty} \left[F_n(x) - F^0(x)\right]^2 \psi\left[F^0(x)\right] dF^0(x)$$
$$= n\int_{-\infty}^{\infty} \left[F_n(x) - F^0(x)\right]^2 \psi\left[F^0(x)\right] f^0(x)dx \tag{4}$$

being large; here (1) holds and $\psi(z)$ is a weight function such that $\psi(z) \ge 0$, and $f^0(x)$ is the density of $F^0(x)$.

If $\psi(z) = 1$, the statistic W_n^2 is the Cramér-von Mises statistic, denoted by $n\omega^2$. Anderson and Darling (1952) gave a table of the limiting distribution of $n\omega^2$ as $n \to \infty$. For example, the 5% significance point is .46136 and the 1% significance point is .74346.

The Anderson–Darling Statistic

For a given x and hypothetical distribution $F^0(\cdot)$, the random variable $n F_n(x)$ has a ▶binomial distribution with probability $F^0(x)$. The expected value of $n F_n(x)$ is $nF^0(x)$ and the variance is $n F^0(x)\left[1 - F^0(x)\right]$. The definition of the goodness-of-fit statistic (4) permits the choice of weight function $\psi(\cdot)$. In particular the investigator may want to emphasize the tails of the presumed distribution $F^0(x)$. In that case the choice is

$$\psi(u) = \frac{1}{u(1-u)}. \tag{5}$$

Then for a specified x

$$\sqrt{n}\frac{F_n(x) - F^0(x)}{\sqrt{F^0(x)\left[1 - F^0(x)\right]}} \tag{6}$$

has mean 0 and variance 1 when the null hypothesis is true. The Anderson–Darling statistic is

$$A_n^2 = n\int_{-\infty}^{\infty} \frac{\left[F_n(x) - F^0(x)\right]^2}{F^0(x)\left[1 - F^0(x)\right]} dF^0(x). \tag{7}$$

It was shown in Anderson and Darling (1954) that (7) can be written as

$$A_n^2 = -n - \frac{1}{n}\sum_{j=1}^{n}(2j-1)\left[\log u_{(j)} + \log\left(1 - u_{(n-j+1)}\right)\right] \tag{8}$$

where $u_{(j)} = F^0\left(x_{(j)}\right)$ and $x_{(1)} < x_{(2)} < \ldots < x_{(n)}$ is the ordered sample.

Anderson and Darling found the limiting distribution of A_n^2 [for weight function (5)]. In the next section the development of this distribution is outlined. The 5% significance point of the limiting distribution is 2.492 and the 1% point is 3.880. The mean of this limiting distribution is 1 and the variance is $2(\pi^2 - 9)/3 \sim .57974$.

Outline of Derivation

Let $u = F^0(x)$, $u_i = F^{(0)}(x_i)$, $i = 1, \ldots, n$, and $u_{(i)} = F^{(0)}(x_{(i)})$, $i = 1, \ldots, n$. Let $G_n(u)$ be the empirical distribution function of $u_1, \ldots, u_n$; that is

$$G_n(u) = \frac{k}{n}, \quad 0 \le u \le 1, \tag{9}$$

if k of $u_1, \ldots, u_n$ are $\le u$. Thus

$$G_n\left[F^0(x)\right] = F_n^0(x), \tag{10}$$

and

$$W_n^2 = n \int_0^1 [G_n(u) - u]^2 \psi(u) du, \tag{11}$$

when the null hypothesis $F(x) = F^{(0)}(x)$ is true. For every u $(0 \le u \le 1)$

$$Y_n(u) = \sqrt{n}\,[G_n(u) - u] \tag{12}$$

is a random variable, and the set of these may be considered as a stochastic process with parameter u. Thus

$$\Pr\left\{W_n^2 \le z\right\} = \Pr\left\{\int_0^1 Y_n^2(u)\psi(u)du \le z\right\} = A_n(z), \tag{13}$$

say. For a fixed set $u_1, \ldots, u_k$ the k-variate distribution of $Y_n(u_1), \ldots, Y_n(u_k)$ approaches a multivariate normal distribution (see ▶Multivariate Normal Distributions) as $n \to \infty$ with mean and covariance function

$$\mathcal{E}[Y_n(u)] = 0, \quad \mathcal{E}Y_n(u)Y_n(v) = \min(u,v) - uv. \tag{14}$$

The limiting process of $\{Y_n(u)\}$ is a Gaussian process $y(u)$, $0 \le u \le 1$, and $\mathcal{E}y(u) = 0$ and $\mathcal{E}y(u)y(v) = \min(u,v) - uv$. Let

$$a(z) = \Pr\left\{\int_0^1 y^2(u)\psi(u)du \le z\right\}. \tag{15}$$

Then $A_n(z) \to a(z)$, $0 \le z < \infty$. The mathematical problem for the Anderson–Darling statistic is to find the distribution function $a(z)$ when $\psi(u) = 1/u(1-u)$.

We briefly sketch the procedure to find the distribution of $\int_0^1 z^2(u)du$, where $z(u)$ is a Gaussian stochastic process with $\mathcal{E}z(u) = 0$ and $\mathcal{E}z(u)z(v) = k(u,v)$. When the kernel is continuous and square integrable (as is the case here), it can be written as

$$k(u,v) = \sum_{j=1}^{\infty} \frac{1}{\lambda_j} f_j(u) f_j(v), \tag{16}$$

where λ_j is an eigenvalue and $f_j(u)$ is the corresponding normalized eigenfunction of the integral equation

$$\lambda \int_0^1 k(u,v) f(u) du = f(v), \tag{17}$$

$$\int_0^1 f_j^2(u)du = 1, \quad \int_0^1 f_i(u)f_j(u)du = 0, \quad i \ne j. \tag{18}$$

Then the process can be written

$$z(u) = \sum_{j=1}^{\infty} \frac{1}{\sqrt{\lambda_j}} X_j f_j(u), \tag{19}$$

where $X_1, X_2, \ldots,$ are independent $N(0,1)$ variables. Then

$$\int_0^1 z^2(u)du = \sum_{j=1}^{\infty} \frac{1}{\lambda_j} X_j^2, \tag{20}$$

with characteristic function

$$\mathcal{E}\exp\left[it\int_0^1 z^2(u)du\right] = \prod_{j=1}^{\infty} \mathcal{E}\left(\exp itX_j^2/\lambda_j\right) = \prod_{j=1}^{\infty}\left(1 - 2it/\lambda_j\right)^{-\frac{1}{2}}. \tag{21}$$

The process $Y_n^*(u) = \sqrt{\psi(u)}\,Y_n(u)$ has covariance function

$$k(u,v) = \sqrt{\psi(u)}\sqrt{\psi(v)}\,[\min(u,v) - uv]; \tag{22}$$

as $n \to \infty$, the process $Y_n^*(u)$ approaches $y^*(u) = \sqrt{\psi(u)}\,y(u)$ with covariance (22). The characteristic function of the limiting distribution of $n\omega^2$ is

$$\sqrt{\frac{\sqrt{2it}}{\sin\sqrt{2it}}} \tag{23}$$

for $\psi(u) = 1$, and that of the limiting distribution of A_n^2 is

$$\sqrt{\frac{-2\pi it}{\cos\left(\frac{\pi}{2}\sqrt{1+8it}\right)}}. \tag{24}$$

for $\psi(u) = 1/u(1-u)$.

The integral equation (17) can be transformed to a differential equation

$$h''(t) + \lambda\psi(t)\,h((t) = 0. \tag{25}$$

Anderson–Darling Tests with Unknown Parameters

When parameters in the tested distribution are not known, but are estimated efficiently, the covariance (14) is modified, and the subsequent limiting distribution theory for both $n\omega^2$ and A_n^2 follows the same lines as above, with this new covariance. If the parameters are location and/or scale, the limiting distributions do not depend on the true parameter values, but depend on the class of tested distributions. If the parameters are shape parameters, the limiting distribution depends on shape. Limiting distributions have been evaluated and percentage points given for a number of different tested distributions; see Stephens (1976, 1986). Tests for three parameter Weibull, and von Mises have been given by Lockhart and Stephens (1985, 1994).

The percentage points for these tests are much smaller than those given above for the case when parameters are known.

Acknowledgments

The assistance of Michael A. Stephens is gratefully acknowledged.

About the Author

Professor Anderson was born June 5, 1918 in Minneapolis, Minnesota. He is Past President, Institute of Mathematical Statistics (1963), Vice President, American Statistical Association (1971–1973), Fellow of the American Academy of Arts and Sciences (elected 1974), Member of the National Academy of Sciences (elected 1976). Professor Anderson has been awarded the R. A. Fisher Award of Committee of Presidents of Statistical Societies (1985) and Samuel S. Wilks Memorial Medal, American Statistical Association (1988). He holds four honorary doctorates. Professor Anderson has published over 170 articles in statistical, econometric, and mathematical journals, and seven books, including the internationally recognized text *An Introduction to Multivariate Statistical Analysis* (1958, Wiley; 3rd edition 2003). The 17th International Workshop in Matrices and Statistics was held in Tomar (Portugal July 2008), in honour of Professor Theodore Wilbur Anderson 90th birthday. *The Collected Papers of T. W. Anderson: 1943–1985* (edited by George P. H. Styan) were published by Wiley in 1990, comprising 109 papers and 16 commentaries, in a 2-volume set covering 1,681 pages.

Approximations for Densities of Sufficient Estimators

Juan Carlos Abril
President of the Argentinean Statistical Society, Professor Universidad Nacional de Tucumán and Consejo Nacional de Investigaciones Científicas y Técnicas, San Miguel de Tucumán, Argentina

Introduction

Durbin (1980a) proposed a simple method for obtaining asymptotic expansions for the densities of sufficient estimators. The expansion is a series which is effectively in powers of n^{-1}, where n is the sample size, as compare with the ►Edgeworth expansion which is in powers of $n^{-1/2}$. The basic approximation is just the first term of this series. This has an error of order n^{-1} compare to the error of $n^{-1/2}$ in the usual asymptotic normal approximation (see ►Asymptotic Normality). The order of magnitude of the error can generally be reduced to order $n^{-3/2}$ by renormalization.

Suppose that the real m-dimensional random vector $\mathbf{S}_n = (S_{1n}, S_{2n}, \ldots, S_{mn})'$ has a density with respect to Lebesgue measure which depends on integer $n > N$ for some positive N and on $\boldsymbol{\theta} \in \boldsymbol{\Theta}$, where $\boldsymbol{\Theta}$ is a subset of $\mathbb{R}^q$ for q an arbitrary positive integer.

Let

$$\mathbf{D}_n(\boldsymbol{\theta}) = n^{-1} E\left\{\mathbf{S}_n - E(\mathbf{S}_n)\right\}\left\{\mathbf{S}_n - E(\mathbf{S}_n)\right\}' \qquad (1)$$

which we assume is finite and positive-definite for all n and $\boldsymbol{\theta}$, and which we assume converges to a finite positive-definite matrix $\mathbf{D}(\boldsymbol{\theta}_0)$ as $n \to \infty$ and $\boldsymbol{\theta} \to \boldsymbol{\theta}_0$, where $\boldsymbol{\theta}_0$ is a particular value of $\boldsymbol{\theta}$, usually the true value.

Let $\phi_n(\mathbf{z}, \boldsymbol{\theta}) = E(e^{i\mathbf{z}'\mathbf{S}_n})$ be the characteristic function of $\mathbf{S}_n$ where $\mathbf{z} = (z_1, z_2, \ldots, z_m)'$. Whenever the appropriate derivatives exists, let

$$\frac{\partial^j \log \phi_n(\widetilde{\mathbf{z}}, \boldsymbol{\theta})}{\partial \mathbf{z}^j}$$

denote the set of jth order derivatives $\partial^j \log \phi_n(\mathbf{z},\boldsymbol{\theta})/\partial z_1^{j_1}\cdots\partial z_m^{j_m}$ for all integers $j_1, j_2, \ldots, j_m \geq 0$ satisfying $\sum_k j_k = j$, evaluated at $\mathbf{z} = \tilde{\mathbf{z}}$. The jth cumulant $\boldsymbol{\kappa}_{nj}(\boldsymbol{\theta})$ of $\mathbf{S}_n$, where it exists, satisfies the relation

$$i^j \boldsymbol{\kappa}_{nj}(\boldsymbol{\theta}) = \frac{\partial^j \log \phi_n(\mathbf{0},\boldsymbol{\theta})}{\partial \mathbf{z}^j}. \tag{2}$$

In what follows, let $\boldsymbol{\theta}$ and $\boldsymbol{\theta}_0$ be points in an open subset $\boldsymbol{\Theta}_0$ of $\boldsymbol{\Theta}$, and let r be a specified integer. We use the word limit in the sense of joint limit, and introduce three assumptions.

Assumption 1. If n is large enough $|\phi_n(\mathbf{z},\boldsymbol{\theta})|$ is integrable over $\mathbb{R}^m$, and if δ_1 is an arbitrary positive constant the limit of

$$n^{\frac{r}{2}-1} \int_{B_{\delta_1\sqrt{n}}} \left|\phi_n\left(\mathbf{z}/\sqrt{n},\boldsymbol{\theta}\right)\right| d\mathbf{z},$$

as $n \to \infty$ and $\boldsymbol{\theta} \to \boldsymbol{\theta}_0$ is zero, where $B_{\delta_1\sqrt{n}}$ is the region $\|\mathbf{z}\| \geq \delta_1\sqrt{n}$ and $\|\cdot\|$denotes the Euclidean norm.

Assumption 2. The rth derivative $\partial^r \log \phi_n(\mathbf{z},\boldsymbol{\theta})/\partial \mathbf{z}^r$ exists for $\mathbf{z}$ in a neighborhood of the origin and the limit of

$$n^{-1}\frac{\partial^r \log \phi_n(\mathbf{z},\boldsymbol{\theta})}{\partial \mathbf{z}^r}$$

as $n \to \infty$, $\boldsymbol{\theta} \to \boldsymbol{\theta}_0$ and $\|\mathbf{z}\| \to 0$ exists.

Assumption 3. The cumulant $\boldsymbol{\kappa}_{nj}(\boldsymbol{\theta}) = O(n)$ uniformly for $\boldsymbol{\theta}$ in a neighborhood of $\boldsymbol{\theta}_0$ for $j = 3, \ldots, r-1$.

Now we present the Edgeworth expansion and the corresponding approximation to the density $h_n(\mathbf{x},\boldsymbol{\theta})$ of $\mathbf{X}_n = n^{-1/2}E\{\mathbf{S}_n - E(\mathbf{S}_n)\}$. Suppose that there is an integer $r \geq 3$ such that Assumptions 1–3 hold. Then there is a neighborhood $\|\boldsymbol{\theta} - \boldsymbol{\theta}_0\| < \delta_2$ of $\boldsymbol{\theta}_0$ such that

$$h_n(\mathbf{x},\boldsymbol{\theta}) - \widehat{h}_n(\mathbf{x},\boldsymbol{\theta}) = o\left\{n^{-(r/2)+1}\right\} \tag{3}$$

uniformly in $\mathbf{x}$ and in $\boldsymbol{\theta}$ for $\|\boldsymbol{\theta} - \boldsymbol{\theta}_0\| < \delta_2$, where

$$\widehat{h}_n(\mathbf{x},\boldsymbol{\theta}) = \frac{|\mathbf{D}_n(\boldsymbol{\theta})|^{-1/2}}{(2\pi)^{m/2}} \exp\left\{-\frac{1}{2}\mathbf{x}'\mathbf{D}_n^{-1}(\boldsymbol{\theta})\mathbf{x}\right\} \left\{1 + \sum_{j=3}^{r} n^{-(j/2)+1} P_{nj}(\mathbf{x},\boldsymbol{\theta})\right\}, \tag{4}$$

and where $P_{nj}(\mathbf{x},\boldsymbol{\theta})$ is a generalized Edgeworth polynomial of order j the definition of which is given in Durbin (1980a). The practical construction of $P_{nj}(\mathbf{x},\boldsymbol{\theta})$ is described by Chambers (1967, pp. 368–369).

Approximations to the Densities of Sufficient Estimators

Suppose that $\mathbf{y} = (\mathbf{y}_1, \ldots, \mathbf{y}_n)'$ is a matrix of observations of n continuos or discrete random $\ell \times 1$ vectors, not necessarily independent or identically distributed, with density

$$f(\mathbf{y},\boldsymbol{\theta}) = G(\mathbf{t},\boldsymbol{\theta})H(\mathbf{y}), \qquad \mathbf{y} \in \mathcal{Y}, \boldsymbol{\theta} \in \boldsymbol{\Theta}, \tag{5}$$

where $\mathbf{t} = (t_1, \ldots, t_m)'$ is the value computed from $\mathbf{y}$ of an estimator $\mathbf{T}_n$ of the m-dimensional parameter $\boldsymbol{\theta}$, where $\mathcal{Y}$ and $\boldsymbol{\Theta}$ are observation and parameter spaces and where $\mathcal{Y}$ and H do not depend upon $\boldsymbol{\theta}$. We assume that $f(\mathbf{y},\boldsymbol{\theta}) > 0$ for all $\mathbf{y} \in \mathcal{Y}$ and $\boldsymbol{\theta} \in \boldsymbol{\Theta}$. By the factorization theorem $\mathbf{T}_n$ is sufficient for $\boldsymbol{\theta}$.

Suppose that a transformation $\mathbf{y}_1, \ldots, \mathbf{y}_n \to t_1, \ldots, t_m, u_{m+1}, \ldots, u_{n\ell}$ exists such that on substituting for $\mathbf{y}$ on the right-hand side of (5) and integrating or summing out $u_{m+1}, \ldots, u_{n\ell}$ we obtain the marginal density $g(\mathbf{t},\boldsymbol{\theta})$ of $\mathbf{T}_n$ in the form $g(\mathbf{t},\boldsymbol{\theta}) = G(\mathbf{t},\boldsymbol{\theta})H_1(\mathbf{t})$ where H_1 does not depend upon $\boldsymbol{\theta}$. We therefore have

$$f(\mathbf{y},\boldsymbol{\theta}) = g(\mathbf{t},\boldsymbol{\theta})h(\mathbf{y}), \tag{6}$$

where $h(\mathbf{y}) = H(\mathbf{y})/H_1(\mathbf{t})$. The derivation of (6) from (5) has been given in this form to avoid measure-theoretic complications.

Suppose further that although functions $G(\mathbf{t},\boldsymbol{\theta})$ satisfying (5) can be deduced immediately from inspection of $f(\mathbf{y},\boldsymbol{\theta})$, the density $g(\mathbf{t},\boldsymbol{\theta})$ is unknown and we want to obtain an approximation to it for a particular value $\boldsymbol{\theta}_0$ of $\boldsymbol{\theta}$. Since (6) holds for all $\boldsymbol{\theta} \in \boldsymbol{\Theta}$ we have

$$f(\mathbf{y},\boldsymbol{\theta}_0) = g(\mathbf{t},\boldsymbol{\theta}_0)h(\mathbf{y}). \tag{7}$$

On dividing (7) by (6) the unknown factor $h(\mathbf{y})$ is eliminated and we obtain immediately

$$g(\mathbf{t},\boldsymbol{\theta}_0) = \frac{f(\mathbf{y},\boldsymbol{\theta}_0)}{f(\mathbf{y},\boldsymbol{\theta})}g(\mathbf{t},\boldsymbol{\theta}). \tag{8}$$

If we substitute $\mathbf{t}$ for $\boldsymbol{\theta}$ in (8), as is legitimate since we have assumed that $\mathbf{t} \in \boldsymbol{\Theta}$, we obtain

$$g(\mathbf{t},\boldsymbol{\theta}_0) = \frac{f(\mathbf{y},\boldsymbol{\theta}_0)}{f(\mathbf{y},\mathbf{t})}g(\mathbf{t},\mathbf{t}). \tag{9}$$

The basic idea is to obtain an approximation $\widehat{g}(\mathbf{t},\boldsymbol{\theta}_0)$ for $g(\mathbf{t},\boldsymbol{\theta}_0)$ by substituting a series approximation $\widehat{g}(\mathbf{t},\mathbf{t})$ for $g(\mathbf{t},\mathbf{t})$ in (9), giving

$$\widehat{g}(\mathbf{t},\boldsymbol{\theta}_0) = \frac{f(\mathbf{y},\boldsymbol{\theta}_0)}{f(\mathbf{y},\mathbf{t})}\widehat{g}(\mathbf{t},\mathbf{t}). \tag{10}$$

In effect, the method rescales the approximation $\widehat{g}(\mathbf{t},\mathbf{t})$ at $\boldsymbol{\theta} = \mathbf{t}$ by the likelihood ratio $f(\mathbf{y},\boldsymbol{\theta}_0)/f(\mathbf{y},\mathbf{t})$.

A second idea is to substitute an Edgeworth series approximation $\widehat{g}(\mathbf{t},\widetilde{\boldsymbol{\theta}})$ for $g(\mathbf{t},\boldsymbol{\theta})$ in (8), where $\widetilde{\boldsymbol{\theta}}$ is chosen as the value of $\boldsymbol{\theta}$ for which the mean of the distribution of $\mathbf{T}_n$ coincides with $\mathbf{t}$. The reason for using this indirect approach instead of approximating $g(\mathbf{t},\boldsymbol{\theta})$ directly is that a straightforward Edgeworth approximation of $g(\mathbf{t},\boldsymbol{\theta})$, would normally be in powers of $n^{-1/2}$ whereas an Edgeworth approximation of $g(\mathbf{t},\mathbf{t})$ or $\widehat{g}(\mathbf{t},\widetilde{\boldsymbol{\theta}})$ is normally a series in powers of n^{-1}.

Suppose that $E(\mathbf{T}_n) = \boldsymbol{\theta} - \boldsymbol{\beta}_n(\boldsymbol{\theta})$, where $\boldsymbol{\beta}_n(\boldsymbol{\theta}) = O(n^{-1})$ uniformly for $\boldsymbol{\theta}$ in a neighborhood of $\boldsymbol{\theta}_0$, and that $n\mathbf{T}_n = \mathbf{S}_n$, where $\mathbf{S}_n$ satisfies the Assumptions 1–3 given above with $r = 4$. Maximum likelihood estimators often satisfy these assumptions. We make the following further assumption:

Assumption 4. Uniformly for $\boldsymbol{\theta}$ in a neighborhood of $\boldsymbol{\theta}_0$,

$$|\mathbf{D}_n(\boldsymbol{\theta})| = |\mathbf{D}(\boldsymbol{\theta})|\left\{1 + O(n^{-1})\right\}.$$

The assumption is, of course, satisfied when $\mathbf{S}_n$ is a sum of independent and identically distributed vectors but it is also satisfied in other cases of interest, notably in some applications in time series analysis. We suppose that we require a single-term approximation which has an error of order n^{-1} at most.

Since $\mathbf{X}_n = n^{-1/2}E\left\{\mathbf{S}_n - E(\mathbf{S}_n)\right\} = \sqrt{n}\left\{\mathbf{T}_n - \boldsymbol{\theta} + \boldsymbol{\beta}_n(\boldsymbol{\theta})\right\}$, the value of $\mathbf{X}_n$ when $\mathbf{T}_n = \mathbf{t}$ and $\boldsymbol{\theta} = \mathbf{t}$ is $\mathbf{x} = \boldsymbol{\beta}_n(\boldsymbol{\theta})\sqrt{n}$. With $r = 4$, () gives

$$\widehat{h}_n(\mathbf{x},\mathbf{t}) = \frac{|\mathbf{D}_n(\mathbf{t})|^{-1/2}}{(2\pi)^{m/2}} \exp\left\{-\frac{1}{2}n\boldsymbol{\beta}_n(\mathbf{t})'\mathbf{D}_n^{-1}(\mathbf{t})\boldsymbol{\beta}_n(\mathbf{t})\right\} \times\left[1 + \sum_{j=3}^{4} n^{-(j/2)+1}P_{nj}\left\{\boldsymbol{\beta}_n(\boldsymbol{\theta})\sqrt{n},\mathbf{t}\right\}\right]. \tag{11}$$

Now $n\boldsymbol{\beta}_n(\mathbf{t})'\mathbf{D}_n^{-1}(\mathbf{t})\boldsymbol{\beta}_n(\mathbf{t}) = O(n^{-1})$ and the constant term of P_{n4} is $O(1)$. Moreover P_{n3} contains no constant term and hence is $O(n^{-1/2})$ when $\mathbf{x} = \boldsymbol{\beta}_n(\boldsymbol{\theta})\sqrt{n}$. We note that these orders of magnitude are uniform for $\mathbf{t}$ in a neighborhood of $\boldsymbol{\theta}_0$ under the Assumptions 1–3. Because of Assumption 4, we have

$$\widehat{h}_n(\mathbf{x},\mathbf{t}) = \frac{|\mathbf{D}(\mathbf{t})|^{-1/2}}{(2\pi)^{m/2}}\left\{1 + O(n^{-1})\right\}$$

uniformly for $\mathbf{t}$ in a neighborhood of $\boldsymbol{\theta}_0$.

Let $h_n(\mathbf{x},\mathbf{t})$ be the true density of $\mathbf{X}_n$, then by (3)

$$\begin{aligned} h_n(\mathbf{x},\mathbf{t}) &= \widehat{h}_n(\mathbf{x},\mathbf{t}) + o(n^{-1}) \\ &= \frac{|\mathbf{D}(\mathbf{t})|^{-1/2}}{(2\pi)^{m/2}}\left\{1 + O(n^{-1})\right\} + o(n^{-1}). \end{aligned} \tag{12}$$

Since the term $o(n^{-1})$ is uniform for $\mathbf{t}$ in a neighborhood of $\|\mathbf{t} - \boldsymbol{\theta}_0\| < \delta_2$, where $\delta_2$is a suitably chosen positive constant independent of n, and since $|\mathbf{D}(\mathbf{t})|$ is continuous at $\boldsymbol{\theta}_0$ and hence is bounded away from zero for $\mathbf{t}$ in the neighborhood, the term $o(n^{-1})$ of (12) can be absorbed inside the curly bracket. We thus have uniformly

$$h_n(\mathbf{x},\mathbf{t}) = \frac{|\mathbf{D}(\mathbf{t})|^{-1/2}}{(2\pi)^{m/2}}\left\{1 + O(n^{-1})\right\}.$$

Transforming from $\mathbf{x}$ to $\mathbf{t}$ we obtain for the density of $\mathbf{T}_n$ at $\mathbf{T}_n = \boldsymbol{\theta} = \mathbf{t}$,

$$g(\mathbf{t},\mathbf{t}) = \left(\frac{n}{2\pi}\right)^{m/2}|\mathbf{D}(\mathbf{t})|^{-1/2}\left\{1 + O(n^{-1})\right\}. \tag{13}$$

Substituting in (9) we obtain

$$g(\mathbf{t},\boldsymbol{\theta}_0) = \left(\frac{n}{2\pi}\right)^{m/2}|\mathbf{D}(\mathbf{t})|^{-1/2}\frac{f(\mathbf{y},\boldsymbol{\theta}_0)}{f(\mathbf{y},\mathbf{t})}\left\{1 + O(n^{-1})\right\}, \tag{14}$$

uniformly in $\mathbf{t}$ for $\|\mathbf{t} - \boldsymbol{\theta}_0\| < \delta_2$.

Expression (14) is the basic approximation for the density of the sufficient estimator $\mathbf{T}_n$. The fact that the error is a proportional error which is uniform over the region $\|\mathbf{t} - \boldsymbol{\theta}_0\| < \delta_2$ is important since the limiting probability that $\mathbf{T}_n$ falls outside this region is zero.

Assuming appropriate regularity conditions to be satisfied, $\mathbf{D}^{-1}(\boldsymbol{\theta})$ is the limiting mean information matrix $\mathcal{I}(\boldsymbol{\theta})$, where

$$\mathcal{I}(\boldsymbol{\theta}) = \lim_{n\to\infty} E\left[-n^{-1}\frac{\partial^2 \log f(\mathbf{y},\boldsymbol{\theta})}{\partial\boldsymbol{\theta}\partial\boldsymbol{\theta}'}\right].$$

We then have for the basic approximation

$$g(\mathbf{t},\boldsymbol{\theta}_0) = \left(\frac{n}{2\pi}\right)^{m/2}|\mathcal{I}(\mathbf{t})|^{1/2}\frac{f(\mathbf{y},\boldsymbol{\theta}_0)}{f(\mathbf{y},\mathbf{t})}\left\{1 + O(n^{-1})\right\}, \tag{15}$$

uniformly in $\mathbf{t}$ for $\|\mathbf{t} - \boldsymbol{\theta}_0\| < \delta_2$.

The simplicity of the structure of this approximation should be noted. It consists of the normal approximation to the density when $\boldsymbol{\theta} = \mathbf{t}$, namely $\{n/(2\pi)\}^{m/2}|\mathcal{I}(\mathbf{t})|^{1/2}$, multiplied by the likelihood ratio $f(\mathbf{y},\boldsymbol{\theta}_0)/f(\mathbf{y},\mathbf{t})$.

Durbin (1980a) proved that when either (14) or (15) is integrated over any subset of $\mathbb{R}^m$, the error term remains $O(n^{-1})$. This result is, in fact, of great importance in practical situations since it demonstrates that the basic approximation can be integrated for inference purposes with an error which is of order n^{-1} at most. He proved as well that when the constant term of the approximation (14), and consequently also of (15), is adjusted to make the integral over the whole space equal to unity, the order of magnitude of the error is often reduced from $O(n^{-1})$ to $O_x(n^{-3/2})$, where $O_x(n^{-q})$ denotes a quantity which is $O(n^{-q})$ for each fixed $\mathbf{x} = \sqrt{n}\{\mathbf{t} - E(\mathbf{T}_n)\}$ but which is not $O(n^{-q})$ uniformly for all $\mathbf{x}$. This process of adjusting the constant term is generally called renormalization.

Approximations to Distributions

Juan Carlos Abril
President of the Argentinean Statistical Society, Professor Universidad Nacional de Tucumán and Consejo Nacional de Investigaciones Científicas y Técnicas, San Miguel de Tucumán, Argentina

Introduction

The exact probability distribution of estimators for finite samples is only available in convenient form for simple functions of the data and when the likelihood function is completely specified. Frequently, these conditions are not satisfied and the inference is based on approximations to the sample distribution. Typically, large sample methods based on the central limit theorem (see ►Central Limit Theorems) are generally used. For example, if T_n is an estimator of the parameter θ based on a sample of size n, it is sometimes possible to obtain functions $\sigma(\theta)$ such that the distribution of the random variable $\sqrt{n}(T_n - \theta)/\sigma(\theta)$ converges to the standard normal distribution as n tends to infinity. In such a case, it is very common to approximate the distribution of T_n by a normal distribution with mean θ and variance $\sigma^2(\theta)/n$.

These asymptotic approximations can be good even for very small samples. The mean of independent draws from a rectangular distribution has a bell-shaped density for n as small as three. But it is easy to construct examples where the asymptotic approximation is bad even when the sample has hundreds of observations. It is therefore desirable to know the conditions under which the asymptotic approximations are reasonable and to have alternative methods available when these approximations do not work properly. Most of the material discussed here is closely related with the topic *Asymptotic, higher order* which is presented as well in this Encyclopedia.

There is a good literature treating the theory and practice of approximations to distributions, but introductory

texts are relatively few. A very brief summary can be seen in Bickel and Doksum (1977), while some discussion is given in Johnson and Kotz (1970). The extension to asymptotic expansions can be seen in the excellent paper by Wallace (1958), although it is outdated. For a good treatment of the subject, an incursion upon the advanced probability and numerical analysis textbooks is needed. For those with enough time and patience, Chaps. 15 and 16 of Feller (1971) are well worth reading.

The Central Limit Theorem

The center of a large part of the asymptotic theory is the central limit theorem, initially formulated for sums of independent random variables. Let $\{Y_n\}$ be a sequence of independent random variables. Denote by H_n the distribution function of the standardized sum

$$X_n = \frac{\sum_{j=1}^{n} \{Y_j - E(Y_j)\}}{\sqrt{\left\{\sum_{j=1}^{n} V(Y_j)\right\}}},$$

where $V(Y_j)$ is the variance of Y_j, and by $\mathcal{N}(.)$ the standard normal distribution function. The central limit theorem then states that $\lim H_n(x) = \mathcal{N}(x)$, as $n \to \infty$, for every fixed x, provided only that the means and variances are finite. If the $\{Y_j\}$ are not identically distributed, an additional condition guaranteeing that the distributions are not too unbalanced is necessary.

For time series problems, for example, where in general the variables are not independent, there have been particularized versions of this theorem guaranteeing the asymptotic behavior of statistics used in this area. Good references are the textbook by Anderson (1971), Brockwell and Davis (1991), Hannan (1970), and Priestley (1982) where one can find an excellent treatment of the asymptotic theory applied to time series problems.

Some authors have shown that the order of magnitude of the errors in the central limit theorem is $O(n^{-1/2})$.

While the central limit theorem is very useful theoretically and often in practice, it is not always satisfactory since for small or moderate n the errors of the normal approximation may be too large.

Curve Fitting

The most simplest form for obtaining an approximation to a distribution is to look for a family of curves with the correct shape and select the member that fits best. If the moments, specially those of low order, of the true distribution are known, they can be used in the fitting process. Otherwise one can use Monte Carlo simulations or any other information about the true distribution.

Durbin and Watson (1971) describe a number of different approximations to the null distribution of the statistic d used for testing serial correlation in regression analysis. One of the most accurate is the beta approximation proposed by Henshaw (1966). Since d is between zero and four and it seems to have a unimodal density, it is reasonable to think that a linear transformation from a beta distributed variable can be a good approximation to the true distribution. Suppose that Y is a random variable with beta distribution function

$$\Pr(Y \le y) = \frac{1}{B(p,q)} \int_0^y t^{p-1}(1-t)^{q-1} dt = G(y; p.q),$$

where

$$B(p,q) = \int_0^\infty t^{p-1}(1-t)^{q-1} dt.$$

Then, for a and b constant, the random variable $a + bY$ has moments depending on p, q, a and b. These moments are easy to express analytically. Moreover, the moments of the Durbin–Watson's statistic d are simple functions of the matrix of explanatory variables. Equating the first four moments of d with the corresponding moments of $a + bY$, one obtains four equations with four unknowns. For a given matrix of explanatory variables these equations give a unique solution, p^*, q^*, a^* and b^* say. So $\Pr(d \le y)$ can be approximated by $G\{(y - a^*)/b^*; p^*, q^*\}$. This approximation gives good results in many cases. Theil and Nagar (1961) proposed a similar approximation but using the approximated moments of d instead of the true moments. Since these approximated moments are independent of the matrix of explanatory variables, Theil–Nagar's approximation does not depend on the data and can be tabulated without any problem. Unfortunately the approximated moments are not always accurate and the resulting approximation to the distribution is less satisfactory than Henshaw's approximation.

If one has enough information over the true density, the curve fitting methods give simple and correct approximations. However these methods are not so attractive when the purpose is not quantitative but qualitative. The comparison of alternative procedures is difficult because the curve fitting methods does not produce, in general, parametric families of curves easily comparable. If two statistics are approximately normal, they can be compared by their means and variances. If one statistic is approximately beta and another is approximately normal, the comparison between them is not easy since the usual parameters that describe one of the distributions are

not of much interest for obtaining information about the other. The flexibility that makes the curve fitting method so accurate is, as well, an inconvenience for using it in comparisons.

Transformations

Suppose that Y is a random variable and b a monotonically increasing function such that $b(Y)$ has a distribution function H which can be approximated by $\widehat{H}$. Since $\Pr(Y \le y)$ is equal to $\Pr\{b(Y) \le b(y)\}$, the distribution function of Y can be approximated by $\widehat{H}\{b(y)\}$. A well known example of this technique is Fisher's z transformation. The sample correlation coefficient $\widehat{\rho}$ based on a random sample from a bivariate normal population is very far from symmetry when the true coefficient ρ is large in absolute value. But, $z = b(\widehat{\rho}) = 2^{-1}\log\{(1+\widehat{\rho})/(1-\widehat{\rho})\}$ is almost symmetric and can be approximated by a normally distributed random variable with mean $2^{-1}\log\{(1+\rho)/(1-\rho)\}$ and variance n^{-1}. Therefore $\Pr(\widehat{\rho} \le y)$ can be approximated by $\mathcal{N}\{\sqrt{n}b(y) - \sqrt{n}b(\rho)\}$ for moderate sample size n.

The use of transformations for approximating distributions is an art. Sometimes, as in the case of the correlation coefficient, the geometry of the problem can suggest the appropriate transformation b. Since $\widehat{\rho}$ can be interpreted as the cosine of the angle between two normally distributed random vectors, an inverse trigonometric transformation can be useful. In other cases, arguments based on approximations to the moments are helpful. Suppose that $b(Y)$ can be expanded as a power series about $\mu = E(Y)$

$$b(Y) = b(\mu) + b'(\mu)(Y-\mu) + \frac{1}{2}b''(\mu)(Y-\mu)^2 + \cdots,$$

where $Y - \mu$ is in some sense small. so we can do

$$\begin{aligned} E(b) &\approx b(\mu) + \frac{1}{2}b''(\mu)E(Y-\mu)^2, \\ V(b) &\approx \{b'(\mu)\}^2 V(Y), \\ E\{b - E(b)\}^3 &\approx \{b'(\mu)\}^3 E(Y-\mu)^3 \\ &\quad + \frac{3}{2}\{b'(\mu)\}^2 b''(\mu)E(Y-\mu)^4, \end{aligned}$$

and choose b in such a way that these approximates moments are equal to the moments of the approximated distribution. If the approximated distribution is normal, we can require that the variance $V(b)$ be a constant independent of μ; or we can require that the third order moment be zero. If the moments of Y are (almost) known and the above approximation is used, the criterion leads to differential equations in $b(\mu)$. Note that Fisher's transformation of $\widehat{\rho}$ stabilizes the approximated variance of b making it independent of ρ.

Jenkins (1954) and Quenouille (1948) apply inverse trigonometric transformations to the case of the autocorrelation coefficient in time series. The use of transformations in econometrics seems, however, to be minimum due mainly to the fact that the method is closely related with univariate distributions.

Asymptotic Expansions

Frequently it is possible to decompose the problem of finding the distribution in a sequence of similar problems. If the sequence has a limit which can easily be found, one can obtain an approximation to the solution of the original problem by a solution of the limit problem. The sequence of the problem is indexed by a parameter, which usually is the sample size n. Suppose for instance that we want an approximation to the distribution of an estimator, computed from a sample, of a parameter θ. We define an infinite sequence $\widehat{\theta}_n$ of estimators, one for each sample size $n = 1, 2, \ldots$, and we consider the problem of obtaining the distribution of each $\widehat{\theta}_n$. Of course, it is necessary to have some description of the joint distribution of the observations for each n. Given such a sequence of problems, the asymptotic approach implies three steps:

(a) To look for a simple monotonic transformation $X_n = b(\widehat{\theta}_n; \theta, n)$ such that the estimator X_n is not very sensitive to n. Since the majority of estimators are centerd upon the true value of the parameter and they have a dispersion which decreases at the same rate as $n^{-1/2}$, the transformation $X_n = \sqrt{n}(\widehat{\theta}_n - \theta)$ is frequently used.

(b) To look for an approximation $\widehat{H}_n(x)$ to the distribution function $H_n(x) = \Pr(X_n \le x)$ such that, when n tends to infinity, the error

$$\left|\widehat{H}_n(x) - H_n(x)\right|$$

tends to zero.

(c) The distribution function of $\widehat{\theta}_n$ is approximated by $\widehat{H}_n$, i.e., $\Pr(\widehat{\theta}_n \le a) = \Pr\{X_n \le b_n(a;\theta,n)\}$ is approximated by $\widehat{H}_n\{b_n(a;\theta,n)\}$.

Let $\widehat{H}_n(x)$ be an approximation to the distribution function $H_n(x)$. If, for every x,

$$\lim_{n\to\infty} n^{(r/2)-1}\left|\widehat{H}_n(x) - H_n(x)\right| = 0, \quad r = 2, 3, \ldots,$$

we write

$$H_n(x) = \widehat{H}_n(x) + o\left\{n^{(r/2)-1}\right\}, \quad r = 2, 3, \ldots,$$

and we say that $\widehat{H}_n(x)$ is an approximation $o\left\{n^{(r/2)-1}\right\}$ or an approximation of order $r-1$. These names are used as well when approximating density functions. The asymptotic distribution is an approximation $o(n^0) = o(1)$ or a first order approximation. These concepts are related with the topic *Asymptotic, higher order* which is presented as well in this Encyclopedia.

The number n measures the velocity at which the error of approximation tends to zero as n tends to infinity. If we choose the transformation b such that H_n and $\widehat{H}_n$ vary gently with n, the value of r can give an indication of the error of approximation for moderate values of n.

There are two well known methods for obtaining high order approximations to distributions, both based on the Fourier inversion of the characteristic function. Let $\phi_n(z,\theta) = E\{\exp(izX_n)\}$ be the characteristic function of X_n and let $\psi_n(z,\theta) = \log\phi_n(z,\theta)$ be the cumulant generating function. If ϕ_n is integrable, the density function h_n of X_n can be written as

$$h_n(x;\theta) = \frac{1}{2\pi}\int_{-\infty}^{\infty} e^{-ixz}\phi_n(z,\theta)dz$$

$$= \frac{1}{2\pi}\int_{-\infty}^{\infty} \exp\{-ixz + \psi_n(z,\theta)\}\,dz. \qquad (1)$$

Frequently it is possible to expand $\psi_n(z,\theta)$ in power series where the successive terms are increasing powers of $n^{-1/2}$. In this case the integrand can be approximated by the first few terms of this series expansion. Integrating term by term, one obtains a series approximation to h_n; afterward integration will give an approximation to the distribution function. The approximation known as *Edgeworth approximation* or ►*Edgeworth expansion* consists in expanding $\psi_n(z,\theta)$ at $z = 0$. This method is the most frequently used in practice because of its relative simplicity. It does not require a complete knowledge of $\psi_n(z,\theta)$. It is enough if one knows the first low order cumulants of X_n. More details about this method is given in this Encyclopedia under the name *Edgeworth expansion*. The approximation known as *saddlepoint approximation* is obtained by expanding $\psi_n(z,\theta)$ at the "saddlepoint" value z^* where the integrand of (1) is maximized. This method, introduced by Daniels (1954), is more complex and requires a deeper knowledge of the function $\psi_n(z,\theta)$.When this knowledge is available, the method gives accurate approximations specially in the "tail" region of the distribution. Daniels (1956) and Phillips (1978) applied this method to some autocorrelation statistics in time series analysis. More details about this method is given in this Encyclopedia under the name *Saddlepoint approximations*.

Wallace (1958) gives an excellent introduction to the approximations based on expansions of the characteristic function. An exposition with emphasis on multivariate expansions can be found in Barndorff-Nielsen and Cox (1979). Durbin (1980) proposed a simple method for obtaining a second order approximation to the density of a large class of statistics. This method is discuss in this Encyclopedia under the name *Approximations for densities of sufficient estimators*.

Attitudes and Perspectives

The theory of approximate distributions, like the theory of exact distributions, depends on the assumptions made about the stochastic process which generates the data. The quality of the approximations will not be better than the quality of the specifications sustaining them. one certainly will not rely upon a theory of distribution unless the conclusions are so robust that they do not vary significantly in front of moderate changes of basic assumptions. Since the majority of the methods of approximation use information about the first four moments at least, while the usual asymptotic theory only need information about the first two moments, some loss of robustness has to be expected. However, if some idea about the degree of skewness and kurtosis is available, this information can be helpful to obtain better approximations to the distribution of statistics.

Recently there has been an increasing interest in asymptotic theory. Great efforts have been made in order to demonstrate that some statistics are asymptotically normal and efficient. Of course, the asymptotic theory is important to have an idea of the sample properties of a given statistical procedure. Unfortunately there has been some confusion with the use of the terms "asymptotic" and "approximated."The fact that a standardized estimator has an asymptotic normal distribution is purely a mathematical proposition about the limit of the probabilities measures under a set of previously specified assumptions. The fact that a given estimator is approximately normal suggests that, for this particular problem, one believes in the possibility of treating the estimator as if it was normal.

Sometimes, under certain circumstances, asymptotic arguments lead to good approximations, bet frequently they do not. A careful analyst, with some knowledge of statistical theory, a modest computer and a great amount of common sense can find reasonable approximations for a given inferential problem.

Association Measures for Nominal Categorical Variables

Tarald O. Kvålseth
Professor Emeritus
University of Minnesota, Minneapolis, MN, USA

As a means of summarizing the potential relationship between two (or more) random categorical variables X and Y, a number of measures of association have been proposed over the years. A historical review of such measures and new proposals have been presented in a series of papers by Goodman and Kruskal (1979) [see also Kendall and Stuart (1979), Ch. 33 and Liebetrau (1983)]. Such summary measures depend on whether X and Y are nominal or ordinal as well as on whether X and Y are to be treated symmetrically or asymmetrically. In the symmetric case, X and Y are treated equivalently and no causal relationship is assumed to exist between them. In the asymmetric case, a causal relationship between X and Y is considered to exist so that one variable is treated as the explanatory variable (X) and the other variable treated as the response variable (Y).

The focus here will be on the case when both X and Y are nominal categorical variables, i.e., no natural ordering exists for the variables. Association measures for both the symmetric and asymmetric case will be considered.

Symmetric Measures

For the variable X with I categories and the variable Y with J categories, their joint and marginal probabilities are defined as $\Pr(X = i, Y = j) = p_{ij}$, $\Pr(X = i) = p_{i+}$, and $\Pr(Y = j) = p_{+j}$ for $i = 1, \ldots, I$ and $j = 1, \ldots, J$ where $\sum_1^2 i = 1I \sum_1^2 j = 1J p_{ij} = \sum_1^2 i = 1I p_{i+} = \sum_1^2 j = 1J p_{+j} = 1$. In terms of a two-way contingency table with I rows and J columns, the cell entries come from the joint distribution $\{p_{ij}\}$, with p_{ij} being the entry in cell (i, j), and $\{p_{i+}\}$ and $\{p_{+j}\}$ are the marginal distributions (totals) for the rows and columns, respectively. The conditional distribution of Y given X is defined in terms of $p_{j|i} = p_{ij}/p_{i+}$ for all i and j.

Several early suggested association measures were based on the (Pearson) coefficient of mean square contingency defined by

$$\Phi^2 = \sum_{i=1}^{I}\sum_{j=1}^{J}\frac{(p_{ij} - p_{i+}p_{+j})^2}{p_{i+}p_{+j}} = \sum_{i=1}^{I}\sum_{j=1}^{J}\frac{p_{ij}^2}{p_{i+}p_{+j}} - 1. \quad (1)$$

If the p_{ij} represent sample estimates (of population probabilities π_{ij}) $p_{ij} = n_{ij}/N$ based on the multinominal frequencies n_{ij} for all i, j and sample size $N = \sum_{1}^{2} i = 1I \sum_{1}^{2} j = 1J n_{ij}$, then it is recognized that $\Phi^2 = X^2/N$ where X^2 is the familiar Pearson chi-square goodness-of-fit statistic for testing the null hypothesis or independence between X and Y, i.e.,

$$X^2 = N\left(\sum_{i=1}^{I}\sum_{j=1}^{J}\frac{n_{ij}^2}{n_{i+}n_{+j}} - 1\right). \quad (2)$$

The most popular such association measure based on X^2 appears to be Cramér's (1946) V defined as

$$V = \sqrt{\frac{X^2}{N(M-1)}}, \quad M = \min\{I, J\}. \quad (3)$$

This V ranges in value between 0 and 1, inclusive, for any given I and J, with $V = 0$ if, and only if, X and Y are independent and $V = 1$ when there is no more than one non-zero entry in either each row or in each column. The V is invariant with any permutations of the rows or the columns. The estimated standard error of V is given in Bishop et al. (1975, p. 386), but its expression is rather messy.

Kendall and Stuart (1979, p. 606), have shown that V^2 is the mean squared canonical correlation. However, it has been argued that values of V are difficult to interpret since V has no obvious probabilistic meaning or interpretation. Nevertheless, V does reflect the divergence (or "distance") of the distribution $\{p_{ij}\}$ from the independence distribution $\{p_{i+}p_{+j}\}$ relative to the maximum divergence.

There is some uncertainty in the literature as to whether V or V^2 is the proper measure to use. This issue will be addressed in a section below. It may also be pointed out that a similar association measure can be formulated in terms of the likelihood-ratio statistic G^2, which has the same asymptotic chi-square distribution as χ^2 under the null hypothesis and is often used instead of χ^2. For the G^2 under independence, i.e., for

$$G^2 = 2\sum_{i=1}^{I}\sum_{j=1}^{J} n_{ij}\log\left(\frac{Nn_{ij}}{n_{i+}n_{+j}}\right) \quad (4)$$

and since $n_{ij} \le n_{i+}$ and $n_{ij} \le n_{+j}$ for all i and j, it follows that

$$\begin{aligned} G^2 \le G_X^2 &= 2\sum_{i=1}^{I} n_{i+}\log\left(\frac{N}{n_{i+}}\right) \text{ and } G^2 \le G_Y^2 \\ &= 2\sum_{j=1}^{J} n_{+j}\log\left(\frac{N}{n_{+j}}\right). \end{aligned} \quad (5)$$

Thus, analogously to V in (3), one could define the association measure

$$W = \sqrt{\frac{G^2}{\min\{G_X^2, G_Y^2\}}} \quad (6)$$

with G_X^2 and G_Y^2 as given in (5).

This new measure W can also be interpreted as the divergence ("distance") of the distribution $\{p_{ij}\}$ from the independence distribution $\{p_{i+}p_{+j}\}$ relative to its maximum [see also Kvålseth (1987)]. The W has the same type of properties as Cramér's V in (3) and can be expected to take on values quite similar to those of V. For instance, for the data

$$n_{11} = 20 \quad n_{12} = 15 \quad n_{13} = 25$$

$$n_{21} = 5 \quad n_{22} = 25 \quad n_{23} = 10$$

it is found from (3) and (6) that $V = .38$ and $W = .33$.

Asymmetric Measures

Goodman and Kruskal 1979 have discussed two different asymmetric association measures $(\lambda_{Y|X})$ and $(\tau_{Y|X})$ for the case when X can be considered to be the explanatory variable and Y the response variable. Such measures are frequently referred to as proportional reduction in error (PRE) measures since they can be interpreted in terms of the relative difference between two error probabilities P_Y and $P_{Y|X}$, i.e.,

$$PRE_{Y|X} = \frac{P_Y - P_{Y|X}}{P_Y} \quad (7)$$

where P_Y is the probability of error when predicting the Y – category of a randomly selected observation or item without knowing its X – category and $P_{Y|X}$ is the corresponding expected (weighted mean) error probability given its X – category.

The optimal prediction strategy would clearly be to predict that a randomly selected observation (item) would belong to a maximum-probability (modal) category, so that with

$$p_{+m} = \max\{p_{+1}, \ldots, p_{+J}\}; \text{ and } p_{im} = \max\{p_{i1}, \ldots, p_{iJ}\}, \quad i = 1, \ldots, I$$

the error probabilities P_Y and $P_{Y|X}$ become

$$P_Y = 1-p_{+m},\ P_{Y|X} = \sum_{i=1}^{I} p_{i+}\,(1-p_{im}/p_{i+}) = 1-\sum_{i=1}^{I} p_{im}. \quad (8)$$

From (7)–(8), the so-called Goodman–Kruskal *lambda* becomes

$$\lambda_{Y|X} = \frac{\sum_{1}^{2} i = 1 I p_{im} - p_{+m}}{1-p_{+m}} \quad (9)$$

which is the relative decrease in the error probability when predicting the Y-category as between not knowing and knowing the X-category.

Another asymmetric measure is based on a different prediction rule: Predictions are made according to the given probabilities. Thus, a randomly chosen observation (item) is predicted to fall in the jth category of Y with probability p_{+j} $(j = 1,\ldots,J)$ if its X-category is unknown. If, however, the observation is known to belong to the ith category of X, it is predicted to belong to the jth category of Y with the (conditional) probability p_{ij}/p_{i+} $(j = 1,\ldots,J)$. The error probabilities are then given by

$$P_Y = 1-\sum_{j=1}^{J} p_{+j}^2, \quad P_{Y|X} = \sum_{i=1}^{I} p_{i+}\left[1-\sum_{j=1}^{J}(p_{ij}/p_{i+})^2\right] \quad (10)$$

so that, from (7) and (10), the following so-called Goodman–Kruskal *tau* results:

$$\tau_{Y|X} = \frac{\sum_{i=1}^{I}\sum_{j=1}^{J} p_{ij}^2/p_{i+} - \sum_{j=1}^{J} p_{+j}^2}{1-\sum_{j=1}^{J} p_{+j}^2} \quad (11)$$

which gives the relative reduction in the error probability when predicting an observation's Y-category as between its X-category not given and given.

Both measures in (9) and (11), and whose estimated standard errors are given elsewhere [e.g., Bishop et al. (1975, pp. 388–391), Goodman and Kruskal (1979), and Liebetrau (1983)], can assume values between 0 and 1, inclusive. Both equal 1 if, and only if, each row of the contingency table contains no more than one non-zero cell entry. Both are invariant under permutations of rows or of columns. However, their zero-value conditions differ. The $\tau_{Y|X} = 0$ if, and only if, X and Y are independent, whereas $\lambda_{Y|X} = 0$ if (1) X and Y are independent or (2) the modal probabilities p_{im} in all rows fall in the same column. This second condition is most likely to occur when the marginal distribution $\{p_{i+}\}$ is highly uneven (non-uniform). Thus, in cases of highly uneven $\{p_{i+}\}$, $\lambda_{Y|X}$ may be 0 or very small, while other measures such as $\tau_{Y|X}$ may be substantially larger. The high sensitivity of $\lambda_{Y|X}$ to $\{p_{i+}\}$ is one limitation of this measure that may lead to misleadingly low association values.

Symmetric version of *lambda* and *tau* can also be formulated in terms of weighted averages (Goodman and Kruskal 1979). Thus, in terms of the general expression in (7), a symmetric *PRE* could be formulated as the following weighted mean of $PRE_{Y|X}$ and $PRE_{X|Y}$:

$$PRE = \frac{P_Y - P_{Y|X} + P_X - P_{X|Y}}{P_Y + P_X}.$$

However, there would seem to be no strong reason for preferring such symmetricized measures over the V or W in (3) and (6).

It should be pointed out that asymmetric association measures can also be formulated in terms of relative reduction in variation, somewhat analogously to the coefficient of determination (R^2) used in regression analysis. This can be done by basically replacing the prediction error probabilities in (7) with appropriate measures of categorical variation (Agresti 2002, pp. 56–69).

Concluding Comment

For Cramér's V in (3), there is inconsistency in the literature concerning the use of V versus V^2 (and Cramér himself proposed V^2 (Cramér 1946, p. 443)). Also, concern has been expressed that different measures such as those in (9) and (11) can produce quite different results. Such issues are indeed important and are often overlooked.

As with any summary measure, and so it is with association measures, it is essential that a measure takes on values throughout its range that are reasonable in that they provide true or valid representations of the attribute being measured. In order to make such an assessment for the above association measures, consider the simple case of a 2×2 table with all the marginal probabilities equal to .5 and with the following cell entries:

$$p_{11} = (1-w)/4 p_{12} = (1+w)/4$$

$$p_{21} = (1+w)/4 p_{22} = (1-w)/4$$

with $0 \le w \le 1$. Each of these probabilities are seen to be the weighted mean of the corresponding probabilities for the case of perfect association and zero association (independence) for the given marginal probabilities, i.e.,

$$p_{11} = p_{22} = w(0)+(1-w)(.25), \quad p_{12} = p_{21} = w(.5)+(1-w)(.25)$$

In order for some association measure $A \in [0,1]$ to take on reasonable values in this ease, the only logical requirement is clearly that

$$A = w(A=1) + (1-w)(A=0) = w,\ w \in [0,1]$$

It is readily seen that the measures in (3) and (9) meet this requirement for all w, i.e., $V = w$ (and not V^2) and $\lambda_{Y|X} = w$ for the above $\{p_{ij}\}$ – distribution. However, it is seen that, for (11), $\lambda_{Y|X} = w^2$. This shows that $\tau'_{Y|X} = \sqrt{\tau_{Y|X}}$ should be used as an association measure rather than $\tau_{Y|X}$. In the case of W in (6), it is apparent that W is only approximately equal to w, but the approximation appears to be sufficiently close for W to be a competitive association measure.

Astrostatistics

Eric D. Feigelson
Professor, Associate Director
Penn State Center for Astrostatistics Pennsylvania State University, University Park, PA, USA

Introduction

The term "astronomy" is best understood as short-hand for "astronomy and astrophysics." Astronomy is the observational study of matter beyond Earth: planets and other bodies in the Solar System, stars in the Milky Way Galaxy, galaxies in the Universe, and diffuse matter between these concentrations of mass. The perspective is rooted in our viewpoint on or near Earth, typically using telescopes or robotic satellites. Astrophysics is the study of the intrinsic nature of astronomical bodies and the processes by which they interact and evolve. This is an inferential intellectual effort based on the well-confirmed assumption that physical processes established to rule terrestrial phenomena – gravity, thermodynamics, electromagnetism, quantum mechanics, plasma physics, chemistry, and so forth – also apply to distant cosmic phenomena.

Statistical techniques play an important role in analyzing astronomical data and at the interface between astronomy and astrophysics. Astronomy encounters a huge range of statistical problems: samples selected with truncation; variables subject to censoring and heteroscedastic measurement errors; parameter estimation of complex models derived from astrophysical theory; anisotropic spatial clustering of galaxies; time series of periodic, stochastic, and explosive phenomena; image processing of both gray-scale and Poissonian images; ►data mining of terabyte-petabyte datasets; and much more. Thus, astrostatistics is not focused on a narrow suite of methods, but rather brings the insights from many fields of statistics to bear on problems arising in astronomical research.

History

As the oldest observational science, astronomy was the driver for statistical innovations over many centuries (Stigler 1986; Hald 1998). Hipparchus, Ptolemy, al-Biruni, and Galileo Galilei were among those who discussed methods for averaging discrepant astronomical measurements. The least squares method (see ►Least Squares) and its understanding in the context of the normal error distribution were developed to address problems in Newtonian celestial mechanics during the early nineteenth century by Pierre-Simon Laplace, Adrian Legendre, and Carl Friedrich Gauss. The links between astronomy and statistics considerably weakened during the first decades of the twentieth century as statistics turned its attention to social and biological sciences while astronomy focused on astrophysics. Maximum likelihood methods emerged slowly starting in the 1970s, and Bayesian methods are now gaining considerably popularity.

Modern astrostatistics has grown rapidly since the 1990s. Several cross-disciplinary research groups emerged to develop advanced methods and critique common practices (http://hea-www.harvard.edu/AstroStat; http://www.incagroup.org; http://astrostatistics.psu.edu). Monographs were written on astrostatistics (Babu and Feigelson 1996), galaxy clustering (Martinez and Saar 2002), image processing (Starck and Murtagh 2006), Bayesian analysis

(Gregory 2005), and Bayesian cosmology (Hobson et al. 2010). The *Statistical Challenges in Modern Astronomy* (Babu and Feigelson 2007) conferences bring astronomers and statisticians together to discuss methodological issues.

The astronomical community is devoting considerable resources to the construction and promulgation of large archival datasets, often based on well-designed surveys of large areas of the sky. These surveys can generate petabytes of images, spectra and time series. Reduced data products include tabular data with approximately ten variables measured for billions of astronomical objects. Major projects include the Sloan Digital Sky Survey, International Virtual Observatory, and planned Large Synoptic Survey Telescope (http://www.sdss.org, http://www.ivoa.net, http://www.lsst.org). Too large for traditional treatments, these datasets are spawning increased interest in computationally efficient data visualization, data mining, and statistical analysis. A nascent field of astroinformatics allied to astrostatistics is emerging.

Topics in Contemporary Astrostatistics

Given the vast range of astrostatistics, only a small portion of relevant issues can be outlined here. We outline three topics of contemporary interest (The astronomical research literature can be accessed online through the SAO/NASA Astrophysics Data System, http://adsabs.harvard.edu.).

Heteroscedastic Measurement Errors

Astronomical measurements at telescopes are made with carefully designed and calibrated instruments, and "background" levels in dark areas of the sky are examined to quantitatively determine the noise levels. Thus, unlike in social and biological science studies, heteroscedastic measurement error are directly obtained for each astronomical measurement. This produces unusual data structures. For example, a multivariate table of brightness of quasars in six photometric bands will have 12 columns of numbers giving the measured brightness and the associated measurement error in each band.

Unfortunately, few statistical techniques are available for this class of non-identically distributed data. Most errors-in-variables methods are designed to treat situations where the heteroscedasticity is not measured, and instead becomes part of the statistical model (Carroll et al. 2006). Methods are needed for density estimation, regression, multivariate analysis and classification, spatial processes, and time series analysis. Common estimation procedures in the astronomical literature weight each measurement by its associated error. For instance, in a functional regression model, the parameters $\hat{\boldsymbol{\theta}}$ in model M are estimated by minimizing the weighted sum of squared residuals $\sum_i (O_i - M_i(\hat{\boldsymbol{\theta}})^2/\sigma_i^2$ of the observed data O_i where σ_i^2 are the known variances of the measurement errors.

More sophisticated methods are being developed, but have not yet entered into common usage. Kelly (2007) treats structural regression as an extension of a normal mixture model, constructing a likelihood which can either be maximized with the EM Algorithm or used in ►Bayes' theorem. The Bayesian approach is more powerful, as it also can simultaneous incorporate censoring and truncation into the measurement error model. Delaigle and Meister (2008) describe a nonparametric kernel density estimator that takes into account the heteroscedastic errors. More methods (e.g., for multivariate clustering and time series modeling) are needed.

Censoring and Truncation

In the telescopic measurement of quasar brightnesses outlined above, some targeted quasars may be too faint to be seen above the background noise level in some photometric bands. These nondetections lead to censored data points. The situation is similar in some ways to censoring treated by standard survival analysis, but differs in other ways: the data are left-censored rather than right-censored; censoring can occur in any variable, not just a single response variable; and censoring levels are linked to measurement error levels. Survival techniques have come into common usage in astronomy since their introduction (Isobe et al. 1986). They treat some problems such as density estimation (with the Kaplan-Meier product-limit estimator), two-sample tests (with the Gehan, logrank and Peto-Prentice tests), correlation (using a generalization of Kendall's τ), and linear regression (using the Buckley-James line).

Consider a survey of quasars at a telescope with limited sensitivity where the quasar sample is not provided in advance, but is derived from the photometric colors of objects in the survey. Now quasars which are too faint for detection are missing entirely from the dataset. Recovery from this form of truncation is more difficult than recovery from censoring with a previously established sample. A major advance was the derivation of the nonparametric estimator for a randomly truncated dataset, analogous to the Kaplan-Meier estimator for censored data, by astrophysicist Lynden-Bell (1971). This solution was later recovered by statistician Woodroofe (1985), and bivariate extensions were developed by Efron and Petrosian (1992).

Periodicity Detection in Difficult Data

Stars exhibit a variety of periodic behaviors: binary star or planetary orbits; stellar rotation; and stellar oscillations. While Fourier analysis is often used to find and characterize such periodicities, the data often present problems such as non-sinusoidal repeating patterns, observations of limited duration, and unevenly-spaced observations. Non-sinusoidal periodicities occur in elliptical orbits, eclipses, and rotational modulation of surface features. Unevenly-spaced data arise from bad weather at the telescope, diurnal cycles for ground-based telescopes, Earth orbit cycles for satellite observatories, and inadequate observing time provided by telescope allocation committees.

Astronomers have developed a number of statistics to locate periodicities under these conditions. The Lomb-Scargle periodogram (Scargle 1982) generalizes the Schuster periodogram to treat unevenly-spaced data. Stellingwerf (1978) presents a widely used least-squared technique where the data are folded modulo trial periods, grouped into phase bins, and intra-bin variance is compared to inter-bin variance using χ^2. The method treats unevenly spaced data, measurement errors, and non-sinusoidal shapes. Dworetsky (1983) gives a similar method without binning suitable for sparse datasets. Gregory and Loredo (1992) develop a Bayesian approach for locating non-sinusoidal periodic behaviors from Poisson distributed event data. Research is now concentrating on methods for computationally efficient discovery of planets orbiting stars as they eclipse a small fraction during repeated transits across the stellar surface. These methods involve matched filters, Bayesian estimation, least-squares box-fitting, maximum likelihood, ►analysis of variance, and other approaches (e.g., Pontopappas et al. 2005).

About the Author

Dr. Eric Feigelson was trained in astronomy at Haverford College and Harvard University during the 1970s, and entered the Astronomy and Astrophysics faculty at Pennsylvania State University in 1983 where he received an NSF Presidential Young Investigator Award and is now Professor. In addition to X-ray astronomical studies of star and planet formation, he has a long-standing collaboration with statisticians. Working with G. Jogesh Babu at Penn State's Center for Astrostatistics, he organizes summer schools, conferences and other resources for advancing statistical methodology in astronomy. He serves as an Associate Editor of the *Astrophysical Journal*, on the Virtual Astronomical Observatory Science Council, and other organizations relating statistics to astronomy.

A

Asymptotic Normality

John E. Kolassa
Professor
Rutgers University, Newark, NJ, USA

Consider a sequence of random variables T_n, whose distribution depends on a parameter n that generally represents sample size. The sequence is said to be asymptotically normal if there exists a sequences μ_n and σ_n such that $\lim_{n\to\infty} P\left[(T_n - \mu_n)/\sigma_n \le x\right] = \Phi(x)$ for all x, where $\Phi(x)$ is the standard Gaussian distribution function

$$\int_{-\infty}^{x} \exp(-y^2/2)(2\pi)^{-1/2}\, dy. \tag{1}$$

One often writes

$$T_n \sim AN(\mu_n, \sigma_n^2) \tag{2}$$

to express asymptotic normality. Note that μ_n generally depend on n, and furthermore may be data-dependent. Furthermore, in some cases T_n might be a sequence of random vectors; in this case, μ_n is a sequence of vectors, σ_n^2 is a sequence of matrices, and Φ the vector valued counterpart of (1). In the scalar case, for fixed n, the quantity σ_n is called the standard error of T_n.

Many frequentist statistical inferential procedures are performed by constructing a T_n so that (2) holds under a null hypothesis, with a dissimilar distribution under interesting alternative hypotheses, and reporting

$$2(1 - \Phi(|(T_n - \mu_n)/\sigma_n|)) \tag{3}$$

as a two-sided p-value; the application for one-sided p-values is similar, and there are also Bayesian applications of a similar flavor. Serfling (1980) provides further information.

Consider the following examples of quantities that are asymptotically normal:

- If T_n is the mean of n independent and identically distributed random variables, each with expectation μ and standard deviation σ, then

  $$T_n \sim AN(\mu, \sigma^2/n). \tag{4}$$

  Furthermore, if s_n is the traditional standard deviation of the contributors the the mean,

  $$T_n \sim AN(\mu, s_n^2/n); \tag{5}$$

  note that the standard error here is data-dependent, and it is incorrect to call $s_n/\sqrt{n}$ a standard deviation of T_n, even approximately. In the present case square root of the second argument to the AN operator estimates the standard deviation of T_n, but a further example shows that even this need not be true. In this case, the standard Z-test for a single sample mean follows from using (4) when σ is known, and when the components of T_n are binary, the standard standard Z-test for a single sample mean follows from using (4) with σ^2 the standard Bernoulli variance. When σ is unknown, (5) is often used instead, and for $n \le 30$, the t distribution function is generally used in place of Φ in (3) for greater accuracy.
- Many rank-based statistics are asymptotically normal; for example, if T_n is the Wilcoxon signed-rank statistic (see ▶Wilcoxon-Signed-Rank Test) for testing whether the expectation of n independent and identically distributed random variables takes on a particular null value, assuming symmetry and continuity of the underlying distribution. Without loss of generality, take this null mean to be zero. Then T_n is obtained by ranking the absolute values of the observations, and summing the ranks of those observations that are positive. Hettmansperger (1984) notes that (2) holds with $\mu_n = n(n+1)/2$ and $\sigma_n = \sqrt{n(n+1)(2n+1)/24}$, and the test against the two-sided alternative reports the p-value (3). In this case, T_n may be written as the sum of independent but not identically-distributed random variables, or as the sum of identically-distributed but not independent random variables.
- Many parameter estimates resulting from fitting models with independent observations are asymptotically normal. For example, consider independent Bernoulli observations Y_i with $P\left[Y_i = 1\right] = \exp(\beta_1 + \beta_2 x_i)/(1 + \exp(\beta_1 + \beta_2 x_i))$. Let

  $$\ell(\boldsymbol{\beta}) = \sum_{i=1}^{n} \left[Y_i\beta_1 + x_i Y_i \beta_2 - \log(1 + \exp(\beta_1 + \beta_2 x_i))\right], \tag{6}$$

  and let $\hat{\boldsymbol{\beta}}$ maximize ℓ; here $\hat{\boldsymbol{\beta}}$ implicitly depends on n. Then

  $$\hat{\boldsymbol{\beta}} \sim AN(\boldsymbol{\beta}, [-\ell''(\boldsymbol{\beta})]^{-1}), \tag{7}$$

  as one can see by heuristically expressing $\ell'(\boldsymbol{\beta}) + \ell''(\boldsymbol{\beta})(\hat{\boldsymbol{\beta}} - \boldsymbol{\beta}) \approx \ell'(\hat{\boldsymbol{\beta}}) = 0$, and solving for $\hat{\boldsymbol{\beta}}$ to obtain $\hat{\boldsymbol{\beta}} \approx \boldsymbol{\beta} - [\ell''(\boldsymbol{\beta})]^{-1}\ell'(\boldsymbol{\beta})$, noting that $\ell''(\boldsymbol{\beta})$ is nonrandom, and noting that a variant of the Central Limit Theorem proves the asymptotic normality of $\ell'(\boldsymbol{\beta})$, and hence of $\hat{\boldsymbol{\beta}}$. This heuristic argument is easily made rigorous once one notes $\hat{\boldsymbol{\beta}}$ is consistent (i.e., for any $\epsilon > 0$, $\lim_{n\to\infty} P\left[\|\hat{\boldsymbol{\beta}} - \boldsymbol{\beta}\| > \epsilon\right] = 0$; see Cox and Hinkley 1974). In this example, the outcome $Y_i = 1\ \forall i$

has positive probability, and for such $\{Y_1, \ldots, Y_n\}$, $\hat{\beta}_1$ is infinite. A similar result holds for $Y_i = 0\ \forall i$. Hence the variance of $\hat{\boldsymbol{\beta}}$ does not exist.

Asymptotic Relative Efficiency in Estimation

Robert Serfling
Professor
University of Texas at Dallas, Richardson, TX, USA

Asymptotic Relative Efficiency of Two Estimators

For statistical estimation problems, it is typical and even desirable that several reasonable estimators can arise for consideration. For example, the mean and median parameters of a symmetric distribution coincide, and so the *sample mean* and the *sample median* become competing estimators of the point of symmetry. *Which is preferred? By what criteria shall we make a choice?*

One natural and time-honored approach is simply to compare the sample sizes at which two competing estimators meet a given standard of performance. This depends upon the chosen measure of performance and upon the particular population distribution F.

To make the discussion of sample mean versus sample median more precise, consider a distribution function F with density function f symmetric about an unknown point θ to be estimated. For $\{X_1, \ldots, X_n\}$ a sample from F, put $\overline{X}_n = n^{-1}\sum_{i=1}^n X_i$ and $\mathrm{Med}_n = \mathrm{median}\{X_1, \ldots, X_n\}$. Each of $\overline{X}_n$ and Med_n is a consistent estimator of θ in the sense of convergence in probability to θ as the sample size $n \to \infty$. To choose between these estimators we need to use further information about their performance. In this regard, one key aspect is *efficiency*, which answers: *How spread out about θ is the sampling distribution of the estimator?* The smaller the variance in its sampling distribution, the more "efficient" is that estimator.

Here we consider "large-sample" sampling distributions. For $\overline{X}_n$, the classical central limit theorem (see ►Central Limit Theorems) tells us: if F has finite variance σ_F^2, then the sampling distribution of $\overline{X}_n$ is approximately $N\left(\theta, \sigma_F^2/n\right)$, i.e., Normal with mean θ and variance σ_F^2/n. For Med_n, a similar classical result (Serfling 1980) tells us: if the density f is continuous and positive at θ, then the sampling distribution of Med_n is approximately $N(\theta, 1/4[f(\theta)]^2 n)$. On this basis, we consider $\overline{X}_n$ and Med_n to perform equivalently at respective sample sizes n_1 and n_2 if

$$\frac{\sigma_F^2}{n_1} = \frac{1}{4[f(\theta)]^2 n_2}.$$

Keeping in mind that these sampling distributions are only approximations assuming that n_1 and n_2 are "large," we define the *asymptotic relative efficiency (ARE)* of Med to $\overline{X}$ as the *large-sample limit* of the ratio n_1/n_2, i.e.,

$$\mathrm{ARE}\left(\mathrm{Med}, \overline{X}, F\right) = 4[f(\theta)]^2 \sigma_F^2. \tag{1}$$

Definition in the General Case

For any parameter η of a distribution F, and for estimators $\widehat{\eta}^{(1)}$ and $\widehat{\eta}^{(2)}$ approximately $N(\eta, V_1(F)/n)$ and $N(\eta, V_2(F)/n)$, respectively, the *ARE of $\widehat{\eta}^{(2)}$ to $\widehat{\eta}^{(1)}$* is given by

$$\mathrm{ARE}\left(\widehat{\eta}^{(2)}, \widehat{\eta}^{(1)}, F\right) = \frac{V_1(F)}{V_2(F)}. \tag{2}$$

Interpretation. If $\widehat{\eta}^{(2)}$ is used with a sample of size n, the number of observations needed for $\widehat{\eta}^{(1)}$ to perform equivalently is $\mathrm{ARE}(\widehat{\eta}^{(2)}, \widehat{\eta}^{(1)}, F) \times n$.

Extension to the case of multidimensional parameter. For a parameter $\boldsymbol{\eta}$ taking values in $\mathbb{R}^k$, and two estimators $\widehat{\boldsymbol{\eta}}^{(i)}$ which are k-variate Normal with mean $\boldsymbol{\eta}$ and nonsingular covariance matrices $\boldsymbol{\Sigma}_i(F)/n$, $i = 1, 2$, we use [see Serfling (1980)]

$$\mathrm{ARE}\left(\widehat{\boldsymbol{\eta}}^{(2)}, \widehat{\boldsymbol{\eta}}^{(1)}, F\right) = \left(\frac{|\boldsymbol{\Sigma}_1(F)|}{|\boldsymbol{\Sigma}_2(F)|}\right)^{1/k}, \tag{3}$$

the ratio of *generalized variances* (determinants of the covariance matrices), raised to the power $1/k$.

Connection with the Maximum Likelihood Estimator

Let F have density $f(x\,|\,\eta)$ parameterized by $\eta \in \mathbb{R}$ and satisfying some differentiability conditions with respect to η. Suppose also that $I(F) = E_\eta\left\{\left[\frac{\partial}{\partial\eta}\log f(x\,|\,\eta)\right]^2\right\}$ (the *Fisher information*) is positive and finite. Then (Lehmann and Casella 1988) it follows that (a) the *maximum likelihood estimator* $\widehat{\eta}^{(\mathrm{ML})}$ of η is approximately $N(\eta, 1/I(F)n)$, and (b) for a wide class of estimators $\widehat{\eta}$ that are approximately $N(\eta, V(\widehat{\eta}, F)/n)$, a *lower bound* to $V(\widehat{\eta}, F)$ is $1/I(F)$. In this situation, (2) yields

$$\mathrm{ARE}\left(\widehat{\eta}, \widehat{\eta}^{(\mathrm{ML})}, F\right) = \frac{1}{I(F)V(\widehat{\eta}, F)} \le 1, \tag{4}$$

making $\widehat{\eta}^{(\mathrm{ML})}$ (asymptotically) the most efficient among the given class of estimators $\widehat{\eta}$. We note, however, as will be discussed later, that (4) does not necessarily make $\widehat{\eta}^{(\mathrm{ML})}$ the estimator of choice, when certain other considerations are taken into account.

Detailed Discussion of Estimation of Point of Symmetry

Let us now discuss in detail the example treated above, with F a distribution with density f symmetric about an unknown point θ and $\{X_1, \ldots, X_n\}$ a sample from F. For estimation of θ, we will consider not only $\overline{X}_n$ and Med_n but also a third important estimator.

Mean versus Median

Let us now formally compare $\overline{X}_n$ and Med_n and see how the ARE differs with choice of F. Using (1) with $F = N\left(\theta, \sigma_F^2\right)$, it is seen that

$$\mathrm{ARE}\left(\mathrm{Med}, \overline{X}, N\left(\theta, \sigma_F^2\right)\right) = 2/\pi = 0.64.$$

Thus, for sampling from a *Normal* distribution, the sample mean performs as efficiently as the sample median using only 64% as many observations. (Since θ and σ_F are location and scale parameters of F, and since the estimators $\overline{X}_n$ and Med_n are location and scale equivariant, their ARE does not depend upon these parameters.) The superiority of $\overline{X}_n$ here is no surprise since it is the MLE of θ in the model $N\left(\theta, \sigma_F^2\right)$.

As noted above, *asymptotic* relative efficiencies pertain to large sample comparisons and need not reliably indicate small sample performance. In particular, for F *Normal*, the *exact* relative efficiency of Med to $\overline{X}$ for sample size $n = 5$ is a very high 95%, although this decreases quickly, to 80% for $n = 10$, to 70% for $n = 20$, and to 64% in the limit.

For sampling from a *double exponential* (or *Laplace*) distribution with density $f(x) = \lambda e^{-\lambda|x-\theta|}/2$, $-\infty < x < \infty$ (and thus variance $2/\lambda^2$), the above result favoring $\overline{X}_n$ over Med_n is reversed: (1) yields

$$\mathrm{ARE}\left(\mathrm{Med}, \overline{X}, \mathrm{Laplace}\right) = 2,$$

so that the sample mean requires 200% as many observations to perform equivalently to the sample median. Again, this is no surprise because for this model the MLE of θ is Med_n.

A Compromise: The Hodges–Lehmann Location Estimator

We see from the above that the ARE depends dramatically upon the shape of the density f and thus must be used cautiously as a benchmark. For Normal versus Laplace, $\overline{X}_n$ is either greatly superior or greatly inferior to Med_n. This is a rather unsatisfactory situation, since in practice we might not be quite sure whether F is Normal or Laplace or some other type. A very interesting solution to this dilemma is given by an estimator that has excellent *overall performance*, the so-called *Hodges–Lehmann location estimator* (Hodges and Lehmann 1963; see ▶Hodges-Lehmann Estimators):

$$\mathrm{HL}_n = \mathrm{Median}\left\{\frac{X_i + X_j}{2}\right\},$$

the median of all pairwise averages of the sample observations. (Some authors include the cases $i = j$, some not.) We have (Lehmann 1998a) that HL_n is asymptotically $N(\theta, 1/12[\int f^2(x)dx]^2 n)$, which yields that $\mathrm{ARE}\left(\mathrm{HL}, \overline{X}, N\left(\theta, \sigma_F^2\right)\right) = 3/\pi = 0.955$ and $\mathrm{ARE}(\mathrm{HL}, \overline{X}, \mathrm{Laplace}) = 1.5$. Also, for the ▶*Logistic* distribution with density $f(x) = \sigma^{-1}e^{(x-\theta)/\sigma}/[1 + e^{(x-\theta)/\sigma}]^2$, $-\infty < x < \infty$, for which HL_n is the MLE of θ and thus optimal, we have $\mathrm{ARE}(\mathrm{HL}, \overline{X}, \mathrm{Logistic}) = \pi^2/9 = 1.097$ [see Lehmann (1998b)]. Further, for $\mathcal{F}$ the class of all distributions symmetric about θ and having finite variance, we have $\inf_{\mathcal{F}} \mathrm{ARE}(\mathrm{HL}, \overline{X}, F) = 108/125 = 0.864$ [see Lehmann (1998a)]. The estimator HL_n is highly competitive with $\overline{X}$ at Normal distributions, can be infinitely more efficient at some other symmetric distributions F, and is never much

less efficient at any distribution F in $\mathcal{F}$. The computation of HL_n appears at first glance to require $O(n^2)$ steps, but a much more efficient $O(n \log n)$ algorithm is available [see Monohan (1984)].

Efficiency versus Robustness Trade-Off

Although the asymptotically most efficient estimator is given by the MLE, the particular MLE depends upon the shape of F and can be drastically inefficient when the actual F departs even a little bit from the nominal F. For example, if the assumed F is $N(\mu, 1)$ but the actual model differs by a small amount ε of "contamination," i.e., $F = (1-\varepsilon)N(\mu,1) + \varepsilon N(\mu, \sigma^2)$, then

$$\mathrm{ARE}(\mathrm{Med}, \overline{X}, F) = \frac{2}{\pi}\left(1 - \varepsilon + \varepsilon\sigma^{-1}\right)^2\left(1 - \varepsilon + \varepsilon\sigma^2\right),$$

which equals $2/\pi$ in the "ideal" case $\varepsilon = 0$ but otherwise $\to \infty$ as $\sigma \to \infty$. A small perturbation of the assumed model thus can destroy the superiority of the MLE.

One way around this issue is to take a *nonparametric* approach and seek an estimator with ARE satisfying a favorable lower bound. Above we saw how the estimator HL_n meets this need.

Another criterion by which to evaluate and compare estimators is *robustness*. Here let us use finite-sample *breakdown point (BP)*: the minimal fraction of sample points which may be taken to a limit L (e.g., $\pm\infty$) without the estimator also being taken to L. A *robust* estimator remains stable and effective when in fact the sample is only partly from the nominal distribution F and contains some non-F observations which might be relatively extreme contaminants.

A single observation taken to ∞ (with n fixed) takes $\overline{X}_n$ with it, so $\overline{X}_n$ has BP = 0. Its optimality at Normal distributions comes at the price of a complete sacrifice of robustness. In comparison, Med_n has extremely favorable BP = 0.5 but at the price of a considerable loss of efficiency at Normal models.

On the other hand, the estimator HL_n appeals broadly, possessing *both* quite high ARE over a wide class of F and relatively high BP $= 1 - 2^{-1/2} = 0.29$.

As another example, consider the problem of estimation of scale. Two classical scale estimators are the *sample standard deviation* s_n and the *sample MAD* (median absolute deviation about the median) MAD_n. They estimate scale in different ways but can be regarded as competitors in the problem of estimation of σ in the model $F = N(\mu, \sigma^2)$, as follows. With both μ and σ unknown, the estimator s_n is (essentially) the MLE of σ and is asymptotically most efficient. Also, for this F, the population MAD is equal to $\Phi^{-1}(3/4)\sigma$, so that the estimator $\widehat{\sigma}_n = \mathrm{MAD}_n/\Phi^{-1}(3/4) = 1.4826\,\mathrm{MAD}_n$ competes with s_n for estimation of σ. (Here Φ denotes the standard normal distribution function, and, for any F, $F^{-1}(p)$ denotes the pth quantile, $\inf\{x : F(x) \geq p\}$, for $0 < p < 1$.) To compare with respect to robustness, we note that a single observation taken to ∞ (with n fixed) takes s_n with it, s_n has BP = 0. On the other hand, MAD_n and thus $\widehat{\sigma}_n$ have BP = 0.5, like Med_n. However, $\mathrm{ARE}(\widehat{\sigma}_n, s_n, N(\mu, \sigma^2)) = 0.37$, even worse than the ARE of Med_n relative to $\overline{X}$. Clearly desired is a more balanced trade-off between efficiency and robustness than provided by either of s_n and $\widehat{\sigma}_n$. Alternative scale estimators having the same 0.5 BP as $\widehat{\sigma}_n$ but much higher ARE of 0.82 relative to s_n are developed in Rousseeuw and Croux (1993). Also, further competitors offering a range of trade-offs given by (BP, ARE) $= (0.29, 0.86)$ or $(0.13, 0.91)$ or $(0.07, 0.96)$, for example, are developed in Serfling (2002).

In general, efficiency and robustness trade off against each other. Thus ARE should be considered in conjunction with robustness, choosing the balance appropriate to the particular application context. This theme is prominent in the many examples treated in Staudte and Sheather (1990).

A Few Additional Aspects of ARE

Connections with Confidence Intervals

In view of the asymptotic normal distribution underlying the above formulation of ARE in estimation, we may also characterize the ARE given by (2) as the limiting ratio of sample sizes at which the *lengths of associated confidence intervals at approximate level* $100(1-\alpha)\%$,

$$\widehat{\eta}^{(i)} \pm \Phi^{-1}\left(1 - \frac{\alpha}{2}\right)\sqrt{\frac{V_i(F)}{n_i}},\ i = 1, 2,$$

converge to 0 at the same rate, when holding fixed the coverage probability $1 - \alpha$. (In practice, of course, consistent estimates of $V_i(F)$, $i = 1, 2$, are used in forming the CI.)

Fixed Width Confidence Intervals and ARE

One may alternatively consider confidence intervals of *fixed length*, in which case (under typical conditions) the noncoverage probability depends on n and tends to 0 at an exponential rate, i.e., $n^{-1}\log\alpha_n \to c > 0$, as $n \to \infty$. For fixed width confidence intervals of the form

$$\widehat{\eta}^{(i)} \pm d\,\sigma_F,\ i = 1, 2,$$

we thus define the *fixed width asymptotic relative efficiency (FWARE)* of two estimators as the limiting ratio of sample sizes at which the respective *noncoverage probabilities* $\alpha_n^{(i)}$, $i = 1, 2$, of the associated fixed width confidence intervals

converge to zero at the same exponential rate. In particular, for Med versus $\overline{X}$, and letting $\eta = 0$ and $\sigma_F = 1$ without loss of generality, we obtain (Serfling and Wackerly 1976)

$$\mathrm{FWARE}(\mathrm{Med}, \overline{X}, F) = \frac{\log m(-d)}{\log[2(F(d) - F^2(d))^{1/2}]}, \quad (5)$$

where $m(-d)$ is a certain parameter of the ▶moment generating function of F. The FWARE is derived using *large deviation theory* instead of the central limit theorem. As $d \to 0$, the FWARE converges to the ARE. Indeed, for F a Normal distribution, this convergence (to $2/\pi = 0.64$) is quite rapid: the expression in (5) rounds to 0.60 for $d = 2$, to 0.63 for $d = 1$, and to 0.64 for $d \le 0.1$.

Confidence Ellipsoids and ARE

For an estimator $\widehat{\boldsymbol{\eta}}$ which is asymptotically k-variate Normal with mean $\boldsymbol{\eta}$ and covariance matrix $\boldsymbol{\Sigma}/n$, as the sample size $n \to \infty$, we may form (see Serfling 1980) an *associated ellipsoidal confidence region of approximate level* $100(1-\alpha)\%$ for the parameter $\boldsymbol{\eta}$,

$$E_{n,\alpha} = \{\boldsymbol{\eta} : n\,(\widehat{\boldsymbol{\eta}} - \boldsymbol{\eta})' \boldsymbol{\Sigma}^{-1} (\widehat{\boldsymbol{\eta}} - \boldsymbol{\eta}) \le c_\alpha\},$$

with $P\left(\chi^2_k > c_\alpha\right) = \alpha$ and in practice using a consistent estimate of $\boldsymbol{\Sigma}$. The *volume* of the region $E_{n,\alpha}$ is

$$\frac{\pi^{k/2} (c_\alpha/n)^{k/2} |\boldsymbol{\Sigma}|^{1/2}}{\Gamma((k+1)/2)}.$$

Therefore, for two such estimators $\widehat{\boldsymbol{\eta}}^{(i)}$, $i = 1, 2$, the ARE given by (3) may be characterized as the limiting ratio of sample sizes at which the *volumes of associated ellipsoidal confidence regions at approximate level* $100(1-\alpha)\%$ converge to 0 at the same rate, when holding fixed the coverage probability $1 - \alpha$.

Under regularity conditions on the model, the maximum likelihood estimator $\widehat{\boldsymbol{\eta}}^{(\mathrm{ML})}$ has a confidence ellipsoid $E_{n,\alpha}$ attaining the *smallest possible volume* and, moreover, lying wholly within that for any other estimator $\widehat{\boldsymbol{\eta}}$.

Connections with Testing

Parallel to ARE in estimation as developed here is the notion of *Pitman ARE* for comparison of two hypothesis test procedures. Based on a different formulation, although the central limit theorem is used in common, the Pitman ARE agrees with (2) when the estimator and the hypothesis test statistic are linked, as for example $\overline{X}$ paired with the *t-test*, or Med_n paired with the ▶*sign test*, or HL_n paired with the ▶*Wilcoxon-signed-rank test*. See Lehmann 1998b, Nikitin 1995, Nikitin 2010, and Serfling 1980.

Other Notions of ARE

As illustrated above with FWARE, several other important approaches to ARE have been developed, typically using either moderate or large deviation theory. For example, instead of asymptotic variance parameters as the criterion, one may compare *probability concentrations* of the estimators in an ε-neighborhood of the target parameter η: $P\left(\left|\widehat{\eta}^{(i)} - \eta\right| > \varepsilon\right)$, $i = 1, 2$. When we have

$$\frac{\log P(|\widehat{\eta}^{(i)}_n - \eta| > \varepsilon)}{n} \to \gamma^{(i)}(\varepsilon, \eta), \; i = 1, 2,$$

as is typical, then the ratio of sample sizes n_1/n_2 at which these concentration probabilities converge to 0 at the same rate is given by $\gamma^{(1)}(\varepsilon, \eta)/\gamma^{(2)}(\varepsilon, \eta)$, which then represents another ARE measure for the efficiency of estimator $\widehat{\eta}^{(2)}_n$ relative to $\widehat{\eta}^{(1)}_n$. See Serfling (1980, 1.15.4) for discussion and Basu (1956) for illustration that the variance-based and concentration-based measures need not agree on which estimator is better. For general treatments, see Nikitin (1995), Puhalskii and Spokoiny (1998), Nikitin (2010), and Serfling (1980, Chap. 10), as well as the other references cited below. A comprehensive bibliography is beyond the present scope. However, very productive is *ad hoc* exploration of the literature using a modern search engine.

Asymptotic Relative Efficiency of Two Tests

Making a substantiated choice of the most efficient statistical test of several ones being at the disposal of the statistician is regarded as one of the basic problems of Statistics. This problem became especially important in the middle of XX century when appeared computationally simple but "inefficient" rank tests.

Asymptotic relative efficiency (ARE) is a notion which enables to implement in large samples the quantitative comparison of two different tests used for testing of the same statistical hypothesis. The notion of the asymptotic efficiency of *tests* is more complicated than that of asymptotic efficiency of *estimates*. Various approaches to this notion were identified only in late forties and early fifties, hence, 20–25 years later than in the estimation theory. We proceed now to their description.

Let $\{T_n\}$ and $\{V_n\}$ be two sequences of statistics based on n observations and assigned for testing the null-hypothesis H against the alternative A. We assume that the alternative is characterized by real parameter θ and for $\theta = \theta_0$ turns into H. Denote by $N_T(\alpha, \beta, \theta)$ the sample size necessary for the sequence $\{T_n\}$ in order to attain the power β under the level α and the alternative value of parameter θ. The number $N_V(\alpha, \beta, \theta)$ is defined in the same way.

It is natural to prefer the sequence with smaller N. Therefore the relative efficiency of the sequence $\{T_n\}$ with respect to the sequence $\{V_n\}$ is specified as the quantity

$$e_{T,V}(\alpha, \beta, \theta) = N_V(\alpha, \beta, \theta) \big/ N_T(\alpha, \beta, \theta),$$

so that it is the reciprocal ratio of sample sizes N_T and N_V.

The merits of the relative efficiency as means for comparing the tests are universally acknowledged. Unfortunately it is extremely difficult to explicitly compute $N_T(\alpha, \beta, \theta)$ even for the simplest sequences of statistics $\{T_n\}$. At present it is recognized that there is a possibility to avoid this difficulty by calculating the limiting values $e_{T,V}(\alpha, \beta, \theta)$ as $\theta \to \theta_0$, as $\alpha \to 0$ and as $\beta \to 1$ keeping two other parameters fixed. These limiting values $e^P_{T,V}$, $e^B_{T,V}$ and $e^{HL}_{T,V}$ are called respectively the Pitman, Bahadur and Hodges–Lehmann asymptotic relative efficiency (ARE), they were proposed correspondingly in Pitman (1949), Bahadur (1960) and Hodges and Lehmann (1956).

Only close alternatives, high powers and small levels are of the most interest from the practical point of view. It keeps one assured that the knowledge of these ARE types will facilitate comparing concurrent tests, thus producing well-founded application recommendations.

The calculation of the mentioned three basic types of efficiency is not easy, see the description of theory and many examples in Serfling (1980), Nikitin (1995) and Van der Vaart (1998). We only mention here, that Pitman efficiency is based on the central limit theorem (see ►Central Limit Theorems) for test statistics. On the contrary, Bahadur efficiency requires the large deviation asymptotics of test statistics under the null-hypothesis, while Hodges–Lehmann efficiency is connected with large deviation asymptotics under the alternative. Each type of efficiency has its own merits and drawbacks.

Pitman Efficiency

Pitman efficiency is the classical notion used most often for the asymptotic comparison of various tests. Under some regularity conditions assuming ▶asymptotic normality of test statistics under H and A, it is a number which has been gradually calculated for numerous pairs of tests.

We quote now as an example one of the first Pitman's results that stimulated the development of nonparametric statistics. Consider the two-sample problem when under the null-hypothesis both samples have the same continuous distribution and under the alternative differ only in location. Let $e^P_{W,t}$ be the Pitman ARE of the two-sample Wilcoxon rank sum test (see ▶Wilcoxon–Mann–Whitney Test) with respect to the corresponding Student test (see ▶Student's t-Tests). Pitman proved that for Gaussian samples $e^P_{W,t} = 3/\pi \approx 0.955$, and it shows that the ARE of the Wilcoxon test in the comparison with the Student test (being optimal in this problem) is unexpectedly high. Later Hodges and Lehmann (1956) proved that

$$0.864 \le e^P_{W,t} \le +\infty,$$

if one rejects the assumption of normality and, moreover, the lower bound is attained at the density

$$f(x) = \begin{cases} 3\left(5 - x^2\right)/\left(20\sqrt{5}\right) & \text{if } |x| \le \sqrt{5}, \\ 0 & \text{otherwise.} \end{cases}$$

Hence the Wilcoxon rank test can be infinitely better than the parametric test of Student but their ARE never falls below 0.864. See analogous results in Serfling (2010) where the calculation of ARE of related estimators is discussed.

Another example is the comparison of independence tests based on Spearman and Pearson correlation coefficients in bivariate normal samples. Then the value of Pitman efficiency is $9/\pi^2 \approx 0.912$.

In numerical comparisons, the Pitman efficiency appear to be more relevant for moderate sample sizes than other efficiencies Groeneboom and Oosterhoff (1981). On the other hand, Pitman ARE can be insufficient for the comparison of tests. Suppose, for instance, that we have a normally distributed sample with the mean θ and variance 1 and we are testing $H : \theta = 0$ against $A : \theta > 0$. Let compare two significance tests based on the sample mean $\bar{X}$ and the Student ratio t. As the t-test does not use the information on the known variance, it should be inferior to the optimal test using the sample mean. However, from the point of view of Pitman efficiency, these two tests are equivalent. On the contrary, Bahadur efficiency $e^B_{t,\bar{X}}(\theta)$ is strictly less than 1 for any $\theta > 0$.

If the condition of asymptotic normality fails, considerable difficulties arise when calculating the Pitman ARE as the latter may not at all exist or may depend on α and β. Usually one considers limiting Pitman ARE as $\alpha \to 0$. Wieand (1976) has established the correspondence between this kind of ARE and the limiting approximate Bahadur efficiency which is easy to calculate.

Bahadur Efficiency

The Bahadur approach proposed in Bahadur (1960; 1967) to measuring the ARE prescribes one to fix the power of tests and to compare the exponential rate of decrease of their sizes for the increasing number of observations and fixed alternative. This exponential rate for a sequence of statistics $\{T_n\}$ is usually proportional to some non-random function $c_T(\theta)$ depending on the alternative parameter θ which is called the *exact slope* of the sequence $\{T_n\}$. The Bahadur ARE $e^B_{V,T}(\theta)$ of two sequences of statistics $\{V_n\}$ and $\{T_n\}$ is defined by means of the formula

$$e^B_{V,T}(\theta) = c_V(\theta) \,/\, c_T(\theta).$$

It is known that for the calculation of exact slopes it is necessary to determine the large deviation asymptotics of a sequence $\{T_n\}$ under the null-hypothesis. This problem is always nontrivial, and the calculation of Bahadur efficiency heavily depends on advancements in large deviation theory, see Dembo and Zeitouni (1998) and Deuschel and Stroock (1989).

It is important to note that there exists an upper bound for exact slopes

$$c_T(\theta) \le 2K(\theta)$$

in terms of Kullback–Leibler information number $K(\theta)$ which measures the "statistical distance" between the alternative and the null-hypothesis. It is sometimes compared in the literature with the ▶Cramér–Rao inequality in the estimation theory. Therefore the absolute (nonrelative) Bahadur efficiency of the sequence $\{T_n\}$ can be defined as $e^B_T(\theta) = c_T(\theta)/2K(\theta)$.

It is proved that under some regularity conditions the likelihood ratio statistic is asymptotically optimal in Bahadur sense (Bahadur 1967; Van der Vaart 1998, Sect. 16.6; Arcones 2005).

Often the exact Bahadur ARE is uncomputable for any alternative θ but it is possible to calculate the limit of Bahadur ARE as θ approaches the null-hypothesis. Then one speaks about the *local* Bahadur efficiency.

The indisputable merit of Bahadur efficiency consists in that it can be calculated for statistics with non-normal asymptotic distribution such as Kolmogorov-Smirnov, omega-square, Watson and many other statistics.

Asymptotic Relative Efficiency in Testing. Table 1 Some local Bahadur efficiencies

Statistic	Distribution					
	Gauss	Logistic	Laplace	Hyperbolic cosine	Cauchy	Gumbel
D_n	0.637	0.750	1	0.811	0.811	0.541
ω_n^2	0.907	0.987	0.822	1	0.750	0.731

Consider, for instance, the sample with the distribution function (df) F and suppose we are testing the goodness-of-fit hypothesis $H_0 : F = F_0$ for some known continuous df F_0 against the alternative of location. Well-known distribution-free statistics for this hypothesis are the Kolmogorov statistic D_n and omega-square statistic ω_n^2. The following table presents their local absolute efficiency in case of six standard underlying distributions:

We see from Table 1 that the integral statistic ω_n^2 is in most cases preferable with respect to the supremum-type statistic D_n. However, in the case of Laplace distribution the Kolmogorov statistic is locally optimal, the same happens for the Cramér-von Mises statistic in the case of hyperbolic cosine distribution. This observation can be explained in the framework of Bahadur local optimality, see Nikitin (1995 Chap. 6).

See also Nikitin (1995) for the calculation of local Bahadur efficiencies in case of many other statistics.

Hodges–Lehmann efficiency

This type of the ARE proposed in Hodges and Lehmann (1956) is in the conformity with the classical Neyman-Pearson approach. In contrast with Bahadur efficiency, let us fix the level of tests and let compare the exponential rate of decrease of their second-kind errors for the increasing number of observations and fixed alternative. This exponential rate for a sequence of statistics $\{T_n\}$ is measured by some non-random function $d_T(\theta)$ which is called the Hodges–Lehmann index of the sequence $\{T_n\}$. For two such sequences the Hodges–Lehmann ARE is equal to the ratio of corresponding indices.

The computation of Hodges–Lehmann indices is difficult as requires large deviation asymptotics of test statistics under the alternative.

There exists an upper bound for the Hodges–Lehmann indices analogous to the upper bound for Bahadur exact slopes. As in the Bahadur theory the sequence of statistics $\{T_n\}$ is said to be *asymptotically optimal in the Hodges–Lehmann sense* if this upper bound is attained.

The drawback of Hodges–Lehmann efficiency is that most *two-sided* tests like Kolmogorov and Cramér-von Mises tests are asymptotically optimal, and hence this kind of efficiency cannot discriminate between them. On the other hand, under some regularity conditions the one-sided tests like linear rank tests can be compared on the basis of their indices, and their Hodges–Lehmann efficiency coincides locally with Bahadur efficiency, see details in Nikitin (1995).

Coupled with three "basic" approaches to the ARE calculation described above, intermediate approaches are also possible if the transition to the limit occurs simultaneously for two parameters at a controlled way. Thus emerged the Chernoff ARE introduced by Chernoff (1952), see also Kallenberg (1982); the intermediate, or the Kallenberg ARE introduced by Kallenberg (1983), and the Borovkov–Mogulskii ARE, proposed in Borovkov and Mogulskii (1993).

Large deviation approach to asymptotic efficiency of tests was applied in recent years to more general problems. For instance, the change-point, "signal plus white noise" and regression problems were treated in Puhalskii and Spokoiny (1998), the tests for spectral density of a stationary process were discussed in Kakizawa (2005), while Taniguchi (2001) deals with the time series problems, and Otsu (2010) studies the empirical likelihood for testing moment condition models.

Asymptotic, Higher Order

Juan Carlos Abril
President of the Argentinean Statistical Society, Professor Universidad Nacional de Tucumán and Consejo Nacional de Investigaciones Científicas y Técnicas, San Miguel de Tucumán, Argentina

Higher order asymptotic deals with two sorts of closely related things. First, there are questions of approximation. One is concerned with expansions or inequalities for a distribution function. Second, there are inferential issues. These involve, among other things, the application of the ideas of the study of higher order efficiency, admissibility and minimaxity. In the matter of expansions, it is as important to have usable, explicit formulas as a rigorous proof that the expansions are valid in the sense of truly approximating a target quantity up to the claimed degree of accuracy.

Classical asymptotics is based on the notion of asymptotic distribution, often derived from the central limit theorem (see ►Central Limit Theorems), and usually the approximations are correct up to $O(n^{-1/2})$, where n is the sample size. Higher order asymptotics provides refinements based on asymptotic expansions of the distribution or density function of an estimator of a parameter. They are rooted in the Edgeworth theory, which is itself a refinement of the central limit theorem. The theory of higher order asymptotic is very much related with the corresponding to *Approximations to distributions* treated as well in this Encyclopedia.

When higher order asymptotic is correct up to $o(n^{-1/2})$, it is second order asymptotic. When further terms are picked up, so that the asymptotic is correct up to $o(n^{-1})$, it is third order asymptotic. In his pioneering papers, C. R. Rao coined the term second order efficiency for a concept that would now is called third order efficiency. The new terminology is essentially owing to Pfanzagl and Takeuchi.

Autocorrelation in Regression

Badi H. Baltagi
Distinguished Professor of Economics
Syracuse University, Syracuse, NY, USA

Linear regressions are a useful empirical tool for economists and social scientists and the standard ►least squares estimates are popular because they are the best linear unbiased estimators (BLUE) under some albeit strict assumptions. These assumptions require the regression disturbances not to be correlated with the regressors, also homoskedastic, i.e., with constant variance, and not autocorrelated. Violation of the no autocorrelation assumption on the disturbances, will lead to inefficiency of the least squares estimates, i.e., no longer having the smallest variance among all linear unbiased estimators. It also leads to wrong standard errors for the regression coefficient estimates. This in turn leads to wrong t-statistics on the significance of these regression coefficients and misleading statistical inference based on a wrong estimate of the variance–covariance matrix computed under the assumption of no autocorrelation. This is why standard regression packages have a robust heteroskedasticity and autocorrelation-consistent covariance matrix (HAC) option for these regressions which at least robustifies the standard errors of least squares and shows how sensitive they would be to such violations, see Newey and West (1987).

Autocorrelation is more likely to occur in time-series than in cross-section studies. Consider estimating the consumption function of a random sample of households. An unexpected event, like a visit of family members will increase the consumption of this household. However, this positive disturbance need not be correlated with the disturbances affecting consumption of other randomly drawn households. However, if we were estimating this consumption function using aggregate time-series data for the U.S., then it is very likely that a recession year affecting consumption negatively that year, may have a carry over effect to the next few years. A shock to the economy like an oil embargo in 1973 is likely to affect the economy for several years. A labor strike this year may affect production for the next few years. The simplest work horse for illustrating this autocorrelation in time series on the regression disturbances, say u_t is the first-order autoregressive process denoted by AR(1):

$$u_t = \rho u_{t-1} + \epsilon_t \qquad t = 1, 2, \ldots, T$$

where ϵ_t is independent and identically distributed with mean 0 and variance σ_ϵ^2. It is autoregressive because u_t is related to its lagged value u_{t-1}. One can show, see for example Baltagi (2008), that the correlation coefficient between u_t and u_{t-1} is ρ. Also, that the correlation coefficient between u_t and u_{t-r} is ρ^r. When $\rho = 0$, there is no autocorrelation and one test for this null hypothesis is the Durbin and Watson (1951) test discussed as a separate entry in this encyclopedia by Krämer. This AR(1) process is also stationary as long as $|\rho| < 1$. If $\rho = 1$, then this process has a unit root and it is called a ►random walk. See the entry by Dickey on testing for this unit root using the ►Dickey-Fuller tests. Note that if the process is stationary, then ρ is a fraction and the correlation for two disturbances r periods apart is ρ^r, i.e., a fraction raised to an integer power. This means that the correlation is decaying between the disturbances the further apart they are. This is reasonable in economics and may be the reason why this AR(1) form is so popular. One should note that this is not the only form that would correlate the disturbances across time. Other forms like the Moving Average (MA) process, and higher order Autoregressive Moving Average (ARMA) processes are popular, see Box and Jenkins (1970), but these are beyond the scope of this entry.

Since least squares is no longer BLUE under autocorrelation of the disturbances, Cochrane and Orcutt (1949) suggested a simple estimator that corrects for autocorrelation of the AR(1) type. This method starts with an initial estimate of ρ, the most convenient is 0, and minimizes the residual sum of squares of the regression. This gives us the least squares estimates of the regression coefficients and the corresponding least squares residuals which we denote by e_t. In the next step, one regresses e_t on e_{t-1} to get an estimate of ρ, say $\widehat{\rho}$. The second step of the Cochrane–Orcutt procedure (2SCO) is to perform the regression of $(Y_t - \widehat{\rho} Y_{t-1})$ on $(X_t - \widehat{\rho} X_{t-1})$ to get estimates of the regression coefficients. One can iterate this procedure (ITCO) until convergence. Both the 2SCO and the ITCO are asymptotically efficient as the sample size gets large. The argument for iterating must be justified in terms of small sample gains. Other methods of correcting for serial correlation include Prais and Winsten (1954), Durbin (1960), as well as maximum likelihood methods, all studied more extensively in Chap. 5 of Baltagi (2008). The Prais and

Winsten method recaptures the initial observation lost in the Cochrane–Orcutt method. Monte Carlo studies using an autoregressive regressor, and various values of ρ, found that least squares is still a viable estimator as long as $|\rho| < 0.3$, but if $|\rho| > 0.3$, then it pays to perform procedures that correct for serial correlation based on an estimator of ρ. For trended regressors, which is usually the case with economic data, least squares outperforms 2SCO, but not the Prais-Winsten procedure that recaptures the initial observation. In fact, Park and Mitchell (1980) who performed an extensive Monte Carlo using trended and untrended regressors recommend that one should not use regressions based on $(T - 1)$ observations as in the Cochrane and Orcutt procedure. They also found that test of hypotheses regarding the regression coefficients performed miserably for all estimators based on an estimator of ρ.

Correcting for serial correlation is not without its critics. Mizon (1995) argues this point forcefully in his article entitled "A simple message for autocorrelation correctors: Don't." The main point being that serial correlation is a symptom of dynamic misspecification which is better represented using a general unrestricted dynamic specification.

About the Author

Badi H. Baltagi is distinguished Professor of Economics, and Senior Research Associate at the Center for Policy Research, Syracuse University. He received his Ph.D. in Economics at the University of Pennsylvania in 1979. He served on the faculty at the University of Houston and Texas A&M University. He was a visiting Professor at the University of Arizona and the University of California, San Diego. He is the author of *Econometric Analysis of Panel Data* (Wiley, 4*th* edn. 2008); *Econometrics* (Springer, 4*th* edn. 2008), and editor of *A Companion to Theoretical Econometrics* (Wiley–Blackwell); *Recent Developments in the Econometrics of Panel Data*, Volumes I and II (Edward-Elgar); *Nonstationary Panels*, *Panel Cointegration*, and *Dynamic Panels* (Elsevier); *Panel Data Econometrics: Theoretical Contributions and Empirical Applications* (Physica-Verlag, 2004); *Spatial Econometrics: Methods and Applications*, (with Giuseppe Arbia), Physica-Verlag, 2009. He is author or co-author of over 100 publications, all in leading economics and statistics journals. Professor Baltagi was the holder of the George Summey, Jr. Professor Chair in Liberal Arts and was awarded the Distinguished Achievement Award in Research at Texas A&M University. He is co-editor of *Empirical Economics*, and Associate editor of *Journal of Econometrics* and *Econometric Reviews*. He is the replication editor of the *Journal of Applied Econometrics* and the series editor for *Contributions to Economic Analysis*. He is a fellow of the Journal of Econometrics and a recipient of the Multa and Plura Scripsit Awards from Econometric Theory. He is a founding fellow and member of the Board of Directors of the Spatial Econometrics Association.

Axioms of Probability

Vincenzo Capasso
Professor of Probability and Mathematical Statistics
University of Milan, Milan, Italy

Ingredients of Probability Spaces

Definition 1 A collection $\mathcal{F}$ of subsets of a set Ω is called a *ring* on Ω if it satisfies the following conditions:

1. $A, B \in \mathcal{F} \Rightarrow A \cup B \in \mathcal{F}$,
2. $A, B \in \mathcal{F} \Rightarrow A \setminus B \in \mathcal{F}$.

A ring $\mathcal{F}$ is called an *algebra* if $\Omega \in \mathcal{F}$.

Definition 2 A ring $\mathcal{F}$ on Ω is called a *σ-ring* if it satisfies the following additional condition:

3. For every countable family $(A_n)_{n\in\mathbb{N}}$ of subsets of $\mathcal{F}$: $\bigcup_{n\in\mathbb{N}} A_n \in \mathcal{F}$.

A σ-ring $\mathcal{F}$ on Ω is called a *σ-algebra* (or *σ-field*) if $\Omega \in \mathcal{F}$.

Proposition 1 The following properties hold:

1. If $\mathcal{F}$ is a σ-algebra of subsets of a set Ω, then it is an algebra.
2. If $\mathcal{F}$ is a σ-algebra of subsets of Ω, then
   - For any countable family $(E_n)_{n\in\mathbb{N}\setminus\{0\}}$ of elements of $\mathcal{F}$: $\bigcap_{n=1}^{\infty} E_n \in \mathcal{F}$,
   - For any finite family $(E_i)_{1\le i\le n}$ of elements of $\mathcal{F}$: $\bigcap_{i=1}^{n} E_i \in \mathcal{F}$,
   - $B \in \mathcal{F} \Rightarrow \Omega \setminus B \in \mathcal{F}$.

Definition 3 Every pair $(\Omega, \mathcal{F})$ consisting of a set Ω and a σ-ring $\mathcal{F}$ of subsets of Ω is a *measurable space*. Furthermore, if $\mathcal{F}$ is a σ-algebra, then $(\Omega, \mathcal{F})$ is a *measurable space on which a probability measure can be built*.

Example 1

1. *Generated σ-algebra*. If $\mathcal{A}$ is a family of subsets of a set Ω, then there exists the smallest σ-algebra of subsets of Ω that contains $\mathcal{A}$. This is the σ-algebra *generated* by $\mathcal{A}$, denoted by $\sigma(\mathcal{A})$. If, now, $\mathcal{G}$ is the set of all σ-algebras of subsets of Ω containing $\mathcal{A}$, then it is not empty because it has the set $\mathcal{P}(\Omega)$ of all subsets of Ω, among its elements, so that $\sigma(\mathcal{A}) = \bigcap_{\mathcal{C}\in\mathcal{G}} \mathcal{C}$.
2. *Borel σ-algebra*. Let Ω be a topological space. Then the *Borel σ-algebra* on Ω, denoted by $\mathcal{B}_\Omega$, is the σ-algebra generated by the set of all open subsets of Ω. Its elements are called Borel sets.
3. *Product σ-algebra*. Let $(\Omega_i, \mathcal{F}_i)_{1\le i\le n}$ be a family of measurable spaces, with all $\mathcal{F}_i, 1 \le i \le n$, σ-algebras, and let $\Omega = \prod_{i=1}^{n} \Omega_i$. Defining

$$\mathcal{R} = \left\{ E \subset \Omega \,|\, \forall i = 1, \ldots, n \; \exists E_i \in \mathcal{F}_i \text{ such that } E = \prod_{i=1}^{n} E_i \right\},$$

   the σ-algebra on Ω generated by $\mathcal{R}$ is called the *product σ-algebra* of the σ-algebras $(\mathcal{F}_i)_{1\le i\le n}$.

Proposition 2 Let $(\Omega_i)_{1\le i\le n}$ be a family of topological spaces with a countable base and let $\Omega = \prod_{i=1}^{n} \Omega_i$. Then the Borel σ-algebra $\mathcal{B}_\Omega$ is identical to the product σ-algebra of the family of Borel σ-algebras $(\mathcal{B}_{\Omega_i})_{1\le i\le n}$.

Axioms of Probability

We assume that the reader is already familiar with the basic motivations and notions of probability theory. We present the axioms of probability according to the Kolmogorov approach [see Kolmogorov (1956)].

Definition 4 Given a set Ω, and a σ-algebra $\mathcal{F}$ of subsets of Ω, a probability measure on $\mathcal{F}$ is any function $P : \mathcal{F} \to [0,1]$ such that

P_1. $P(\Omega) = 1$,

P_2. for any countable family $A_1, \ldots, A_n, \ldots$ of elements of $\mathcal{F}$ such that $A_i \cap A_j = \emptyset$, whenever $i \neq j$:

$$P\left(\bigcup_n A_n\right) = \sum_n P(A_n).$$

Definition 5 A *probability space* is an ordered triple $(\Omega, \mathcal{F}, P)$, where Ω is a set, $\mathcal{F}$ is a σ-algebra of subsets of Ω, and $P : \mathcal{F} \to [0,1]$ is a probability measure on $\mathcal{F}$. The set Ω is called the *sample space*, the elements of $\mathcal{F}$ are called *events*.

Definition 6 A probability space $(\Omega, \mathcal{F}, P)$ is *finite* if Ω has finitely many elements.

Remark 1 If Ω is at most countable, then it is usual to assume that $\mathcal{F} = \mathcal{P}(\Omega)$, the σ-algebra of all subsets of Ω. In this case all sets $\{\omega\}$ reduced to sample points $\omega \in \Omega$ are events; they are called *elementary events*.

Remark 2 If the σ−algebra of events $\mathcal{F}$ is finite, then the requirement of countable additivity in the definition of the probability measure P can be reduced to finite additivity.

Remark 3 It is worth mentioning that an important alternative approach to probability theory is the so called *subjective probability*; this approach does not insist on Axiom P_2., and rather uses the finite version of it (De Finetti 1974–1975).

Definition 7 A finite probability space $(\Omega, \mathcal{F}, P)$ with $\mathcal{F} = \mathcal{P}(\Omega)$ is an *equiprobable* or *uniform* space, if

$$\forall\, \omega \in \Omega : \qquad P(\{\omega\}) = k \text{ (constant)};$$

i.e., its elementary events are equiprobable.

Remark 4 Following the axioms of a probability space and the definition of a uniform space, if $(\Omega, \mathcal{F}, P)$ is equiprobable, then

$$\forall\, \omega \in \Omega : \qquad P(\{\omega\}) = \frac{1}{|\Omega|},$$

where $|\cdot|$ denotes the cardinal number of elementary events in Ω, and

$$\forall A \in \mathcal{F} \equiv \mathcal{P}(\Omega) : \qquad P(A) = \frac{|A|}{|\Omega|}.$$

Intuitively, in this case we may say that $P(A)$ is the ratio of the number of favorable outcomes, divided by the number of all possible outcomes.

Example 2 Consider an urn that contains 100 balls, of which 80 are red and 20 are black but that are otherwise identical, from which a player draws a ball. Define the event

R: The first drawn ball is red.

Then

$$P(R) = \frac{|R|}{|\Omega|} = \frac{80}{100} = 0.8.$$

Definition 8 We shall call any event $F \in \mathcal{F}$ such that $P(F) = 0$, a *null event*.

Elementary consequences of the above definitions are the following ones.

Proposition 3 Let $(\Omega, \mathcal{F}, P)$ be is a probability space.

1. $P(A^c) = 1 - P(A)$, for any $A \in \mathcal{F}$;
2. $P(\emptyset) = 0$;
3. If $A, B \in \mathcal{F}$, $A \subseteq B$, then $P(B) = P(A) + P(B \setminus A)$;
4. If $A, B \in \mathcal{F}$, $A \subseteq B$, then $P(A) \leq P(B)$ (monotonicity);
5. If $A, B \in \mathcal{F}$, then

$$P(B \setminus A) = P(B) - P(B \cap A)$$

$$P(A \cup B) = P(A) + P(B) - P(A \cap B);$$

6. If $A, B \in \mathcal{F}$, $A \subseteq B$, then $P(B \setminus A) = P(B) - P(A)$;
7. (Principle of inclusion-exclusion) Let $A_1, \ldots, A_n \in \mathcal{F}$, then

$$P\left(\cup_{i=1}^{n} A_i\right) = \sum_{i=1}^{n} P(A_i) - \sum_{i<j} P(A_i \cap A_j) + \ldots + (-1)^{n+1} P(A_1 \cap \ldots \cap A_n);$$

8. If $A_1, \ldots, A_n \in \mathcal{F}$, then

$$P\left(\bigcup_{i=1}^{n} A_i\right) \leq \sum_{i=1}^{n} P(A_i).$$

Balanced Sampling

Yves Tillé
Professor
University of Neuchâtel, Neuchâtel, Switzerland

Balanced sampling is a random method of selection of units from a population that provides a sample such that the Horvitz–Thompson estimators (see ►Horvitz–Thompson Estimator) of the totals are the same or almost the same as the true population totals for a set of control variables.

More precisely, let $U = \{1, \ldots, k, \ldots, N\}$ be a finite population and $s \subset U$ a sample or a subset of U. A sampling design $p(s)$ is a probability distribution on the set of all the subsets $s \subset U$, i.e. $p(s) \geq 0$ and

$$\sum_{s \subset U} p(s) = 1.$$

The inclusion probability $\pi_k = pr(k \in s)$ of a unit k is its probability of being selected in the sample s.

Consider a variable of interest y that takes the value y_k on unit k. Let also Y be the total of the values taken by y on the units of the population

$$Y = \sum_{k \in U} y_k.$$

If $\pi_k > 0$, for all $k \in U$, the Horvitz–Thompson (1952) estimator

$$\widehat{Y} = \sum_{k \in S} \frac{y_k}{\pi_k}$$

is unbiased for Y.

Let also $x_1, \ldots, x_j, \ldots, x_J$ be a sequence of auxiliary variables whose the values $x_{k1}, \ldots, x_{kj}, \ldots, x_{kJ}$ are known for each unit k of the population. According to the definition given in Tillé (2006), a sampling design is said to be balanced on the x variables if

$$\sum_{k \in S} \frac{x_{kj}}{\pi_k} \approx \sum_{k \in U} x_{kj}, \text{ for } j = 1, \ldots, J.$$

Balanced sampling involves sampling with fixed sample size and stratification. Indeed, a stratified design is balanced on the indicator variables of the strata, because the Horvitz–Thompson estimators of the sizes of the strata are equal to the population sizes of the strata. In the design-based inference, balanced sampling allows a strong improvement of the efficiency of the Horvitz–Thompson estimator when the auxiliary variables are correlated with the interest variable (see Deville and Tillé 2004). In the model-based inference, balanced samples are advocated to protect under miss-specification of the model (see Valliant et al. 2000).

Balanced sampling must not be confused with a representative sample. Representativity is a vague concept that usually means that some groups have the same proportions in the sample and in the population. This definition is fallacious because some groups can be over or under-represent in a sample to obtain a more accurate unbiased estimator. Moreover, balanced sampling implies that the sample is randomly selected and that predefined inclusion probabilities, that can be unequal, are satisfied at least approximately.

There exists a large family of methods for selecting balanced samples. The first one was probably proposed by Yates (1949) and consists of selecting a sample by a simple random sampling and next eventually changing some units to get a more balanced sample. Other methods, called rejective, consist of selecting several samples with an initial sampling design until obtaining a sample that is well balanced. Rejective methods however have the drawback that the inclusion probabilities of the rejective design are not the same as the ones of the initial design and are generally impossible to compute.

The cube method proposed by Deville and Tillé (2004) is a general multivariate algorithm for selecting balanced samples that can use several decades of auxiliary variables with equal of unequal inclusion probabilities. The cube method exactly satisfies the predefined inclusion probabilities and provides a sample that is balanced as well as possible. SAS and R language implementations are available.

Banking, Statistics in

Héctor Manuel Zárate Solano
Professor, Head of Statistics Section
Universidad Nacional de Colombia, Banco de la República Bogotá, Colombia

Statistics in banking is becoming increasingly important to the extent that modern banking at all levels would be impossible without the application of statistical methods (Hand 2006, p. 361). Particularly the financial crisis has underlined the importance of high quality and timely data to the banking sector. Indeed, "information shortages – directly related to a lack of timely and accurate data – with regard to complex credit derivatives lie at the heart of the current crisis and have complicated the crisis management efforts of central banks around the world." (Current challenges and the Future of Central Bank Statistics).

According to the Monetary and Financial Statistics (International Monetary Fund 2000), the banking sector consists of all resident corporations mainly engaged in financial intermediation in any given economy. These corporations consist of the central bank which is the national financial institution with the principal responsibility of ensuring monetary stability and financial sector soundness (Bangura 2005), and other depository corporations including commercial retail banks, merchant banks, savings banks, credit unions, credit cooperatives, rural and agricultural banks, etc.

The range of statistical tools and models in banking applications is vast, starting from purely descriptive models, risk assessment, statistics of extreme values, Markov chain approaches (including mover–stayer models), cluster analysis (see ►Cluster Analysis: An Introduction), statistical methods of fraud detection (see Bolton and Hand 2002; Hand 2007, 2010; Sudjianto et al. 2010), ►logistic regression, classification trees, etc.

Statistics in Banking: The Colombian Perspective

The Central Bank has focused significantly on the use of statistics to conduct monetary policy. Statistical methodologies have evolved in quantity, depth, and degree of sophistication as economic and financial systems have become more complex because of the generalized economic growth over time, increased market participants, and all sorts of financial transactions. Moreover, the adoption annual inflation-targeting, based on the consumer price index (CPI), to achieve a long-term GDP growth trend as the monetary policy rule since 1991 has set new challenges for our statistics section and practitioners as well. As a result, we have had to adapt to new demands for information. First, the inflation forecasting model of the Banco de la República requires monitoring the inflationary pressures continually, and second, assessing the economic activity. To accomplish these, econometric models based on observational data have been put into place, and the Bank has made efforts in using best practices with respect to surveys as an alternative to full reporting.

To elaborate on the above, we need to produce statistics in an efficient way, including a new form of data analysis provided by individual reports coming from financial and nonfinancial institutions mostly through electronic reporting. The degree of sophistication of statistical techniques depends on the data availability. A priority task involves data compilation, which is a statistical activity that requires the implementation of new ideas that combine statistical techniques, view points from economists, and the management of large databases. For instance, nominal short-term interest rates have remained as a main policy tool in this country, which depend on the reliability of the micro data reported daily to the Bank. We have to establish graphical and statistical tools to guarantee the quality and accuracy of the aggregate data. Aggregation also involves the incorporation of new methodologies, such as the index number theory, which explains the behavior of crucial indicators over time in carrying out monetary policy management. Consequently, we have worked on building core inflation indices, forward looking indicators, stock indices, real estate prices, and real exchange rates. Furthermore, one important part of the transmission mechanism is to know how monetary policy affects aggregate demand and it has

been important to identify shocks of trade terms, fiscal policy, and real world price of commodities.

With regard to surveys, we should note that the recent increased responses of financial markets, and others, to economic expectations. Thus, the Bank has made several surveys protecting statistical confidentiality: The Monthly Business Surveys, which provide clues on formation expectations in the private sector and fill the need for more timely indicators that can be used to gain insight into the economic climate before official statistics are published. Furthermore, they indicate signals of turning points in economic activity. The regional aspect of this survey also creates network contacts in the business community. Another survey is the Monthly Expert Inflation Forecasts, which summarize short macroeconomic forecasts from the experts. The statistics derived from the latter provide relevant information on the professional inflation consensus and allow us to assess the credibility of monetary policy through the dispersion of the forecast of the inflation. In addition, we developed Quarterly Market Expectation Surveys to ascertain the entrepreneurship perception of current and expected economic developments over the very short term in the main macroeconomic variables. We are also working on surveys involved with remittance flows and the cost of remitting money. Nevertheless, the realization of surveys has imposed central bank statisticians do serious efforts on issues related to statistical survey methodologies. For instance, introducing good questionnaire design, using probabilistic sampling techniques, and assuring adequate response rates. Also, we have to notice difficulty of survey implementation as there is a lack of incentives for respondent to cooperate, absence of proper legal mandate to collect information, and resources constraints. These factors are considered through the cost-benefit evaluation of the generation of this kind of information.

Statistics is decisive to monetary policy decisions by central bank policy makers, who face diverse forms of uncertainty, and it is important to rely on various information sources assessment of economic statistics and judgment. In fact, they need to analyze financial markets, watch carefully national accounts and labor force statistics. This statistical challenge has intensified cooperation with the national statistical institute (DANE) and producers of statistics in the private sector to try to improve data coherence, minimize the response burden to reporting agents, exchange micro data, share methodologies, and ameliorate data quality under international recognized standards. In addition, the experience from other countries has led to coordinate regional tasks in order to homogenize key economic indicators. It is also of paramount importance for the central bank's credibility to keep the public clearly informed about the actions that have been taken by the monetary authorities. As a result, new ways of presenting statistics have been implemented in different channels of communication such as Inflation Report, Report to Congress, and Press releases, among others. Statistics contribute to understand trends in the economy policy evaluations and help to design future policies. Therefore, the ability to research inflation issues and find recent statistical methodologies to present new economic indicators mainly where information is insufficient is a challenge for central bank statisticians. For example, it is actually required to understand the service sector trends, the behavior of flexible labor markets, and how the population's quality of life has improved.

Bartlett and Bartlett-Type Corrections

Gauss M. Cordeiro
Professor
Universidade Federal Rural de Pernambuco, Recife, Brazil

Bartlett Correction

The log-likelihood ratio (*LR*) statistic is one of the most commonly used statistics for inference in parametric models. Let w be the *LR* statistic for testing some composite or simple null hypothesis H_0 against an alternative hypothesis H. In regular problems, the null distribution of w is asymptotically χ^2_q, where q is the difference between the dimensions of the parameter spaces under the two hypotheses tested. However, as the samples sizes decreases, the use of such a statistic becomes less justifiable.

One way of improving the χ^2 approximation to the *LR* statistic is by multiplying w by a correction factor c known as the Bartlett correction (Lawley 1956; Hayakawa 1977; Cordeiro 1987). This idea was pioneered by Bartlett (1937) and later put into a general framework by Lawley (1956). Bartlett obtained a number of these corrections in the area of multivariate analysis in several papers published between 1938 and 1955, and these corrections became widely used for improving the large-sample χ^2 approximation to the null distribution of w.

Bartlett (1937) used the following approach to improve the χ^2 approximation to the null distribution of w. Suppose that, under the null hypothesis H_0, $E(w)$ is calculated up to order n^{-1}, say $E(w) = q + b + O(n^{-2})$, where b is a constant of order n^{-1} and n is the number of observations or some related quantity. Specifically, the Bartlett correction is determined by the relation $c = (1+b/q)$ and it represents an important tool for improving the χ^2 approximation for w. The corrected statistic $w^* = w/c$ has an expected value that comes closer to that of χ^2_q than does the expected value of w. Moreover, for continuous data, the distribution of w^* is, in general, closer to χ^2_q than is the distribution of w. Box (1949) used Bartlett's approach to investigate in detail the general expression for the moments of the statistic w in the following cases: the test of constancy of variance and covariance of k sets of p-variate samples and Wilk's test for the independence of k sets of residuals, the ith set having p_i variables. He showed, at least for these cases, that the modified statistic w^* follows a χ^2_q distribution more closely than does the unmodified statistic w. Box's results are applicable to all tests for which the Laplace transform of the test statistic can be explicitly written in terms of gamma functions and reciprocal gamma functions.

A general method to obtain Bartlett corrections for regular statistical models was developed in full generality by Lawley (1956), who gave a general formula for the correction c as function of covariant tensors. He derived expressions for the moments of certain derivatives of the log-likelihood function, and, via an exceedingly complicated calculation, obtained a general formula for the null expected value of w. Further, he showed that all cumulants of the corrected statistic w^* for testing composite hypotheses agree with those of the reference χ^2_q distribution with error of order $O(n^{-2})$ [see Hayakawa (1977) and Cordeiro (1987)]. Calculations of the Bartlett corrections via Lawley's approach are, however, notoriously cumbersome since they involve substantial effort into computing certain joint cumulants of log-likelihood derivatives. See also Eqs. 5.30–5.32 in Barndorff-Nielsen and Cox's (1994) book.

A further step on the improvement of the statistic w was taken by Hayakawa (1977), who derived an asymptotic expansion for the null distribution of w for testing a composite null hypothesis H_0 against a composite alternative hypothesis H. He showed that to order $O(n^{-1})$

$$Pr(w \le z) = F_q(z) + (24n)^{-1}[A_2 F_{q+4}(z) - (2A_2 - A_1)F_{q+2}(z) + (A_2 - A_1)F_q(z)], \quad (1)$$

where $F_s(\cdot)$ is the cumulative distribution function of a χ^2 random variable with s degrees of freedom. Here, A_1 is a function of expected values of the first four log-likelihood derivatives and of the first two derivatives of these expected values with respect to the parameters of the model and its expression holds for both simple and composite hypotheses, thus allowing for nuisance parameters. When nuisance parameters are present, A_1 can be calculated as the difference between two identical functions evaluated under the null and alternative hypotheses. The error in Equation 1 is $\mathcal{O}(n^{-2})$ and not $\mathcal{O}(n^{-3/2})$ as it is sometimes reported. However, the Bartlett correction is given by $c = 1 + (12nq)^{-1}A_1$, which differs from the one obtained from the above expansion, unless $A_2 = 0$. This points to a conflict between Hayakawa's and Lawley's results. The answer to this puzzle came with papers by Harris (1986) and Cordeiro (1987). Harris showed that A_2 should not be present in (1), whereas Cordeiro showed that the term A_2 is always equal to zero. The main contribution of Equation 1 with $A_2 = 0$ is that it provides a relatively simple demonstration that $w^* = w/c$ has a χ^2_q distribution with error $\mathcal{O}(n^{-2})$. In fact, Cordeiro (1987) demonstrated that the simple correction of the first moment of w to order $O(n^{-1})$, quite generally has the effect of eliminating the term of

this order in the asymptotic expansion of the corrected statistic w^*. This result was a starting point for numerous subsequent research efforts in the direction of establishing several expressions for Bartlett corrections in various classes of statistical models.

One difficulty encountered with the use of w^* rather than w is the fact that the required expectation may be very difficult or even impossible to compute. A general matrix formula for c was derived by Cordeiro (1993a), which has advantages for numerical and analytical purposes. For continuous data the effect of the Bartlett correction is amazingly good even for very small sample sizes. However, for discrete data, the Bartlett correction does not in general yield an improvement in the asymptotic error rate of the chi-squared approximation. Several papers have focused on deriving these corrections for special regression models by using matrix formulae for specific models, bypassing the traditional machinery of calculating these cumulants. We can always obtain these matrix formulae when the joint cumulants of log-likelihood derivatives are invariant under permutation of parameters. The matrix formulae in conjunction with computer algebra systems (Mathematica or Maple for example) and programming languages with support for matrix operations (Gauss, R and Ox) represent a computationally much simpler way of deriving Bartlett corrections in rather general classes of statistical models.

Several papers have focused on deriving matrix formulae for Bartlett corrections in general classes of regression models. Cordeiro (1983, 1987) described Bartlett's approach for univariate ▶generalized linear models. Corrected LR statistics for exponential family nonlinear models were obtained by Cordeiro and Paula (1989). They gave general matrix expressions for Bartlett corrections in these models involving an unpleasant looking quantity which may be regarded as a measure of nonlinearity of the systematic component of the model. Attfield (1991) and Cordeiro (1993b) showed how to correct LR statistics for heteroskedasticity. An algorithm for computing Bartlett corrections was given by Andrews and Stafford (1993). Cordeiro et al. (1994) proposed matrix formulae for Bartlett corrections in dispersion models. Cordeiro (1995) presented extensive simulation results on the performance of the corrected statistic w^* in generalized linear models focusing on gamma and log-linear models. For a detailed account of the applicability of Bartlett corrections, see Cribari-Neto and Cordeiro (1996).

Barndorff-Nielsen and Cox (1984) gave an indirect method for computing Bartlett corrections under rather general parametric models by establishing a simple connection between the correction term b and the norming constants of the general expression for the conditional distribution of the maximum likelihood estimator, namely $b = \left(\frac{A_0}{A}\right)^q \frac{n}{2\pi}$, where A and A_0 are the normalized constants of the general formula for the density of the maximum likelihood estimator conditional on an exact or approximate ancillary statistic when this formula is applied to the full and null models, respectively. It is usually easier to obtain the Bartlett correction for special cases using Lawley's formula than using Barndorff-Nielsen and Cox's expression, since the former involves only moments of log-likelihood derivatives whereas the latter requires exact or approximate computation of the conditional distribution of the maximum likelihood estimator. When there are many nuisance parameters, it may not be easy to obtain ancillary statistics for these parameters, and hence the evaluation of Barndorff-Nielsen and Cox's formula can be quite cumbersome. The constants A_0 and A are usually functions of the maximal ancillary statistic, although to the relevant order of magnitude, w^* is independent of the ancillary statistic selected. They have also obtained various expressions for these quantities and, in particular, an approximation which does not require integration over the sample space for the one-parameter case.

Since the statistic w is invariant under reparametrization, it is possible to obtain a large sample expansion for this statistic and its expectation in terms of invariants. McCullagh and Cox (1986) used this fact to represent the Bartlett correction as a function of invariant combinations of cumulants of the first two log-likelihood derivatives and gave it a geometric interpretation in full generality in terms of the model curvature. It is also noteworthy that McCullagh and Cox's (1986) general formula coincides with Lawley's (1956) formula. The advantage of McCullagh and Cox's formula is its geometric interpretation, whereas the main advantage of Lawley's result is that it can be more easily implemented to obtain Bartlett corrections for special models.

Bartlett-Type Correction

The problem of developing a correction similar to the Bartlett correction to other test statistics, such as the score (S) and Wald (W) statistics, was posed by Cox (1988) and addressed three years later in full generality by Cordeiro and Ferrari (1991), and by Chandra and Mukerjee (1991) and Taniguchi (1991) for certain special cases. We shall focus on Cordeiro and Ferrari's results since they are more general in the sense that they allow for nuisance parameters.

The score test has been widely used in statistics because it has an advantage over other large sample tests such as the LR and Wald tests. Thus, while these tests involve

estimation of the parameters under the alternative hypothesis, the score test requires estimation only under the null hypothesis. The *LR*, Wald and score statistics have the same chi-squared distribution asymptotically. Harris (1985) obtained an asymptotic expansion for the null distribution of the score statistic S to order $O(n^{-1})$ as

$$Pr(S \le z) = F_q(z) + (24n)^{-1}[A_3F_{q+6}(z) + (A_2 - 3A_3)F_{q+4}(z) + (3A_3 - 2A_2 + A_1)F_{q+2}(z) + (A_2 - A_1 + A_3)F_q(z)], \quad (2)$$

where A_1, A_2 and A_3 are functions of some cumulants of log-likelihood derivatives. The general expressions for these coefficients are given in Harris' paper. He showed that the first three cumulants of the score statistic are (to order n^{-1}) given by $\kappa_1 = q + A_1/(12n)$, $\kappa_2 = 2q + (A_1 + A_2)/(3n)$ and $\kappa_3 = 8q + (A_1 + 2A_2 + A_3)/n$.

Equation 2 holds for both simple and composite hypotheses. More importantly, this result implies that there exists no scalar transformation based on the score statistic which corrects all cumulants to a certain order of precision, as it is the case with the Bartlett correction to the *LR* statistic. The coefficients A's can be used to obtain corrections for models based on independent, but not necessarily identically distributed observations, thus covering a number of linear and nonlinear regression models (see ►Nonlinear Regression).

From Eq. 2, Cordeiro and Ferrari (1991) proposed a Bartlett-type correction to improve the score statistic. They defined a modified score statistic having a chi-squared distribution to order $O(n^{-1})$ under the null hypothesis

$$S^* = S\left(1 - \frac{1}{n}\sum_{j=1}^{3}\gamma_j S^{j-1}\right), \quad (3)$$

where $\gamma_1 = (A_1 - A_2 + A_3)/(12q)$, $\gamma_2 = (A_2 - 2A_3)/\{12q(q+2)\}$ and $\gamma_3 = A_3/\{12q(q+2)(q+4)\}$. They demonstrated that S^* is distributed as χ^2_q when terms of order smaller than $O(n^{-1})$ are neglected. When the A's involve unknown parameters they should be replaced by their maximum likelihood estimates under the null hypothesis but this does not affect the order of approximation of the correction. The correction factor in (3) is a function of the unmodified statistic, and hence this correction is not a "Bartlett correction" in the classical sense. Given its similarity with the Bartlett correction, however, it is termed "Bartlett-type correction."

Cordeiro and Ferrari (1991) obtained a more general result to be applied to any test statistic which converges to χ^2 which can be described as follows. Let S be a test statistic which is asymptotically distributed as χ^2_q. Chandra (1985) showed, under mild regularity conditions, that

$$Pr(S \le z) = F_q(z) + \frac{1}{n}\sum_{i=0}^{k} a_i F_{q+2i}(z) \quad (4)$$

when terms of order $O(n^{-2})$ or smaller are neglected. Equation 4 implies that the distribution function to $O(n^{-1})$ of a test statistic asymptotically distributed as chi-squared is, under certain conditions, a linear combination of chi-squareds with degrees of freedom $q, q+2, \ldots, q+2k$. The coefficients a's are linear functions of cumulants of log-likelihood derivatives for a general test statistic T. For *LR* and S_R, $k = 1$ and $k = 3$, respectively, where the a's are linear functions of the A's in Eqs. 1 and 2.

Let $\mu'_i = 2^i\Gamma(i + q/2)/\{\Gamma(q/2)\}$ be the ith moment about zero of the χ^2_q distribution, where $\Gamma(\cdot)$ is the gamma function. Cordeiro and Ferrari (1991) demonstrated that the modified test statistic

$$S^* = S\left\{1 - 2\sum_{i=1}^{k}\left(\sum_{j=1}^{k} a_j\right)(\mu'_i)^{-1} S^{i-1}\right\}$$

is distributed as χ^2_q to order $O(n^{-1})$. This is a very general result which can be used to improve many important tests in econometrics and statistics.

Building upon the result described above, Cordeiro et al. (1993) and Cribari-Neto and Ferrari (1995) obtained Bartlett-type corrections to improve score tests in generalized linear models with known and unknown dispersion parameter, respectively. Cordeiro and Ferrari (1991) demonstrated gave matrix formula for computing Bartlett-type corrections to improve score tests in a general statistical model and in exponential family nonlinear models, respectively. Finally, Cordeiro and Ferrari (1998) derived Bartlett-type corrections for chi-squared statistics based on the calculation of their moments.

About the Author

Gauss M. Cordeiro was President of the Brazilian Statistical Association (2000–2002). He has published more than 130 research articles in international journals. He was one of the founding editors of the *Brazilian Journal of Probability and Statistics* and the Editor in Chief of this journal (1995–2000). He was awarded the "Prêmio ABE" award from the Brazilian Statistical Association for his contributions to statistics.

Bartlett's Test

Hossein Arsham[1], Miodrag Lovric[2]

Bartlett's test (introduced in 1937 by Maurice Barlett (1910–2002)) is an inferential procedure used to assess the equality of variance in different populations (*not in samples* as sometimes can be found, since there is no point in testing whether the samples have equal variances – we can always easily calculate and compare their values). Some common statistical methods assume that variances of the populations from which different samples are drawn are equal. Bartlett's test assesses this assumption. It tests the null hypothesis that the population variances are equal.

All statistical procedures have underlying assumptions. In some cases, violation of these assumptions will not change substantive research conclusions. In other cases, violation of assumptions is critical to meaningful research. Establishing that one's data meet the assumptions of the procedure one is using is an expected component of all quantitatively based journal articles, theses, and dissertations. The following are the two general areas where Bartlett's test is applicable:

1. In regression analysis and time series analyses, the residuals should have a constant variance (i.e., homoskedastic condition). One may check this condition by dividing the residuals data into two or more groups, then using the Bartlett's test.
2. Another area of application is the *F*-test in ANOVA that requires the assumption that each underlying population has the same variance (i.e., homogeneity condition).

Bartlett's test is derived from the likelihood ratio test under the normal distribution. Therefore, it is dependent on meeting the assumption of normality.

Bartlett's test of homogeneity of variance is based on a chi-square statistic with $(k-1)$ degrees of freedom, where k is the number of categories (or groups) in the independent variable. In other words, Bartlett's test is used to test if k populations have equal variances.

We wish to test the null hypothesis:

$$H_0 : \sigma_1^2 = \sigma_2^2 = \ldots = \sigma_k^2$$

against the alternative that at least two population variances are not equal. The following briefly explains the procedure employed by Bartlett's test.

To investigate the significance of the differences between the variances of k normally distributed populations, independent samples are drawn from each of the populations. Let S_j^2 denote the variance of a sample of n_j items from the jth population ($j = 1, \ldots, k$).

The test statistic has the following expression:

$$B = \frac{(N-k)\ln\left(\dfrac{\sum_{i=1}^{k}(n_i-1)s_i^2}{N-k}\right) - \sum_{i=1}^{k}(n_i-1)\ln\left(s_i^2\right)}{1+\dfrac{1}{3(k-1)}\left[\left(\sum_{i=1}^{k}\dfrac{1}{n_i-1}\right)-\dfrac{1}{N-k}\right]}$$

where N corresponds to the sum of all sample sizes. It is asymptotically distributed as a χ^2 distribution with $(k-1)$ degrees of freedom. The null hypothesis of equal population variances is rejected if test statistics is larger than the critical value. One may also use online tools to perform this test, under condition that each sample contains at least five observations.

Bartlett's test is known to be powerful if the underlying populations are normal. According to some recent results based on simulation (Legendre and Borcard), Bartlett's test and Box's test are the best overall methods to test the homogeneity of variances. With non-normal data, Bartlett's and Box's tests can be used if the samples are fairly large.

It was shown that Bartlett's test is unbiased (Pitman 1939) and consistent (Brown 1939). One of its major drawbacks, however, is that it is extremely sensitive (that is non-robust) to the departures from normality (Box 1953). Since in reality heterogeneity and non-normality frequently simultaneously occur, when the null hypothesis is rejected, we cannot know whether this is due to unequal population variances or non-normality, or both. This test is so sensitive to departures from normality that Box commented that it well may be used as a good test of the population normality. Box also remarked that using Bartlett's test to check whether it is appropriate to apply ANOVA would be rather like "putting a rowing boat to sea to find out whether conditions are sufficiently calm for an ocean liner to leave a port" (Box 1953, p 333).

Finally, for the unequal sample-sizes case, several approaches have been advised for finding exact critical values (see, for example, Chao and Glaser (1978) and Manoukian et al. (1986)).

Bayes' Theorem

Joseph B. Kadane
Leonard J. Savage University Professor of Statistics, Emeritus
Carnegie Mellon University, Pittsburg, PA, USA

The conditional probability $P\{A \mid B\}$ of event A given event B, is commonly defined as follows:

$$P\{A \mid B\} = \frac{P\{AB\}}{P\{B\}} \tag{1}$$

provided $P\{B\} > 0$. Alternatively, (1) can be reexpressed as

$$P\{AB\} = P\{A \mid B\}P\{B\}. \tag{2}$$

The left-hand side of (2) is symmetric in A and B, while the right-hand side does not appear to be. Therefore we have

$$P\{A \mid B\}P\{B\} = P\{B \mid A\}P\{A\}, \tag{3}$$

or

$$P\{A \mid B\} = \frac{P\{B \mid A\}P\{A\}}{P\{B\}}, \tag{4}$$

which is the first form of Bayes' Theorem.

Note that the event B can be reexpressed as

$$B = AB \cup \overline{A}B. \tag{5}$$

Because AB and $\overline{A}B$ are disjoint, we have

$$P\{B\} = P\{AB\} + P\{\overline{A}B\} = P\{B|A\}P\{A\} + P\{B|\overline{A}\}P\{\overline{A}\}. \tag{6}$$

Substituting (6) into (5) yields the second form of Bayes' Theorem:

$$P\{A \mid B\} = \frac{P\{B \mid A\}P\{A\}}{P\{B \mid A\}P\{A\} + P\{B \mid \overline{A}\}P\{\overline{A}\}}. \tag{7}$$

Finally, let $A_1, A_2, \ldots, A_k$ be disjoint sets whose union is the whole space S. Then, generalizing (5),

$$B = \cup_{i=1}^{k} A_i B \tag{8}$$

and the sets $A_i B$ are disjoint. Then

$$P\{B\} = \sum_{i=1}^{k} P\{A_i B\} = \sum_{i=1}^{k} P\{B \mid A_i\}P(A_i\}. \tag{9}$$

Then generalizing (7), we have

$$P\{A_j \mid B\} = \frac{P\{B \mid A_j\}P\{A_j\}}{\sum_{i=1}^{k} P\{B \mid A_i\}P_i\{A_i\}}, \tag{10}$$

the third form of Bayes' Theorem.

As an example, let A be the event that a particular person has HIV, and suppose $P\{A\} = 0.001$. Suppose there is a test for the presence of HIV in a patient. If B is the event of a positive result from the test, suppose

$$P\{B \mid A\} = 0.95 \text{ and } P\{B \mid \overline{A}\} = 0.05,$$

which means that if the person has HIV, the test is 95% likely to find it, and if the person does not have HIV, the test is 5% likely to report a positive result.

Then

$$\begin{aligned} P\{A \mid B\} &= \frac{(0.95)(0.001)}{(0.95)(0.001) + (0.05)(0.999)} \\ &= \frac{0.00095}{0.00095 + 0.04995} \\ &= \frac{0.00095}{0.0509} \\ &= 0.0187 \end{aligned}$$

Thus a positive test result, on a respectable test, does not imply a high probability that the patient actually has HIV.

Bayes' Theorem has an aura of being controversial. Since everything above is a consequence of the laws of probability and the definition of conditional probability, the correctness of the formulas above is conceded by all the various schools of interpretation of probability.

The Bayesian school uses Bayes' Theorem as a way to understand the extent to which knowing that the event B (test result in the example) has changed the probability of the event A, resulting in a map from $P\{A\}$ to $P\{A \mid B\}$. In the example, $P\{A\} = 0.001$ is the probability the person has HIV given that person's risk factors. $P\{A \mid B\} = 0.0187$ is the updated probability that takes into account the positive test result B.

The controversy comes from the fact that some statisticians (Fisher 1959) take the view that the only events that have probabilities are those that can be regarded as elements of an infinite (or large) sequence of independent and identically distributed events. Then the probability of A is taken to be the relative frequency of the event A in this sequence. Thus the controversy has to do not with the legitimacy of Bayes' Theorem itself, but rather with the applications of it.

Introduction

The original Bayes proposal leads to likelihood and confidence for many simple examples. More generally it gives approximate confidence but to achieve exact confidence reliability it needs refinement of the argument and needs more than just the usual minimum of the likelihood function from observed data. A general Bayes approach provides a flexible and fruitful methodology that has blossomed in contrast to the widely-based long-standing frequentist testing with focus on the 5% level. We examine some key events in the evolution of the Bayes approach promoted as an alternative to the present likelihood based frequentist analysis of data with model, the evidence-based approach of central statistics. And we are led to focus on the bane of Bayes: parameter curvature.

Bayes 1763

Bayes (1763) examined the Binomial model $f(y;\theta) = \binom{n}{\theta}$ $\theta^y(1-\theta)^{n-y}$ and proposed the flat prior $\pi(\theta) = 1$ on $[0,1]$. Then with data y^0 he used a lemma from probability calculus to derive the posterior $\pi(\theta|y^0) = c\theta^{y^0}(1-\theta)^{n-y^0}$ on $[0,1]$. And then for an interval say $(\theta,1)$ he calculated the integral of the posterior,

$$s(\theta) = \int_\theta^1 \theta^{y^0}(1-\theta)^{n-y^0}d\theta \Big/ \int_0^1 \theta^{y^0}(1-\theta)^{n-y^0}d\theta$$

and referred to it as probability that the parameter belonged to the interval $(\theta,1)$. Many endorsed the proposed calculation and many disputed it.

As part of his presentation he used an analogy. A ball was rolled on a level table, perhaps an available billiard table, and was viewed as having equal probability of stopping in any equal sized area. The table was then divided conceptually by a North-South line through the position where the ball stopped, with area θ to the West and $(1-\theta)$ to the East. The ball was then rolled n further times and the number y^0 of time that it stopped left of the line observed. In the analogy itself, the posterior probability calculation given data seems entirely appropriate.

The Economist 2000

In an article entitled "In praise of Bayes," the Economist (2000) speaks of an "increasingly popular approach to statistics (but) not everyone is persuaded of its validity." The article mentions many areas of recent application of the Bayesian approach, and cites "the essence …is to provide a mathematical rule explaining how you should change your existing beliefs in the light of new evidence." The indicated areas of application are wide spread and there is emphasis on attaining definitive answers. And this is set in full contrast to "traditional ways of presenting results" indicated to be the mid-twentieth-century decision theoretic view of accepting a null view 95–5% on some departure scale. The article does offer some caution for "when used indiscriminently" in the form of a quotation from Larry Wasserman that it can become "more a religion than a science."

The mathematical rule cited as the essence of the Bayesian approach is a very broad expansion from Bayes original proposal where a statistical model $f(y;\theta)$ evaluated at an observed data value y^0 giving $f(y^0;\theta)$ is combined with a constant mathematical prior $\pi(\theta) = 1$ and

treated as a conditional density. The force of the rule is that with new model-data information the new likelihood would be folded with the old. But this is of course standard practice in statistics: use the up-to-date likelihood, and possibly refine such a procedure with meta-analysis. What is different is that the Bayesian method essentially overlooks evidence beyond the observed likelihood function and does so on principle.

Validity or Analogy

Bayes considered a uniform prior and a Binomial (n,p) model, and used analogy to justify combining them by a standard lemma from probability calculus. For the analogy involving balls on a billiard table, the calculations seem entirely proper and appropriate. The more generally interpreted Bayes approach has a statistical model $f(y;\theta)$ with data y^0 coupled with a mathematical prior $\pi(\theta)$ representing symmetries or other properties of the model or context. Analogies can be great for explaining an argument but not to be the argument itself: there is no billiard table equivalent in the typical binomial or more general context.

There is an explicit time line: There is a context with a true value θ_* for the parameter θ; there is an investigation $f(y;\theta)$ yielding an observed y^0 from the true value model $f(y;\theta_*)$; and possibilities for θ are then to be assessed. Thus in order: θ_* is realized but unknown; y^0 is observed; then assess θ. The values θ_* and y^0 are realized and are in the past. And the issue is what can be said about θ given the model $f(y;\theta)$ and data y^0.

If θ is understood in fact to come from an objective source $\pi(\theta)$ with realized value θ_*; then the time line is longer. Accordingly: $\pi(\theta)$ produces θ_*; $f(y;\theta_*)$ produces y^0; and the issue is to assess θ. In this situation $\pi(\theta)$ is properly an objective prior. And an option is of course is to examine and present the composite model $\pi(\theta)f(y;\theta)$ with observed y^0. But an even more compelling option is to examine and present $\pi(\theta)$ and to separately examine and present $f(y;\theta)$ with y^0.

Now consider the model $f(y;\theta)$ with data y^0; and the mathematical prior $\pi(\theta)$ as proposed by Bayes. The lemma from the probability calculus has two probability inputs say $\pi(x)$ and $f(y|x)$ and it has one probability output $\pi(x|y^0)$; the output records the behavior of x that is associated with the observed value $y = y^0$. For the Bayes case $\pi(x)$ would be $\pi(\theta)$ and $\pi(x|y^0)$ would be $\pi(\theta|y^0)$. Is the lemma applicable or relevant in the Bayes case? In the Bayes case there is just one probability input $f(y;\theta)$; and the other nominal input is $\pi(\theta)$, a mathematical object that refers to symmetry or patterns in the model and has no probability status whatsoever. Thus the assumptions of the lemma do not hold, and consequently the output of the lemma is ... by analogy ... not by derivation. The usage of the lemma in the proposed argument is not proper and can be viewed as fraudulent logic.

The standard frequentist would refer to $f(y^0;\theta)$ as likelihood $L(\theta;y^0) = L^0(\theta)$. An exploration with weighted likelihood $\pi(\theta)L^0(\theta)$ can be a very natural, obvious and sensible procedure ... for just that, for exploring possibilities for θ. But for obtaining probabilities, perhaps a pipe dream!

Likelihood and Confidence

Bayes' (1763) original approach suggested a density $c\pi(\theta)f(y^0;\theta)$ as a description of an unknown θ in the presence of observed data y^0. As such it records likelihood $L^0(\theta)$ or weighted likelihood. And this was long before the formal introduction (Fisher 1922) of likelihood. Both viewpoints record the same formal information concerning the parameter; the differences are in the color or flavor associated with the particular argument; and with properties attributed to the output.

Bayes (1763) also offered a distribution as a summary of information concerning the parameter θ; the distribution had density $c\pi(\theta)f(y^0;\theta) = c\pi(\theta)L^0(\theta)$. The majority of models at that time had least-squares location structure and for such models the posterior $\pi(\theta)L^0(\theta)$ using a natural prior just reproduces what is now called confidence (Fisher 1930, 1935).

It thus seems appropriate to acknowledge that Bayes introduced the primary concepts of likelihood and confidence long before Fisher (1922, 1930) and long before the refinement offered by Neyman (1937). For likelihood he offered the extra flexibility of the weight function but for confidence he did not have the statistical refinement that later provided the logical extension to non-location models; this latter can be viewed as a matter of reasonable fine tuning of the argument, of intellectual evolution, and of the familiar iterative processes of science.

Laplace and Venn

Laplace (1812) seems to have fully endorsed the proposals arising from Bayes (1763). And Venn (1886) seems equally to have rejected them. Certainly asserting the conclusions of a theorem or lemma when one of the premises does not hold is unacceptable from a mathematical or logical viewpoint. Nonetheless the results were impressive and filled a substantial need, but indeed with downstream risks. And it does have, as is now becoming apparent, the support of approximate confidence (Fraser 2010). At present Bayes and confidence lead a coexistence, perhaps an uneasy unstable coexistence!

Priors and Priors

The original Bayes prior was a flat prior $\pi(\theta) = 1$ for a probability θ that then in sequence becomes the parameter in a Binomial (n, θ) model; the resulting posterior is $\pi(\theta)L^0(\theta)$, which focally uses the observed likelihood from the Binomial context. Some aspects of invariance were invoked to support the particular choice. The possible plausible extensions are immense.

For a location model $f\{y - \beta(\theta)\}$ the natural prior would be $\pi(\theta)d\theta = d\beta(\theta) = \beta'(\theta)d\theta$. Thus for $f(y - X\beta)$ we would have $\pi(\beta)d\beta = dX\beta = cd\beta$, giving a flat prior for the regression coefficients. Motivation would come by noting that $y - \beta(\theta)$ has a fixed θ-free distribution.

Extensions are possible by seeking approximate θ-free distributions. This was initiated by Jeffreys (1939) and then fine-tuned to acknowledge various types of parameters (Jeffreys 1946). These extensions use expected information $i(\theta) = E\{-\ell_{\theta\theta}(\theta; y); \theta\}$ in the model to calibrate the scale for θ; here $-\ell_{\theta\theta}(\theta)$ is the negative second derivative of likelihood and the initial Jeffreys prior is $\pi(\theta)d\theta = |i(\theta)|^{1/2}d\theta$, and it is parameterization invariant. For the regression model, where $y = X\beta + \sigma z$ with $N(0,1)$ error, the Jeffreys (1939) prior is $\pi(\theta)d\theta = d\beta d\sigma/\sigma^{r+1}$ where r is the column rank of X. The second or modified Jeffreys (1946) is $\pi(\theta)d\theta = d\beta d\sigma/\sigma$ and gives generally more acceptable results, often in agreement with confidence.

The approximate approach can be modified (Fraser et al. 2010) to work more closely with the location invariance indicated by the initial Bayes (1763) approach. In many regular problems continuity within the model leads to a relationship $d\hat{\theta} = W(\theta)d\theta$ where $W(\theta)$ is a $p \times p$ matrix; the $d\hat{\theta}$ refers to an increment at the data y^0 and the $d\theta$ refers to an increment $d\theta$ at θ. This immediately indicates the prior $\pi(\theta)d\theta = |W(\theta)|d\theta$ based on simple extension of the translation invariance $dy = \beta'(\theta)d\theta$ for the model $f(y - \beta(\theta))d\theta$; and it widely agrees with preferred priors in many problems. But the parameter must not have curvature: the bane of Bayes!

The approximate approach can also be modified to make use of an asymptotic result that to second order the statistical model can be treated as an exponential model (Reid and Fraser 2010; Fraser et al. 2010). This uses continuity to obtain a nominal reparameterization $\varphi(\theta)$ that yields second and third order inference by acting as if the model were just $g(s; \theta) = \exp\{\ell(\theta) + \varphi(\theta)s\}h(s)$ with data $s^0 = 0$. This allows information to be calculated within the approximating model using the information function $j_{\varphi\varphi}(\theta; s) = -\ell_{\varphi\varphi}\{\theta(\varphi)\}$; this draws attention to marginalization and to curvature effects that are not usually apparent in the search for default priors (Fraser et al. 2010).

The preceding can also be viewed as a somewhat natural evolution from the original Bayes proposal with some reference to location invariance. The evolution has been assisted by the fact that many posterior distributions have appealing and sensible properties. It is our view here that these sensible properties are precisely the approximate confidence properties that have become evident quite separately. In any case the priors just described can all be classified as default priors, priors that one might choose to use as a default without strong arguments for something different.

The Bayesian approach is committed to using a weight function applied to an observed likelihood and thus to formally omitting other properties of the model. Within this approach the default priors are widely called objective priors. But the term objective means objective reference, and this as a property is specifically absent here; there is a strong flavor of deception. Thus using the term objective for default priors seems highly inappropriate, but could be viewed as just a seeking for a wider area of application. The author was present at the Bayesian convention when the term was being chosen and did not register an objection, being perhaps somewhat of an outsider, not a good defense! We will however explicitly refer to them as default priors, and keep the term objective for contexts where the prior does have an explicit reference in context.

A difficulty with the use of default priors is that a posterior probability obtained by marginalization from a full posterior distribution may not be equal the posterior probability calculated directly from the appropriate marginal model; this was given prominence by Dawid et al. (1973) and applies equally to confidence distributions and other attempts to present model-data information as a distribution for the parameter. The complication in any of these cases derives from parameter curvature: for some discussion see Fraser et al. (2010) and Fraser and Sun (2010).

The wealth of possibilities available from a weight-function combined with likelihood is well documented in the development of the Bayesian methods as just described. Its success can amply be supported as "approximate confidence" but derived by a route that is typically much easier. Approximate confidence provides full support for the acceptable, often meritorious behavior of Bayes posterior probabilities. We address later whether there can be anything beyond approximate confidence in support of the Bayesian approach.

Another approach, somewhat different from the original Bayes way of obtaining a weight function is derived from Kullback-Leibler distance on measure spaces (Bernardo 1971): this chooses a prior to maximize the

statistical distance from prior to posterior. Modifications of this distance approach have been developed to obtain specialized priors for different component parameters of interest, often parameters that have a statistical curvature.

The richness available from using just a likelihood function is clearly evident to Bayesians if not to frequentists; but is not widely acknowledged. Much of recent likelihood theory divides on whether or not to use more than the observed likelihood, specifically sampling properties that are associated with likelihood characteristics but are not widely or extensively available. In many ways central statistics has ignored the extra in going beyond likelihood, and indeed has ignored the wealth available from just likelihood alone.

Meanwhile those committed to using just the weighted likelihoods, those associated with the development of the Bayes approach as we have just described, have aggressively sought to use the weighted likelihood approach as a general approach to updating information and to producing decisions. Central to this direction is the subjective approach with a major initiative coming from Savage (1972). This takes a prior to represent the views, the understanding, the personal probabilities concerning the true value of the parameter; these might come from highly personal thoughts, from detailed elicitation from knowledgeable people, from gut feelings as one approaches a game at a casino; and they can have the benefit of intuition or the merits of a seasoned gambler, with or without insider information. But who should use it? Certainly the chronic gambler will. But from the statistical perspective here there is nothing of substance to say that such prior "information" $\pi(\theta)$ should be combined with likelihood. With due respect it can be presented as $\pi(\theta)$ alongside a presentation of the evidence-based well calculated confidence. If a user would like to combine them, it would certainly be plausible for him to do so but it would not be an imperative despite Bayesian persuasion. Certainly place them both to be seen and available. In wide generality combining them is not a necessary statistical step, although sometimes expedient.

Lindley and Territory

Fisher's (1930, 1935) proposal for confidence with effective support from Neyman (1937) offered strong alternatives to a prominent sympathy for the Bayesian approach. Then Jeffreys (1939, 1946) with great prominence in geophysics provided reinforcement for the use of the Bayesian approach in the physical sciences. Meanwhile the confidence approach gained strength both in mathematics departments and in scientific applications. Both approaches lead from model and data to a distribution for the parameter, but the results were often in conflict. Both sides clearly felt threatened, and each side in a practical sense had territory to defend.

Lindley (1958) focused on the very basic case, a scalar parameter and a scalar variable, say with distribution function $F(y;\theta)$. The Bayesian answer with prior $\pi(\theta)$ is given by the posterior distribution $c\pi(\theta)F_y(y;\theta)d\theta$ where the subscript y denotes differentiation with respect to the argument y thus giving the density or likelihood function. By contrast the Fisher (1930, 1935) approach gives the confidence distribution $|F_\theta(y;\theta)|d\theta$. Lindley examined when these would be equal and solved for $\pi(\theta)$:

$$\pi(\theta) = c\frac{F_{;\theta}(y;\theta)}{F_y(y;\theta)} = c\frac{\partial}{\partial\theta}y(u;\theta);$$

the right hand expression records the derivative of the quantile function for fixed p-value $u = f(y;\theta)$ as pursued in Fraser et al. (2010). The equation is actually a differential equation that asserts that the model must be a location model, the form of model actually found in section "►Likelihood and Confidence" to have good Bayesian answers. In Fraser et al. (ibid) the equation is used to determine the data dependent priors that give posterior probabilities having objective validation.

Lindley was concerned that the confidence approach did not follow the primal Bayesian concept that a probability statement concerning a parameter should be updated by multiplication by new likelihood and his criticism had a profound effect suggesting that the confidence distribution approach was defective. We now know that the defect is the attempt to use a distribution as the summary, either by Bayes or by confidence. And if there were to be a lesser of two evils then calling confidence probability and calling Bayes approximate confidence would be safer.

Another view might be that this was just a territorial dispute as to who had the rights to provide a distributional description of the parameter in the model data context. But the social conflict aspects were not in evidence. Rather there was a wide spread perception that giving a distribution of confidence was wrong. Neyman (1937) of course had provided a route around. But nonetheless, the judgment stuck: a confidence distribution was wrong and a Bayesian analysis was all right. Of course, in Dawid et al. (1973), there is a clear message that neither approach can handle vector parameters without special fine-tuning. Clearly Lindley had focused on a substantive issue but the arguments invoked had not quite attained the point of acknowledging that an effective prior must in general be data dependent; for some current discussion see Fraser et al. (2010).

Bayesian Analysis and Imperatives

Bayesian (1763) analysis has been around for a long time, but alternative views perhaps now identified as frequentist are perhaps older although somewhat less formalized. These approaches have cross dialogued and often been in open conflict. Each has made various appeals to holding the truth. And they have actively sought territorial advantage. In particular Fisher's 1930 initial steps towards confidence were directly to provide an alternative to inverse probability, the name at the time attached to the Bayesian approach. So it is not surprising that there would be a very focal reverse criticism (Lindley 1958) of the confidence approach.

Those favoring the Bayesian approach have frequently felt they were underdogs, often for example having their articles rejected by journals for just being Bayesian. It thus seems rather natural that the Bayesian supporters would seek to broaden their methodology and their community. The subjective approach as strongly initiated by Savage (1954) has led to a powerful following in an area where prior probabilities are extended to include personal feelings, elicited feelings, and betting view points. Certainly such extensions are a guide for gambling and much more. But there is nothing of substance to assert that they should be ... the imperative ... used for the analysis. The prior subjective assessment and the objective evidence-based assessment can be placed side by side for anyone to see and to use as deemed appropriate. And the Bayes combination of these can also be presented for anyone to use if so inclined. Perhaps the Bayesian expansion was ill advised to promote the imperative: that the proper analysis was that of the Bayes paradigm.

What is perhaps even more dangerous is the widely promoted hierarchical model where each parameter is given a prior distribution, and then parameters in the prior distributions are themselves given priors, perhaps then multilevel. Often an impressive edifice that seems only equaled by the lack of evidence for the various introduced elements and the impressive resort to McMC. The resort to multilevel Bayes modeling would seemingly be best viewed as one of expediency, to extend the base of Bayes without supporting evidence.

And then of course there are model data situations where the true parameter has come from a source with a known frequency distribution. In such cases the obvious name for the prior would be objective prior. But assembled Bayesians as mentioned earlier have adopted that name for the opposite situation, where there is in fact no objective reference, and the prior is purely a mathematical construct. But what about the multitude of cases where there is an identified source for the true parameter value? These can arise widely when the entity being examined has been obtained by sampling from some identified subpopulation; or they can arise by genetics or by Mendel or perhaps by updated genetic laws. Or much more. In reality this is just a modeling issue: what aspect of the context, of the immediate environment, or the more extended environment should be modeled. It is a modeling issue. It is perhaps only natural that Bayesian promotion should seek to subsume wider and wider contexts as part of the evolution of the approach. Especially when traditional statistics has been widely immersed in technical criteria connected with some global optimization or with decision rules to reject at some 5% level or accept at some 19/20 level, even when it was becoming abundantly apparent that these rules for scientific publication have serious defects.

But if there is an objective source $\pi(\theta)$ for a true value in a model-data context, there is nothing that says it should be folded into a combined model for analysis. The prior source $\pi(\theta)$ can be set in parallel with the more directly evidence-based analysis of the model-data combination. And of course even the combined model-data-prior analysis presented. But again there is no substantive precept that says the combined analysis is the statistical inference. Such a step would be purely an assertion of extended territory for Bayesian analysis.

Curvature: The Bane of Bayes

Contours of a parameter can have obvious curvature. A simple example can throw light on the effects of such curvature.

Consider (y_1, y_2) with a Normal $\{(\theta_1, \theta_2); I\}$ distribution on the plane. With data $\left(y_1^0, y_2^0\right)$ the basic original Bayes approach would say that (θ_1, θ_2) was Normal $\left\{\left(y_1^0, y_2^0\right); I\right\}$. First we examine an obviously linear parameter $\psi = \theta_1$ and assess say the value $\psi = 0$ on the basis of data, say $\left(y_1^0, y_2^0\right) = (0, 0)$.

In an obvious way y_1 measures ψ and has the Normal$(\psi; 1)$ distribution. Accordingly the p-value for ψ from the observed data is

$$p(\psi) = \Phi\left\{\left(y_1^0 - \psi\right)/1\right\} = \Phi(-\psi).$$

And for assessing the value $\psi = 0$ we have $p(0) = 50\%$.

Now consider the Bayesian assessment of the value ψ. the marginal posterior distribution of ψ is $N\left(y_1^0, 1\right)$ and the corresponding posterior survivor value is

$$s(\psi) = 1 - \Phi\left(\left(\psi - y_1^0\right)/1\right) = 1 - \Phi(\psi)$$

at the observed data. In particular for assessing $\psi = 0$ we would have $s(0) = 50\%$. The Bayesian and frequentist values are equal for the special $\psi = 0$ and also for general ψ.

Now consider a clearly curved parameter, the distance ψ on the parameter space from the point $(-1, 0)$ to the parameter value (θ_1, θ_2),

$$\psi = \left\{(\theta_1 + 1)^2 + \theta_2^2\right\}^{1/2}.$$

An obvious way to measure this parameter is by using the distance r from the point $(-1, 0)$; thus $r = \left\{(y_1 + 1)^2 + y_2^2\right\}^{1/2}$. The distribution of r^2 is noncentral Chi-square with two degrees of freedom and noncentrality $\delta^2 = \psi^2$. The indicated p-value for assessing ψ is then

$$p(\psi) = H_2(r^2; \psi^2)$$

where H_2 is the noncentral Chi-square distribution function with two degrees of freedem and noncentrality $\delta^2 = \psi^2$. This is readily available in *R*. In particular for assessing $\psi = 1$ we would have

$$p(1) = H_2(1; 1) = 26.7\%$$

which is substantially less than 50%.

Now consider the Bayesian assessment of the curved parameter ψ. The posterior distribution of ψ^2 from the observed data is noncentral Chi-square with two degrees of freedom and noncentrality $\delta^2 = 1$. If follows that the posterior survivor value for assessing $\psi = 1$ is

$$s(1) = 1 - H_2(1; 1) = 73.3\%$$

which is substantially larger than 50%.

For this simple example we have seen that the p-value and the survivor value are equal for a linear parameter. This happens generally for linear parameters (Fraser and Reid 2002). And with the introduction of a curvature change to the parameter, the Bayesian and frequentist values go in opposite directions. This happens widely with curved parameters: as a parameter contour is changed from linear to curved, the Bayesian survivor changes in the opposite direction from the frequentist. Thus the Bayesian can be viewed as correcting negativity, that is making an adjustment opposite to what is appropriate in a context. For some recent discussion see Fraser (2010). The example above suggests that curvature is precisely the reason that Bayes fails to correctly assess parameters.

Consider y with a Normal $\{\theta, \sigma^2(\theta)\}$ distribution where the variance $\sigma^2(\theta)$ depends weakly on the mean θ. Precise p-values are available for assessing θ:

$$p(\theta) = \Phi\{(y - \theta)/\sigma(\theta)\}$$

with a clear frequency interpretations. The confidence inversion is well established (Fisher 1930, 1935). The Bayesian inversion does not seem to have an obvious prior that targets the parameter θ.

How does one assess the merits of a proposed distribution for a parameter? The use of two-sided intervals provides a slippery slope. Strange tradeoffs can be made between two interval bounds; see for example Fraser et al. (2004) on statistics for discovering new particles in High Energy Physics. A more direct approach is to examine a particular quantile of a proposed distribution, say the β-th quantile $\hat{\theta}_\beta$ which has posterior probability β to the right and $(1 - \beta)$ to the left. One can certainly simulate or have an oracle and determine what proportion of the time the true value is larger than the particular quantile being considered; and determine whether the true proportion bears a sensible relation to the alleged value β. This has been addressed at length in Fraser (2010).

In particular for the Normal$\{\theta, \sigma^2(\theta)\}$ example there is no determination of a prior that will give the third order accuracy that is available from the confidence approach unless the prior is directly specific to the observed data value. This result holds in wide generality: the use of a default or Bayesian prior cannot lead to the third order accuracy readily available from the evidence-based procedures of frequentist inference. And parameter curvature is the number one culprit.

Why Bayes?

Linear approximations are widely used throughout statistics, mathematics, physics, the sciences generally, and much more. They provide a local replica of something that might be intangible otherwise and when used iteratively can provide exploration of something unknown otherwise. There is substantial evidence that the Bayes procedure provides an excellent first order approximation for the analysis of a statistical model. There are also ample warnings that global acceptance of Bayes results can be extremely hazardous. Use but be cautious!

The Bayes calculus asserts that the posterior results are probabilities. And the name itself is assertive. The Bayesian supporters have also been vocal, asserting that confidence results do not have the status of probabilities calculated by the Bayes paradigm; some indication of this is implicit in Lindley (1958); and further indication is found in the active broadening of the application area for Bayesian analysis. From an evidence-based approach it

is clear that the direct use of the likelihood function provides substantial information, first order information. And higher order results are available with the careful choice of prior. But beyond that, the Bayes procedure comes up short, unless the priors become data dependent and the calculations are carefully targeted using an evidence-based formulation.

Thus linear approximations can be hugely useful but they can carry substantial risks. The assertion of probability status is directly contradicted by reality! And no indications seem available that a Bayesian calculation could yield more than just approximate confidence. The promotional assertiveness that accompanies current Bayes development is misleading and misleading to the extent of being fraudulent.

Of course there can be contexts where there is an objective prior $\pi(\theta)$ that records how the true value was generated. The Bayes paradigm can be applied but it is inappropriate; the direct approach is a matter of modeling, of what aspect of the context is appropriate to include. From this viewpoint the indicated methodology predates Bayes; it is just probability analysis. Even then it allows the prior information and the evidence based information to be presented separately, thus of course allowing the end user to combine if needed or wanted.

There is no imperative that says the prior and the evidence-based should be combined. It is an option. And it is an option with risks!

About the Author

Donald A.S. Fraser was born in Toronto in 1925. He obtained his Ph.D. in 1949 under the supervision of Samuel Wilks at Princeton University. He was the first Chair of the Department of Statistics, University of Toronto (1977–1983). Among many awards, Professor Fraser was the first recipient of the Gold Medal of the Statistical Society of Canada, inaugurated in 1985. He received the R.A. Fisher Award and Prize, American Statistical Association (1990), and Gold Medal, Islamic Statistical Society (2000). He was the first statistician to be named a Fellow of the Royal Society of Canada (1967). He has supervised 55 Ph.D. students. Professor Fraser has (co-)authored over 250 papers and authored five books, including *Nonparametric Methods in Statistics* (Wiley 1957), *The Structure of Inference* (Wiley 1968) and *Inference and Linear Models* (McGraw Hill 1979). In 2002, he was awarded a degree of Doctor of Science, *honoris causa*, by the University of Toronto. In 2010 (April 30–May 1), the third in a series of conferences, titled Data Analysis and Statistical Foundations III, was held to honor the accomplishments of Professor Fraser.

Bayesian Approach of the Unit Root Test

Hocine Fellag[1], Lynda Atil[2]
[1]Professor in Statistics
University of Tizi-Ouzou, Tizi-Ouzou, Algeria
[2]University of Tizi-Ouzou, Tizi-Ouzou, Algeria

In statistical inference, two approaches of hypothesis testing can be used. The first one, called classical approach, is based on calculating probabilities of the data in hand under certain conditions (which are encompassed by the null and alternative hypotheses). The second one, named Bayesian approach, looks at probabilities of competing conditions (which are the hypotheses being compared) given the data in hand. This approach integrates prior probabilities associated with competing conditions into the assessment of which condition is the most likely explanation for the data in hand. Also, it allows to evaluate the likelihood of competing conditions by evaluating the change in the odds associated with these conditions, a change produced by assessing the data in hand. If the odds change sufficiently when the data are examined, then the scientist may alter his opinion about which competing condition is the most likely. One of the main papers published on this topic is the paper of Schotman and Van Dijk (1991a), where a very important problem in Bayesian analysis is tackled, namely, the Bayesian approach for unit root testing. Several economists, Dejong and Whiteman (1991), Koop (1992), and in particular, Sims (1988), and Sims and Uhlig (1991), have advocated forcefully for Bayesian alternatives over the more traditional classical approach such as the ADF tests (Dickey and Fuller 1981) in unit root testing. Despite the apparent advantages of the Bayesian approach over the classical approach in unit root testing, a relatively small number of studies have used the Bayesian approach. The reasons may be that the Bayesian approach requires a likelihood function and the use of prior information.

The modeling objective of the Bayesian approach is not to reject a hypothesis based on a predetermined level of significance, but to determine how probable a hypothesis is relative to other competing hypotheses. Schotman and Van Dijk (1991a) propose a posterior odds analysis of the hypothesis of a unit root in real exchange rates because nominal and real exchange rates behave almost like random walks (see ▶Random Walk).

Now, suppose that we have a sample of T consecutive observations on a time series y_t generated by

$$y_t = \rho y_{t-1} + \mu_t \tag{1}$$

where

1. y_0 is a known constant.
2. μ_t are identically and independently (i.i.d) normally distributed with mean zero and unknown variance σ^2.
3. $\rho \in S \cup \{1\}$, $S = \{\rho / -1 < a \leq \rho < 1\}$.

The econometric analysis aims at discriminating between a stationary model (here defined as $a \leq \rho < 1$) and the nonstationary model with $\rho = 1$. The lower bound a in assumption (3) largely determines the specification of the prior for ρ. Recall that the principal Bayesian tool to compare a sharp null hypothesis with a composite alternative hypothesis is the posterior odds ratio, which is defined as

$$K_1 = K_0 \frac{\int_0^\infty p(\sigma) L(y \mid \rho = 1, \sigma, y_0) d\sigma}{\int_S \int_0^\infty p(\sigma) p(\rho) L(y \mid \rho, \sigma, y_0) d\sigma d\rho} = \frac{p(\rho = 1 \mid y)}{p(\rho \in S \mid y)} \tag{2}$$

K_0 and K_1 are the prior odds and the posterior odds in favor of the hypothesis $\rho = 1$, respectively. $p(\rho)$ represents the prior density of $\rho \in S$, $p(\sigma)$ the prior density of σ.

$L(y \mid .)$ is the likelihood function of the observed data $y = (y_1 \ldots y_T)'$ and $Y = (y_0, y')'$ is all observed data.

The Bayes factor is defined as the ratio of the marginal posterior density of ρ under the null hypothesis $\rho = 1$ over a weighted average of the marginal posterior under the alternative using the prior density of ρ as a weight function. Then, one can notice that the posterior odds K_1 is equal to the prior odds K_0 times the Bayes factor. The prior odds express the special weight given to the null hypothesis, the point $\rho = 1$ is given the discrete prior probability $\vartheta = K_0/(1 + K_0)$. From the posterior odds, one can compute the posterior probability of the null hypothesis as $K_1/(1 + K_1)$.

For the complete specification of the marginal prior of ρ and σ, we assume that

$$Pr(\rho = 1) = \nu \tag{3}$$

$$p(\rho \mid \rho \in S) = \frac{1}{1 - a} \tag{4}$$

$$p(\sigma) \propto \frac{1}{\sigma} \tag{5}$$

The prior of ρ is uniform on S but has a discrete probability ϑ that $\rho = 1$. The likelihood function for the vector of T observations y is

$$L(y \mid \rho, \sigma, y_0) = (2\pi\sigma^2)^{-T/2} \exp\left\{-\frac{1}{2\sigma^2}\mu'\mu\right\} \quad (6)$$

where $\mu = y - y_{-1}\rho$, and $y_{-1} = (y_0, \ldots, y_{T-1})'$

Having computed the relevant integrals in (2), the posterior odds ratio becomes

$$K_1 = \frac{C_T^{-1}}{(T-1)^{1/2}} \frac{\nu}{1-\nu} \left(\frac{\sigma_0^2}{\hat{\sigma}^2}\right)^{-T/2} \left(\frac{1-a}{s_{\hat{\rho}}}\right) \left[F\left(\frac{1-\hat{\rho}}{s_{\hat{\rho}}}\right) - F\left(\frac{a-\hat{\rho}}{s_{\hat{\rho}}}\right)\right]^{-1} \quad (7)$$

where

$$\sigma_0^2 = \frac{1}{T-1}(y-y_{-1})'(y-y_{-1}) \quad \hat{\sigma}^2 = \frac{1}{T-1}\left(y'y - \frac{(y'_{-1}y)^2}{(y'_{-1}y_{-1})}\right)$$

$$s_{\hat{\rho}}^2 = \hat{\sigma}^2 \left(y'_{-1}y_{-1}\right)^{-1} \quad \hat{\rho} = \frac{y'_{-1}y}{y'_{-1}y_{-1}} \quad C_T = \frac{\Gamma((T-1)/2)\Gamma(1/2)}{\Gamma(T/2)} \quad (8)$$

The empirical lower bound a^* is given by $a^* = \hat{\rho} + s_{\hat{\rho}} F^{-1}(\alpha F(-\hat{\tau}))$. $F(.)$ is the cumulative t-distribution with $(T-1)$ degrees of freedom and $\hat{\tau} = \frac{\hat{\rho}-1}{s_{\hat{\rho}}}$ is the Dickey–Fuller test statistic. The unit root model is preferred if $K_1 > 1$ or $P(\rho = 1|y, y_0) \geq 0.50$, thus treating the null and the alternative in a symmetric way.

After fixing numerical values for ϑ and α, the posterior odds is just a function of the data like any other test statistic. Due to a specific way that the lower bound has been constructed, the posterior odds are directly related to the ►Dickey–Fuller test. Setting the prior odds equal to one and for large T, Schotman & Van Dijk approximate $F(.)$ to the cumulative normal distribution. The posterior odds become a function of the Dickey–Fuller statistic $\hat{\tau}$.

$$\ln K_1 = -\frac{1}{2}\ln(2\pi) - \frac{1}{2}\hat{\tau}^2 + \ln\left(\frac{-\hat{\tau} - F^{-1}(\alpha F(-\hat{\tau}))}{F(-\hat{\tau})}\right) \quad (9)$$

Since the posterior odds is a function of the Dickey–Fuller test statistic, its sampling properties correspond exactly to those of the Dickey–Fuller test. In literature, there is a great attention to the nature of suitable noninformative priors for the autoregressive coefficients. For example, Sims (1988) and Sims and Uhlig (1991) advocate the use of flat priors. Phillips (1991a) proved that flat priors bias the inference toward stationary models, and suggests to use Jeffrey priors derived from conditional likelihood functions. Also, Uhlig (1994a) determines the Jeffreys priors for an AR(1) process from the exact likelihoods and justifies the use of flat priors in some specific cases only. Uhlig (1994b) summarizes the Bayesian contribution to the unit root problem and discusses the sensitivity of the tails of the predictive densities on the prior treatment of explosive roots. Schotman and Van Dijk (1991a) stress the sensitivity of the posterior odds to the size of the stationary region and suggest restricting the later's size. Berger and Yang (1994) consider a reference prior approach for the AR(1) model. It is particularly interesting to note that Marriott and Newbold (1998) criticized the use of priors, such as the uniform or the Jeffreys prior, for the autoregressive coefficients in this context and advocate the use of sharp informative prior distributions. However, for the simple problem of testing for a unit root in a first-order autoregressive process, they find that the prior distribution for the autoregressive coefficient has a substantial impact on the posterior odds, so that, a very sharp beta prior performs extremely well when the generating process is stationary autoregressive, but the uniform prior is preferable when the true model is nonstationary. Marriott and Newbold (1998) explore the use of the ►beta distribution as a prior specification. They have explained how Bayesian calculations can be carried out, noting the importance of the analyst, giving careful thought to the question of what might be an appropriate prior.

Conclusions

Generally, authors agree with the idea that the Bayesian approach offers an alternative and a more useful way than the classical approach in empirical modeling. In unit root testing, Sims (1988), Sims and Uhlig (1991), and Koop (1992, 1994) have advocated the Bayesian approach over the classical ADF tests. In some papers, various opinions were expressed saying that the Bayesian solution is clear and simple when the classical approach is logically unsound. In a series of empirical applications, using a Bayesian approach, Dejong and Whiteman (1989, 1991a, b) obtained results rejecting the presence of a unit root in various economic series, which contradicted those of Nelson and Plosser (1982). Ahking (2004) studied the power of Koop's "objective" unit root test. In particular, he was interested in whether or not it provides a better alternative to the classical ADF unit root test, and whether or not the use of "objective" priors are appropriate. However, there is no evidence to suggest that the "objective" Bayesian test is better than the classical ADF tests in unit root tests. Moreover, the "objective" priors do not seem to be appropriate since they tend to produce results that are biased in favor of the trend stationary hypothesis. Thus, unfortunately, while there is a need for more objective analysis of Bayesian time series, Koop's "objective" Bayesian test does not appear to move us closer to that goal. So, one can ask, what is the best use in unit root tests, classical or Bayesian procedure? Intuitively,

it is very hazardous to discriminate between two competing economic theories on the basis of a univariate model. However, unit root tests may be helpful when they are used in a more complete modeling strategy as a protection against gross errors, as well as misspecification tests.

About the Author

Professor Fellag was Vice chancellor of Mouloud Mammeri University of Tizi-Ouzou, Algeria, in charge of international relations from 2005 until 2010. He is also a honorary professor of Rey Juan Carlos University of Madrid (Spain) in 2010. He is Director of the national Algerian doctoral school of statistics since 2007. Dr. Fellag has supervised more than 20 doctoral students in statistics and has published around 20 papers in international journals.

Bayesian Nonparametric Statistics

Jaeyong Lee
Associate Professor
Seoul National University, Seoul, Korea

Bayesian nonparametric statistics covers Bayesian analysis of nonparametric models, statistical models whose parameter space is not finite-dimensional, and allows more flexible modeling than the parameteric alternatives. Bayesian analysis of a statistical model consists of three ingredients: prior, model (or likelihood), and posterior. The prior $\pi(\theta)$ is a probability measure on the parameter space Θ that reflects the analyst's knowledge about the unknown parameter θ before he or she observes the data. The model describes the random mechanism by which the observation X is generated given the parameter θ, that is, $X|\theta \sim f(x|\theta)$. The posterior is the conditional distribution of θ given X, $\pi(\theta|X)$, which reflects the analyst's knowledge about θ after X is observed. The prior and posterior of nonparametric models are, thus, probability measures of infinite dimensional parameter spaces. Examples of such parameter spaces include the space of all probability measures on the real line, the space of all probability density functions on the real line, the space of all smooth functions, and many more.

The most widely used nonparametric prior is the Dirichlet process (Ferguson 1973), a probability measure on the space of all probability measures. Let $\mathcal{X}$ be a measurable space with a σ-field $\mathcal{A}$ and α be a nonnull finite measure on $\mathcal{X}$. A random probability measure P on $\mathcal{X}$ is said to follow a Dirichlet process with parameter α, denoted by $DP(\alpha)$, if for every measurable partition $(A_1, A_2, \ldots, A_k)$ of $\mathcal{X}$, $(P(A_1), P(A_2), \ldots, P(A_k))$ follows

(finite-dimensional) Dirichlet distribution with parameter $(\alpha(A_1), \alpha(A_2), \ldots, \alpha(A_k))$.

The Dirichlet process has many important properties that have theoretical and practical consequences. The class of Dirichlet processes is a conjugate prior class in the following sense. Suppose

$$P \sim DP(\alpha), \quad X_1, X_2, \ldots | P \sim P. \tag{1}$$

Then, the posterior P given $X_1, X_2, \ldots, X_n$ also follows Dirichlet process, that is, $P|X_1, \ldots, X_n \sim DP\left(\alpha + \sum_{i=1}^{n} \delta_{X_i}\right)$, where δ_x is a degenerate probability measure at x. Under model (1), the sequence $X_1, X_2, \ldots$ form, marginally, the Pölya urn sequence, that is, $X_1 \sim \alpha/\alpha(\mathcal{X})$ and for $n \geq 1$,

$$X_{n+1}|X_1, \ldots, X_n \sim \frac{\alpha + \sum_{i=1}^{n} \delta_{X_i}}{\alpha(\mathcal{X}) + n}. \tag{2}$$

This property is the key to the posterior computation of the mixtures of Dirichlet process models. Sethuraman (1994) derived an alternative constructive definition of the Dirichlet process. Suppose $Y_1, Y_2, \ldots$ are iid $\alpha/\alpha(\mathcal{X})$, $\theta_1, \theta_2 \ldots$ are iid $Beta(1, \alpha(\mathcal{X}))$ independently of $Y_i's$. Let

$$p_1 = \theta_1, \quad p_n = \theta_n \prod_{i=1}^{n-1} (1 - \theta_i), n \geq 2. \tag{3}$$

Then, $P = \sum_{i=1}^{\infty} p_i \delta_{Y_i} \sim DP(\alpha)$. This property shows P is discrete with probability 1 if $P \sim DP(\alpha)$, which was initially thought to be a shortcoming of the Dirichlet process.

To remedy the discreteness of the Dirichlet process, the mixtures of Dirichlet process model has been proposed, which turns out to be the most successful model with Dirichlet process. It has the following structure:

$$P \sim DP(\alpha)$$
$$X_1, X_2, \ldots, X_n | P \overset{iid}{\sim} \int h(x|\theta) dP(\theta),$$

where $h(x|\theta)$ is a probability density function with parameter θ, or equivalently,

$$P \sim DP(\alpha)$$
$$\theta_1, \theta_2, \ldots, \theta_n | P \overset{iid}{\sim} P$$
$$X_i | \theta_i \overset{ind}{\sim} h(x|\theta_i), \quad 1 \leq i \leq n.$$

The mixtures of Dirichlet processes have been used for different problems, for example, Bayesian density estimation, cluster analysis (see ►Cluster Analysis: An Introduction), etc. Especially, mixtures of Dirichlet processes have been successful in cluster analysis. Since the random probability measure P is discrete, the random sample θs from P naturally have ties, and clusters of Xs are based on ties in θs.

Since the Dirichlet process was proposed, many other nonparametric priors have appeared. Among them are neutral to the right process (Doksum 1974), Gaussian process (O'Hagan 1978), beta process (Hjort 1990; Lo 1993), Polya tree process (Lavine 1992), and species sampling model (Pitman 1996), all of which are priors for distribution except beta process and gaussian process. The beta process and gaussian process are priors for cumulative hazard function and regression function, respectively.

The posterior computation with nonparametric models can be complicated. There are algorithms specialized for specific priors (e.g., MacEachern 1994; MacEachern and Müller 1998; Lee 2007). Recently, DPpackage (Jara 2007), an R package that automates the posterior computation of some nonparametric models, has been built and lessens computational effort of practical users of nonparametric models.

Unlike parametric models, whose posteriors behave asymptotically optimal in the frequentist sense, nonparametric posteriors can behave suboptimally. Diaconis and Freedman (1986) have shown that even an innocent-looking prior may generate inconsistent posterior. This observation spurs the research effort to obtain conditions for posterior consistency, posterior convergence rate, and ►asymptotic normality of the posterior (Bernstein-von Mises theorem). There is now a large body of literature on the asymptotic issue of ►Bayesian statistics (e.g., Ghosal et al. 2000; Shen and Wasserman 2001; Kim and Lee 2001; Freedman 1999).

Bayesian P-Values

Jayanta K. Ghosh[1], Mohan Delampady[2]
[1]Professor of Statistics
Purdue University, West Lafayette, IN, USA
[2]Professor
Indian Statistical Institute, Bangalore, India

While Bayesians do not like classical ▶P-values and prefer measuring evidence in data through posterior probabilities of parameters or models, some problems like testing or exploration of goodness of fit of a single given model have led to the introduction of P-values. We confine ourselves to this particular context of goodness of fit in the brief discussion of Bayesian P-values. Most of this material is taken from Ghosh, Delampady and Samanta (2006) and Ghosh, Purkayastha and Samanta (2005).

Suppose that we have a single model M that specifies a density $f(x|\theta), \theta \in \Theta$ for the observable X and the Bayesian has a prior $\pi(\theta)$. The Bayesian wishes to examine how well the model M fits the data x_{obs} on the basis of a statistic $T(X)$ which measures the goodness of fit of data and model. Of course, T is also chosen by the Bayesian even though it is not part of the usual paradigm for Bayesian inference.

Let

$$m_\pi(x) = \int_\Theta f(x|\theta)\pi(\theta)\, d\theta$$

be the prior predictive density. Box (1980) defines

$$p = \int_{\{T(x)>T(x_{obs})\}} m_\pi(x)\, dx$$

as a prior predictive P-value. Of course, this depends on the prior π of the Bayesian.

To reduce the dependence on π and also to make it possible to use an improper non-informative prior π with proper posterior $\pi(\theta|x_{obs})$, Gutman (1967), Rubin (1984), Meng (1996) and Gelman et al. (1996) propose a posterior predictive P-value p^* defined as follows.

Let

$$m^*(x|x_{obs}) = \int_\Theta f(x|\theta)\pi(\theta|x_{obs})\, d\theta,$$

$$p^* = \int_{\{T(x)>T(x_{obs})\}} m^*(x|x_{obs})\, dx.$$

However, as pointed out by Bayarri and Berger (1998), p^* involves a double use of the data in both the integrand and the tail area of the integrand defining p^*. In order to remove this undesirable feature, Bayarri and Berger (1998) introduce what they call a conditional predictive P-value which is defined as follows.

Identify a statistic $U(X)$ which is not a function of $T(X)$ and let $m(t|u)$ be the conditional predictive density of T given U. Then the conditional predictive P-value is

$$p_c = \int_{\{T(x)>T(x_{obs})\}} m(t|u_{obs})\, dt.$$

Bayarri and Berger (1998) also define a partial posterior predictive P-value in the same vein. This alternative P-value does not require the choice of the auxiliary statistic U and to that extent is less arbitrary.

When the model is simple, meaning that the distribution of the random observable has no unknown parameters, then under this model, all these P-values reduce to the tail area probability under this distribution (which is exactly the classical P-value). In this case, the P-value treated as random (i.e., $p = p(X)$) has the $U(0,1)$ distribution, a desirable property as far as its interpretation is concerned. This property is desirable even when the model is composite and the nuisance parameters are eliminated

in some way. However, this is not always likely and what can be expected is that they be asymptotically uniformly distributed. Robins et al. (2000) argue that in the absence of the $U(0,1)$ property, one should at least require that these P-values not suffer from serious conservative or anti-conservative behavior; $p(X)$ is defined to be conservative (anti-conservative) when $P(p(X) < u)$ is smaller (larger) than u for all $u < 1/2$, with P denoting the distribution of X under (any θ from) the model.

Assuming certain regularity conditions on the model as well as the prior, Robins et al. (2000) prove that the conditional predictive and partial predictive P-values are asymptotically uniformly distributed, whereas the posterior predictive P-value is often conservative.

The different P-values are illustrated below with two examples from Bayarri and Berger (1998, 2000).

Example 1 Suppose $\mathbf{X} = (X_1, X_2, \ldots, X_n)$ is a random sample from some distribution, and we want to check if it is $N(\mu_0, \sigma^2)$, σ^2 unknown and μ_0 is a specified value for its mean. The natural discrepancy statistic is $T(\mathbf{X}) = (\bar{X} - \mu_0)$. Consider the usual non-informative prior $\pi(\sigma^2) \propto 1/\sigma^2$. Then the prior predictive P-value doesn't exist since this prior is improper. Let $s^2 = \sum_{i=1}^n (X_i - \bar{X})^2/n$. We obtain

$$\pi(\sigma^2|\mathbf{x}_{obs}) \propto (\sigma^2)^{-n/2-1} \exp\left(-n\left(s_{obs}^2 + t_{obs}^2\right)/(2\sigma^2)\right),$$

and thus the posterior predictive density of T is

$$m(t|\mathbf{x}_{obs}) \propto \left(1 + \frac{1}{n}\frac{nt^2}{s_{obs}^2 + t_{obs}^2}\right)^{-(n+1)/2}.$$

therefore the posterior predictive P-value is

$$p^* = 2\left\{1 - \mathcal{T}_n\left(\frac{\sqrt{n}t_{obs}}{\sqrt{s_{obs}^2 + t_{obs}^2}}\right)\right\},$$

with $\mathcal{T}_\nu$ denoting the c.d.f. of Student's t_ν.

Choose $U(X) \equiv s^2$, and note that $nU|\sigma^2 \sim \sigma^2\chi_{n-1}^2$. Therefore,

$$\pi(\sigma^2|U = s^2) \propto (\sigma^2)^{-(n-1)/2-1} \exp(-ns^2/(2\sigma^2)),$$

and consequently, the conditional predictive density of T given $U = s_{obs}^2$ is

$$\begin{aligned} m(t|s_{obs}^2) &= \int_0^\infty f_T(t|\sigma^2)\pi\left(\sigma^2|s_{obs}^2\right) d\sigma^2 \\ &\propto \int_0^\infty (\sigma^2)^{-1/2} \exp\left(-\frac{nt^2}{2\sigma^2}\right)(\sigma^2)^{-(n-1)/2} \\ &\quad \exp\left(-\frac{n}{2\sigma^2}s_{obs}^2\right)\frac{d\sigma^2}{\sigma^2} \\ &\propto \int_0^\infty \exp\left(-nv\left\{s_{obs}^2 + t^2\right\}\right) v^{n/2}\frac{dv}{v} \\ &\propto \left(1 + \frac{1}{n-1}\frac{(n-1)t^2}{s_{obs}^2}\right)^{-n/2}. \end{aligned}$$

This implies, under the conditional predictive distribution,

$$\sqrt{n-1}\frac{T}{s_{obs}} \sim t_{n-1}.$$

The conditional predictive P-value, therefore, is

$$p_c = 2\left\{1 - \mathcal{T}_{n-1}\left(\frac{\sqrt{n-1}t_{obs}}{s_{obs}}\right)\right\}.$$

Bayarri and Berger (1998, 2000) show that in this example the partial predictive P-value and the conditional predictive P-value coincide.

Listed in Table 1 are values of p^*, $t_{obs} = \sqrt{n-1}(\bar{x}_{obs} - \mu_0)/s_{obs}$ and $t^* = \sqrt{n/(n-1)}t_{obs}/\sqrt{1 + t_{obs}^2/(n-1)}$ corresponding to different values of n when p_c is fixed at 0.01, 0.05 and 0.10, respectively.

Example 2 Suppose, as in the previous example, X_1, $X_2, \ldots, X_n$ is a random sample from some population. The target model now is Exponential(λ). Consider $\pi(\lambda) \propto 1/\lambda$. Let $T = X_{(1)}$ be the model checking statistic and let $S = \sum_{i=1}^n X_i$. The posterior density of λ given $S = s_{obs}$ is proportional to $\lambda^{n-1}\exp(-s_{obs}\lambda)$ so that the posterior predictive density of T given $S = s_{obs}$ is

$$n^2 s_{obs}^n (nt + s_{obs})^{-(n+1)}.$$

Bayesian P-Values. Table 1 P-values: p^* versus p_c for the normal model

		n						
		2	3	5	10	20	50	100
$p_c = 0.01$	t_{obs}	63.66	9.92	4.60	3.25	2.86	2.68	2.63
$p_c = 0.01$	t^*	1.414	1.715	2.051	2.324	2.454	2.528	2.552
$p_c = 0.01$	p^*	0.293	0.185	0.096	0.042	0.023	0.015	0.012
$p_c = 0.05$	t_{obs}	12.71	4.30	2.78	2.26	2.09	2.01	1.98
$p_c = 0.05$	t^*	1.410	1.645	1.814	1.904	1.936	1.951	1.956
$p_c = 0.05$	p^*	0.293	0.198	0.129	0.086	0.067	0.057	0.053
$p_c = 0.10$	t_{obs}	6.31	2.92	2.13	1.83	1.73	1.68	1.66
$p_c = 0.10$	t^*	1.397	1.559	1.631	1.649	1.649	1.647	1.646
$p_c = 0.10$	p^*	0.297	0.217	0.164	0.130	0.115	0.106	0.103

Bayesian P-Values. Table 2 P-values: p^* versus p_c for the exponential model

		n				
		2	3	5	10	20
$t^* = 1.00$	p_c	0	0	0	0	0
$t^* = 1.00$	p^*	0.25	0.125	0.031	0	0
$t^* = 0.75$	p_c	0.25	0.063	0.004	0	0
$t^* = 0.75$	p^*	0.327	0.187	0.061	0.004	0
$t^* = 0.60$	p_c	0.4	0.16	0.026	0	0
$t^* = 0.60$	p^*	0.391	0.244	0.095	0.009	0
$t^* = 0.50$	p_c	0.5	0.25	0.063	0.002	0
$t^* = 0.50$	p^*	0.444	0.296	0.132	0.017	0
$t^* = 0.40$	p_c	0.6	0.36	0.13	0.01	0
$t^* = 0.40$	p^*	0.51	0.364	0.186	0.035	0.001
$t^* = 0.25$	p_c	0.75	0.563	0.316	0.075	0.004
$t^* = 0.25$	p^*	0.64	0.512	0.328	0.107	0.012

This yields the posterior predictive P-value of

$$p^* = \left(1 + \frac{nt_{obs}}{s_{obs}}\right)^{-n}.$$

A direct calculation gives

$$f(\mathbf{x}|T = t, \lambda) \propto \lambda^{n-1} \exp(-\lambda(s - nt)),$$

from which the partial posterior density for λ is seen to be

$$\frac{\lambda^{n-2} \exp(-\lambda(s_{obs} - nt_{obs}))}{\Gamma(n-1)(s_{obs} - nt_{obs})^{-(n-1)}};$$

This is called partial posterior because it is obtained from the partial likelihood, $f(\mathbf{x}_{obs}|T = t_{obs}, \lambda)$ instead of the full likelihood $f(\mathbf{x}_{obs}|\lambda)$. Then the partial posterior predictive density of T is obtained as

$$\frac{n(n-1)(s_{obs} - nt_{obs})^{n-1}}{(nt + s_{obs} - nt_{obs})^n}.$$

This leads to the following expression for the partial posterior predictive P-value:

$$\left(1 - \frac{nt_{obs}}{s_{obs}}\right)^{n-1}.$$

Bayarri and Berger (2000) go on to show that this coincides with the conditional predictive P-value p_c upon taking the conditioning (auxiliary) statistic to be the MLE of λ from $f(\mathbf{x}|T = t, \lambda)$ (which is given by $(n-1)/(S-nT)$.

In Table 2, values of p^* and p_c corresponding to some values of $t^* = nt_{obs}/s_{obs}$ and n are displayed.

About the Authors

Dr Jayanta Kumar Ghosh (born May 22, 1937) is Professor of Statistics, Department of Statistics, Purdue University. He graduated from the University of Calcutta. He has spent a substantial part of his career in the Indian Statistical Institute, Calcutta. He served as the Director of ISI and later held the Jawaharlal Nehru Professorship. "Professor Jayanta Kumar Ghosh, or J. K. Ghosh, as he is commonly known, has been a prominent contributor to the discipline of statistics for five decades. The spectrum of his contributions encompasses sequential analysis, the foundations of statistics, Finite populations, Edgeworth expansions, second order efficiency, Bartlett corrections, noninformative, and especially matching priors, semiparametric inference, posterior limit theorems, Bayesian non-parametrics, model selection, Bayesian hypothesis testing and high dimensional data analysis, as well as some applied work in reliability theory, statistical quality control, modeling hydrocarbon discoveries, geological mapping and DNA Fingerprinting." [B. Clarke and S. Ghosal (2008). J. K. Ghosh's contribution to statistics: A brief outline, In: *Pushing the Limits of Contemporary Statistics: Contributions in Honor of Jayanta K. Ghosh*, IMS Collections, Institute of Mathematical Statistics, Beachwood, Ohio (3), p. 1.] He has (co-)authored over 150 papers and several books, including: *Higher Order Asymptotics* (published jointly by Institute of Mathematical Statistics and American Statistical Association, 1994), *Bayesian Nonparametrics* (with R.V. Ramamoorthi, Springer, 2003), and *An Introduction to Bayesian Analysis, Theory and Methods* (with M. Delampady and T. Samanta, Springer, 2006). He has supervised more than 30 PhD students. He was awarded the Shanti Swarup Bhatnagar Award for Mathematical Science (1981), Mahalanobis Gold Medal of Indian Science Congress Association (1998) and P.V. Sukhatme Prize for Statistics (2000). Professor Jayanta Ghosh is a Fellow of the Indian Academy of Sciences, Fellow of the Indian National Science Academy, and Vice-President of the Calcutta Statistical Association. He is Past President, International Statistical Institute (1993).

Mohan Delampady is Professor, Theoretical Statistics and Mathematics Division, Indian Statistical Institute, Bangalore. He was awarded the Professor L.J. Savage prize for excellence in research towards a Ph.D. thesis in Bayesian econometrics and statistics by NBER and NSF in 1987.

Bayesian Reliability Modeling

Renkuan Guo
Professor
University of Cape Town, Cape Town, South Africa

Bayesian reliability modeling is an application of rigorous Bayesian statistical inference theory, one of the frontiers of modern statistics. It is particularly useful in the context of the scarcity of system failure (or quality index) data. Bayesian decision theory can guide reliability engineers to utilize both "soft" and "hard" evidence relevant to the reliability index under investigation. Soft evidence includes expert knowledge, design and performance of similar products, and their mathematical treatment, etc. In contrast, hard evidence includes the direct failure (or quality testing) data, any other transformable evidence having functional relationship with failure rate, such as test data from proving ground sources, factors in a product operating environment and any partially relevant evidence, say, warranty data, customer research surveys, etc.

The basic form of Bayesian reliability modeling can be illustrated by following formulation and example. When evidence of system performance denoted by $\underline{x}$, is scarce, a reliability (or quality) index of the system, denoted by $s\,(0 \le s \le 1)$, we may use the soft evidence on s in the form of a prior density $\rho(s)$ in terms of ►Bayes' theorem to calculate the posterior density of s,

$$f(s|\underline{x}) = \frac{l(s|\underline{x})\rho(s)}{\int_0^1 l(s|\underline{x})\rho(s)ds}. \tag{1}$$

where $l(s|\underline{x}) \triangleq f(\underline{x}|s)$ is called the likelihood function, obtained from the joint density of the sample evidence $\underline{x}$.

For example, N electronic devices are under testing until a preset time T, by assuming that the failure time of a random individual device follows an exponential distribution with the density:

$$f(t|\lambda) = \lambda e^{-\lambda t}, t \ge 0, \lambda > 0. \tag{2}$$

Suppose that in testing period $[0, T]$, x units failed and the failure times are recorded as $t_1, t_2, \cdots, t_x$, thus the sample evidence as $\underline{t} = (t_1, t_2, \cdots, t_x, T, T, \cdots, T)$, and the likelihood function is then given by

$$l(\lambda|\underline{t}) = \left[\prod_{i=1}^{x}\left(\lambda e^{-\lambda t_i}\right)\right]\left[1-\left(1-e^{-\lambda T}\right)\right]^{n-x} = \lambda^x e^{-\lambda\eta}, \tag{3}$$

where $\eta = (n-x)\,T + \sum_{i=1}^{x} t_i$. Then a gamma prior density on the failure rate λ, with priori parameters α and β, may represent the expert knowledge:

$$\rho(\lambda) = \frac{\beta^\alpha}{\Gamma(\alpha)}\lambda^{\beta-1}e^{-\alpha\lambda}, \lambda > 0, \alpha \ge 0, \beta \ge 0. \tag{4}$$

The posterior density of the failure rate λ is evaluated in terms of Eq. 1:

$$f(\lambda|\underline{x}) = \frac{l(\lambda|\underline{x})\rho(\lambda)}{\int_0^1 l(\lambda|\underline{x})\rho(\lambda)d\lambda} = \frac{(\alpha+\eta)^{\beta+x}}{\Gamma(\alpha+x)}\lambda^{\beta+x+1}e^{-(\alpha+\eta)\lambda}, \tag{5}$$

which is also a gamma density because the prior density takes the form of the conjugate family. Further analysis or inference will be based on the posterior density.

It is necessary to emphasize that in reliability engineering reality, the formations and applications of Bayesian reliability modeling are far more complicated and diversified than that shown as the basic form in Eq. 1 because the concrete formation of an individual reliability problem is heavily dependent upon the compositional form of Bayesian decision criterion engaged, the form of distribution of

quality index and hence the form of the likelihood function, which is inevitably linked to a host of factors which may have serious impacts. The factors include any sample censoring mechanism, the form of prior and the design or physical structure of the system under study, the manner of collecting evidence (e.g., sequential or otherwise) and even research progress of the relevant mathematical branches.

For example, Dai et al. (2007), demonstrated that graph theory related fault tree analysis is a common classical reliability analysis model, while the Bayesian counterpart, Bayesian networks (abbreviated as BN), is just a combination of fault trees and appropriate arrangement of conditional probability and on probability assessments which can combine the soft and hard evidence under a Bayesian risk criterion. Bayesian networks can model the complicated physical structure as well as failure dependence structures of a complex system and predict the system failure behavior. A dynamic version of BN (DBN) was also developed for large system reliability modeling.

Artificial ▶Neural Networks form a powerful regression modeling tool, permitting a non-linear analysis. Combination of a Bayesian theoretical frame and Standard Neural Networks structure creates the Bayesian Neural Networks (abbreviated as BNNs), which allow active Bayesian reliability modeling for complex systems with complicated sample evidence. Mathematically, BNNs are nothing but probabilistic networks. For details, see Waszczyszyn et al. (2008). Markov chain Monte Carlo (abbreviated as MCMC) simulation (see ▶Markov Chain Monte Carlo) is another frontier of modern computational statistics. Merging of BNN and MCMC has created an extremely powerful but convenient computational reliability engineering model type.

It is well-known that the conventional Bayesian risk criterion is based on quadratic loss function and use of a conjugate family. Maximum Entropy modeling is an important Bayesian inference. The reliability engineering community has made efforts in this direction. However, Maximum entropy (abbreviated as Maxent) modeling software development and application in environmental context may improve from attention to Bayesian reliability modeling efforts. See Phillips et al. (2006).

Therefore, Bayesian reliability modeling is widely applied in business and industries, particularly in complex systems, nano-electronics and software industry, say, accelerating life testing models, reliability growth models, testing models for new product design, etc. See Blischke and Murthy (2000), Kuo (2006), and Garg et al. (2007).

As we pointed out at the beginning, Bayesian reliability modeling is a small-sample inference in its mathematical nature. Hence there is no reason to ignore the other developments in small-sample inference. It will be beneficial to combine some elements in small-sample inference with developments in the Bayesian reliability modeling. Jin et al. (2009) illustrated how to use a "grey differential equation" approach to improve BNNs in software reliability modeling, although the "grey" concept is not yet well-accepted in mathematical and statistical societies. Guo et al. (2009) proposed a differential equation associated regression (abbreviated as DEAR) model, which is small-sample based inference with a rigorous mathematical foundations and resolves the problem in "grey differential equations."

Ushakov and Harrison (1994) offered a systematic treatment in Chap. 16. Singpurwalla's book (2006) is authoritative in Bayesian reliability modeling, and reflects the author's state-of-art modeling experiences and judgments.

About the Author

Dr Renkuan Guo is a Professor in the Department of Statistical Sciences, University of Cape Town, South Africa. He served as Regional Editor for *Economic Quality Control*. His research work and publications (159 papers and four book chapters) can be divided into three aspects: (1) from 1990 to 2000, he focused on reliability modeling, including Cox PH models, and Kijima age models; (2) from 2001 to 2008, he concentrated on fuzzy reliability and quality modeling, including credibilistic fuzzy reliability models, grey differential equation models, random fuzzy models, particularly, the DEAR (Differential Equation Associated Regression) models; (3) from 2009 up to now, he starts initiating the uncertainty statistics on Professor Baoding Liu's axiomatic uncertain measure foundation, including uncertain Bayesian decision model, uncertain reliability models and hybrid reliability models with uncertain parameter.

Bayesian Semiparametric Regression

Ludwig Fahrmeir
Professor
Ludwig-Maximilians-University, Munich, Germany

Linear or ►generalized linear models assume that the (conditional) mean $\mu = E(y|\mathbf{x})$, of the response y, given the covariate vector $\mathbf{x}$, is linked to a linear predictor μ by

$$\mu = h(\eta), \quad \eta = \mathbf{x}'\boldsymbol{\beta}.$$

Here, h is a known response function and $\boldsymbol{\beta}$ is an unknown vector of regression parameters. More generally, other characteristics of the response distribution, such as ►variance or ►skewness may be related to covariates in similar manner. Another example is the Cox model for ►survival data, where the hazard rate is assumed to have the form

$$\lambda(t|\mathbf{x}) = \lambda_0(t)\exp(\mathbf{x}'\boldsymbol{\beta})$$

with $\lambda_0(t)$ as an (unspecified) baseline hazard rate. In most practical regression situations, however, we are facing at least one of the following problems.

(a) For the continuous covariates in the data set, the assumption of a strictly linear effect on the predictor may not be appropriate.
(b) Observations may be spatially correlated.
(c) Heterogeneity among individuals or units may be insufficiently described by covariates. Hence, unobserved unit- or cluster specific heterogeneity must be considered appropriately.
(d) Interactions between covariates may be of complex, nonlinear form.

►Semiparametric regression models extend models with linear predictors by incorporating additional non- and semiparametric components. Bayesian semiparametric regression regularizes the resulting high-dimensional inferential problem by imposing appropriate priors.

Observation Models

We consider some semiparametric regression models that may be considered as special classes of structured additive regression (STAR) models (Fahrmeir et al. 2004). Generalized additive models (GAMs) extend the linear predictor of GLMs to

$$\eta_i = x_i'\beta + f_1(z_1) + \ldots + f_p(z_{ip}), \quad i = 1, \ldots, n \qquad (1)$$

where f_j are smooth functions of continuous covariates $z_1, \ldots, z_p$. Most semiparametric regression approaches assume that unknown functions are represented or approximated through a linear combination of basis functions, i.e.,

$$f(z) = \sum_{k=1}^{K} \gamma_k B_k(z)$$

for a typical function f. The most popular basis function representations are spline functions, with truncated power series or B-spline basis functions $B_k(z)$, a relatively large number of knots, and a correspondingly high-dimensional vector $\boldsymbol{\gamma}$ of basis function coefficients $\gamma_1, ..., \gamma_K$.

Collecting all predictors η_i in the predictor vector $\boldsymbol{\eta}$, and constructing appropriate design matrix, the predictor (1) can be rewritten in matrix notation as a high-dimensional linear predictor

$$\boldsymbol{\eta} = \mathbf{X}\boldsymbol{\beta} + \mathbf{Z}_1\boldsymbol{\gamma}_1 + \ldots + \mathbf{Z}_p\boldsymbol{\gamma}_p. \qquad (2)$$

GAMs can be extended by additively incorporating e.g., interaction terms $f_{1|2}(z_1, z_2)$ of two continuous covariates, varying coefficient terms $g(z)x$, where the effect of x varies with z, a spatial effect $f_{\text{spat}}(s)$ where s denotes spatial location and individual – or group specific i.i.d. random effects $\boldsymbol{\alpha}_g$, $g = 1, \ldots, G$. Combining these different types of effects in additive form leads to STAR models with generalized additive mixed models (GAMMs), varying coefficient models and geoadditive models as important subclasses. The Cox model can be extended in quite similar fashion, see Hennerfeind et al. (2006) and Kneib and Fahrmeir (2006). It turns out that after appropriate definition of

design matrices and coefficient vectors, the predictor still is of additive structure as in (2).

Priors and Inference

For Bayesian inference, flat priors $p(\beta) \propto const$ or weakly informative Gaussian priors are usually assumed for linear effects. In a Gaussian smoothness prior approach, it turns out that all priors for parameters γ_j representing smooth functions, Gaussian Markov random fields for spatial effects, i.i.d. random effects, etc., have the same generic conditionally Gaussian form

$$p\left(\boldsymbol{\gamma}_j|\tau_j^2\right) \propto \exp\left(-\frac{1}{2\tau_j^2}\boldsymbol{\gamma}_j'\mathbf{K}_j\boldsymbol{\gamma}_j\right). \tag{3}$$

The precision matrix $\mathbf{K}_j$ depends on the specific effect and acts as a penalty matrix to enforce smoothness, and τ_j^2 is an inverse smoothing parameter, controlling the amount of smoothness. In full Bayesian inference, a hyperprior is assigned to τ_j^2, and regression and smoothness parameters are estimated jointly through MCMC techniques (Brezger and Lang 2006). Another possibility is to look at (2) and (3) as a mixed model with correlated random effects, enabling empirical Bayes inference with mixed model technology, see Fahrmeir et al. (2004) and Ruppert et al. (2003). A recent review on (Bayesian) semiparametric regression is Ruppert et al. (2009). A forthcoming book (Fahrmeir and Kneib 2010) provides details on all issues. Approximate full Bayesian inference avoiding MCMC has been recently proposed by Rue et al. (2009).

A somewhat different approach to Bayesian inference in semiparametric regression is based on adaptive selection of knots of *B*-splines or coefficients of basis functions through concepts of Bayesian variable selection, see for example the book by Denison et al. (2002) or Smith et al. (2000), Kohn et al. (2001).

Bayesian Statistics

José M. Bernardo
Professor of Statistics, Facultad de Matemáticas
Universitat de València, Burjassot, Spain

Introduction

Available observations generally consist of (possibly many) sets of data of the general form $D = \{\boldsymbol{x}_1, \ldots, \boldsymbol{x}_n\}$, where the $\boldsymbol{x}_i$'s are somewhat "homogeneous" (possibly multidimensional) observations $\boldsymbol{x}_i$. Statistical methods are then typically used to derive conclusions on both the nature of the process which has produced those observations, and on the expected behavior at future instances of the same process. A central element of *any* statistical analysis is the specification of a *probability model* which is assumed to describe

the mechanism which has generated the observed data D as a function of a (possibly multidimensional) parameter (vector) $\boldsymbol{\omega} \in \boldsymbol{\Omega}$, sometimes referred to as the *state of nature*, about whose value only limited information (if any) is available. All derived statistical conclusions are obviously conditional on the assumed probability model.

Unlike most other branches of mathematics, conventional methods of statistical inference suffer from the lack of an axiomatic basis; as a consequence, their proposed desiderata are often mutually incompatible, and the analysis of the same data may well lead to incompatible results when different, apparently intuitive procedures are tried (see Lindley (1970) and Jaynes (1976) for many instructive examples). In marked contrast, the Bayesian approach to statistical inference is firmly based on axiomatic foundations which provide a unifying logical structure, and guarantee the mutual consistency of the methods proposed. Bayesian methods constitute a *complete* paradigm to statistical inference, a scientific revolution in Kuhn's sense.

Bayesian statistics only require the *mathematics* of probability theory and the *interpretation* of probability which most closely corresponds to the standard use of this word in everyday language: it is no accident that some of the more important seminal books on Bayesian statistics, such as the works of Laplace (1812), Jeffreys (1961) or de Finetti (1970) are actually entitled "Probability Theory." The practical consequences of adopting the Bayesian paradigm are far reaching. Indeed, Bayesian methods (1) reduce statistical inference to problems in probability theory, thereby minimizing the need for completely new concepts, and (2) serve to discriminate among conventional statistical techniques, by either providing a logical justification to some (and making explicit the conditions under which they are valid), or proving the logical inconsistency of others.

The main consequence of these foundations is the mathematical *need* to describe by means of probability distributions all uncertainties present in the problem. In particular, unknown parameters in probability models *must* have a joint probability distribution which describes the available information about their values; this is often regarded as *the* characteristic element of a Bayesian approach. Notice that (in sharp contrast to conventional statistics) *parameters are treated as random variables* within the Bayesian paradigm. This is not a description of their variability (parameters are typically *fixed unknown* quantities) but a description of the *uncertainty* about their true values.

An important particular case arises when either no relevant prior information is readily available, or that information is subjective and an "objective" analysis is desired, one that is exclusively based on accepted model assumptions and well-documented data. This is addressed by *reference analysis*, which uses information-theoretic concepts to derive appropriate reference posterior distributions, defined to encapsulate inferential conclusions on the quantities of interest solely based on the supposed model and the observed data.

In this article it is assumed that probability distributions may be described through their probability density functions, and no distinction is made between a random quantity and the particular values that it may take. Bold italic roman fonts are used for *observable* random vectors (typically data) and bold italic greek fonts are used for unobservable random vectors (typically parameters); lower case is used for variables and upper case for their dominion sets. Moreover, the standard mathematical convention of referring to *functions*, say f and g of $\boldsymbol{x} \in \boldsymbol{\chi}$, respectively by $f(\boldsymbol{x})$ and $g(\boldsymbol{x})$, will be used throughout. Thus, $p(\boldsymbol{\theta} \mid C)$ and $p(\boldsymbol{x} \mid C)$ respectively represent general *probability densities* of the random vectors $\boldsymbol{\theta} \in \boldsymbol{\Theta}$ and $\boldsymbol{x} \in \boldsymbol{\chi}$ under conditions C, so that $p(\boldsymbol{\theta} \mid C) \geq 0$, $\int_{\boldsymbol{\Theta}} p(\boldsymbol{\theta} \mid C)\, d\boldsymbol{\theta} = 1$, and $p(\boldsymbol{x} \mid C) \geq 0$, $\int_{\boldsymbol{\chi}} p(\boldsymbol{x} \mid C)\, d\boldsymbol{x} = 1$. This admittedly imprecise notation will greatly simplify the exposition. If the random vectors are discrete, these functions naturally become probability mass functions, and integrals over their values become sums.

Density functions of specific distributions are denoted by appropriate names. Thus, if x is a random quantity with a normal distribution of mean μ and standard deviation σ, its probability density function will be denoted $\mathrm{N}(x \mid \mu, \sigma)$.

Bayesian methods make frequent use of the concept of logarithmic divergence, a very general measure of the goodness of the approximation of a probability density $p(\boldsymbol{x})$ by another density $\hat{p}(\boldsymbol{x})$. The Kullback-Leibler, or *logarithmic divergence* of a probability density $\hat{p}(\boldsymbol{x})$ of the random vector $\boldsymbol{x} \in \boldsymbol{\chi}$ from its true probability density $p(\boldsymbol{x})$, is defined as $\delta\{\hat{p}(\boldsymbol{x}) \mid p(\boldsymbol{x})\} = \int_{\boldsymbol{\chi}} p(\boldsymbol{x}) \log\{p(\boldsymbol{x})/\hat{p}(\boldsymbol{x})\}\, d\boldsymbol{x}$. It may be shown that (1) the logarithmic divergence is non-negative (and it is zero if, and only if, $\hat{p}(\boldsymbol{x}) = p(\boldsymbol{x})$ almost everywhere), and (2) that $\delta\{\hat{p}(\boldsymbol{x}) \mid p(\boldsymbol{x})\}$ is invariant under one-to-one transformations of $\boldsymbol{x}$.

This article contains a brief summary of the mathematical foundations of Bayesian statistical methods (section "►Foundations"), an overview of the paradigm (section "►The Bayesian Paradigm"), a description of useful inference summaries, including both point an region estimation and hypothesis testing (section "►Inference Summaries"), an explicit discussion of objective Bayesian methods (section "►Reference Analysis"), and a final

discussion which includes pointers to further issues not addressed here (section "►Discussion").

Foundations

A central element of the Bayesian paradigm is the use of probability distributions to describe all relevant unknown quantities, interpreting the probability of an event as a conditional measure of uncertainty, on a $[0,1]$ scale, about the occurrence of the event in some specific conditions. The limiting extreme values 0 and 1, which are typically inaccessible in applications, respectively describe impossibility and certainty of the occurrence of the event. This interpretation of probability includes and extends all other probability interpretations. There are two independent arguments which prove the mathematical inevitability of the use of probability distributions to describe uncertainties; these are summarized later in this section.

Probability as a Measure of Conditional Uncertainty

Bayesian statistics uses the word *probability* in precisely the same sense in which this word is used in everyday language, as a *conditional measure of uncertainty* associated with the occurrence of a particular event, given the available information and the accepted assumptions. Thus, $\Pr(E \mid C)$ is a measure of (presumably rational) belief in the occurrence of the *event* E under *conditions* C. It is important to stress that probability is *always* a function of two arguments, the event E whose uncertainty is being measured, and the conditions C under which the measurement takes place; "absolute" probabilities do not exist. In typical applications, one is interested in the probability of some event E given the available *data* D, the set of *assumptions* A which one is prepared to make about the mechanism which has generated the data, and the relevant contextual *knowledge* K which might be available. Thus, $\Pr(E \mid D, A, K)$ is to be interpreted as a measure of (presumably rational) belief in the occurrence of the *event* E, given data D, assumptions A and any other available knowledge K, as a measure of how "likely" is the occurrence of E in these conditions. Sometimes, but certainly not always, the probability of an event under given conditions may be associated with the relative frequency of "similar" events in "similar" conditions. The following examples are intended to illustrate the use of probability as a conditional measure of uncertainty.

Probabilistic diagnosis. A human population is known to contain 0.2% of people infected by a particular virus. A person, *randomly selected* from that population, is subject to a test which, from laboratory data, is known to yield positive results in 98% of infected people and in 1% of non-infected, so that, if V denotes the event that a person carries the virus and + denotes a positive result, $\Pr(+ \mid V) = 0.98$ and $\Pr(+ \mid \overline{V}) = 0.01$. Suppose that the result of the test turns out to be positive. Clearly, one is then interested in $\Pr(V \mid +, A, K)$, the *probability* that the person carries the virus, given the positive result, the assumptions A about the probability mechanism generating the test results, and the available knowledge K of the prevalence of the infection in the population under study (described here by $\Pr(V \mid K) = 0.002$). An elementary exercise in probability algebra, which involves ►Bayes' theorem in its simplest form (see section "►The Bayesian Paradigm"), yields $\Pr(V \mid +, A, K) = 0.164$. Notice that the four probabilities involved in the problem have *the same interpretation*: they are all conditional measures of uncertainty. Besides, $\Pr(V \mid +, A, K)$ is *both* a measure of the uncertainty associated with the event that the particular person who tested positive is actually infected, *and* an *estimate* of the proportion of people in that population (about 16.4%) that would eventually prove to be infected among those which yielded a positive test.

Estimation of a proportion. A survey is conducted to estimate the proportion θ of individuals in a population who share a given property. A random sample of n elements is analyzed, r of which are found to possess that property. One is then typically interested in using the results from the sample to establish regions of $[0,1]$ where the unknown value of θ may plausibly be expected to lie; this information is provided by *probabilities* of the form $\Pr(a < \theta < b \mid r, n, A, K)$, a conditional measure of the uncertainty about the event that θ belongs to (a, b) *given* the information provided by the data (r, n), the assumptions A made on the behavior of the mechanism which has generated the data (a random sample of n Bernoulli trials), and any relevant knowledge K on the values of θ which might be available. For example, after a political survey in which 720 citizens out of a random sample of 1500 have declared their support to a particular political measure, one may conclude that $\Pr(\theta < 0.5 \mid 720, 1,500, A, K) = 0.933$, indicating a probability of about 93% that a referendum of that issue would be lost. Similarly, after a screening test for an infection where 100 people have been tested, none of which has turned out to be infected, one may conclude that $\Pr(\theta < 0.01 \mid 0, 100, A, K) = 0.844$, or a probability of about 84% that the proportion of infected people is smaller than 1%.

Measurement of a physical constant. A team of scientists, intending to establish the unknown value of a physical constant μ, obtain data $D = \{x_1, \ldots, x_n\}$ which are considered to be measurements of μ subject to error. The probabilities of interest are then typically of the form

$\Pr(a < \mu < b \,|\, x_1, \ldots, x_n, A, K)$, the *probability* that the unknown value of μ (fixed in nature, but unknown to the scientists) lies within an interval (a, b) given the information provided by the data D, the assumptions A made on the behavior of the measurement mechanism, and whatever knowledge K might be available on the value of the constant μ. Again, those probabilities are conditional measures of uncertainty which describe the (necessarily probabilistic) conclusions of the scientists on the true value of μ, given available information and accepted assumptions. For example, after a classroom experiment to measure the gravitational field with a pendulum, a student may report (in m/sec^2) something like $\Pr(9.788 < g < 9.829 \,|\, D, A, K) = 0.95$, meaning that, under accepted knowledge K and assumptions A, the *observed* data D indicate that the true value of g lies within 9.788 and 9.829 with probability 0.95, a conditional uncertainty measure on a [0,1] scale. This is naturally compatible with the fact that the value of the gravitational field at the laboratory may well be known with high precision from available literature or from precise previous experiments, but the student may have been instructed *not* to use that information as part of the accepted knowledge K. Under some conditions, it is also true that if the same *procedure* were actually used by many other students with similarly obtained data sets, their reported intervals would actually cover the true value of g in approximately 95% of the cases, thus providing some form of *calibration* for the student's probability statement (see section "►Frequentist Properties").

Prediction. An experiment is made to count the number r of times that an event E takes place in each of n replications of a well defined situation; it is observed that E does take place r_i times in replication i, and it is desired to forecast the number of times r that E will take place in a future, similar situation. This is a *prediction* problem on the value of an *observable* (discrete) quantity r, given the information provided by data D, accepted assumptions A on the probability mechanism which generates the r_i's, and any relevant available knowledge K. Hence, simply the computation of the probabilities $\{\Pr(r \,|\, r_1, \ldots, r_n, A, K)\}$, for $r = 0, 1, \ldots$, is required. For example, the quality assurance engineer of a firm which produces automobile restraint systems may report something like $\Pr(r = 0 \,|\, r_1 = \ldots = r_{10} = 0, A, K) = 0.953$, after observing that the entire production of airbags in each of $n = 10$ consecutive months has yielded no complaints from their clients. This should be regarded as a measure, on a $[0, 1]$ scale, of the conditional uncertainty, given observed data, accepted assumptions and contextual knowledge, associated with the event that no airbag complaint will come from next month's production and, if conditions remain constant, this is also an estimate of the proportion of months expected to share this desirable property.

A similar problem may naturally be posed with continuous observables. For instance, after measuring some continuous magnitude in each of n randomly chosen elements within a population, it may be desired to forecast the proportion of items in the whole population whose magnitude satisfies some precise specifications. As an example, after measuring the breaking strengths $\{x_1, \ldots, x_{10}\}$ of ten randomly chosen safety belt webbings to verify whether or not they satisfy the requirement of remaining above 26 kN, the quality assurance engineer may report something like $\Pr(x > 26 \,|\, x_1, \ldots, x_{10}, A, K) = 0.9987$. This should be regarded as a measure, on a $[0, 1]$ scale, of the conditional uncertainty (given observed data, accepted assumptions and contextual knowledge) associated with the event that a randomly chosen safety belt webbing will support no less than 26 kN. If production conditions remain constant, it will also be an estimate of the proportion of safety belts which will conform to this particular specification.

Often, additional information of future observations is provided by related covariates. For instance, after observing the outputs $\{\boldsymbol{y}_1, \ldots, \boldsymbol{y}_n\}$ which correspond to a sequence $\{\boldsymbol{x}_1, \ldots, \boldsymbol{x}_n\}$ of different production conditions, it may be desired to forecast the output $\boldsymbol{y}$ which would correspond to a particular set $\boldsymbol{x}$ of production conditions. For instance, the viscosity of commercial condensed milk is required to be within specified values a and b; after measuring the viscosities $\{y_1, \ldots, y_n\}$ which correspond to samples of condensed milk produced under different physical conditions $\{\boldsymbol{x}_1, \ldots, \boldsymbol{x}_n\}$, production engineers will require probabilities of the form $\Pr(a < y < b \,|\, \boldsymbol{x}, (y_1, \boldsymbol{x}_1), \ldots, (y_n, \boldsymbol{x}_n), A, K)$. This is a conditional measure of the uncertainty (always given observed data, accepted assumptions and contextual knowledge) associated with the event that condensed milk produced under conditions $\boldsymbol{x}$ will actually satisfy the required viscosity specifications.

Statistical Inference and Decision Theory

Decision theory not only provides a precise methodology to deal with decision problems under uncertainty, but its solid axiomatic basis also provides a powerful reinforcement to the logical power of the Bayesian approach. We now summarize the basic argument.

A decision problem exists whenever there are two or more possible courses of action; let $\mathcal{A}$ be the class of possible actions. Moreover, for each $a \in \mathcal{A}$, let $\boldsymbol{\Theta}_a$ be the set of *relevant events* which may affect the result of choosing a, and let $c(a, \boldsymbol{\theta}) \in \mathcal{C}_a$, $\boldsymbol{\theta} \in \boldsymbol{\Theta}_a$, be the *consequence* of having chosen action a when event $\boldsymbol{\theta}$ takes place. The class of

pairs $\{(\Theta_a, \mathcal{C}_a), a \in \mathcal{A}\}$ describes the *structure* of the decision problem. Without loss of generality, it may be assumed that the possible actions are mutually exclusive, for otherwise one would work with the appropriate Cartesian product.

Different sets of principles have been proposed to capture a minimum collection of logical rules that could sensibly be required for "rational" decision-making. These all consist of axioms with a strong intuitive appeal; examples include the *transitivity* of preferences (if $a_1 > a_2$ given C, and $a_2 > a_3$ given C, then $a_1 > a_3$ given C), and the *sure-thing principle* (if $a_1 > a_2$ given C and E, and $a_1 > a_2$ given C and $\bar{E}$, then $a_1 > a_2$ given C). Notice that these rules are *not* intended as a description of actual human decision-making, but as a *normative* set of principles to be followed by someone who aspires to achieve coherent decision-making.

There are naturally different options for the set of acceptable principles, but all of them lead basically to the same conclusions, namely:

1. Preferences among consequences should necessarily be measured with a real-valued bounded *utility* function $u(c) = u(a, \boldsymbol{\theta})$ which specifies, on some numerical scale, their desirability.
2. The uncertainty of relevant events should be measured with a set of *probability* distributions $\{(p(\boldsymbol{\theta} \mid C, a), \boldsymbol{\theta} \in \Theta_a), a \in \mathcal{A}\}$ describing their plausibility given the conditions C under which the decision must be taken.
3. The desirability of the available actions is measured by their corresponding *expected utility*

$$\overline{u}(a \mid C) = \int_{\Theta_a} u(a, \boldsymbol{\theta})\, p(\boldsymbol{\theta} \mid C, a)\, d\boldsymbol{\theta}, \quad a \in \mathcal{A}.$$

It is often convenient to work in terms of the non-negative *loss* function defined by

$$\ell(a, \boldsymbol{\theta}) = \sup_{a \in \mathcal{A}} \{u(a, \boldsymbol{\theta})\} - u(a, \boldsymbol{\theta}),$$

which directly measures, as a function of $\boldsymbol{\theta}$, the "penalty" for choosing a wrong action. The relative undesirability of available actions $a \in \mathcal{A}$ is then measured by their *expected loss*

$$\overline{\ell}(a \mid C) = \int_{\Theta_a} \ell(a, \boldsymbol{\theta})\, p(\boldsymbol{\theta} \mid C, a)\, d\boldsymbol{\theta}, \quad a \in \mathcal{A}.$$

Notice that, in particular, the argument described above establishes the need to quantify the uncertainty about all relevant unknown quantities (the actual values of the $\boldsymbol{\theta}$'s), and specifies that this quantification *must* have the mathematical structure of probability distributions. These probabilities are conditional on the circumstances C under which the decision is to be taken, which typically, but not necessarily, include the results D of some relevant experimental or observational data.

It has been argued that the development described above (which is not questioned when decisions have to be made) does not apply to problems of statistical inference, where no specific decision making is envisaged. However, there are two powerful counterarguments to this. Indeed, (1) a problem of statistical inference is typically considered worth analyzing because it *may* eventually help make sensible decisions (as Ramsey (1931) put it, a lump of arsenic is poisonous because it *may* kill someone, not because it has actually killed someone), and (2) it has been shown (Bernardo 1979a) that statistical inference on $\boldsymbol{\theta}$ actually *has* the mathematical structure of a decision problem, where the class of alternatives is the functional space

$$\mathcal{A} = \left\{ p(\boldsymbol{\theta} \mid D); \quad p(\boldsymbol{\theta} \mid D) > 0, \int_{\Theta} p(\boldsymbol{\theta} \mid D)\, d\boldsymbol{\theta} = 1 \right\}$$

of the conditional probability distributions of $\boldsymbol{\theta}$ given the data, and the utility function is a measure of the amount of information about $\boldsymbol{\theta}$ which the data may be expected to provide.

Exchangeability and Representation Theorem

Available data often take the form of a set $\{\boldsymbol{x}_1, \ldots, \boldsymbol{x}_n\}$ of "homogeneous" (possibly multidimensional) observations, in the precise sense that only their *values* matter and not the *order* in which they appear. Formally, this is captured by the notion of *exchangeability*. The set of random vectors $\{\boldsymbol{x}_1, \ldots, \boldsymbol{x}_n\}$ is exchangeable if their joint distribution is invariant under permutations. An infinite sequence $\{\boldsymbol{x}_j\}$ of random vectors is exchangeable if all its finite subsequences are exchangeable. Notice that, in particular, any random sample from any model is exchangeable in this sense. The concept of exchangeability, introduced by de Finetti (1937) put it, is central to modern statistical thinking. Indeed, the general *representation theorem* implies that if a set of observations is assumed to be a subset of an exchangeable sequence, then it constitutes *a random sample* from some probability model $\{p(\boldsymbol{x} \mid \boldsymbol{\omega}), \boldsymbol{\omega} \in \boldsymbol{\Omega}\}$, $\boldsymbol{x} \in \mathcal{X}$, described in terms of (labeled by) some *parameter vector* $\boldsymbol{\omega}$; furthermore this parameter $\boldsymbol{\omega}$ is *defined* as the limit (as $n \to \infty$) of some function of the observations. Available information about the value of $\boldsymbol{\omega}$ in prevailing conditions C is *necessarily* described by *some* probability distribution $p(\boldsymbol{\omega} \mid C)$.

For example, in the case of a sequence $\{x_1, x_2, \ldots\}$ of dichotomous exchangeable random quantities $x_j \in \{0, 1\}$, de Finetti's representation theorem establishes that the

joint distribution of $(x_1, \ldots, x_n)$ has an *integral representation* of the form

$$p(x_1, \ldots, x_n \,|\, C) = \int_0^1 \prod_{i=1}^{n} \theta^{x_i} (1-\theta)^{1-x_i} \, p(\theta \,|\, C) \, d\theta,$$

$$\theta = \lim_{n \to \infty} \frac{r}{n},$$

where $r = \sum x_j$ is the number of positive trials. This is nothing but the joint distribution of a set of (conditionally) independent Bernoulli trials with parameter θ, over which some probability distribution $p(\theta \,|\, C)$ is therefore proven to exist. More generally, for sequences of arbitrary random quantities $\{\boldsymbol{x}_1, \boldsymbol{x}_2, \ldots\}$, exchangeability leads to integral representations of the form

$$p(\boldsymbol{x}_1, \ldots, \boldsymbol{x}_n \,|\, C) = \int_{\boldsymbol{\Omega}} \prod_{i=1}^{n} p(\boldsymbol{x}_i \,|\, \boldsymbol{\omega}) \, p(\boldsymbol{\omega} \,|\, C) \, d\boldsymbol{\omega},$$

where $\{p(\boldsymbol{x} \,|\, \boldsymbol{\omega}), \boldsymbol{\omega} \in \boldsymbol{\Omega}\}$ denotes some probability *model*, $\boldsymbol{\omega}$ is the limit as $n \to \infty$ of some function $f(\boldsymbol{x}_1, \ldots, \boldsymbol{x}_n)$ of the observations, and $p(\boldsymbol{\omega} \,|\, C)$ is some probability distribution over $\boldsymbol{\Omega}$. This formulation includes "nonparametric" (distribution free) modeling, where $\boldsymbol{\omega}$ may index, for instance, all continuous probability distributions on $\mathcal{X}$. Notice that $p(\boldsymbol{\omega} \,|\, C)$ does *not* describe a possible variability of $\boldsymbol{\omega}$ (since $\boldsymbol{\omega}$ will typically be a fixed *unknown* vector), but a description on the uncertainty associated with its actual value.

Under appropriate conditioning, exchangeability is a very general assumption, a powerful extension of the traditional concept of a *random sample*. Indeed, many statistical analyses directly assume data (or subsets of the data) to be a random sample of conditionally independent observations from some probability model, so that $p(\boldsymbol{x}_1, \ldots, \boldsymbol{x}_n \,|\, \boldsymbol{\omega}) = \prod_{i=1}^{n} p(\boldsymbol{x}_i \,|\, \boldsymbol{\omega})$; but *any* random sample is exchangeable, since $\prod_{i=1}^{n} p(\boldsymbol{x}_i \,|\, \boldsymbol{\omega})$ is obviously invariant under permutations. Notice that the observations in a random sample are only independent *conditional* on the parameter value $\boldsymbol{\omega}$; as nicely put by Lindley, the mantra that the observations $\{\boldsymbol{x}_1, \ldots, \boldsymbol{x}_n\}$ in a random sample are independent is ridiculous when they are used to infer $\boldsymbol{x}_{n+1}$. Notice also that, under exchangeability, the general representation theorem provides an *existence theorem* for a probability distribution $p(\boldsymbol{\omega} \,|\, C)$ on the parameter space Ω, and that this is an argument which only depends on mathematical probability theory.

Another important consequence of exchangeability is that it provides a formal *definition* of the parameter $\boldsymbol{\omega}$ which labels the model as the limit, as $n \to \infty$, of *some* function $f(\boldsymbol{x}_1, \ldots, \boldsymbol{x}_n)$ of the observations; the function f obviously depends both on the assumed model and the chosen parametrization. For instance, in the case of a sequence of Bernoulli trials, the parameter θ is *defined* as the limit, as $n \to \infty$, of the relative frequency r/n. It follows that, under exchangeability, the sentence "the true value of $\boldsymbol{\omega}$" has a well-defined meaning, if only asymptotically verifiable. Moreover, if two different models have parameters which are functionally related by their definition, then the corresponding posterior distributions may be meaningfully compared, for they refer to functionally related quantities. For instance, if a finite subset $\{x_1, \ldots, x_n\}$ of an exchangeable sequence of integer observations is assumed to be a random sample from a Poisson distribution $\mathrm{Po}(x \,|\, \lambda)$, so that $\mathrm{E}[x \,|\, \lambda] = \lambda$, then λ is *defined* as $\lim_{n \to \infty} \{\bar{x}_n\}$, where $\bar{x}_n = \sum_j x_j / n$; similarly, if for some fixed non-zero integer r, the same data are assumed to be a random sample for a negative binomial $\mathrm{NBi}(x \,|\, r, \theta)$, so that $\mathrm{E}[x \,|\, \theta, r] = r(1-\theta)/\theta$, then θ is *defined* as $\lim_{n \to \infty} \{r/(\bar{x}_n + r)\}$. It follows that $\theta \equiv r/(\lambda + r)$ and, hence, θ and $r/(\lambda + r)$ may be treated as the *same* (unknown) quantity whenever this might be needed as, for example, when comparing the relative merits of these alternative probability models.

The Bayesian Paradigm

The statistical analysis of some observed data D typically begins with some informal *descriptive* evaluation, which is used to suggest a tentative, formal *probability model* $\{p(D \,|\, \boldsymbol{\omega}), \boldsymbol{\omega} \in \boldsymbol{\Omega}\}$ assumed to represent, for some (unknown) value of $\boldsymbol{\omega}$, the probabilistic mechanism which has generated the observed data D. The arguments outlined in section "▶Foundations" establish the logical need to assess a *prior* probability distribution $p(\boldsymbol{\omega} \,|\, K)$ over the parameter space $\boldsymbol{\Omega}$, describing the available knowledge K about the value of $\boldsymbol{\omega}$ prior to the data being observed. It then follows from standard probability theory that, if the probability model is correct, all available information about the value of $\boldsymbol{\omega}$ after the data D have been observed is contained in the corresponding *posterior* distribution whose probability density, $p(\boldsymbol{\omega} \,|\, D, A, K)$, is immediately obtained from Bayes' theorem,

$$p(\boldsymbol{\omega} \,|\, D, A, K) = \frac{p(D \,|\, \boldsymbol{\omega}) \, p(\boldsymbol{\omega} \,|\, K)}{\int_{\boldsymbol{\Omega}} p(D \,|\, \boldsymbol{\omega}) \, p(\boldsymbol{\omega} \,|\, K) \, d\boldsymbol{\omega}},$$

where A stands for the assumptions made on the probability model. It is this systematic use of Bayes' theorem to incorporate the information provided by the data that justifies the adjective *Bayesian* by which the paradigm is usually known. It is obvious from Bayes' theorem that any value of $\boldsymbol{\omega}$ with zero prior density will have zero posterior density. Thus, it is typically assumed (by appropriate restriction, if necessary, of the *parameter space* $\boldsymbol{\Omega}$) that prior distributions are *strictly positive* (as Savage put it,

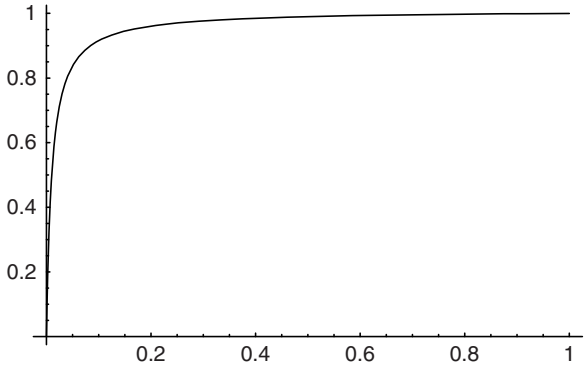
keep the mind open, or at least ajar). To simplify the presentation, the accepted assumptions A and the available knowledge K are often omitted from the notation, but the fact that *all* statements about $\boldsymbol{\omega}$ given D are *also* conditional to A and K should always be kept in mind.

Example 1 (Bayesian inference with a finite parameter space). Let $p(D\,|\,\theta)$, where $\theta \in \{\theta_1, \ldots, \theta_m\}$, be the probability mechanism which is assumed to have generated the observed data D, so that θ may only take a *finite* number of values. Using the finite form of Bayes' theorem, and omitting the prevailing conditions from the notation, the posterior probability of θ_i after data D have been observed is

$$\Pr(\theta_i\,|\,D) = \frac{p(D\,|\,\theta_i)\,\Pr(\theta_i)}{\sum_{j=1}^{m} p(D\,|\,\theta_j)\,\Pr(\theta_j)}, \quad i = 1, \ldots, m.$$

For any prior distribution $p(\theta) = \{\Pr(\theta_1), \ldots, \Pr(\theta_m)\}$ describing available knowledge about the value of θ, $\Pr(\theta_i\,|\,D)$ measures how likely should θ_i be judged, given both the initial knowledge described by the prior distribution, and the information provided by the data D.

An important, frequent application of this simple technique is provided by probabilistic diagnosis. For example, consider the simple situation where a particular test designed to detect a virus is known from laboratory research to give a positive result in 98% of infected people and in 1% of non-infected. Then, the posterior probability that a person who tested positive is infected is given by $\Pr(V\,|\,+) = (0.98\,p)/\{0.98\,p + 0.01\,(1-p)\}$ as a function of $p = \Pr(V)$, the prior probability of a person being infected (the *prevalence* of the infection in the population under study). Figure 1 shows $\Pr(V\,|\,+)$ as a function of $\Pr(V)$.



Bayesian Statistics. Fig. 1 Posterior probability of infection $\Pr(V\,|\,+)$ given a positive test, as a function of the prior probability of infection $\Pr(V)$

As one would expect, the posterior probability is only zero if the prior probability is zero (so that it is *known* that the population is free of infection) and it is only one if the prior probability is one (so that it is *known* that the population is universally infected). Notice that if the infection is rare, then the posterior probability of a randomly chosen person being infected will be relatively low even if the test is positive. Indeed, for say $\Pr(V) = 0.002$, one finds $\Pr(V\,|\,+) = 0.164$, so that in a population where only 0.2% of individuals are infected, only 16.4% of those testing positive within a random sample will actually prove to be infected: most positives would actually be *false* positives.

In the rest of this section, we describe in some detail the learning process described by Bayes' theorem, discuss its implementation in the presence of nuisance parameters, show how it can be used to forecast the value of future observations, and analyze its large sample behavior.

The Learning Process

In the Bayesian paradigm, the process of learning from the data is systematically implemented by making use of Bayes' theorem to combine the available prior information with the information provided by the data to produce the required posterior distribution. Computation of posterior densities is often facilitated by noting that Bayes' theorem may be simply expressed as

$$p(\boldsymbol{\omega}\,|\,D) \propto p(D\,|\,\boldsymbol{\omega})\,p(\boldsymbol{\omega}),$$

(where $\propto$ stands for 'proportional to' and where, for simplicity, the accepted assumptions A and the available knowledge K have been omitted from the notation), since the missing proportionality constant $[\int_{\Omega} p(D\,|\,\boldsymbol{\omega})\,p(\boldsymbol{\omega})\,d\boldsymbol{\omega}]^{-1}$ may always be deduced from the fact that $p(\boldsymbol{\omega}\,|\,D)$, a probability density, must integrate to one. Hence, to identify the form of a posterior distribution it suffices to identify a *kernel* of the corresponding probability density, that is a function $k(\boldsymbol{\omega})$ such that $p(\boldsymbol{\omega}\,|\,D) = c(D)\,k(\boldsymbol{\omega})$ for some $c(D)$ which does not involve $\boldsymbol{\omega}$. In the examples which follow, this technique will often be used.

An *improper prior function* is defined as a positive function $\pi(\boldsymbol{\omega})$ such that $\int_{\Omega} \pi(\boldsymbol{\omega})\,d\boldsymbol{\omega}$ is not finite. The formal expression of Bayes' theorem, remains technically valid if $p(\boldsymbol{\omega})$ is replaced by an improper prior function $\pi(\boldsymbol{\omega})$ provided the proportionality constant exists, thus leading to a well defined *proper* posterior density $\pi(\boldsymbol{\omega}\,|\,D) \propto p(D\,|\,\boldsymbol{\omega})\pi(\boldsymbol{\omega})$. It will later be established (section "▶Reference Analysis") that Bayes' theorem also remains philosophically valid if $p(\boldsymbol{\omega})$ is replaced by an appropriately chosen *reference* "noninformative" (typically improper) prior function $\pi(\boldsymbol{\omega})$.

Considered as a function of $\boldsymbol{\omega}$, $p(D\,|\,\boldsymbol{\omega})$ is often referred to as the *likelihood function*. Thus, Bayes' theorem is simply expressed in words by the statement that *the posterior is proportional to the likelihood times the prior*. It follows from Bayes' theorem that, provided the *same* prior $p(\boldsymbol{\omega})$ is used, two different data sets D_1 and D_2, with possibly different probability models $p_1(D_1\,|\,\boldsymbol{\omega})$ and $p_2(D_2\,|\,\boldsymbol{\omega})$ but yielding *proportional* likelihood functions, will produce identical posterior distributions for $\boldsymbol{\omega}$. This immediate consequence of Bayes theorem has been proposed as a principle on its own, the *likelihood principle*, and it is seen by many as an obvious requirement for reasonable statistical inference. In particular, for any given prior $p(\boldsymbol{\omega})$, the posterior distribution does not depend on the set of possible data values, or the *outcome space*. Notice, however, that the likelihood principle only applies to inferences about the parameter vector $\boldsymbol{\omega}$ *once the data have been obtained*. Consideration of the outcome space is essential, for instance, in model criticism, in the design of experiments, in the derivation of predictive distributions, or (see section "►Reference Analysis") in the construction of objective Bayesian procedures.

Naturally, the terms prior and posterior are only *relative* to a particular set of data. As one would expect from the coherence induced by probability theory, if data $D = \{\boldsymbol{x}_1, \ldots, \boldsymbol{x}_n\}$ are sequentially presented, the final result will be the same whether data are globally or sequentially processed. Indeed, $p(\boldsymbol{\omega}\,|\,\boldsymbol{x}_1, \ldots, \boldsymbol{x}_{i+1}) \propto p(\boldsymbol{x}_{i+1}\,|\,\boldsymbol{\omega})\, p(\boldsymbol{\omega}\,|\,\boldsymbol{x}_1, \ldots, \boldsymbol{x}_i)$, for $i = 1, \ldots, n-1$, so that the "posterior" at a given stage becomes the "prior" at the next.

In most situations, the posterior distribution is "sharper" than the prior so that, in most cases, the density $p(\boldsymbol{\omega}\,|\,\boldsymbol{x}_1, \ldots, \boldsymbol{x}_{i+1})$ will be more concentrated around the true value of $\boldsymbol{\omega}$ than $p(\boldsymbol{\omega}\,|\,\boldsymbol{x}_1, \ldots, \boldsymbol{x}_i)$. However, this is not always the case: occasionally, a "surprising" observation will increase, rather than decrease, the uncertainty about the value of $\boldsymbol{\omega}$. For instance, in probabilistic diagnosis, a sharp posterior probability distribution (over the possible causes $\{\omega_1, \ldots, \omega_k\}$ of a syndrome) describing, a "clear" diagnosis of disease ω_i (that is, a posterior with a large probability for ω_i) would typically update to a less concentrated posterior probability distribution over $\{\omega_1, \ldots, \omega_k\}$ if a new clinical analysis yielded data which were unlikely under ω_i.

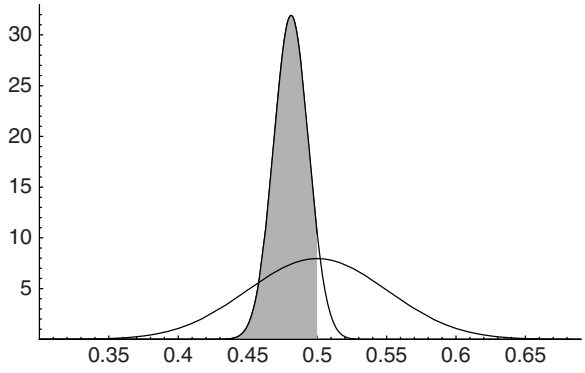
For a given probability model, one may find that some particular function of the data $\boldsymbol{t} = \boldsymbol{t}(D)$ is a *sufficient* statistic in the sense that, given the model, $\boldsymbol{t}(D)$ contains all information about $\boldsymbol{\omega}$ which is available in D. Formally, $\boldsymbol{t} = \boldsymbol{t}(D)$ is sufficient if (and only if) there exist nonnegative functions f and g such that the likelihood function may be factorized in the form $p(D\,|\,\boldsymbol{\omega}) = f(\boldsymbol{\omega}, \boldsymbol{t})g(D)$. A sufficient statistic always exists, for $\boldsymbol{t}(D) = D$ is obviously sufficient; however, a much simpler sufficient statistic, with a fixed dimensionality which is independent of the sample size, often exists. In fact this is known to be the case whenever the probability model belongs to the *generalized exponential family*, which includes many of the more frequently used probability models. It is easily established that if $\boldsymbol{t}$ is sufficient, the posterior distribution of $\boldsymbol{\omega}$ only depends on the data D through $\boldsymbol{t}(D)$, and may be directly computed in terms of $p(\boldsymbol{t}\,|\,\boldsymbol{\omega})$, so that, $p(\boldsymbol{\omega}\,|\,D) = p(\boldsymbol{\omega}\,|\,\boldsymbol{t}) \propto p(\boldsymbol{t}\,|\,\boldsymbol{\omega})\, p(\boldsymbol{\omega})$.

Naturally, for fixed data and model assumptions, different priors lead to different posteriors. Indeed, Bayes' theorem may be described as a data-driven probability transformation machine which maps prior distributions (describing prior knowledge) into posterior distributions (representing combined prior and data knowledge). It is important to analyze whether or not sensible changes in the prior would induce noticeable changes in the posterior. Posterior distributions based on reference "noninformative" priors play a central role in this ►*sensitivity analysis* context. Investigation of the sensitivity of the posterior to changes in the prior is an important ingredient of the comprehensive analysis of the sensitivity of the final results to *all* accepted assumptions which any responsible statistical study should contain.

Example 2 (Inference on a binomial parameter). If the data D consist of n Bernoulli observations with parameter θ which contain r positive trials, then $p(D\,|\,\theta, n) = \theta^r(1-\theta)^{n-r}$, so that $\boldsymbol{t}(D) = \{r, n\}$ is sufficient. Suppose that prior knowledge about θ may be approximately described by a ►Beta distribution $\mathrm{Be}(\theta\,|\,\alpha, \beta)$, so that $p(\theta\,|\,\alpha, \beta) \propto \theta^{\alpha-1}(1-\theta)^{\beta-1}$. Using Bayes' theorem, the posterior density of θ is $p(\theta\,|\,r, n, \alpha, \beta) \propto \theta^r(1-\theta)^{n-r}\,\theta^{\alpha-1}(1-\theta)^{\beta-1} \propto \theta^{r+\alpha-1}(1-\theta)^{n-r+\beta-1}$, the Beta distribution $\mathrm{Be}(\theta\,|\,r+\alpha, n-r+\beta)$.

Suppose, for example, that in the light of precedent surveys, available information on the proportion θ of citizens who would vote for a particular political measure in a referendum is described by a Beta distribution $\mathrm{Be}(\theta\,|\,50, 50)$, so that it is judged to be equally likely that the referendum would be won or lost, and it is judged that the probability that either side wins less than 60% of the vote is 0.95.

A random survey of size 1500 is then conducted, where only 720 citizens declare to be in favor of the proposed measure. Using the results above, the corresponding posterior distribution is then $\mathrm{Be}(\theta\,|\,770, 830)$. These prior and posterior densities are plotted in Fig. 2; it may be appreciated that, as one would expect, the effect of the data is to drastically reduce the initial uncertainty on the value of θ



Bayesian Statistics. Fig. 2 Prior and posterior densities of the proportion θ of citizens that would vote in favor of a referendum text

and, hence, on the referendum outcome. More precisely, $\Pr(\theta < 0.5 \,|\, 720, 1, 500, H, K) = 0.933$ (shaded region in Fig. 2) so that, after the information from the survey has been included, the probability that the referendum will be lost should be judged to be about 93%.

The general situation where the vector of interest is not the whole parameter vector $\boldsymbol{\omega}$, but some function $\boldsymbol{\theta} = \boldsymbol{\theta}(\boldsymbol{\omega})$ of possibly lower dimension than $\boldsymbol{\omega}$, will now be considered. Let D be some observed data, let $\{p(D \,|\, \boldsymbol{\omega}), \boldsymbol{\omega} \in \Omega\}$ be a probability model assumed to describe the probability mechanism which has generated D, let $p(\boldsymbol{\omega})$ be a probability distribution describing any available information on the value of $\boldsymbol{\omega}$, and let $\boldsymbol{\theta} = \boldsymbol{\theta}(\boldsymbol{\omega}) \in \Theta$ be a function of the original parameters over whose value inferences based on the data D are required. Any valid conclusion on the value of the *vector of interest* $\boldsymbol{\theta}$ will then be contained in its posterior probability distribution $p(\boldsymbol{\theta} \,|\, D)$ which is conditional on the observed data D and will naturally also depend, although not explicitly shown in the notation, on the assumed model $\{p(D \,|\, \boldsymbol{\omega}), \boldsymbol{\omega} \in \boldsymbol{\Omega}\}$, and on the available prior information encapsulated by $p(\boldsymbol{\omega})$. The required posterior distribution $p(\boldsymbol{\theta} \,|\, D)$ is found by standard use of probability calculus. Indeed, by Bayes' theorem, $p(\boldsymbol{\omega} \,|\, D) \propto p(D \,|\, \boldsymbol{\omega})\, p(\boldsymbol{\omega})$. Moreover, let $\boldsymbol{\lambda} = \boldsymbol{\lambda}(\boldsymbol{\omega}) \in \boldsymbol{\Lambda}$ be some other function of the original parameters such that $\boldsymbol{\psi} = \{\boldsymbol{\theta}, \boldsymbol{\lambda}\}$ is a one-to-one transformation of $\boldsymbol{\omega}$, and let $J(\boldsymbol{\omega}) = (\partial \boldsymbol{\psi} / \partial \boldsymbol{\omega})$ be the corresponding Jacobian matrix. Naturally, the introduction of $\boldsymbol{\lambda}$ is not necessary if $\boldsymbol{\theta}(\boldsymbol{\omega})$ is a one-to-one transformation of $\boldsymbol{\omega}$. Using standard change-of-variable probability techniques, the posterior density of $\boldsymbol{\psi}$ is

$$p(\boldsymbol{\psi} \,|\, D) = p(\boldsymbol{\theta}, \boldsymbol{\lambda} \,|\, D) = \left[\frac{p(\boldsymbol{\omega} \,|\, D)}{|J(\boldsymbol{\omega})|} \right]_{\boldsymbol{\omega} = \boldsymbol{\omega}(\boldsymbol{\psi})}$$

and the required posterior of $\boldsymbol{\theta}$ is the appropriate *marginal* density, obtained by integration over the *nuisance parameter* $\boldsymbol{\lambda}$,

$$p(\boldsymbol{\theta} \,|\, D) = \int_{\boldsymbol{\Lambda}} p(\boldsymbol{\theta}, \boldsymbol{\lambda} \,|\, D)\, d\boldsymbol{\lambda}.$$

Notice that elimination of unwanted nuisance parameters, a simple integration within the Bayesian paradigm is, however, a difficult (often polemic) problem for conventional statistics.

Sometimes, the range of possible values of $\boldsymbol{\omega}$ is effectively restricted by contextual considerations. If $\boldsymbol{\omega}$ is known to belong to $\boldsymbol{\Omega}_c \subset \boldsymbol{\Omega}$, the prior distribution is only positive in $\boldsymbol{\Omega}_c$ and, using Bayes' theorem, it is immediately found that the restricted posterior is

$$p(\boldsymbol{\omega} \,|\, D, \boldsymbol{\omega} \in \boldsymbol{\Omega}_c) = \frac{p(\boldsymbol{\omega} \,|\, D)}{\int_{\boldsymbol{\Omega}_c} p(\boldsymbol{\omega} \,|\, D)}, \quad \boldsymbol{\omega} \in \boldsymbol{\Omega}_c,$$

and obviously vanishes if $\boldsymbol{\omega} \notin \boldsymbol{\Omega}_c$. Thus, to incorporate a restriction on the possible values of the parameters, it suffices to *renormalize* the unrestricted posterior distribution to the set $\boldsymbol{\Omega}_c \subset \boldsymbol{\Omega}$ of parameter values which satisfy the required condition. Incorporation of known constraints on the parameter values, a simple renormalization within the Bayesian pardigm, is another very difficult problem for conventional statistics.

Example 3 (Inference on normal parameters). Let $D = \{x_1, \ldots x_n\}$ be a random sample from a normal distribution $N(x \,|\, \mu, \sigma)$. The corresponding likelihood function is immediately found to be proportional to $\sigma^{-n} \exp[-n\{s^2 + (\bar{x} - \mu)^2\}/(2\sigma^2)]$, with $n\bar{x} = \sum_i x_i$, and $ns^2 = \sum_i (x_i - \bar{x})^2$. It may be shown (see section "►Reference Analysis") that absence of initial information on the value of both μ and σ may formally be described by a joint prior function which is uniform in both μ and $\log(\sigma)$, that is, by the (improper) prior function $p(\mu, \sigma) = \sigma^{-1}$. Using Bayes' theorem, the corresponding joint posterior is

$$p(\mu, \sigma \,|\, D) \propto \sigma^{-(n+1)} \exp[-n\{s^2 + (\bar{x} - \mu)^2\}/(2\sigma^2)].$$

Thus, using the Gamma integral in terms of $\lambda = \sigma^{-2}$ to integrate out σ,

$$p(\mu \,|\, D) \propto \int_0^{\infty} \sigma^{-(n+1)} \exp\left[-\frac{n}{2\sigma^2} [s^2 + (\bar{x} - \mu)^2] \right] d\sigma \propto [s^2 + (\bar{x} - \mu)^2]^{-n/2},$$

which is recognized as a kernel of the Student density $\mathrm{St}\left(\mu \,|\, \bar{x}, s/\sqrt{n-1}, n-1\right)$. Similarly, integrating out μ,

$$p(\sigma \,|\, D) \propto \int_{-\infty}^{\infty} \sigma^{-(n+1)} \exp\left[-\frac{n}{2\sigma^2}\left[s^2 + (\bar{x}-\mu)^2\right]\right] d\mu \propto \sigma^{-n} \exp\left[-\frac{ns^2}{2\sigma^2}\right].$$

Changing variables to the precision $\lambda = \sigma^{-2}$ results in $p(\lambda \,|\, D) \propto \lambda^{(n-3)/2} e^{ns^2\lambda/2}$, a kernel of the Gamma density $\mathrm{Ga}(\lambda \,|\, (n-1)/2, ns^2/2)$. In terms of the standard deviation σ this becomes $p(\sigma \,|\, D) = p(\lambda \,|\, D)|\partial\lambda/\partial\sigma| = 2\sigma^{-3}\mathrm{Ga}(\sigma^{-2} \,|\, (n-1)/2, ns^2/2)$, a square-root inverted gamma density.

A frequent example of this scenario is provided by laboratory measurements made in conditions where central limit conditions apply, so that (assuming no experimental bias) those measurements may be treated as a random sample from a normal distribution centered at the quantity μ which is being measured, and with some (unknown) standard deviation σ. Suppose, for example, that in an elementary physics classroom experiment to measure the gravitational field g with a pendulum, a student has obtained $n = 20$ measurements of g yielding (in m/s^2) a mean $\bar{x} = 9.8087$, and a standard deviation $s = 0.0428$. Using no other information, the corresponding posterior distribution is $p(g \,|\, D) = \mathrm{St}(g \,|\, 9.8087, 0.0098, 19)$ represented in the upper panel of Fig. 3. In particular, $\Pr(9.788 < g < 9.829 \,|\, D) = 0.95$, so that, with the information provided by this experiment, the value of g at the location of the laboratory may be expected to lie between 9.788 and 9.829 with probability 0.95.

Formally, the posterior distribution of g should be restricted to $g > 0$; however, as immediately obvious from Fig. 3, this would not have any appreciable effect, due to the fact that the likelihood function is actually concentrated on positive g values.

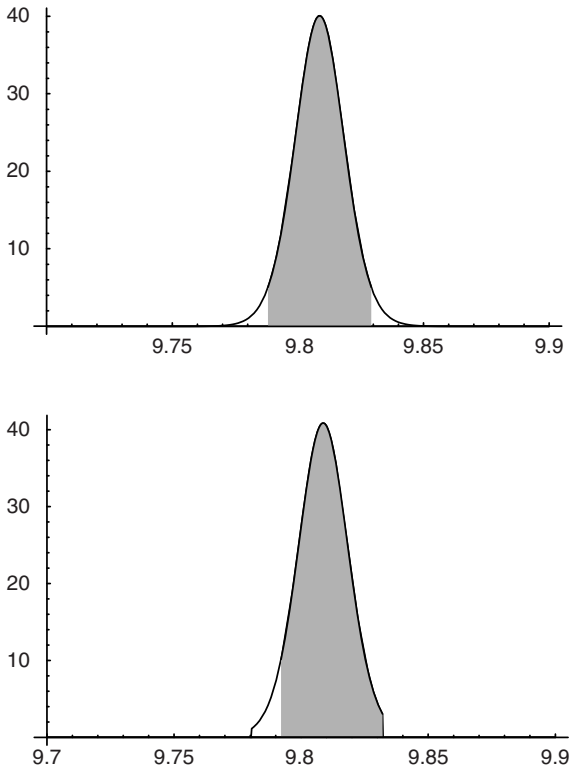
Suppose now that the student is further instructed to incorporate into the analysis the fact that the value of the gravitational field g at the laboratory is known to lie between 9.7803 m/s^2 (average value at the Equator) and 9.8322 m/s^2 (average value at the poles). The updated posterior distribution will then be

$$p(g \,|\, D, g \in G_c) = \frac{\mathrm{St}\left(g \,|\, m, s/\sqrt{n-1}, n\right)}{\int_{g \in G_c} \mathrm{St}\left(g \,|\, m, s/\sqrt{n-1}, n\right)}, \quad g \in G_c,$$

represented in lower panel of Fig. 3, where $G_c = \{g; 9.7803 < g < 9.8322\}$. Simple ▶numerical integration may be used to verify that $\Pr(g > 9.792 \,|\, D, g \in G_c) = 0.95$. Moreover, if inferences about the standard deviation σ of the measurement procedure are also requested, the corresponding posterior distribution is found to be $p(\sigma \,|\, D) = 2\sigma^{-3}\mathrm{Ga}(\sigma^{-2} \,|\, 9.5, 0.0183)$. This has a mean $\mathrm{E}[\sigma \,|\, D] = 0.0458$ and yields $\Pr(0.0334 < \sigma < 0.0642 \,|\, D) = 0.95$.

Predictive Distributions

Let $D = \{\boldsymbol{x}_1, \ldots, \boldsymbol{x}_n\}$, $\boldsymbol{x}_i \in \mathcal{X}$, be a set of exchangeable observations, and consider now a situation where it is desired to predict the value of a future observation $\boldsymbol{x} \in \mathcal{X}$ generated by the same random mechanism that has generated the data D. It follows from the foundations arguments discussed in section "▶Foundations" that the solution to this prediction problem is simply encapsulated by the *predictive* distribution $p(\boldsymbol{x} \,|\, D)$ describing the uncertainty on the value that $\boldsymbol{x}$ will take, given the information provided by D and any other available knowledge. Suppose that contextual information suggests the assumption that data D may be considered to be a random sample from a distribution in the family $\{p(\boldsymbol{x} \,|\, \boldsymbol{\omega}), \boldsymbol{\omega} \in \Omega\}$, and let $p(\boldsymbol{\omega})$ be a prior distribution describing available information on the value of $\boldsymbol{\omega}$. Since $p(\boldsymbol{x} \,|\, \boldsymbol{\omega}, D) = p(\boldsymbol{x} \,|\, \boldsymbol{\omega})$, it then



Bayesian Statistics. Fig. 3 Posterior densities $p(g \,|\, m, s, n)$ of the value g of the gravitational field

follows from standard probability theory that $p(\boldsymbol{x}\,|\,D) = \int_{\Omega} p(\boldsymbol{x}\,|\,\boldsymbol{\omega})\, p(\boldsymbol{\omega}\,|\,D)\, d\boldsymbol{\omega}$, which is an average of the probability distributions of $\boldsymbol{x}$ conditional on the (unknown) value of $\boldsymbol{\omega}$, weighted with the posterior distribution of $\boldsymbol{\omega}$ given D.

If the assumptions on the probability model are correct, the posterior predictive distribution $p(\boldsymbol{x}\,|\,D)$ will converge, as the sample size increases, to the distribution $p(\boldsymbol{x}\,|\,\boldsymbol{\omega})$ which has generated the data. Indeed, the best technique to assess the quality of the inferences about $\boldsymbol{\omega}$ encapsulated in $p(\boldsymbol{\omega}\,|\,D)$ is to check against the observed data the predictive distribution $p(\boldsymbol{x}\,|\,D)$ generated by $p(\boldsymbol{\omega}\,|\,D)$.

Example 4 (Prediction in a Poisson process). Let $D = \{r_1, \ldots, r_n\}$ be a random sample from a Poisson distribution $\text{Po}(r\,|\,\lambda)$ with parameter λ, so that $p(D\,|\,\lambda) \propto \lambda^t e^{-\lambda n}$, where $t = \sum r_i$. It may be shown (see section "►Reference Analysis") that absence of initial information on the value of λ may be formally described by the (improper) prior function $p(\lambda) = \lambda^{-1/2}$. Using Bayes' theorem, the corresponding posterior is

$$p(\lambda\,|\,D) \propto \lambda^t e^{-\lambda n}\, \lambda^{-1/2} \propto \lambda^{t-1/2} e^{-\lambda n},$$

the kernel of a Gamma density $\text{Ga}(\lambda\,|\,, t + 1/2, n)$, with mean $(t + 1/2)/n$. The corresponding predictive distribution is the Poisson-Gamma mixture

$$p(r\,|\,D) = \int_0^{\infty} \text{Po}(r\,|\,\lambda)\, \text{Ga}\left(\lambda\,|\,, t + \frac{1}{2}, n\right) d\lambda$$
$$= \frac{n^{t+1/2}}{\Gamma(t+1/2)}\, \frac{1}{r!}\, \frac{\Gamma(r+t+1/2)}{(1+n)^{r+t+1/2}}.$$

Suppose, for example, that in a firm producing automobile restraint systems, the entire production in each of 10 consecutive months has yielded no complaint from their clients. With no additional information on the average number λ of complaints per month, the quality assurance department of the firm may report that the probabilities that r complaints will be received in the next month of production are given by the last equation, with $t = 0$ and $n = 10$. In particular, $p(r = 0\,|\,D) = 0.953$, $p(r = 1\,|\,D) = 0.043$, and $p(r = 2\,|\,D) = 0.003$. Many other situations may be described with the same model. For instance, if meteorological conditions remain similar in a given area, $p(r = 0\,|\,D) = 0.953$ would describe the chances of no flash flood next year, given 10 years without flash floods in the area.

Example 5 (Prediction in a Normal process). Consider now prediction of a continuous variable. Let $D = \{x_1, \ldots, x_n\}$ be a random sample from a normal distribution $N(x\,|\,\mu, \sigma)$. As mentioned in Example 3, absence of initial information on the values of both μ and σ is formally described by the *improper* prior function $p(\mu, \sigma) = \sigma^{-1}$, and this leads to the joint posterior density describe above. The corresponding (posterior) predictive distribution is

$$p(x\,|\,D) = \int_0^{\infty} \int_{-\infty}^{\infty} \text{N}(x\,|\,\mu, \sigma)\, p(\mu, \sigma\,|\,D)\, d\mu d\sigma$$
$$= \text{St}\left(x\,|\,\overline{x}, s\sqrt{\frac{n+1}{n-1}}, n-1\right).$$

If μ is known to be positive, the appropriate prior function will be the restricted function $p(\mu, \sigma) = \sigma^{-1}$ if $\mu > 0$ and $p(\mu, \sigma) = 0$ otherwise. However, the result will still hold, provided the likelihood function $p(D\,|\,\mu, \sigma)$ is concentrated on positive μ values. Suppose, for example, that in the firm producing automobile restraint systems, the observed breaking strengths of $n = 10$ randomly chosen safety belt webbings have mean $\overline{x} = 28.011$ kN and standard deviation $s = 0.443$ kN, and that the relevant engineering specification requires breaking strengths to be larger than 26 kN. If data may truly be assumed to be a random sample from a normal distribution, the likelihood function is only appreciable for positive μ values, and only the information provided by this small sample is to be used, then the quality engineer may claim that the probability that a safety belt randomly chosen from the same batch as the sample tested would satisfy the required specification is $\Pr(x > 26\,|\,D) = 0.9987$. Besides, if conditions remain constant, 99.87% of the safety belt webbings may be expected to have acceptable breaking strengths.

Asymptotic Behavior

The behavior of posterior distributions when the sample size is large is now considered. This is important for, at least, two different reasons: (1) asymptotic results provide useful first-order approximations when actual samples are relatively large, and (2) objective Bayesian methods typically depend on the asymptotic properties of the assumed model. Let $D = \{\boldsymbol{x}_1, \ldots, \boldsymbol{x}_n\}$, $\boldsymbol{x} \in \mathcal{X}$, be a random sample of size n from $\{p(\boldsymbol{x}\,|\,\boldsymbol{\omega}), \boldsymbol{\omega} \in \boldsymbol{\Omega}\}$. It may be shown that, as $n \to \infty$, the posterior distribution $p(\boldsymbol{\omega}\,|\,D)$ of a *discrete* parameter $\boldsymbol{\omega}$ typically converges to a degenerate distribution which gives probability one to the true value of $\boldsymbol{\omega}$, and that the posterior distribution of a *continuous* parameter $\boldsymbol{\omega}$ typically converges to a normal distribution centered at its *maximum likelihood estimate* $\hat{\boldsymbol{\omega}}$ (MLE), with a variance matrix which decreases with n as $1/n$.

Consider first the situation where $\boldsymbol{\Omega} = \{\boldsymbol{\omega}_1, \boldsymbol{\omega}_2, \ldots\}$ consists of a *countable* (possibly infinite) set of values, such that the probability model which corresponds to the true parameter value $\boldsymbol{\omega}_t$ is *distinguishable* from

the others in the sense that the logarithmic divergence $\delta\{p(\boldsymbol{x}\,|\,\boldsymbol{\omega}_i)\,|\,p(\boldsymbol{x}\,|\,\boldsymbol{\omega}_t)\}$ of each of the $p(\boldsymbol{x}\,|\,\boldsymbol{\omega}_i)$ from $p(\boldsymbol{x}\,|\,\boldsymbol{\omega}_t)$ is strictly positive. Taking logarithms in Bayes' theorem, defining $z_j = \log[p(\boldsymbol{x}_j\,|\,\boldsymbol{\omega}_i)/p(\boldsymbol{x}_j\,|\,\boldsymbol{\omega}_t)]$, $j = 1,\ldots,n$, and using the strong law of large numbers on the n conditionally independent and identically distributed random quantities $z_1,\ldots,z_n$, it may be shown that

$$\lim_{n\to\infty} p(\boldsymbol{\omega}_t\,|\,\boldsymbol{x}_1,\ldots,\boldsymbol{x}_n) = 1,$$
$$\lim_{n\to\infty} p(\boldsymbol{\omega}_i\,|\,\boldsymbol{x}_1,\ldots,\boldsymbol{x}_n) = 0, \quad i \neq t.$$

Thus, under appropriate regularity conditions, the posterior probability of the true parameter value converges to one as the sample size grows.

Consider now the situation where $\boldsymbol{\omega}$ is a k-dimensional *continuous* parameter. Expressing Bayes' theorem as $p(\boldsymbol{\omega}\,|\,\boldsymbol{x}_1,\ldots,\boldsymbol{x}_n) \propto \exp\left\{\log[p(\boldsymbol{\omega})] + \sum_{j=1}^{n}\log[p(\boldsymbol{x}_j\,|\,\boldsymbol{\omega})]\right\}$, expanding $\sum_j \log[p(\boldsymbol{x}_j\,|\,\boldsymbol{\omega})]$ about its maximum (the MLE $\hat{\boldsymbol{\omega}}$), and assuming regularity conditions (to ensure that terms of order higher than quadratic may be ignored and that the sum of the terms from the likelihood will dominate the term from the prior) it is found that the posterior density of $\boldsymbol{\omega}$ is the approximate k-variate normal

$$p(\boldsymbol{\omega}\,|\,\boldsymbol{x}_1,\ldots,\boldsymbol{x}_n) \approx \mathrm{N}_k\{\hat{\boldsymbol{\omega}}, \boldsymbol{S}(D,\hat{\boldsymbol{\omega}})\},$$
$$\boldsymbol{S}^{-1}(D,\boldsymbol{\omega}) = \left(-\sum_{l=1}^{n}\frac{\partial^2\log[p(\boldsymbol{x}_l\,|\,\boldsymbol{\omega})]}{\partial\omega_i\partial\omega_j}\right).$$

A simpler, but somewhat poorer, approximation may be obtained by using the strong law of large numbers on the sums above to establish that $\boldsymbol{S}^{-1}(D,\hat{\boldsymbol{\omega}}) \approx n\boldsymbol{F}(\hat{\boldsymbol{\omega}})$, where $\boldsymbol{F}(\boldsymbol{\omega})$ is *Fisher's information matrix*, with general element

$$\boldsymbol{F}_{ij}(\boldsymbol{\omega}) = -\int_X p(\boldsymbol{x}\,|\,\boldsymbol{\omega})\,\frac{\partial^2\log[p(\boldsymbol{x}\,|\,\boldsymbol{\omega})]}{\partial\omega_i\partial\omega_j}\,d\boldsymbol{x},$$

so that

$$p(\boldsymbol{\omega}\,|\,\boldsymbol{x}_1,\ldots,\boldsymbol{x}_n) \approx N_k(\boldsymbol{\omega}\,|\,\hat{\boldsymbol{\omega}}, n^{-1}\boldsymbol{F}^{-1}(\hat{\boldsymbol{\omega}})).$$

Thus, under appropriate regularity conditions, the posterior probability density of the parameter vector $\boldsymbol{\omega}$ approaches, as the sample size grows, a multivarite normal density centered at the MLE $\hat{\boldsymbol{\omega}}$, with a variance matrix which decreases with n as n^{-1}.

Example 2 (Inference on a binomial parameter, continued). Let $D = (x_1,\ldots,x_n)$ consist of n independent Bernoulli trials with parameter θ, so that $p(D\,|\,\theta,n) = \theta^r(1-\theta)^{n-r}$. This likelihood function is maximized at $\hat{\theta} = r/n$, and Fisher's information function is $F(\theta) = \theta^{-1}(1-\theta)^{-1}$. Thus, using the results above, the posterior distribution of θ will be the approximate normal,

$$p(\theta\,|\,r,n) \approx \mathrm{N}\left(\theta\,|\,\hat{\theta}, s(\hat{\theta})/\sqrt{n}\right), \quad s(\theta) = \{\theta(1-\theta)\}^{1/2}$$

with mean $\hat{\theta} = r/n$ and variance $\hat{\theta}(1-\hat{\theta})/n$. This will provide a reasonable approximation to the exact posterior if (1) the prior $p(\theta)$ is relatively "flat" in the region where the likelihood function matters, and (2) both r and n are moderately large. If, say, $n = 1{,}500$ and $r = 720$, this leads to $p(\theta\,|\,D) \approx \mathrm{N}(\theta\,|\,0.480, 0.013)$, and to $\Pr(\theta > 0.5\,|\,D) \approx 0.940$, which may be compared with the exact value $\Pr(\theta > 0.5\,|\,D) = 0.933$ obtained from the posterior distribution which corresponds to the prior $\mathrm{Be}(\theta\,|\,50,50)$.

It follows from the *joint* posterior asymptotic behavior of $\boldsymbol{\omega}$ and from the properties of the multivariate normal distribution (see ▶Multivariate Normal Distributions) that, if the parameter vector is decomposed into $\boldsymbol{\omega} = (\boldsymbol{\theta},\boldsymbol{\lambda})$, and Fisher's information matrix is correspondingly partitioned, so that

$$\boldsymbol{F}(\boldsymbol{\omega}) = \boldsymbol{F}(\boldsymbol{\theta},\boldsymbol{\lambda}) = \begin{pmatrix} \boldsymbol{F}_{\theta\theta}(\boldsymbol{\theta},\boldsymbol{\lambda}) & \boldsymbol{F}_{\theta\lambda}(\boldsymbol{\theta},\boldsymbol{\lambda}) \\ \boldsymbol{F}_{\lambda\theta}(\boldsymbol{\theta},\boldsymbol{\lambda}) & \boldsymbol{F}_{\lambda\lambda}(\boldsymbol{\theta},\boldsymbol{\lambda}) \end{pmatrix}$$

and

$$\boldsymbol{S}(\boldsymbol{\theta},\boldsymbol{\lambda}) = \boldsymbol{F}^{-1}(\boldsymbol{\theta},\boldsymbol{\lambda}) = \begin{pmatrix} \boldsymbol{S}_{\theta\theta}(\boldsymbol{\theta},\boldsymbol{\lambda}) & \boldsymbol{S}_{\theta\lambda}(\boldsymbol{\theta},\boldsymbol{\lambda}) \\ \boldsymbol{S}_{\lambda\theta}(\boldsymbol{\theta},\boldsymbol{\lambda}) & \boldsymbol{S}_{\lambda\lambda}(\boldsymbol{\theta},\boldsymbol{\lambda}) \end{pmatrix},$$

then the *marginal* posterior distribution of $\boldsymbol{\theta}$ will be

$$p(\boldsymbol{\theta}\,|\,D) \approx \mathrm{N}\{\boldsymbol{\theta}\,|\,\hat{\boldsymbol{\theta}}, n^{-1}\boldsymbol{S}_{\theta\theta}(\hat{\boldsymbol{\theta}},\hat{\boldsymbol{\lambda}})\},$$

while the *conditional* posterior distribution of $\boldsymbol{\lambda}$ given $\boldsymbol{\theta}$ will be

$$p(\boldsymbol{\lambda}\,|\,\boldsymbol{\theta},D) \approx \mathrm{N}\left\{\boldsymbol{\lambda}\,|\,\hat{\boldsymbol{\lambda}} - \boldsymbol{F}_{\lambda\lambda}^{-1}(\boldsymbol{\theta},\hat{\boldsymbol{\lambda}})\right.$$
$$\left.\boldsymbol{F}_{\lambda\theta}(\boldsymbol{\theta},\hat{\boldsymbol{\lambda}})(\hat{\boldsymbol{\theta}}-\boldsymbol{\theta}),\, n^{-1}\boldsymbol{F}_{\lambda\lambda}^{-1}(\boldsymbol{\theta},\hat{\boldsymbol{\lambda}})\right\}.$$

Notice that $\boldsymbol{F}_{\lambda\lambda}^{-1} = \boldsymbol{S}_{\lambda\lambda}$ if (and only if) $\boldsymbol{F}$ is block diagonal, i.e., if (and only if) $\boldsymbol{\theta}$ and $\boldsymbol{\lambda}$ are asymptotically independent.

Example 3 (Inference on normal parameters, continued). Let $D = (x_1,\ldots,x_n)$ be a random sample from a normal distribution $\mathrm{N}(x\,|\,\mu,\sigma)$. The corresponding likelihood function $p(D\,|\,\mu,\sigma)$ is maximized at $(\hat{\mu},\hat{\sigma}) = (\bar{x},s)$, and Fisher's information matrix is diagonal, with $F_{\mu\mu} = \sigma^{-2}$. Hence, the posterior distribution of μ is *approximately* $\mathrm{N}\left(\mu\,|\,\bar{x}, s/\sqrt{n}\right)$; this may be compared with the *exact* result $p(\mu\,|\,D) = \mathrm{St}\left(\mu\,|\,\bar{x}, s/\sqrt{n-1}, n-1\right)$ obtained previously under the assumption of no prior knowledge.

Inference Summaries

From a Bayesian viewpoint, the final outcome of a problem of inference about *any* unknown quantity is nothing but the corresponding posterior distribution. Thus, given some data D and conditions C, *all* that can be said about any function $\boldsymbol{\omega}$ of the parameters which govern the model is contained in the posterior distribution $p(\boldsymbol{\omega}\,|\,D,C)$, and

all that can be said about some function $\boldsymbol{y}$ of future observations from the same model is contained in its posterior predictive distribution $p(\boldsymbol{y}\,|\,D, C)$. As mentioned before, Bayesian inference may technically be described as a decision problem where the space of available actions is the class of those posterior probability distributions of the quantity of interest which are compatible with accepted assumptions.

However, to make it easier for the user to assimilate the appropriate conclusions, it is often convenient to *summarize* the information contained in the posterior distribution by (1) providing values of the quantity of interest which, in the light of the data, are likely to be "close" to its true value and by (2) measuring the compatibility of the results with hypothetical values of the quantity of interest which might have been suggested in the context of the investigation. In this section, those Bayesian counterparts of traditional *estimation* and *hypothesis testing* problems are briefly considered.

Estimation

In one or two dimensions, a graph of the posterior probability density of the quantity of interest (or the probability mass function in the discrete case) immediately conveys an intuitive, "impressionist" summary of the main conclusions which may possibly be drawn on its value. Indeed, this is greatly appreciated by users, and may be quoted as an important asset of Bayesian methods. From a plot of its posterior density, the region where (given the data) a univariate quantity of interest is likely to lie is easily distinguished. For instance, all important conclusions about the value of the gravitational field in Example 3 are qualitatively available from Fig. 3. However, this does not easily extend to more than two dimensions and, besides, *quantitative* conclusions (in a simpler form than that provided by the mathematical expression of the posterior distribution) are often required.

Point Estimation. Let D be the available data, which are assumed to have been generated by a probability model $\{p(D\,|\,\boldsymbol{\omega}), \boldsymbol{\omega} \in \boldsymbol{\Omega}\}$, and let $\boldsymbol{\theta} = \boldsymbol{\theta}(\boldsymbol{\omega}) \in \boldsymbol{\Theta}$ be the quantity of interest. A *point estimator* of $\boldsymbol{\theta}$ is some function of the data $\tilde{\boldsymbol{\theta}} = \tilde{\boldsymbol{\theta}}(D)$ which could be regarded as an appropriate proxy for the actual, unknown value of $\boldsymbol{\theta}$. Formally, to choose a point estimate for $\boldsymbol{\theta}$ is a *decision problem*, where the action space is the class $\boldsymbol{\Theta}$ of possible $\boldsymbol{\theta}$ values. From a decision-theoretic perspective, to choose a point estimate $\tilde{\boldsymbol{\theta}}$ of some quantity $\boldsymbol{\theta}$ is a *decision* to act as if the true value of $\boldsymbol{\theta}$ were $\tilde{\boldsymbol{\theta}}$, not to assert something about the value of $\boldsymbol{\theta}$ (although desire to assert something simple may well be the reason to obtain an estimate). As prescribed by the foundations of decision theory (section "▶Foundations"), to solve this decision problem it is necessary to specify a *loss function* $\ell(\tilde{\boldsymbol{\theta}}, \boldsymbol{\theta})$ measuring the consequences of acting *as if* the true value of the quantity of interest were $\tilde{\boldsymbol{\theta}}$, when it is actually $\boldsymbol{\theta}$. The expected posterior loss if $\tilde{\boldsymbol{\theta}}$ were used is

$$\overline{\ell}[\tilde{\boldsymbol{\theta}}\,|\,D] = \int_{\Theta} \ell(\tilde{\boldsymbol{\theta}}, \boldsymbol{\theta})\, p(\boldsymbol{\theta}\,|\,D)\, d\boldsymbol{\theta},$$

and the corresponding *Bayes estimator* $\boldsymbol{\theta}^*$ is that function of the data, $\boldsymbol{\theta}^* = \boldsymbol{\theta}^*(D)$, which minimizes this expectation.

Example 6 (Conventional Bayes estimators). For any given model and data, the Bayes estimator obviously depends on the chosen ▶loss function. The loss function is context specific, and should be chosen in terms of the anticipated uses of the estimate; however, a number of conventional loss functions have been suggested for those situations where no particular uses are envisaged. These loss functions produce estimates which may be regarded as simple descriptions of the *location* of the posterior distribution. For example, if the loss function is quadratic, so that $\ell(\tilde{\boldsymbol{\theta}}, \boldsymbol{\theta}) = (\tilde{\boldsymbol{\theta}} - \boldsymbol{\theta})^t(\tilde{\boldsymbol{\theta}} - \boldsymbol{\theta})$, then the Bayes estimator is the *posterior mean* $\boldsymbol{\theta}^* = E[\boldsymbol{\theta}\,|\,D]$, assuming that the mean exists. Similarly, if the loss function is a zero-one function, so that $\ell(\tilde{\boldsymbol{\theta}}, \boldsymbol{\theta}) = 0$ if $\tilde{\boldsymbol{\theta}}$ belongs to a ball or radius ϵ centered in $\boldsymbol{\theta}$ and $\ell(\tilde{\boldsymbol{\theta}}, \boldsymbol{\theta}) = 1$ otherwise, then the Bayes estimator $\boldsymbol{\theta}^*$ tends to the *posterior mode* as the ball radius ϵ tends to zero, assuming that a unique mode exists. If θ is univariate and the loss function is linear, so that $\ell(\tilde{\theta}, \theta) = c_1(\tilde{\theta} - \theta)$ if $\tilde{\theta} \geq \theta$, and $\ell(\tilde{\theta}, \theta) = c_2(\theta - \tilde{\theta})$ otherwise, then the Bayes estimator is the *posterior quantile* of order $c_2/(c_1 + c_2)$, so that $\Pr[\theta < \theta^*] = c_2/(c_1 + c_2)$. In particular, if $c_1 = c_2$, the Bayes estimator is the *posterior median*. The results derived for linear loss functions clearly illustrate the fact that *any* possible parameter value may turn out be the Bayes estimator: it all depends on the loss function describing the consequences of the anticipated uses of the estimate.

Example 7 (Intrinsic estimation). Conventional loss functions are typically non-invariant under reparametrization, so that the Bayes estimator $\boldsymbol{\phi}^*$ of a one-to-one transformation $\boldsymbol{\phi} = \boldsymbol{\phi}(\boldsymbol{\theta})$ of the original parameter $\boldsymbol{\theta}$ is not necessarily $\boldsymbol{\phi}(\boldsymbol{\theta}^*)$ (the *univariate* posterior median, which *is* invariant, is an interesting exception). Moreover, conventional loss functions focus on the "distance" between the estimate $\tilde{\boldsymbol{\theta}}$ and the true value $\boldsymbol{\theta}$, rather than on the "distance" between the probability models they label. Intrinsic losses directly focus on how different the probability *model* $p(D\,|\,\boldsymbol{\theta}, \boldsymbol{\lambda})$ is from its closest approximation within the family $\{p(D\,|\,\tilde{\boldsymbol{\theta}}, \boldsymbol{\lambda}_i), \boldsymbol{\lambda}_i \in \Lambda\}$, and typically produce invariant solutions. An attractive example is the *intrinsic discrepancy*, $d(\tilde{\boldsymbol{\theta}}, \boldsymbol{\theta})$ defined as the minimum logarithmic divergence between a probability model labeled by $\boldsymbol{\theta}$

and a probability model labeled by $\tilde{\boldsymbol{\theta}}$. When there are no nuisance parameters, this is given by

$$d(\tilde{\boldsymbol{\theta}}, \boldsymbol{\theta}) = \min\{\delta(\tilde{\boldsymbol{\theta}} \,|\, \boldsymbol{\theta}), \delta(\boldsymbol{\theta} \,|\, \tilde{\boldsymbol{\theta}})\},$$
$$\delta(\boldsymbol{\theta}_i \,|\, \boldsymbol{\theta}) = \int_{\mathcal{T}} p(\boldsymbol{t} \,|\, \boldsymbol{\theta}) \log \frac{p(\boldsymbol{t} \,|\, \boldsymbol{\theta})}{p(\boldsymbol{t} \,|\, \boldsymbol{\theta}_i)} \, d\boldsymbol{t},$$

where $\boldsymbol{t} = \boldsymbol{t}(D) \in \mathcal{T}$ is *any* sufficient statistic (which may well be the whole data set D). The definition is easily extended to problems with nuisance parameters; in this case,

$$d(\tilde{\boldsymbol{\theta}}, \boldsymbol{\theta}, \boldsymbol{\lambda}) = \min_{\boldsymbol{\lambda}_i \in \boldsymbol{\Lambda}} d(\tilde{\boldsymbol{\theta}}, \boldsymbol{\lambda}_i, \boldsymbol{\theta}, \boldsymbol{\lambda})$$

measures the logarithmic divergence from $p(\boldsymbol{t} \,|\, \boldsymbol{\theta}, \boldsymbol{\lambda})$ of its closest approximation with $\boldsymbol{\theta} = \tilde{\boldsymbol{\theta}}$, and the loss function now depends on the complete parameter vector $(\boldsymbol{\theta}, \boldsymbol{\lambda})$. Although not explicitly shown in the notation, the intrinsic discrepancy function typically depends on the sample size n; indeed, when the data consist of a random sample $D = \{\boldsymbol{x}_1, \ldots, \boldsymbol{x}_n\}$ from some model $p(\boldsymbol{x} \,|\, \boldsymbol{\theta})$ then

$$\delta(\boldsymbol{\theta}_i \,|\, \boldsymbol{\theta}) = n \int_{\mathcal{X}} p(\boldsymbol{x} \,|\, \boldsymbol{\theta}) \log \frac{p(\boldsymbol{x} \,|\, \boldsymbol{\theta})}{p(\boldsymbol{x} \,|\, \boldsymbol{\theta}_i)} \, d\boldsymbol{x},$$

so that the discrepancy associated with the full model is simply n times the discrepancy which corresponds to a single observation. The intrinsic discrepancy is a symmetric, non-negative loss function with a direct interpretation in information-theoretic terms as the minimum amount of information which is expected to be necessary to distinguish between the model $p(D \,|\, \boldsymbol{\theta}, \boldsymbol{\lambda})$ and its closest approximation within the class $\{p(D \,|\, \tilde{\boldsymbol{\theta}}, \boldsymbol{\lambda}_i), \boldsymbol{\lambda}_i \in \boldsymbol{\Lambda}\}$. Moreover, it is invariant under one-to-one reparametrization of the parameter of interest $\boldsymbol{\theta}$, and does not depend on the choice of the nuisance parameter $\boldsymbol{\lambda}$. The *intrinsic estimator* is naturally obtained by minimizing the posterior expected intrinsic discrepancy

$$\overline{d}(\tilde{\boldsymbol{\theta}} \,|\, D) = \int_{\boldsymbol{\Lambda}} \int_{\Theta} d(\tilde{\boldsymbol{\theta}}, \boldsymbol{\theta}, \boldsymbol{\lambda}) p(\boldsymbol{\theta}, \boldsymbol{\lambda} \,|\, D) \, d\boldsymbol{\theta} d\boldsymbol{\lambda}.$$

Since the intrinsic discrepancy is invariant under reparametrization, minimizing its posterior expectation produces invariant estimators.

Example 2 (Inference on a binomial parameter, continued). In the estimation of a binomial proportion θ, given data $D = (n, r)$ and a Beta prior $\text{Be}(\theta \,|\, \alpha, \beta)$, the Bayes estimator associated with the quadratic loss (the corresponding posterior mean) is $E[\theta \,|\, D] = (r+\alpha)/(n+\alpha+\beta)$, while the quadratic loss based estimator of, say, the log-odds $\phi(\theta) = \log[\theta/(1-\theta)]$, is $E[\phi \,|\, D] = \psi(r+\alpha) - \psi(n-r+\beta)$ (where $\psi(x) = d\log[\Gamma(x)]/dx$ is the *digamma* function), which is *not* equal to $\phi(E[\theta \,|\, D])$. The intrinsic loss function in this problem is

$$d(\tilde{\theta}, \theta) = n \min\{\delta(\tilde{\theta} \,|\, \theta), \delta(\theta \,|\, \tilde{\theta})\},$$
$$\delta(\theta_i \,|\, \theta) = \theta \log \frac{\theta}{\theta_i} + (1-\theta) \log \frac{1-\theta}{1-\theta_i},$$

and the corresponding intrinsic estimator θ^* is obtained by minimizing the expected posterior loss $\overline{d}(\tilde{\theta} \,|\, D) = \int d(\tilde{\theta}, \theta) \, p(\theta \,|\, D) \, d\theta$. The exact value of θ^* may be obtained by numerical minimization, but a very good approximation is given by

$$\theta^* \approx \frac{1}{2} \frac{r+\alpha}{n+\alpha+\beta} + \frac{1}{2} \frac{e^{\psi(r+\alpha)}}{e^{\psi(r+\alpha)} + e^{\psi(n-r+\beta)}}.$$

Since intrinsic estimation is an invariant procedure, the intrinsic estimator of the log-odds will simply be the log-odds of the intrinsic estimator of θ. As one would expect, when $r+\alpha$ and $n-r+\beta$ are both large, all Bayes estimators of any well-behaved function $\phi(\theta)$ will cluster around $\phi(E[\theta \,|\, D])$.

Interval Estimation. To describe the inferential content of the posterior distribution of the quantity of interest $p(\boldsymbol{\theta} \,|\, D)$ it is often convenient to quote regions $R \subset \boldsymbol{\Theta}$ of given probability under $p(\boldsymbol{\theta} \,|\, D)$. For example, the identification of regions containing 50%, 90%, 95%, or 99% of the probability under the posterior may be sufficient to convey the general quantitative messages implicit in $p(\boldsymbol{\theta} \,|\, D)$; indeed, this is the intuitive basis of graphical representations of univariate distributions like those provided by boxplots. Any region $R \subset \boldsymbol{\Theta}$ such that $\int_R p(\boldsymbol{\theta} \,|\, D) d\boldsymbol{\theta} = q$ (so that, given data D, the true value of $\boldsymbol{\theta}$ belongs to R with probability q), is said to be a posterior *q-credible region* of $\boldsymbol{\theta}$. Notice that this provides immediately a direct intuitive statement about the unknown quantity of interest $\boldsymbol{\theta}$ in probability terms, in marked contrast to the circumlocutory statements provided by frequentist confidence intervals. Clearly, for any given q there are generally infinitely many credible regions. A credible region is invariant under reparametrization; thus, for any q-credible region R of $\boldsymbol{\theta}$, $\boldsymbol{\phi}(R)$ is a q-credible region of $\boldsymbol{\phi} = \boldsymbol{\phi}(\boldsymbol{\theta})$. Sometimes, credible regions are selected to have minimum size (length, area, volume), resulting in *highest probability density* (HPD) regions, where all points in the region have larger probability density than all points outside. However, HPD regions are *not* invariant under reparametrization: the image $\boldsymbol{\phi}(R)$ of an HPD region R will be a credible region for $\boldsymbol{\phi}$, but will not generally be HPD; indeed, there is no compelling reason to restrict attention to HPD credible regions. Posterior quantiles are often used to derive credible regions. Thus, if $\boldsymbol{\theta}_q = \boldsymbol{\theta}_q(D)$ is the $100q\%$ posterior quantile of $\boldsymbol{\theta}$, then $R = \{\boldsymbol{\theta}; \boldsymbol{\theta} \leq \boldsymbol{\theta}_q\}$ is a one-sided, typically unique

q-credible region, and it is invariant under reparametrization. Indeed, *probability centered* q-credible regions of the form $R = \{\boldsymbol{\theta}; \boldsymbol{\theta}_{(1-q)/2} \leq \boldsymbol{\theta} \leq \boldsymbol{\theta}_{(1+q)/2}\}$ are easier to compute, and are often quoted in preference to HPD regions.

Example 3 (Inference on normal parameters, continued). In the numerical example about the value of the gravitational field described in the top panel of Fig. 3, the interval $[9.788, 9.829]$ in the unrestricted posterior density of g is a HPD, 95%-credible region for g. Similarly, the interval $[9.7803, 9.8322]$ in the bottom panel of Fig. 3 is also a 95%-credible region for g, but it is not HPD.

The concept of a credible region for a function $\boldsymbol{\theta} = \boldsymbol{\theta}(\boldsymbol{\omega})$ of the parameter vector is trivially extended to prediction problems. Thus, a posterior q-credible region for $\boldsymbol{x} \in \boldsymbol{\chi}$ is a subset R of the outcome space $\mathcal{X}$ with posterior predictive probability q, so that $\int_R p(\boldsymbol{x} \mid D) d\boldsymbol{x} = q$.

For a description of the choice of credible regions using the intrinsic loss function, see Bernardo (2005b).

Hypothesis Testing

The posterior distribution $p(\boldsymbol{\theta} \mid D)$ of the quantity of interest $\boldsymbol{\theta}$ conveys immediate intuitive information on those values of $\boldsymbol{\theta}$ which, given the assumed model, may be taken to be *compatible* with the observed data D, namely, those with a relatively high probability density. Sometimes, a *restriction* $\boldsymbol{\theta} \in \boldsymbol{\Theta}_0 \subset \boldsymbol{\Theta}$ of the possible values of the quantity of interest (where $\boldsymbol{\Theta}_0$ may possibly consists of a single value $\boldsymbol{\theta}_0$) is suggested in the course of the investigation as deserving special consideration, either because restricting $\boldsymbol{\theta}$ to $\boldsymbol{\Theta}_0$ would greatly simplify the model, or because there are additional, context specific arguments suggesting that $\boldsymbol{\theta} \in \boldsymbol{\Theta}_0$. Intuitively, the *hypothesis* $H_0 \equiv \{\boldsymbol{\theta} \in \boldsymbol{\Theta}_0\}$ should be judged to be *compatible* with the observed data D if there are elements in $\boldsymbol{\Theta}_0$ with a relatively high posterior density. However, a more precise conclusion is often required and, once again, this is made possible by adopting a decision-oriented approach. Formally, testing the hypothesis $H_0 \equiv \{\boldsymbol{\theta} \in \boldsymbol{\Theta}_0\}$ is a *decision problem* where the action space has only two elements, namely to accept (a_0) or to reject (a_1) the proposed restriction. To solve this decision problem, it is necessary to specify an appropriate loss function, $\ell(a_i, \boldsymbol{\theta})$, measuring the consequences of accepting or rejecting H_0 as a function of the actual value $\boldsymbol{\theta}$ of the vector of interest. Notice that this requires the statement of an *alternative* a_1 to accepting H_0; this is only to be expected, for an action is taken not because it is good, but because it is better than anything else that has been imagined.

Given data D, the optimal action will be to reject H_0 if (and only if) the expected posterior loss of accepting, $\int_\Theta \ell(a_0, \boldsymbol{\theta})\, p(\boldsymbol{\theta} \mid D)\, d\boldsymbol{\theta}$, is larger than the expected posterior loss of rejecting, $\int_\Theta \ell(a_1, \boldsymbol{\theta})\, p(\boldsymbol{\theta} \mid D)\, d\boldsymbol{\theta}$, that is, if (and only if)

$$\int_\Theta [\ell(a_0, \boldsymbol{\theta}) - \ell(a_1, \boldsymbol{\theta})]\, p(\boldsymbol{\theta} \mid D)\, d\boldsymbol{\theta} = \int_\Theta \Delta\ell(\boldsymbol{\theta})\, p(\boldsymbol{\theta} \mid D)\, d\boldsymbol{\theta} > 0.$$

Therefore, only the loss difference $\Delta\ell(\boldsymbol{\theta}) = \ell(a_0, \boldsymbol{\theta}) - \ell(a_1, \boldsymbol{\theta})$, which measures the *advantage* of rejecting H_0 as a function of $\boldsymbol{\theta}$, has to be specified. Thus, as common sense dictates, the hypothesis H_0 should be rejected whenever the expected advantage of rejecting H_0 is positive.

A crucial element in the specification of the loss function is a description of what is actually meant by rejecting H_0. By assumption a_0 means to act *as if* H_0 were true, i.e.,as if $\boldsymbol{\theta} \in \boldsymbol{\Theta}_0$, but there are at least two obvious options for the alternative action a_1. This may either mean (1) the *negation* of H_0, that is to act as if $\boldsymbol{\theta} \notin \boldsymbol{\Theta}_0$ or, alternatively, it may rather mean (2) to reject the simplification implied by H_0 and to keep the unrestricted model, $\boldsymbol{\theta} \in \Theta$, which is true by assumption. Both options have been analyzed in the literature, although it may be argued that the problems of scientific data analysis where hypothesis testing procedures are typically used are better described by the second alternative. Indeed, an established model, identified by $H_0 \equiv \{\boldsymbol{\theta} \in \boldsymbol{\Theta}_0\}$, is often embedded into a more general model, $\{\boldsymbol{\theta} \in \Theta, \boldsymbol{\Theta}_0 \subset \Theta\}$, constructed to include possibly promising departures from H_0, and it is required to verify whether presently available data D are still compatible with $\boldsymbol{\theta} \in \boldsymbol{\Theta}_0$, or whether the extension to $\boldsymbol{\theta} \in \Theta$ is really required.

Example 8 (Conventional hypothesis testing). Let $p(\boldsymbol{\theta} \mid D)$, $\boldsymbol{\theta} \in \Theta$, be the posterior distribution of the quantity of interest, let a_0 be the decision to work under the restriction $\boldsymbol{\theta} \in \boldsymbol{\Theta}_0$ and let a_1 be the decision to work under the complementary restriction $\boldsymbol{\theta} \notin \boldsymbol{\Theta}_0$. Suppose, moreover, that the loss structure has the simple, zero-one form given by $\{\ell(a_0, \boldsymbol{\theta}) = 0, \ell(a_1, \boldsymbol{\theta}) = 1\}$ if $\boldsymbol{\theta} \in \boldsymbol{\Theta}_0$ and, similarly, $\{\ell(a_0, \boldsymbol{\theta}) = 1, \ell(a_1, \boldsymbol{\theta}) = 0\}$ if $\boldsymbol{\theta} \notin \boldsymbol{\Theta}_0$, so that the *advantage* $\Delta\ell(\boldsymbol{\theta})$ of rejecting H_0 is 1 if $\boldsymbol{\theta} \notin \boldsymbol{\Theta}_0$ and it is -1 otherwise. With this loss function it is immediately found that the optimal action is to reject H_0 if (and only if) $\Pr(\boldsymbol{\theta} \notin \boldsymbol{\Theta}_0 \mid D)$ is larger than $\Pr(\boldsymbol{\theta} \in \boldsymbol{\Theta}_0 \mid D)$. Notice that this formulation requires that $\Pr(\boldsymbol{\theta} \in \boldsymbol{\Theta}_0) > 0$, that is, that the hypothesis H_0 has a strictly positive prior probability. If $\boldsymbol{\theta}$ is a continuous parameter and $\boldsymbol{\Theta}_0$ has zero measure (for instance if H_0 consists of a single point $\boldsymbol{\theta}_0$), this requires the use of a non-regular "sharp" prior concentrating a positive probability mass on $\boldsymbol{\Theta}_0$.

Example 9 (Intrinsic hypothesis testing). Again, let $p(\boldsymbol{\theta}\,|\,D)$, $\boldsymbol{\theta} \in \Theta$, be the posterior distribution of the quantity of interest, and let a_0 be the decision to work under the restriction $\boldsymbol{\theta} \in \boldsymbol{\Theta}_0$, but let a_1 now be the decision to keep the general, unrestricted model $\boldsymbol{\theta} \in \Theta$. In this case, the advantage $\Delta\ell(\boldsymbol{\theta})$ of rejecting H_0 as a function of $\boldsymbol{\theta}$ may safely be assumed to have the form $\Delta\ell(\boldsymbol{\theta}) = d(\boldsymbol{\Theta}_0, \boldsymbol{\theta}) - d^*$, for some $d^* > 0$, where (1) $d(\boldsymbol{\Theta}_0, \boldsymbol{\theta})$ is some measure of the discrepancy between the assumed model $p(D\,|\,\boldsymbol{\theta})$ and its closest approximation within the class $\{p(D\,|\,\boldsymbol{\theta}_0), \boldsymbol{\theta}_0 \in \boldsymbol{\Theta}_0\}$, such that $d(\boldsymbol{\Theta}_0, \boldsymbol{\theta}) = 0$ whenever $\boldsymbol{\theta} \in \boldsymbol{\Theta}_0$, and (2) d^* is a context dependent *utility constant* which measures the (necessarily positive) advantage of being able to work with the simpler model when it is true. Choices of both $d(\boldsymbol{\Theta}_0, \boldsymbol{\theta})$ and d^* which may be appropriate for general use will now be described.

For reasons similar to those supporting its use in point estimation, an attractive choice for the function $d(\boldsymbol{\Theta}_0, \boldsymbol{\theta})$ is an appropriate extension of the intrinsic discrepancy; when there are no nuisance parameters, this is given by

$$d(\boldsymbol{\Theta}_0, \boldsymbol{\theta}) = \inf_{\boldsymbol{\theta}_0 \in \boldsymbol{\Theta}_0} \min\{\delta(\boldsymbol{\theta}_0\,|\,\boldsymbol{\theta}),\, \delta(\boldsymbol{\theta}\,|\,\boldsymbol{\theta}_0)\}$$

where $\delta(\boldsymbol{\theta}_0\,|\,\boldsymbol{\theta}) = \int_T p(\boldsymbol{t}\,|\,\boldsymbol{\theta}) \log\{p(\boldsymbol{t}\,|\,\boldsymbol{\theta})/p(\boldsymbol{t}\,|\,\boldsymbol{\theta}_0)\}\, d\boldsymbol{t}$, and $\boldsymbol{t} = \boldsymbol{t}(D) \in T$ is *any* sufficient statistic, which may well be the whole dataset D. As before, if the data $D = \{\boldsymbol{x}_1, \ldots, \boldsymbol{x}_n\}$ consist of a random sample from $p(\boldsymbol{x}\,|\,\boldsymbol{\theta})$, then

$$\delta(\boldsymbol{\theta}_0\,|\,\boldsymbol{\theta}) = n \int_{\mathcal{X}} p(\boldsymbol{x}\,|\,\boldsymbol{\theta}) \log \frac{p(\boldsymbol{x}\,|\,\boldsymbol{\theta})}{p(\boldsymbol{x}\,|\,\boldsymbol{\theta}_0)}\, d\boldsymbol{x}.$$

Naturally, the loss function $d(\boldsymbol{\Theta}_0, \boldsymbol{\theta})$ reduces to the intrinsic discrepancy $d(\boldsymbol{\theta}_0, \boldsymbol{\theta})$ of Example 6 when $\boldsymbol{\Theta}_0$ contains a single element $\boldsymbol{\theta}_0$. Besides, as in the case of estimation, the definition is easily extended to problems with nuisance parameters, with

$$d(\boldsymbol{\Theta}_0, \boldsymbol{\theta}, \boldsymbol{\lambda}) = \inf_{\boldsymbol{\theta}_0 \in \boldsymbol{\Theta}_0, \boldsymbol{\lambda}_0 \in \boldsymbol{\Lambda}} d(\boldsymbol{\theta}_0, \boldsymbol{\lambda}_o, \boldsymbol{\theta}, \boldsymbol{\lambda}).$$

The hypothesis H_0 should be rejected if the posterior expected advantage of rejecting is

$$\overline{d}(\boldsymbol{\Theta}_0\,|\,D) = \int_{\boldsymbol{\Lambda}} \int_{\Theta} d(\boldsymbol{\Theta}_0, \boldsymbol{\theta}, \boldsymbol{\lambda})\, p(\boldsymbol{\theta}, \boldsymbol{\lambda}\,|\,D)\, d\boldsymbol{\theta} d\boldsymbol{\lambda} > d^*,$$

for some $d^* > 0$. It is easily verified that the function $\overline{d}(\boldsymbol{\Theta}_0, D)$ is nonnegative. Morovever, if $\boldsymbol{\phi} = \boldsymbol{\phi}(\boldsymbol{\theta})$ is a one-to-one transformation of $\boldsymbol{\theta}$, then $\overline{d}(\boldsymbol{\phi}(\boldsymbol{\Theta}_0), D) = \overline{d}(\boldsymbol{\Theta}_0, D)$, so that the expected intrinsic loss of rejecting H_0 is invariant under reparametrization.

It may be shown that, as the sample size increases, the expected value of $\overline{d}(\boldsymbol{\Theta}_0, D)$ under sampling tends to one when H_0 is true, and tends to infinity otherwise; thus $\overline{d}(\boldsymbol{\Theta}_0, D)$ may be regarded as a continuous, positive measure of how inappropriate (in loss of information units) it would be to simplify the model by accepting H_0. In traditional language, $\overline{d}(\boldsymbol{\Theta}_0, D)$ is a *test statistic* for H_0 and the hypothesis should be rejected if the value of $\overline{d}(\boldsymbol{\Theta}_0, D)$ exceeds some *critical value* d^*. In sharp contrast to conventional hypothesis testing, this critical value d^* is found to be a context specific, positive utility constant d^*, which may precisely be described as the number of *information units* which the decision maker is prepared to lose in order to be able to work with the simpler model H_0, and does not depend on the sampling properties of the probability model. The procedure may be used with standard, continuous regular priors even in *sharp* hypothesis testing, when $\boldsymbol{\Theta}_0$ is a zero-measure set (as would be the case if $\boldsymbol{\theta}$ is continuous and $\boldsymbol{\Theta}_0$ contains a single point $\boldsymbol{\theta}_0$). Naturally, to implement the test, the utility constant d^* which defines the rejection region must be chosen.

All measurements are based on a comparison with a standard; comparison with the "canonical" problem of testing a value $\mu = \mu_0$ for the mean of a normal distribution with known variance (see below) makes it possible to *calibrate* this *information scale*. Values of $\overline{d}(\boldsymbol{\Theta}_0, D)$ of about one should be regarded as an indication of no evidence against H_0, since the expected value of $\overline{d}(\boldsymbol{\Theta}_0, D)$ under H_0 is exactly equal to one. Values of $\overline{d}(\boldsymbol{\Theta}_0, D)$ of about 2.5, and 5 should be respectively regarded as an indication of mild evidence against H_0, and significant evidence against H_0 since, in the canonical normal problem, these values correspond to the observed sample mean $\overline{x}$ respectively lying two or three posterior standard deviations from the null value μ_0. Notice that, in sharp contrast to frequentist hypothesis testing, where it is hazily recommended to adjust the significance level for dimensionality and sample size, this provides an absolute scale (in information units) which remains valid for any sample size and any dimensionality.

Example 10 (Testing the value of a normal mean). Let the data $D = \{x_1, \ldots, x_n\}$ be a random sample from a normal distribution $\mathrm{N}(x\,|\,\mu, \sigma)$, where σ is assumed to be known, and consider the "canonical" problem of testing whether these data are or are not compatible with some specific sharp hypothesis $H_0 \equiv \{\mu = \mu_0\}$ on the value of the mean.

The conventional approach to this problem requires a non-regular prior which places a probability mass, say p_0, on the value μ_0 to be tested, with the remaining $1 - p_0$ probability continuously distributed over $\Re$. If this prior is chosen to be $p(\mu\,|\,\mu \neq \mu_0) = N(\mu\,|\,\mu_0, \sigma_0)$, Bayes theorem

may be used to obtain the corresponding posterior probability,

$$\Pr[\mu_0 \mid D, \lambda] = \frac{B_{01}(D,\lambda)\, p_0}{(1-p_0) + p_0\, B_{01}(D,\lambda)},$$

$$B_{01}(D,\lambda) = \left(1+\frac{n}{\lambda}\right)^{1/2} \exp\left[-\frac{1}{2}\frac{n}{n+\lambda}\, z^2\right],$$

where $z = (\bar{x}-\mu_0)/\left(\sigma/\sqrt{n}\right)$ measures, in standard deviations, the distance between $\bar{x}$ and μ_0 and $\lambda = \sigma^2/\sigma_0^2$ is the ratio of model to prior variance. The function $B_{01}(D,\lambda)$, a ratio of (integrated) likelihood functions, is called the *Bayes factor* in favor of H_0. With a conventional zero-one loss function, H_0 should be rejected if $\Pr[\mu_0 \mid D, \lambda] < 1/2$. The choices $p_0 = 1/2$ and $\lambda = 1$ or $\lambda = 1/2$, describing particular forms of *sharp* prior knowledge, have been suggested in the literature for routine use. The conventional approach to sharp hypothesis testing deals with situations of *concentrated* prior probability; it *assumes* important prior knowledge about the value of μ and, hence, should *not* be used unless this is an appropriate assumption. Moreover, as pointed out by Bartlett (1957), the resulting posterior probability is extremely sensitive to the specific prior specification. In most applications, H_0 is really a hazily defined small region rather than a point. For moderate sample sizes, the posterior probability $\Pr[\mu_0 \mid D, \lambda]$ is an *approximation* to the posterior probability $\Pr[\mu_0 - \epsilon < \mu < \mu_0 - \epsilon \mid D, \lambda]$ for some small interval around μ_0 which would have been obtained from a regular, continuous prior heavily concentrated around μ_0; however, this approximation *always* breaks down for sufficiently large sample sizes. One consequence (which is immediately apparent from the last two equations) is that for any *fixed* value of the pertinent statistic z, the posterior probability of the null, $\Pr[\mu_0 \mid D, \lambda]$, tends to one as $n \to \infty$. Far from being specific to this example, this unappealing behavior of posterior probabilities based on sharp, non-regular priors (discovered by Lindley 1957, and generally known as *Lindley's paradox*) is *always* present in the conventional Bayesian approach to *sharp* hypothesis testing.

The intrinsic approach may be used without assuming any sharp prior knowledge. The intrinsic discrepancy is $d(\mu_0,\mu) = n(\mu-\mu_0)^2/(2\sigma^2)$, a simple transformation of the standardized distance between μ and μ_0. As later explained (section "▶Reference Analysis"), absence of initial information about the value of μ may formally be described in this problem by the (improper) uniform prior function $p(\mu) = 1$; Bayes' theorem may then be used to obtain the corresponding (proper) posterior distribution, $p(\mu \mid D) = N\left(\mu \mid \bar{x}, \sigma/\sqrt{n}\right)$. The expected value of $d(\mu_0,\mu)$ with respect to this posterior is $\overline{d}(\mu_0, D) = (1+z^2)/2$, where $z = (\bar{x}-\mu_0)/\left(\sigma/\sqrt{n}\right)$ is the standardized distance between $\bar{x}$ and μ_0. As foretold by the general theory, the expected value of $\overline{d}(\mu_0, D)$ under repeated sampling is one if $\mu = \mu_0$, and increases linearly with n if $\mu = \mu_0$. Moreover, in this canonical example, to reject H_0 whenever $|z| > 2$ or $|z| > 3$, that is whenever μ_0 is two or three posterior standard deviations away from $\bar{x}$, respectively corresponds to rejecting H_0 whenever $\overline{d}(\mu_0, D)$ is larger than 2.5, or larger than 5. But the information scale is independent of the problem, so that rejecting the null whenever its expected discrepancy from the true model is larger than $d^* = 5$ units of information is a *general* rule (and one which corresponds to the conventional "3σ" rule in the canonical normal case).

If σ is unknown, the intrinsic discrepancy becomes

$$d(\mu_0, \mu, \sigma) = \frac{n}{2} \log\left[1 + \left(\frac{\mu-\mu_0}{\sigma}\right)^2\right].$$

Moreover, as mentioned before, absence of initial information about both μ and σ may be described by the (improper) prior function $p(\mu,\sigma) = \sigma^{-1}$. The intrinsic test statistic $\overline{d}(\mu_0, D)$ is found as the expected value of $d(\mu_0, \mu, \sigma)$ under the corresponding joint posterior distribution; this may be exactly expressed in terms of hypergeometric functions, and is approximated by

$$\overline{d}(\mu_0, D) \approx \frac{1}{2} + \frac{n}{2} \log\left(1 + \frac{t^2}{n}\right),$$

where t is the traditional statistic $t = \sqrt{n-1}(\bar{x}-\mu_0)/s$, $ns^2 = \sum_j (x_j - \bar{x})^2$. For instance, for samples sizes 5, 30 and 1,000, and using the utility constant $d^* = 5$, the hypothesis H_0 would be rejected whenever $|t|$ is respectively larger than 5.025, 3.240, and 3.007.

Reference Analysis

Under the Bayesian paradigm, the outcome of any inference problem (the posterior distribution of the quantity of interest) combines the information provided by the data with relevant available prior information. In many situations, however, either the available prior information on the quantity of interest is too vague to warrant the effort required to have it formalized in the form of a probability distribution, or it is too subjective to be useful in scientific communication or public decision making. It is therefore important to be able to identify the mathematical form of a "noninformative" prior, a prior that would have a minimal effect, relative to the data, on the posterior inference. More formally, suppose that the probability mechanism which has generated the available data D is assumed to be $p(D \mid \boldsymbol{\omega})$, for some $\boldsymbol{\omega} \in \Omega$,

and that the quantity of interest is some real-valued function $\theta = \theta(\boldsymbol{\omega})$ of the model parameter $\boldsymbol{\omega}$. Without loss of generality, it may be assumed that the probability model is of the form $p(D \mid \theta, \boldsymbol{\lambda})$, $\theta \in \Theta$, $\boldsymbol{\lambda} \in \boldsymbol{\Lambda}$, where $\boldsymbol{\lambda}$ is some appropriately chosen nuisance parameter vector. As described in section "▶The Bayesian Paradigm", to obtain the required posterior distribution of the quantity of interest $p(\theta \mid D)$ it is necessary to specify a *joint* prior $p(\theta, \boldsymbol{\lambda})$. It is now required to identify the form of that joint prior $\pi_\theta(\theta, \boldsymbol{\lambda})$, the θ-*reference prior*, which would have a *minimal effect* on the corresponding posterior distribution of θ,

$$\pi(\theta \mid D) \propto \int_{\boldsymbol{\Lambda}} p(D \mid \theta, \boldsymbol{\lambda})\, \pi_\theta(\theta, \boldsymbol{\lambda})\, d\boldsymbol{\lambda},$$

a prior which, to use a conventional expression, "would let the data speak for themselves" about the likely value of θ. Properly defined, reference *posterior* distributions have an important role to play in scientific communication, for they provide the answer to a central question in the sciences: conditional on the assumed model $p(D \mid \theta, \boldsymbol{\lambda})$, and on any further assumptions of the value of θ on which there might be universal agreement, the reference posterior $\pi(\theta \mid D)$ should specify what *could* be said about θ *if* the only available information about θ were some well-documented data D.

Much work has been done to formulate "reference" priors which would make the idea described above mathematically precise. This section concentrates on an approach that is based on information theory to derive reference distributions which may be argued to provide the most advanced general procedure available. In the formulation described below, far from ignoring prior knowledge, the reference posterior exploits certain well-defined features of a *possible* prior, namely those describing a situation where relevant knowledge about the quantity of interest (beyond that universally accepted) may be held to be negligible compared to the information about that quantity which repeated experimentation (from a particular data generating mechanism) might possibly provide. Reference analysis is appropriate in contexts where the set of inferences which could be drawn in this *possible* situation is considered to be pertinent.

Any statistical analysis contains a fair number of subjective elements; these include (among others) the data selected, the model assumptions, and the choice of the quantities of interest. Reference analysis may be argued to provide an "objective" Bayesian solution to statistical inference problems in just the same sense that conventional statistical methods claim to be "objective": in that the solutions only depend on model assumptions and observed data. The whole topic of objective Bayesian methods is, however, subject to polemic; interested readers will find in Bernardo (2005a) and references therein some pointers to the relevant literature.

Reference Distributions

One parameter. Consider the experiment which consists of the observation of data D, generated by a random mechanism $p(D \mid \theta)$ which only depends on a real-valued parameter $\theta \in \Theta$, and let $\boldsymbol{t} = \boldsymbol{t}(D) \in \mathcal{T}$ be *any* sufficient statistic (which may well be the complete data set D). In Shannon's general information theory, the *amount of information* $I^\theta\{\mathcal{T}, p(\theta)\}$ which may be expected to be provided by D, or (equivalently) by $\boldsymbol{t}(D)$, about the value of θ is defined by

$$I^\theta\{\mathcal{T}, p(\theta)\} = \int_{\mathcal{T}} \int_{\Theta} p(\boldsymbol{t}, \theta) \log \frac{p(\boldsymbol{t}, \theta)}{p(\boldsymbol{t})p(\theta)}\, d\theta d\boldsymbol{t}$$

$$= \mathrm{E}_{\boldsymbol{t}}\left[\int_{\Theta} p(\theta \mid \boldsymbol{t}) \log \frac{p(\theta \mid \boldsymbol{t})}{p(\theta)}\, d\theta \right]$$

the expected logarithmic divergence of the prior from the posterior. This is naturally a *functional* of the prior $p(\theta)$: the larger the prior information, the smaller the information which the data may be expected to provide. The functional $I^\theta\{\mathcal{T}, p(\theta)\}$ is concave, non-negative, and invariant under one-to-one transformations of θ. Consider now the amount of information $I^\theta\{\mathcal{T}^k, p(\theta)\}$ about θ which may be expected from the experiment which consists of k conditionally independent replications $\{\boldsymbol{t}_1, \ldots, \boldsymbol{t}_k\}$ of the original experiment. As $k \to \infty$, such an experiment would provide any *missing information* about θ which could possibly be obtained within this framework; thus, as $k \to \infty$, the functional $I^\theta\{\mathcal{T}^k, p(\theta)\}$ will approach the missing information about θ associated with the prior $p(\theta)$. Intuitively, a θ-"noninformative" prior is one which *maximizes the missing information* about θ. Formally, if $\pi_k(\theta)$ denotes the prior density which maximizes $I^\theta\{\mathcal{T}^k, p(\theta)\}$ in the class $\mathcal{P}$ of strictly positive prior distributions which are compatible with accepted assumptions on the value of θ (which may well be the class of *all* strictly positive proper priors) then the θ-reference prior $\pi(\theta)$ is the limit as $k \to \infty$ (in a sense to be made precise) of the sequence of priors $\{\pi_k(\theta), k = 1, 2, \ldots\}$.

Notice that this limiting procedure is *not* some kind of asymptotic approximation, but an essential element of the *definition* of a reference prior. In particular, this definition implies that reference distributions only depend on the *asymptotic* behavior of the assumed probability model, a feature which greatly simplifies their actual derivation.

Example 11 (Maximum entropy). If θ may only take a *finite* number of values, so that the parameter space is $\Theta = \{\theta_1, \ldots, \theta_m\}$ and $p(\theta) = \{p_1, \ldots, p_m\}$, with $p_i = \Pr(\theta = \theta_i)$, then the missing information associated to $\{p_1, \ldots, p_m\}$ may be shown to be

$$\lim_{k \to \infty} I^{\theta}\{T^k, p(\theta)\} = H(p_1, \ldots, p_m) = -\sum_{i=1}^{m} p_i \log(p_i),$$

that is, the *entropy* of the prior distribution $\{p_1, \ldots, p_m\}$. Thus, in the finite case, if there is no further structure in the problem (which should then be taken into account), the reference prior is that with *maximum entropy* in the class $\mathcal{P}$ of priors compatible with accepted assumptions. Consequently, the reference prior algorithm contains "maximum entropy" priors as the particular case which obtains when the parameter space is *finite*, the *only* case where the original concept of ►entropy (in statistical mechanics, as a measure of uncertainty) is unambiguous and well-behaved. If, in particular, $\mathcal{P}$ contains *all* priors over $\{\theta_1, \ldots, \theta_m\}$, then the reference prior is the uniform prior, $\pi(\theta) = \{1/m, \ldots, 1/m\}$.

Formally, the *reference prior function* $\pi(\theta)$ of a univariate parameter θ is defined to be the limit of the sequence of the proper priors $\pi_k(\theta)$ which maximize $I^{\theta}\{T^k, p(\theta)\}$ in the precise sense that, for any value of the sufficient statistic $\boldsymbol{t} = \boldsymbol{t}(D)$, the *reference posterior*, the pointwise limit $\pi(\theta \mid \boldsymbol{t})$ of the corresponding sequence of posteriors $\{\pi_k(\theta \mid \boldsymbol{t})\}$, may be obtained from $\pi(\theta)$ by formal use of Bayes theorem, so that $\pi(\theta \mid \boldsymbol{t}) \propto p(\boldsymbol{t} \mid \theta)\, \pi(\theta)$.

Reference prior *functions* are often simply called reference priors, even though they are usually *not* probability distributions. They should *not* be considered as expressions of belief, but technical devices to obtain (proper) posterior distributions which are a limiting form of the posteriors which could have been obtained from possible prior beliefs which were relatively uninformative with respect to the quantity of interest when compared with the information which data could provide.

If (1) the sufficient statistic $\boldsymbol{t} = \boldsymbol{t}(D)$ is a consistent estimator $\tilde{\theta}$ of a continuous parameter θ, and (2) the class $\mathcal{P}$ contains *all* strictly positive priors, then the reference prior may be shown to have a simple form in terms of any *asymptotic* approximation to the posterior distribution of θ. Notice that, by construction, an *asymptotic* approximation to the posterior does *not* depend on the prior. Specifically, if the posterior density $p(\theta \mid D)$ has an asymptotic approximation of the form $p(\theta \mid \tilde{\theta}, n)$, the reference prior is simply

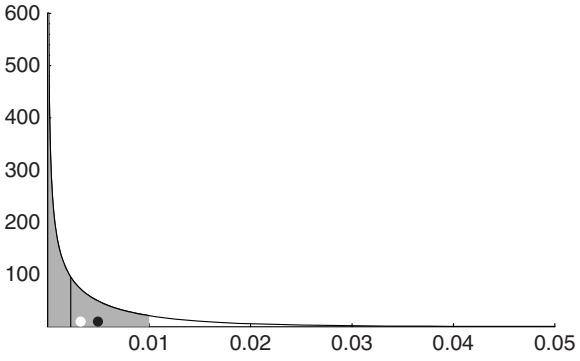
$$\pi(\theta) \propto p(\theta \mid \tilde{\theta}, n)\Big|_{\tilde{\theta}=\theta}$$

One-parameter reference priors are shown to be *invariant* under reparametrization; thus, if $\psi = \psi(\theta)$ is a piecewise one-to-one function of θ, then the ψ-reference prior is simply the appropriate probability transformation of the θ-reference prior.

Example 12 (Jeffreys' prior). If θ is univariate and continuous, and the posterior distribution of θ given $\{x_1 \ldots, x_n\}$ is asymptotically normal with standard deviation $s(\tilde{\theta})/\sqrt{n}$, then, using the last displayed equation, the reference prior function is $\pi(\theta) \propto s(\theta)^{-1}$. Under regularity conditions (often satisfied in practice, see section "►Asymptopic Behavior"), the posterior distribution of θ is asymptotically normal with variance $n^{-1} F^{-1}(\hat{\theta})$, where $F(\theta)$ is Fisher's information function and $\hat{\theta}$ is the MLE of θ. Hence, the reference prior function in these conditions is $\pi(\theta) \propto F(\theta)^{1/2}$, which is known as Jeffreys' prior. It follows that the reference prior algorithm contains Jeffreys' priors as the particular case which obtains when the probability model only depends on a single continuous univariate parameter, there are regularity conditions to guarantee ►asymptotic normality, and there is no additional information, so that the class of possible priors $\mathcal{P}$ contains all strictly positive priors over Θ. These are precisely the conditions under which there is general agreement on the use of Jeffreys' prior as a "noninformative" prior.

Example 2 (Inference on a binomial parameter, continued). Let data consist of a sequence $D = \{x_1, \ldots, x_n\}$ of n conditionally independent Bernoulli trials, so that $p(x \mid \theta) = \theta^x (1-\theta)^{1-x}$, $x \in \{0,1\}$; this is a regular, one-parameter continuous model, whose Fisher's information function is $F(\theta) = \theta^{-1}(1-\theta)^{-1}$. Thus, the reference prior $\pi(\theta)$ is proportional to $\theta^{-1/2}(1-\theta)^{-1/2}$, so that the reference prior is the (proper) Beta distribution $\mathrm{Be}(\theta \mid 1/2, 1/2)$. Since the reference algorithm is invariant under reparametrization, the reference prior of $\phi(\theta) = 2\,arc\sin\sqrt{\theta}$ is $\pi(\phi) = \pi(\theta)/|\partial\phi/\partial\theta| = 1$; thus, the reference prior is *uniform on the variance-stabilizing transformation* $\phi(\theta) = 2arc\sin\sqrt{\theta}$, a feature generally true under regularity conditions. In terms of the original parameter θ, the corresponding reference posterior is $\mathrm{Be}(\theta \mid r + 1/2, n - r + 1/2)$, where $r = \sum x_j$ is the number of positive trials.

Suppose, for example, that $n = 100$ randomly selected people have been tested for an infection and that all tested negative, so that $r = 0$. The reference posterior distribution of the proportion θ of people infected is then the Beta distribution $\mathrm{Be}(\theta \mid 0.5, 100.5)$, represented in Fig. 4. It may well be known that the infection was rare, leading to the assumption that $\theta < \theta_0$, for some upper bound



Bayesian Statistics. Fig. 4 Posterior distribution of the proportion of infected people in the population, given the results of $n = 100$ tests, none of which were positive

θ_0; the (restricted) reference prior would then be of the form $\pi(\theta) \propto \theta^{-1/2}(1-\theta)^{-1/2}$ if $\theta < \theta_0$, and zero otherwise. However, provided the likelihood is concentrated in the region $\theta < \theta_0$, the corresponding posterior would virtually be identical to $\text{Be}(\theta \,|\, 0.5, 100.5)$. Thus, just on the basis of the observed experimental results, one may claim that the proportion of infected people is surely smaller than 5% (for the reference posterior probability of the event $\theta > 0.05$ is 0.001), that θ is smaller than 0.01 with probability 0.844 (area of the shaded region in Fig. 4), that it is equally likely to be over or below 0.23% (for the median, represented by a vertical line, is 0.0023), and that the probability that a person randomly chosen from the population is infected is 0.005 (the posterior mean, represented in the figure by a black circle), since $\Pr(x = 1 \,|\, r, n) = \text{E}[\theta \,|\, r, n] = 0.005$. If a particular point estimate of θ is required (say a number to be quoted in the summary headline) the *intrinsic* estimator suggests itself; this is found to be $\theta^* = 0.0032$ (represented in the figure with a white circle). Notice that the traditional solution to this problem, based on the asymptotic behavior of the MLE, here $\hat{\theta} = r/n = 0$ for any n, makes absolutely no sense in this scenario.

One nuisance parameter. The extension of the reference prior algorithm to the case of two parameters follows the usual mathematical procedure of reducing the problem to a sequential application of the established procedure for the single parameter case. Thus, if the probability model is $p(\boldsymbol{t} \,|\, \theta, \lambda)$, $\theta \in \Theta$, $\lambda \in \Lambda$ and a θ-reference prior $\pi_\theta(\theta, \lambda)$ is required, the reference algorithm proceeds in two steps:

1. Conditional on θ, $p(\boldsymbol{t} \,|\, \theta, \lambda)$ only depends on the nuisance parameter λ and, hence, the one-parameter algorithm may be used to obtain the *conditional* reference prior $\pi(\lambda \,|\, \theta)$.
2. If $\pi(\lambda \,|\, \theta)$ is proper, this may be used to integrate out the nuisance parameter thus obtaining the one-parameter integrated model $p(\boldsymbol{t} \,|\, \theta) = \int_\Lambda p(\boldsymbol{t} \,|\, \theta, \lambda)\, \pi(\lambda \,|\, \theta)\, d\lambda$, to which the one-parameter algorithm may be applied again to obtain $\pi(\theta)$. The θ-reference prior is then $\pi_\theta(\theta, \lambda) = \pi(\lambda \,|\, \theta)\, \pi(\theta)$, and the required reference posterior is $\pi(\theta \,|\, \boldsymbol{t}) \propto p(\boldsymbol{t} \,|\, \theta) \pi(\theta)$.

If the conditional reference prior is *not* proper, then the procedure is performed within an increasing sequence $\{\Lambda_i\}$ of subsets converging to Λ over which $\pi(\lambda \,|\, \theta)$ is integrable. This makes it possible to obtain a corresponding sequence of θ-reference posteriors $\{\pi_i(\theta \,|\, \boldsymbol{t}\}$ for the quantity of interest θ, and the required reference posterior is the corresponding pointwise limit $\pi(\theta \,|\, \boldsymbol{t}) = \lim_i \pi_i(\theta \,|\, \boldsymbol{t})$. A θ-reference prior is then defined as a positive function $\pi_\theta(\theta, \lambda)$ which may be formally used in Bayes' theorem as a prior to obtain the reference posterior, i.e., such that, for any $\boldsymbol{t} \in T$, $\pi(\theta \,|\, \boldsymbol{t}) \propto \int_\Lambda p(\boldsymbol{t} \,|\, \theta, \lambda)\, \pi_\theta(\theta, \lambda)\, d\lambda$. The approximating sequences should be *consistently* chosen within a given model. Thus, given a probability model $\{p(\boldsymbol{x} \,|\, \boldsymbol{\omega}), \boldsymbol{\omega} \in \boldsymbol{\Omega}\}$ an appropriate approximating sequence $\{\boldsymbol{\Omega}_i\}$ should be chosen for the whole parameter space $\boldsymbol{\Omega}$. Thus, if the analysis is done in terms of, say, $\boldsymbol{\psi} = \{\psi_1, \psi_2\} \in \Psi(\boldsymbol{\Omega})$, the approximating sequence should be chosen such that $\Psi_i = \psi(\boldsymbol{\Omega}_i)$. A natural approximating sequence in location-scale problems is $\{\mu, \log \sigma\} \in [-i, i]^2$.

The θ-reference prior does *not* depend on the choice of the nuisance parameter λ; thus, for any $\psi = \psi(\theta, \lambda)$ such that (θ, ψ) is a one-to-one function of (θ, λ), the θ-reference prior in terms of (θ, ψ) is simply $\pi_\theta(\theta, \psi) = \pi_\theta(\theta, \lambda)/|\partial(\theta, \psi)/\partial(\theta, \lambda)|$, the appropriate probability transformation of the θ-reference prior in terms of (θ, λ). Notice, however, that the reference prior *may* depend on the parameter of interest; thus, the θ-reference prior may differ from the ϕ-reference prior unless either ϕ is a piecewise one-to-one transformation of θ, or ϕ is asymptotically independent of θ. This is an expected consequence of the fact that the conditions under which the missing information about θ is maximized are not generally the same as the conditions which maximize the missing information about some function $\phi = \phi(\theta, \lambda)$.

The *non-existence* of a unique "noninformative prior" which would be appropriate for any inference problem within a given model was established by Dawid et al. (1973), when they showed that this is incompatible with *consistent marginalization*. Indeed, if given the model $p(D \,|\, \theta, \lambda)$, the reference posterior of the quantity of interest θ, $\pi(\theta \,|\, D) = \pi(\theta \,|\, \boldsymbol{t})$, only depends on the data through a statistic $\boldsymbol{t}$ whose sampling distribution, $p(\boldsymbol{t} \,|\, \theta, \lambda) = p(\boldsymbol{t} \,|\, \theta)$, only depends on θ, one would expect the reference posterior to be of the form $\pi(\theta \,|\, \boldsymbol{t}) \propto \pi(\theta)\, p(\boldsymbol{t} \,|\, \theta)$

for some prior $\pi(\theta)$. However, examples were found where this cannot be the case if a *unique* joint "noninformative" prior were to be used for all possible quantities of interest.

Example 13 (Regular two dimensional continuous reference prior functions). If the joint posterior distribution of (θ, λ) is asymptotically normal, then the θ-reference prior may be derived in terms of the corresponding Fisher's information matrix, $\boldsymbol{F}(\theta, \lambda)$. Indeed, if

$$\boldsymbol{F}(\theta,\lambda) = \begin{pmatrix} F_{\theta\theta}(\theta,\lambda) & F_{\theta\lambda}(\theta,\lambda) \\ F_{\theta\lambda}(\theta,\lambda) & F_{\lambda\lambda}(\theta,\lambda) \end{pmatrix}, \quad \text{and}$$
$$\boldsymbol{S}(\theta,\lambda) = \boldsymbol{F}^{-1}(\theta,\lambda),$$

then the θ-reference prior is $\pi_\theta(\theta,\lambda) = \pi(\lambda \,|\, \theta)\,\pi(\theta)$, where

$$\pi(\lambda \,|\, \theta) \propto F_{\lambda\lambda}^{1/2}(\theta,\lambda), \quad \lambda \in \Lambda.$$

If $\pi(\lambda \,|\, \theta)$ is proper,

$$\pi(\theta) \propto \exp\Big\{ \int_\Lambda \pi(\lambda \,|\, \theta)\, \log\Big[S_{\theta\theta}^{-1/2}(\theta,\lambda)\Big]\, d\lambda \Big\}, \quad \theta \in \Theta.$$

If $\pi(\lambda \,|\, \theta)$ is not proper, integrations are performed on an approximating sequence $\{\Lambda_i\}$ to obtain a sequence $\{\pi_i(\lambda \,|\, \theta)\, \pi_i(\theta)\}$, (where $\pi_i(\lambda \,|\, \theta)$ is the proper renormalization of $\pi(\lambda \,|\, \theta)$ to Λ_i) and the θ-reference prior $\pi_\theta(\theta,\lambda)$ is defined as its appropriate limit. Moreover, if (1) both $F_{\lambda\lambda}^{1/2}(\theta,\lambda)$ and $S_{\theta\theta}^{-1/2}(\theta,\lambda)$ *factorize*, so that

$$S_{\theta\theta}^{-1/2}(\theta,\lambda) \propto f_\theta(\theta)\, g_\theta(\lambda), \quad F_{\lambda\lambda}^{1/2}(\theta,\lambda) \propto f_\lambda(\theta)\, g_\lambda(\lambda),$$

and (2) the parameters θ and λ are *variation independent*, so that Λ does not depend on θ, then the θ-reference prior is simply $\pi_\theta(\theta,\lambda) = f_\theta(\theta)\, g_\lambda(\lambda)$, even if the conditional reference prior $\pi(\lambda \,|\, \theta) = \pi(\lambda) \propto g_\lambda(\lambda)$ (which will not depend on θ) is actually improper.

Example 3 (Inference on normal parameters, continued). The information matrix which corresponds to a normal model $\mathrm{N}(x \,|\, \mu, \sigma)$ is

$$\boldsymbol{F}(\mu,\sigma) = \begin{pmatrix} \sigma^{-2} & 0 \\ 0 & 2\sigma^{-2} \end{pmatrix},$$
$$\boldsymbol{S}(\mu,\sigma) = \boldsymbol{F}^{-1}(\mu,\sigma) = \begin{pmatrix} \sigma^2 & 0 \\ 0 & \frac{1}{2}\sigma^2 \end{pmatrix};$$

hence $F_{\sigma\sigma}^{1/2}(\mu,\sigma) = \sqrt{2}\,\sigma^{-1} = f_\sigma(\mu)\, g_\sigma(\sigma)$, with $g_\sigma(\sigma) = \sigma^{-1}$, and $\pi(\sigma \,|\, \mu) = \sigma^{-1}$. Similarly, $S_{\mu\mu}^{-1/2}(\mu,\sigma) = \sigma^{-1} = f_\mu(\mu)\, g_\mu(\sigma)$, with $f_\mu(\mu) = 1$, and $\pi(\mu) = 1$. Therefore, the μ-reference prior is $\pi_\mu(\mu,\sigma) = \pi(\sigma \,|\, \mu)\,\pi(\mu) = \sigma^{-1}$, as already anticipated. Moreover, as one would expect from the fact that $\boldsymbol{F}(\mu,\sigma)$ is diagonal and also anticipated, it is similarly found that the σ-reference prior is $\pi_\sigma(\mu,\sigma) = \sigma^{-1}$, the same as $\pi_\mu(\mu,\sigma)$.

Suppose, however, that the quantity of interest is *not* the mean μ or the standard deviation σ, but the *standardized* mean $\phi = \mu/\sigma$. Fisher's information matrix in terms of the parameters ϕ and σ is $\boldsymbol{F}(\phi,\sigma) = J^t\, \boldsymbol{F}(\mu,\sigma)\, J$, where $J = (\partial(\mu,\sigma)/\partial(\phi,\sigma))$ is the Jacobian of the inverse transformation; this yields

$$\boldsymbol{F}(\phi,\sigma) = \begin{pmatrix} 1 & \phi\sigma^{-1} \\ \phi\sigma^{-1} & \sigma^{-2}(2+\phi^2) \end{pmatrix},$$
$$\boldsymbol{S}(\phi,\sigma) = \begin{pmatrix} 1+\frac{1}{2}\phi^2 & -\frac{1}{2}\phi\sigma \\ -\frac{1}{2}\phi\sigma & \frac{1}{2}\sigma^2 \end{pmatrix}.$$

Thus, $S_{\phi\phi}^{-1/2}(\phi,\sigma) \propto \left(1+\frac{1}{2}\phi^2\right)^{-1/2}$ and $F_{\sigma\sigma}^{1/2}(\phi,\sigma) \propto \sigma^{-1}(2+\phi^2)^{1/2}$. Hence, using again the results in Example 13, $\pi_\phi(\phi,\sigma) = \left(1+\frac{1}{2}\phi^2\right)^{-1/2}\sigma^{-1}$. In the original parametrization, this is $\pi_\phi(\mu,\sigma) = \left(1+\frac{1}{2}(\mu/\sigma)^2\right)^{-1/2}\sigma^{-2}$, which is *very* different from $\pi_\mu(\mu,\sigma) = \pi_\sigma(\mu,\sigma) = \sigma^{-1}$. The corresponding reference posterior of ϕ is $\pi(\phi \,|\, x_1, \ldots, x_n) \propto \left(1+\frac{1}{2}\phi^2\right)^{-1/2} p(t \,|\, \phi)$ where $t = (\sum x_j)/\left(\sum x_j^2\right)^{1/2}$, a one-dimensional (marginally sufficient) statistic whose sampling distribution, $p(t \,|\, \mu,\sigma) = p(t \,|\, \phi)$, only depends on ϕ. Thus, the reference prior algorithm is seen to be consistent under marginalization.

Many parameters. The reference algorithm is easily generalized to an arbitrary number of parameters. If the model is $p(\boldsymbol{t} \,|\, \omega_1, \ldots, \omega_m)$, a joint reference prior

$$\pi(\theta_m \,|\, \theta_{m-1}, \ldots, \theta_1) \times \ldots \times \pi(\theta_2 \,|\, \theta_1) \times \pi(\theta_1)$$

may sequentially be obtained for each *ordered* parametrization $\{\theta_1(\boldsymbol{\omega}), \ldots, \theta_m(\boldsymbol{\omega})\}$ of interest, and these are invariant under reparametrization of any of the $\theta_i(\boldsymbol{\omega})$'s. The choice of the ordered parametrization $\{\theta_1, \ldots, \theta_m\}$ precisely describes the particular prior required, namely that which *sequentially* maximizes the missing information about each of the θ_i's, conditional on $\{\theta_1, \ldots, \theta_{i-1}\}$, for $i = m, m-1, \ldots, 1$.

Example 14 (Stein's paradox). Let D be a random sample from a m-variate normal distribution with mean $\boldsymbol{\mu} = \{\mu_1, \ldots, \mu_m\}$ and unitary variance matrix. The reference prior which corresponds to any permutation of the μ_i's is uniform, and this prior leads indeed to appropriate reference posterior distributions for any of the μ_i's, namely $\pi(\mu_i \,|\, D) = N\left(\mu_i \,|\, \bar{x}_i, 1/\sqrt{n}\right)$. Suppose, however, that the quantity of interest is $\theta = \sum_i \mu_i^2$, the distance of $\boldsymbol{\mu}$ to the origin. As showed by Stein in the 1950s, the

posterior distribution of θ based on that uniform prior (or in any "flat" *proper* approximation) has very undesirable properties; this is due to the fact that a uniform (or nearly uniform) prior, although "noninformative" with respect to each of the individual μ_i's, is actually highly informative on the sum of their squares, introducing a severe positive bias (Stein's paradox). However, the reference prior which corresponds to a parametrization of the form $\{\theta, \lambda_1, \ldots, \lambda_{m-1}\}$ produces, for any choice of the nuisance parameters $\lambda_i = \lambda_i(\boldsymbol{\mu})$, the reference posterior $\pi(\theta \,|\, D) = \pi(\theta \,|\, t) \propto \theta^{-1/2} \chi^2(nt \,|\, m, n\theta)$, where $t = \sum_i \bar{x}_i^2$, and this posterior is shown to have the appropriate consistency properties.

Far from being specific to Stein's example, the inappropriate behavior in problems with many parameters of specific marginal posterior distributions derived from multivariate "flat" priors (proper or improper) is indeed very frequent. Hence, sloppy, uncontrolled use of "flat" priors (rather than the relevant reference priors), is strongly discouraged.

Limited information. Although often used in contexts where no universally agreed prior knowledge about the quantity of interest is available, the reference algorithm may be used to specify a prior which incorporates any acceptable prior knowledge; it suffices to maximize the missing information within the class $\mathcal{P}$ of priors which is compatible with such accepted knowledge. Indeed, by progressive incorporation of further restrictions into $\mathcal{P}$, the reference prior algorithm becomes a method of (prior) *probability assessment*. As described below, the problem has a fairly simple analytical solution when those restrictions take the form of known expected values. The incorporation of other type of restrictions usually involves numerical computations.

Example 15 (Univariate restricted reference priors). If the probability mechanism which is assumed to have generated the available data only depends on a univarite continuous parameter $\theta \in \Theta \subset \Re$, and the class $\mathcal{P}$ of acceptable priors is a class of proper priors which satisfies some expected value restrictions, so that

$$\mathcal{P} = \left\{ p(\theta); \quad p(\theta) > 0, \int_\Theta p(\theta)\, d\theta = 1, \right.$$
$$\left. \int_\Theta g_i(\theta)\, p(\theta)\, d\theta = \beta_i,\ i = 1, \ldots, m \right\}$$

then the (restricted) reference prior is

$$\pi(\theta \,|\, \mathcal{P}) \propto \pi(\theta)\, \exp\left[\textstyle\sum_{j=1}^{m} \gamma_i\, g_i(\theta)\right]$$

where $\pi(\theta)$ is the unrestricted reference prior and the γ_i's are constants (the corresponding Lagrange multipliers), to be determined by the restrictions which define $\mathcal{P}$. Suppose, for instance, that data are considered to be a random sample from a location model centered at θ, and that it is further assumed that $\mathrm{E}[\theta] = \mu_0$ and that $\mathrm{Var}[\theta] = \sigma_0^2$. The unrestricted reference prior for any regular location problem may be shown to be uniform. Thus, the restricted reference prior must be of the form $\pi(\theta \,|\, \mathcal{P}) \propto \exp\{\gamma_1 \theta + \gamma_2 (\theta - \mu_0)^2\}$, with $\int_\Theta \theta\, \pi(\theta \,|\, \mathcal{P})\, d\theta = \mu_0$ and $\int_\Theta (\theta - \mu_0)^2\, \pi(\theta \,|\, \mathcal{P})\, d\theta = \sigma_0^2$. Hence, $\pi(\theta \,|\, \mathcal{P})$ is a *normal* distribution with the specified mean and variance.

Frequentist Properties

Bayesian methods provide a *direct* solution to the problems typically posed in statistical inference; indeed, posterior distributions precisely state what can be said about unknown quantities of interest *given* available data and prior knowledge. In particular, unrestricted reference posterior distributions state what could be said if no prior knowledge about the quantities of interest were available.

A frequentist analysis of the behavior of Bayesian procedures under repeated sampling may, however, be illuminating, for this provides some interesting connections between frequentist and Bayesian inference. It is found that the frequentist properties of Bayesian reference procedures are typically excellent, and may be used to provide a form of calibration for reference posterior probabilities.

Point Estimation. It is generally accepted that, as the sample size increases, a "good" estimator $\tilde{\boldsymbol{\theta}}$ of $\boldsymbol{\theta}$ ought to get the correct value of $\boldsymbol{\theta}$ eventually, that is to be *consistent*. Under appropriate regularity conditions, any Bayes estimator $\boldsymbol{\phi}^*$ of any function $\boldsymbol{\phi}(\boldsymbol{\theta})$ converges in probability to $\boldsymbol{\phi}(\boldsymbol{\theta})$, so that sequences of Bayes estimators are typically *consistent*. Indeed, it is known that if there is a consistent sequence of estimators, then Bayes estimators are consistent. The rate of convergence is often best for reference Bayes estimators.

It is also generally accepted that a "good" estimator should be *admissible*, that is, *not dominated* by any other estimator in the sense that its expected loss under sampling (conditional to $\boldsymbol{\theta}$) cannot be larger for all $\boldsymbol{\theta}$ values than that corresponding to another estimator. Any *proper* Bayes estimator is admissible; moreover, as established by Wald (1950), a procedure *must* be Bayesian (proper or improper) to be admissible. Most published admissibility results refer to quadratic loss functions, but they often extend to more general loss functions. Reference Bayes estimators are typically admissible with respect to intrinsic loss functions.

Notice, however, that many other apparently intuitive frequentist ideas on estimation have been proved to be potentially misleading. For example, given a sequence of n

Bernoulli observations with parameter θ resulting in r positive trials, the *best unbiased* estimate of θ^2 is found to be $r(r-1)/\{n(n-1)\}$, which yields $\tilde{\theta}^2 = 0$ when $r = 1$; but to estimate the probability of two positive trials as zero, when one positive trial has been observed, is not at all sensible. In marked contrast, any Bayes reference estimator provides a reasonable answer. For example, the intrinsic estimator of θ^2 is simply $(\theta^*)^2$, where θ^* is the intrinsic estimator of θ described in section "►Estimation". In particular, if $r = 1$ and $n = 2$ the intrinsic estimator of θ^2 is (as one would naturally expect) $(\theta^*)^2 = 1/4$.

Interval Estimation. As the sample size increases, the frequentist coverage probability of a posterior q-credible region typically converges to q so that, for *large samples*, Bayesian credible intervals may (under regularity conditions) be interpreted as *approximate* frequentist confidence regions: under repeated sampling, a Bayesian q-credible region of $\boldsymbol{\theta}$ based on a large sample will cover the true value of $\boldsymbol{\theta}$ approximately $100q\%$ of times. Detailed results are readily available for univariate problems. For instance, consider the probability model $\{p(D\,|\,\boldsymbol{\omega}), \boldsymbol{\omega} \in \Omega\}$, let $\theta = \theta(\boldsymbol{\omega})$ be any univariate quantity of interest, and let $\boldsymbol{t} = \boldsymbol{t}(D) \in T$ be any sufficient statistic. If $\theta_q(\boldsymbol{t})$ denotes the $100q\%$ quantile of the posterior distribution of θ which corresponds to some unspecified prior, so that

$$\Pr[\theta \le \theta_q(\boldsymbol{t})\,|\,\boldsymbol{t}] = \int_{\theta \le \theta_q(\boldsymbol{t})} p(\theta\,|\,\boldsymbol{t})\, d\theta = q,$$

then the coverage probability of the q-credible interval $\{\theta; \theta \le \theta_q(\boldsymbol{t})\}$,

$$\Pr[\theta_q(\boldsymbol{t}) \ge \theta\,|\,\boldsymbol{\omega}] = \int_{\theta_q(\boldsymbol{t}) \ge \theta} p(\boldsymbol{t}\,|\,\boldsymbol{\omega})\, d\boldsymbol{t},$$

is such that $\Pr[\theta_q(\boldsymbol{t}) \ge \theta\,|\,\boldsymbol{\omega}] = \Pr[\theta \le \theta_q(\boldsymbol{t})\,|\,\boldsymbol{t}] + O(n^{-1/2})$. This *asymptotic* approximation is true for *all* (sufficiently regular) positive priors. However, the approximation is better, actually $O(n^{-1})$, for a particular class of priors known as (first-order) *probability matching* priors. Reference priors are typically found to be probability matching priors, so that they provide this improved asymptotic agreement. As a matter of fact, the agreement (in regular problems) is typically quite good even for relatively small samples.

Example 16 (Product of normal means). Consider the case where independent random samples $\{x_1, \ldots, x_n\}$ and $\{y_1, \ldots, y_m\}$ have respectively been taken from the normal densities $N(x\,|\,\omega_1, 1)$ and $N(y\,|\,\omega_2, 1)$, and suppose that the quantity of interest is the product of their means, $\phi = \omega_1\omega_2$ (for instance, one may be interested in inferences about the area ϕ of a rectangular piece of land, given measurements $\{x_i\}$ and $\{y_j\}$ of its sides). Notice that this is a simplified version of a problem that it is often encountered in the sciences, where one is interested in the product of several magnitudes, all of which have been measured with error. Using the procedure described in Example 13, with the natural approximating sequence induced by $(\omega_1, \omega_2) \in [-i, i]^2$, the ϕ-reference prior is found to be

$$\pi_\phi(\omega_1, \omega_2) \propto \left(n\,\omega_1^2 + m\,\omega_2^2\right)^{-1/2},$$

very different from the uniform prior $\pi_{\omega_1}(\omega_1, \omega_2) = \pi_{\omega_2}(\omega_1, \omega_2) = 1$ which should be used to make objective inferences about either ω_1 or ω_2. The prior $\pi_\phi(\omega_1, \omega_2)$ may be shown to provide approximate agreement between Bayesian credible regions and frequentist confidence intervals for ϕ; indeed, this prior (with $m = n$) was originally suggested by Stein in the 1980s to obtain such approximate agreement. The same example was later used by Efron (1986) to stress the fact that, even within a fixed probability model $\{p(D\,|\,\boldsymbol{\omega}), \boldsymbol{\omega} \in \Omega\}$, the prior required to make objective inferences about some function of the parameters $\phi = \phi(\boldsymbol{\omega})$ must generally depend on the function ϕ.

The numerical agreement between reference Bayesian credible regions and frequentist confidence intervals is actually perfect in special circumstances. Indeed, as Lindley (1958) pointed out, this is the case in those problems of inference which may be transformed to location-scale problems.

Example 3 (Inference on normal parameters, continued). Let $D = \{x_1, \ldots x_n\}$ be a random sample from a normal distribution $N(x\,|\,\mu, \sigma)$. As mentioned before, the reference posterior of the quantity of interest μ is the Student distribution $\mathrm{St}\left(\mu\,|\,\bar{x}, s/\sqrt{n-1}, n-1\right)$. Thus, normalizing μ, the *posterior* distribution of $t(\mu) = \sqrt{n-1}(\bar{x} - \mu)/s$, as a function of μ given D, is the standard Student $\mathrm{St}(t\,|\,0, 1, n-1)$ with $n-1$ degrees of freedom. On the other hand, this function t is recognized to be precisely the conventional t statistic, whose *sampling distribution* is well known to *also* be standard Student with $n-1$ degrees of freedom. It follows that, *for all sample sizes*, posterior *reference* credible intervals for μ given the data will be *numerically identical* to frequentist confidence intervals based on the sampling distribution of t.

A similar result is obtained in inferences about the variance. Thus, the reference *posterior* distribution of $\lambda = \sigma^{-2}$ is the ►Gamma distribution $\mathrm{Ga}(\lambda\,|\,(n-1)/2, ns^2/2)$ and, hence, the *posterior* distribution of $r = ns^2/\sigma^2$, as a function of σ^2 given D, is a (central) χ^2 with $n-1$ degrees of freedom. But the function r is recognized to be a conventional statistic for this problem, whose *sampling distribution* is well known to *also* be χ^2 with $n-1$ degrees of freedom. It follows that, *for all sample sizes*, posterior *reference* credible intervals for σ^2 (or any one-to-one

function of σ^2) given the data will be *numerically identical* to frequentist confidence intervals based on the sampling distribution of r.

For a recent review or modern objective Bayesian inference, see Bernardo (2010).

Discussion

In writing a broad article it is always hard to decide what to leave out. This article focused on the basic concepts of the Bayesian paradigm; methodological topics which have unwillingly been omitted include design of experiments, sample surveys, linear models and sequential methods. The interested reader is referred to the bibliography for further information. This final section briefly reviews the main arguments for the Bayesian approach, and includes pointers to further issues which have not been discussed in more detail due to space limitations.

Coherence

By using probability distributions to characterize *all* uncertainties in the problem, the Bayesian paradigm reduces statistical inference to applied probability, thereby ensuring the coherence of the proposed solutions. There is no need to investigate, on a case by case basis, whether or not the solution to a particular problem is logically correct: a Bayesian result is only a *mathematical consequence of explicitly stated assumptions* and hence, unless a logical mistake has been committed in its derivation, it cannot be formally wrong. In marked contrast, conventional statistical methods are plagued with counterexamples. These include, among many others, negative estimators of positive quantities, q-confidence regions ($q < 1$) which consist of the whole parameter space, empty sets of "appropriate" solutions, and incompatible answers from alternative methodologies simultaneously supported by the theory.

The Bayesian approach does require, however, the specification of a (prior) probability distribution over the parameter space. The sentence "a prior distribution does not exist for this problem" is often stated to justify the use of non-Bayesian methods. However, the general representation theorem *proves the existence* of such a distribution whenever the observations are assumed to be exchangeable (and, if they are assumed to be a random sample then, *a fortiori*, they are assumed to be exchangeable). To ignore this fact, and to proceed as if a prior distribution did not exist, just because it is not easy to specify, is mathematically untenable.

Objectivity

It is generally accepted that any statistical analysis is subjective, in the sense that it is always conditional on accepted assumptions (on the structure of the data, on the probability model, and on the outcome space) and those assumptions, although possibly well founded, are definitely *subjective* choices. It is, therefore, mandatory to make all assumptions very explicit.

Users of conventional statistical methods rarely dispute the mathematical foundations of the Bayesian approach, but claim to be able to produce "objective" answers in contrast to the possibly subjective elements involved in the choice of the prior distribution.

Bayesian methods do indeed require the choice of a prior distribution, and critics of the Bayesian approach systematically point out that in many important situations, including scientific reporting and public decision making, the results must exclusively depend on documented data which might be subject to independent scrutiny. This is of course true, but those critics choose to ignore the fact that this particular case is covered within the Bayesian approach by the use of *reference* prior distributions which (1) are mathematically derived from the accepted probability model (and, hence, they are "objective" insofar as the choice of that model might be objective) and, (2) by construction, they produce posterior probability distributions which, given the accepted probability model, *only* contain the information about their values which data may provide and, *optionally*, any further contextual information over which there might be universal agreement.

An issue related to objectivity is that of the operational meaning of reference posterior probabilities; it is found that the analysis of their behavior under repeated sampling provides a suggestive form of calibration. Indeed, $\Pr[\boldsymbol{\theta} \in R \,|\, D] = \int_R \pi(\boldsymbol{\theta} \,|\, D)\, d\boldsymbol{\theta}$, the reference posterior probability that $\boldsymbol{\theta} \in R$, is *both* a measure of the conditional uncertainty (given the assumed model and the observed data D) about the event that the unknown value of $\boldsymbol{\theta}$ belongs to $R \subset \Theta$, and the limiting proportion of the regions which would cover $\boldsymbol{\theta}$ under repeated sampling conditional on data "sufficiently similar" to D. Under broad conditions (to guarantee regular asymptotic behavior), all large data sets from the same model are "sufficiently similar" among themselves in this sense and hence, given those conditions, reference posterior credible regions are *approximate* unconditional frequentist confidence regions.

The conditions for this approximate *unconditional* equivalence to hold exclude, however, important special cases, like those involving "extreme" or "relevant" observations. In very special situations, when probability models may be transformed to location-scale models, there is an exact unconditional equivalence; in those cases reference posterior credible intervals are, for any sample size, exact unconditional frequentist confidence intervals.

Applicability

In sharp contrast to most conventional statistical methods, which may only be exactly applied to a handful of relatively simple stylized situations, Bayesian methods are (in theory) totally general. Indeed, for a given probability model and prior distribution over its parameters, the derivation of posterior distributions is a well-defined mathematical exercise. In particular, Bayesian methods do not require any particular regularity conditions on the probability model, do not depend on the existence of sufficient statistics of finite dimension, do not rely on asymptotic relations, and do not require the derivation of any sampling distribution, nor (a fortiori) the existence of a "pivotal" statistic whose sampling distribution is independent of the parameters.

However, when used in complex models with many parameters, Bayesian methods often require the computation of multidimensional definite integrals and, for a long time in the past, this requirement effectively placed practical limits on the complexity of the problems which could be handled. This has dramatically changed in recent years with the general availability of large computing power, and the parallel development of simulation-based numerical integration strategies like *importance sampling* or ►*Markov chain Monte Carlo* (MCMC). These methods provide a structure within which many complex models may be analyzed using generic software. MCMC is numerical integration using Markov chains. Monte Carlo integration proceeds by drawing samples from the required distributions, and computing sample averages to approximate expectations. MCMC methods draw the required samples by running appropriately defined ►Markov chains for a long time; specific methods to construct those chains include the Gibbs sampler and the Metropolis algorithm, originated in the 1950s in the literature of statistical physics. The development of improved algorithms and appropriate diagnostic tools to establish their convergence, remains a very active research area.

Actual scientific research often requires the use of models that are far too complex for conventional statistical methods. This article concludes with a glimpse at some of them.

Hierarchical structures. Consider a situation where a possibly variable number n_i of observations, $\{\boldsymbol{x}_{ij}, j = 1, \ldots, n_i\}$, $i = 1, \ldots, m$, are made on each of m internally homogeneous subsets of some population. For instance, a firm might have chosen m production lines for inspection, and n_i items might have been randomly selected among those made by production line i, so that $\boldsymbol{x}_{ij}$ is the result of the measurements made on item j of production line i. As another example, animals of some species are captured to study their metabolism, and a blood sample taken before releasing them again; the procedure is repeated in the same habitat for some time, so that some of the animals are recaptured several times, and $\boldsymbol{x}_{ij}$ is the result of the analysis of the j-th blood sample taken from animal i. It those situations, it is often appropriate to assume that the n_i observations on subpopulation i are exchangeable, so that they may be treated as a random sample from some model $p(\boldsymbol{x} \mid \boldsymbol{\theta}_i)$ indexed by a parameter $\boldsymbol{\theta}_i$ which depends on the subpopulation observed, and that the parameters which label the subpopulations may also be assumed to be exchangeable, so that $\{\boldsymbol{\theta}_1, \ldots, \boldsymbol{\theta}_m\}$ may be treated as a random sample from some distribution $p(\boldsymbol{\theta} \mid \boldsymbol{\omega})$. Thus, the complete *hierarchical* model which is assumed to have generated the observed data $D = \{\boldsymbol{x}_{11}, \ldots, \boldsymbol{x}_{mn_m}\}$ is of the form

$$p(D \mid \boldsymbol{\omega}) = \int_{\Theta^m} \left[\prod_{j=1}^{n_i} p(\boldsymbol{x}_{ij} \mid \boldsymbol{\theta}_i) \right] \left[\prod_{i=1}^{m} p(\boldsymbol{\theta}_i \mid \boldsymbol{\omega}) \right] \left[\prod_{i=1}^{m} d\boldsymbol{\theta}_i \right].$$

Hence, under the Bayesian paradigm, a family of conventional probability models, say $p(\boldsymbol{x} \mid \boldsymbol{\theta})$, $\boldsymbol{\theta} \in \Theta$, and an appropriate "structural" prior $p(\boldsymbol{\theta} \mid \boldsymbol{\omega})$, may be naturally combined to produce a versatile, complex model $\{p(D \mid \boldsymbol{\omega}), \boldsymbol{\omega} \in \boldsymbol{\Omega}\}$ whose analysis is often well beyond the scope of conventional statistics. The Bayesian solution only requires the specifiction a prior distribution $p(\boldsymbol{\omega})$, the use Bayes' theorem to obtain the corresponding posterior $p(\boldsymbol{\omega} \mid D) \propto p(D \mid \boldsymbol{\omega})\, p(\boldsymbol{\omega})$, and the performance of the appropriate probability transformations to derive the posterior distributions of the quantities of interest (which may well be functions of $\boldsymbol{\omega}$, functions of the $\boldsymbol{\theta}_i$'s, or functions of future observations). As in any other Bayesian analysis, the prior distribution $p(\boldsymbol{\omega})$ has to describe available knowledge about $\boldsymbol{\omega}$; if none is available, or if an objective analysis is required, an appropriate reference prior function $\pi(\boldsymbol{\omega})$ may be used.

Contextual information. In many problems of statistical inference, objective and universally agreed contextual information is available on the parameter values. This information is usually very difficult to handle within the framework of conventional statistics, but it is easily incorporated into a Bayesian analysis by simply restricting the prior distribution to the class $\mathcal{P}$ of priors which are compatible with such information. As an example, consider the frequent problem in archaeology of trying to establish the occupation period $[\alpha, \beta]$ of a site by some past culture on the basis of the radiocarbon dating of organic samples taken from the excavation. Radiocarbon dating is not precise, so that each dating x_i is typically taken to be a normal observation from a distribution $N(x \mid \mu(\theta_i), \sigma_i)$, where θ_i is the actual, unknown calendar date of the sample, $\mu(\theta)$

is an internationally agreed calibration curve, and σ_i is a known standard error quoted by the laboratory. The actual calendar dates $\{\theta_1, \ldots, \theta_m\}$ of the samples are typically assumed to be uniformly distributed within the occupation period $[\alpha, \beta]$; however, stratigraphic evidence indicates some partial orderings for, if sample i was found on top of sample j in undisturbed layers, then $\theta_i > \theta_j$. Thus, if $\mathcal{C}$ denotes the class of values of $\{\theta_1, \ldots, \theta_m\}$ which satisfy those known restrictions, data may be assumed to have been generated by the hierarchical model

$$p(x_1, \ldots, x_m \mid \alpha, \beta) = \int_{\mathcal{C}} \left[\prod_{i=1}^{m} N\left(x_i \mid \mu(\theta_i), \sigma_i^2\right) \right] (\beta - \alpha)^{-m} \, d\theta_1 \ldots d\theta_m.$$

Often, contextual information further indicates an absolute lower bound α_0 and an absolute upper bound β_0 for the period investigated, so that $\alpha_0 < \alpha < \beta < \beta_0$. If no further documented information is available, the corresponding restricted reference prior for the quantities of interest, $\{\alpha, \beta\}$ should be used; this is found to be $\pi(\alpha, \beta) \propto (\beta - \alpha)^{-1}$ whenever $\alpha_0 < \alpha < \beta < \beta_0$ and zero otherwise. The corresponding reference posterior $\pi(\alpha, \beta \mid x_1, \ldots, x_m) \propto p(x_1, \ldots, x_m \mid \alpha, \beta)\, \pi(\alpha, \beta)$ summarizes all available information on the occupation period.

Covariate information. Over the last 30 years, both linear and non-linear regression models have been analyzed from a Bayesian point of view at increasing levels of sophistication. These studies range from the elementary objective Bayesian analysis of simple linear regression structures (which parallel their frequentist counterparts) to the sophisticated analysis of time series involved in dynamic forecasting which often make use of complex hierarchical structures. The field is far too large to be reviewed in this article, but the bibliography contains some relevant pointers.

Model Criticism. It has been stressed that *any* statistical analysis is conditional on the accepted assumptions of the probability model which is presumed to have generated the data. Recent years have shown a huge effort into the development of Bayesian procedures for *model criticism* and *model choice*. Most of these are sophisticated elaborations of the procedures described in section "►Hypothesis Testing" under the heading of hypothesis testing. Again, this is too large a topic to be reviewed here, but some key references are included in the bibliography.

About the Author

Professor José Bernardo is founder co-President of the International Society for Bayesian Analysis (1992–1994). He is the personal organizer and Programme Committee Member of the Valencia International Meetings on Bayesian Statistics, established world forums on Bayesian Methods, held every 4 years in Spain since 1979. Spanish Royal Academy of Science invited Professor Bernardo to become the Editor of the special issue of its journal *the Rev. Acad. Cien. Madrid*, devoted entirely to Bayesian Methods in the Sciences (1999). He has co-edited (as the first author) eight proceedings of the Valencia meetings on Bayesian Statistics. Professor Bernardo is a Fellow of the American Statistical Association, Royal Statistical Society and Elected Member of the International Statistical Institute. He was Founding Editor of *Test* (1992–1997), associate editor for the *Journal of the Royal Statistical Society* (Series B) (1989–1993), *The Statistician* (1987–1997), *Questio* (1983–2002); Contributing Editor of the *Current Index of Statistics* and *Statistics Theory and Methods Abstracts* (1996–2003). Currently he is an Associate editor for the *Journal of the Iranian Statistical Society*. He was delivering lectures at more than 60 universities worldwide. He is a co-author (with Adrian Smith) of the well known text *Bayesian Theory* (Wiley, 1994).

Bayesian Versus Frequentist Statistical Reasoning

Jordi Vallverdú
Universitat Autònoma de Barcelona, Catalonia, Spain

We can consider the existence of two main statistical schools: Bayesian and frequentist. Both provide ways to deal with probability, although their methods and theories are mutually exclusive (Vallverdú 2008).

Bayesian Statistics

From a historical perspective, Bayesian appeared first, in 1763, when Richard Price published posthumously the paper of late Rev. Thomas Bayes "An Essay towards solving a Problem in the Doctrine of Chances" (Dale 2003). In this paper, Bayes presented his ideas about the best way

of dealing with probability (and trying to solve the problem of *inverse probability*), which can be exemplified today with the classic formula called "Bayes' Rule" or "Bayes' Theorem":

$$P(A|B) = \frac{P(B|A)\,P(A)}{P(B)}.$$

We must look at the notation and terminology involved:

- $P(A|B)$ is the *conditional probability* of A, given B. It is also called the *posterior probability* because it is derived from or depends upon the specified value of B.
- $P(B|A)$ is the conditional probability of B given A.
- $P(A)$ is the *prior probability* or *marginal probability* of A. It is "prior" in the sense that it does not take into account any information about B.
- $P(B)$ is the prior or marginal probability of B, and acts as a *normalizing constant*.

We can see, then, that our *posterior* belief $P(A|B)$ is calculated by multiplying our *prior* belief $P(A)$ by the *likelihood* $P(B|A)$ that B will occur if A is true. Although Bayes' method was enthusiastically taken up by Laplace and other leading probabilists of the day, it fell into disrepute in the nineteenth century because they did not yet know how to handle *prior probabilities* properly. The *prior probability* of A represents our best estimate of the probability of the fact we are considering, prior to consideration of the new piece of evidence. Therefore, in the Bayesian paradigm, current knowledge about the model parameters is expressed by placing a probability distribution on the parameters, called the "prior distribution." When new data become available, the information they contain regarding the model parameters is expressed in the "likelihood," which is proportional to the distribution of the observed data given the model parameters. This information is then combined with the prior to produce an updated probability distribution called the "posterior distribution," on which all Bayesian inference is based. ►Bayes' Theorem, an elementary identity in probability theory, states how the update is done mathematically: the posterior is proportional to the prior times the likelihood.

There are a large number of types of Bayesians (speaking ironically, Good (1971) spoke of "46,656 kinds of Bayesians"), depending on their attitude toward subjectivity in postulating priors. Some recent Bayesian books are Earman (1992), Howson and Urbach (1991), Bernardo and Smith (1996).

Frequentist Statistics

On the other hand, we have the frequentist paradigm. Its followers understand probability as a long-run frequency of a "repeatable" event and developed a notion of confidence intervals. Probability would be, then, a measurable frequency of events determined from repeated experiments. We can express it as:

$$P(A) = n/N,$$

where n is the number of times event A occurs in N opportunities.

From the frequentist viewpoint two closely related methods have been developed. One is the Neyman–Pearson theory of significance tests and the other is based on Fisher's notion of ►*p*-values. The researchers who follow this approach, consider frequentism as the only allowed statistical method for achieving sound scientific inferences (Mayo and Cox 2006).

The Debate: Degrees of Belief Versus Relative Frequencies

As early as in 1949, Maurice George Kendall (1949) wrote a paper, "On the Reconciliation of Theories of Probability," in which he coined the word "frequentist" and stated: "Few branches of scientific method have been subject to so much difference of opinion as the theory of probability." He tried to attempt mediation between the contestants, but failed.

Clearly, one of the recurrent arguments against/in favor of one of the two positions (frequentist or Bayesian) consists in saying that a true scientist is always/never frequentist/Bayesian (you can *choose* between the two possibilities). As an example of this confrontation see the ideas of Giere (1988): "Are Scientists Bayesian Agents? (. . .) The overwhelming conclusion is that humans are not bayesian agents," and of Efron (1986) or Cousins (1995). The last two do not need to be quoted. It seems to be an epistemological law about statistical practices: "A true scientist never belongs to the opposite statistical school" (Vallverdú 2008).

It could seem that frequentists are realists, when they consider relative frequencies and that Bayesian are subjective, when they defend degrees of belief of prior probabilities but the truth is that in cluster investigations, for example, the frequentist approach is just as subjective as the Bayesian approach, although the Bayesian approach is less ambitious in that it treats the analysis as a synthesis of data and personal judgments (possibly poor ones), rather than objective reality (Coory et al. 2009).

Why to Become Frequentist/Bayesian?

Bland and Altman (1998, p. 1160) have their own answer: "Most statisticians have become Bayesians or Frequentists as a result of their choice of university." And as the epidemiologist Berger (2003) says: "practicing epidemiologists are given little guidance in choosing between these approaches apart from the ideological adherence of mentors, colleagues and editors."

So, the arguments go beyond the ethereal philosophical arena and become more practical ones. Better opportunities to find a good job is an important argument, and the value of a Bayesian academic training is now accepted: "where once graduate students doing Bayesian dissertations were advised to try not to look too Bayesian when they went on the job market, now great numbers of graduate students try to include some Bayesian flavor in their dissertations to increase their marketability" (Wilson 2003, p. 372). Therefore, and following Hacking (1972, p. 133): "Euler at once retorted that this advice is metaphysical, not mathematical. Quite so! The choice of primitive concepts for inference *is* a matter of 'metaphysics'. The orthodox statistician has made one metaphysical choice and the Bayesian another." To be honest, there is not a fatally flawed position, but different context-based applications of both main approaches. As Gigerenzer et al. (1990) express "we need statistical thinking, not statistical rituals." Lilford and Braunholtz (1996, p. 604) go further: "when the situation is less clear cut (...) conventional statistics may drive decision makers into a corner and produce sudden, large changes in prescribing. The problem does not lie with any of the individual decision makers, but with the very philosophical basis of scientific inference. We propose that conventional statistics should not be used in such cases and that the Bayesian approach is both epistemologically and practically superior." There is also a structural aspect: computational facilities; due to recent innovations in scientific computing (faster computer processors) and drastic drops in the cost of computers, the number of statisticians trained in Bayesian methodology has increased (Tan 2001). Trying to offer a midpoint perspective, Berger (2003) proposes using both models and studying case by case their possibilities: "based on the philosophical foundations of the approaches, Bayesian models are best suited to addressing hypotheses, conjectures, or public-policy goals, while the frequentist approach is best suited to those epidemiological studies which can be considered 'experiments', i.e., testing constructed sets of data." Usually, we find no such equitable position.

Considering all these facts, we can conclude that both frequentist and Bayesian statisticians use sound science in their researches and that, in the end, this debate is a deep philosophical one, not a matter of rational argument.

Bayesian vs. Classical Point Estimation: A Comparative Overview

Francisco J. Samaniego
Professor
University of California-Davis, Davis, CA, USA

The foundations of the classical theory of point estimation are embedded in the work of Frederick Gauss, Karl Pearson and Ronald Fisher, though there have been many other contributors, as documented in Stigler's (1986) historical masterpiece or, in more technical terms, in Lehmann and Casella (1998). In the framework of independent, identically distributed (i.i.d.) observations, the theory seeks to obtain good estimators (or "best guesses") of an unknown scalar or vector-valued parameter θ based on a "random sample" of observations drawn from a distribution indexed by this parameter. The adjective "frequentist" is often used in referring to classical methods, largely because the theory of their performance is based on the premise that the experiment from which data is drawn can be replicated repeatedly and that estimators (and other statistical procedures) may be evaluated and compared on the basis of their expected performance over the intended number of replications or on a hypothesized infinite number of i.i.d. trials. Finite sample methods leading, for example, to ►least-squares, best-unbiased or best-invariant estimators, and estimators based on asymptotic theory, the premier example of which is the maximum likelihood estimators proposed by Fisher, are generally studied separately and are, together, the mainstays of the theory and practice of frequentist estimation. These are discussed in more detail below, as well as elsewhere in the Encyclopedia.

Bayesian estimation theory tends to start at the same place outlined above. It begins with a model for the observable data, and assumes the existence of data upon which inference about a target parameter will be based. The important point of departure from classical inference is the position that uncertainty should be treated stochastically. From this, it follows that since the target parameter in a point estimation problem is unknown, one's uncertainty about its value is appropriately represented by a "prior probability distribution" on that parameter. The Bayesian position is not simply a whim or a matter of convenience; it is in fact motivated and defended through a system of axioms about the comparison of possible uncertain events and the fact that the axiom system leads to this position as a derived result. See De Groot (1970) for further details. The Bayesian paradigm for estimation can be by described as involving three steps: the specification of a prior distribution (through introspection or the elicitation of expert opinion), the updating of that prior on the basis of available data, leading to the "posterior distribution" on the parameter, and the estimation of the parameter based on characteristics of the posterior distribution. The mean of the posterior distribution is probably the most commonly used Bayesian point estimator.

Comparisons between frequentist and Bayesian estimators raise some challenging issues. There are important philosophical differences between the approaches that make it difficult to compare them side by side. For example, the Likelihood Principle (see, for example, Berger and Wolpert (1984)) stipulates that inference about an unknown parameter should depend of the experiment only through the observed data $\mathbf{x} = (x_1, x_2, \ldots, x_n)$ or, equivalently, through the likelihood function, which for the present purposes, may be thought of as a constant multiple of the joint density

$$L(\theta|\mathbf{x}) = f(\mathbf{x}|\theta),$$

with $\mathbf{x}$ fixed and known. As a consequence, the process of averaging over the sample space, as the frequentist does, for example, in minimizing the variance among unbiased estimators of a parameter, is inappropriate from the Bayesian viewpoint. Only the observed data, rather than what might have been observed in the experiment but wasn't, is relevant in Bayesian inference about θ. Maximum likelihood estimation, which obeys the likelihood principle in the sense that its calculation relies solely on the maximization of $L(\theta|\mathbf{x})$, might thus seem consistent with the Bayesian approach, but it runs afoul of that paradigm on the basis of the facts that it fails to quantify the uncertainty about θ stochastically and its entire theoretical justification is based on the familiar averaging process over the sample space, albeit in a limiting sense.

There are many texts, monographs and research papers which treat Bayesian and frequentist estimators and offer some discussion on how one might compare them. In this brief review, the discussion of this literature is clearly out of the question. We will limit ourselves to arguments and theory that may be found in the books by Lehmann and Casella (1998), Robert (2001), Cox (2006) and in the paper by Samaniego and Reneau (1994). A more comprehensive treatment of the subject of the comparative analysis of Bayesian and frequentist point estimators can be found in the monograph by Samaniego (2010). The references cited in the sources above are wide in scope and will provide the interested reader with an enormous collection of collateral reading that is highly relevant to the subject of interest here.

When one seeks to compare the Bayesian and frequentist approaches to point estimation, one might begin with a

foundational issue, namely, which approach has defensible logical underpinnings. As it happens, this is a rather easy matter to resolve. The classical theory of estimation has no logical underpinnings to speak of. The theories of unbiased estimators, invariant estimators and maximum likelihood estimators (MLEs) are justified by frequentists on intuitive grounds. For example, "unbiasedness" and "invariance" are intuitively appealing ways of restricting the class of all possible estimators, a class which is "too large" and contains no "best estimator" in any nontrivial problem. Maximum likelihood estimators "work well" based on a sample of infinite size, so perhaps they will work well the given finite-sample problem at hand. The frequentist approach to estimation is unabashedly *ad hoc*, and there is widespread recognition that the particular frequentist tool one might wish to use in different problems might vary, with least squares (or its well-known variants) used in regression and ANOVA problems, UMVUEs used in finite-sample problems in which their derivation is feasible and MLEs used in estimation problems in which the sample size is thought to be suitably large. In contrast with these circumstances, the Bayesian approach to point estimation is based on a system of "plausible" axioms about how one should deal with uncertainty. The fact that the Bayesian approach to statistical inference is built upon a logical basis which one can formally study and scrutinize places it on a higher "logical" plane than frequentist inference. Most readers of the axioms of Bayesian inference will find them "reasonable"; for example, the transitivity of one's assessments about which events are more likely to occur than others is typical of the assumptions one is expected to make. On logical grounds, the Bayesian approach appears to have a strong advantage. Is that enough to justify the claim that Bayesian inference is the preferred approach? The approach does provide a logically consistent process of prior assessment, updating and posterior assessment, leading to inference that can clearly be defended on logical grounds. A disturbing counterargument is that logic, by itself, is not enough. After all, it is possible to be perfectly logical and yet woefully wrong. Poor prior specification can lead to logically consistent estimation in which the Bayesian estimator is way off the mark. Other considerations must be brought to bear on these comparisons.

Bayesian estimation (as well as other modes of Bayesian inference) has a fairly apparent Achilles heal, the fact that the Bayesian interjects subjective prior information into the inference process, potentially infusing errors or biases that would not otherwise be present. This is a legitimate concern, and one that the "orthodox" Bayesian (that is, one who uses a proper probability distribution for his prior) must always be mindful of and careful about. While the usual counterargument does diffuse the criticism somewhat, a general fix does not exist. The argument that helps mitigate the criticism is that it is often the case that the Bayesian approach is essential in making sensible inferences. For example, a frequentist who observes ten heads in ten tosses of a newly minted coin has no choice but to estimate the probability of heads as $p = 1$, while a typical Bayesian, using a quite reasonable beta prior, might instead estimate p to be about 0.52. In situations such as this, Bayesian methods may be seen as a reasonable way of averting disaster.

There are many other grounds on which comparisons can be made. Regarding asymptotic performance for example, it is known that proper Bayes estimators based on priors that place positive mass on all open subsets of the parameter space enjoy the same asymptotic properties as the best asymptotically normal (BAN) estimators of frequentist estimation theory (most notably, MLEs). Multivariate analysis poses greater challenges to the Bayesian than to the frequentist, largely due to the difficulty of obtaining and quantifying useful prior information on high-dimensional parameters. The frequentists would seem to have a bit of an advantage in this area. Robert (2001) employs decision theoretic arguments quite prominently in his defense of Bayesian methods. One of the centerpieces of that defense is the so-called complete class theorem which, in essence, says that any admissible decision rule (here, estimator) is Bayes (or nearly Bayes) with respect to some prior. This statement begs the question: why ever use anything else? To some, this argument seems to have obvious weaknesses, and the question is rather easy to answer. The fact that an estimator belongs to a class that contains all the "good" estimators hardly justifies its use. After all, the estimator that always estimates the scalar parameter θ to be 5 is admissible but would (essentially) never be recommended for use. In addition to the inconclusive arguments above, there are examples on both sides that show that the other approach gives silly answers to particular statistical questions. Bayesians often use the term "incoherent" when referring to frequentist procedures of this sort. To the frequentist school, the most pressing concern is the very real possibility of obtaining poor answers from a Bayesian analysis due to poor prior input.

Samaniego and Reneau (1994) offer a quite different, performance-based comparison of Bayesian and frequentist estimators – the Bayes risk of an estimator relative to the "truth", with the latter modeled as a (possibly degenerate) "true prior distribution" on the unknown parameter. The threshold problem (i.e., finding the boundary separating Bayes estimators that outperform the frequentist estimator of choice from Bayes estimators that don't) is introduced. Explicit solutions to the threshold problem are

obtained in the context of sampling distributions belonging to one-parameter exponential families, conjugate prior families and squared error loss. In Samaniego (2010), subsequent extensions of this work to the estimation of high-dimensional parameters and to estimation under asymmetric loss are treated. While the "true state" of the target parameter remains unknown throughout these analyses, it is seen that useful practical guidance can nevertheless be gleaned from them. In many problems, the class of Bayes estimators that are superior to frequentist alternatives is surprisingly broad. Bayesians who are both misguided (with a poorly centered prior distribution) and stubborn (with a tightly concentrated prior distribution) will generally not do well. Interestingly, it is shown that one flaw or the other need not be fatal by itself. But perhaps the most important conclusion of these studies is the simple fact that that neither the Bayesian nor the frequentist approach to point estimation will be uniformly dominant in any well-defined point estimation problem. In all such problems, there will be a threshold separating "good" priors from "bad" ones, and the remaining challenge, one that is by no means trivial, is trying to make a sensible judgment about which side of the threshold one is on, given the prior information one has in hand. This examination may lead one to a Bayes estimator or to a frequentist estimator in the particular problem of interest.

About the Author

Francisco Samaniego holds the title of Distinguished Professor of Statistics at the University of California, Davis. He has authored two recent Springer monographs, the first on "system signatures," a notion that he introduced to the engineering literature in a 1985 IEEE paper, and the second on "comparative statistical inference" focusing on the relative performance of Bayesian and frequentist point estimators. He is a Fellow of the ASA, IMS, RSS and a member of the ISI. He is a former Editor of *The Journal of the American Statistical Association*. In 2008, he received the U.S. Army Samuel S. Wilks Award for career contributions to reliability.

Behrens–Fisher Problem

Allan S. Cohen, Seock-Ho Kim
Professors
University of Georgia, Athens, GA, USA

Introduction

The Behrens–Fisher problem is the problem in statistics of hypothesis testing and interval estimation regarding the difference between the means of two independent normal populations without assuming the variances are equal. The solution of this problem was first offered by Behrens (1929) and reformulated later by Fisher (1939) using

$$t' = \frac{(\bar{x}_1 - \bar{x}_2) - (\mu_1 - \mu_2)}{\sqrt{s_1^2/n_1 + s_2^2/n_2}} = t_1 \sin\theta - t_2 \cos\theta,$$

where the sample mean $\bar{x}_1$ and sample variance s_1^2 are obtained from the random sample of size n_1 from the normal distribution with mean μ_1 and variance σ_1^2, $t_1 = (\bar{x}_1 - \mu_1)/\sqrt{s_1^2/n_1}$ has a t distribution with $\nu_1 = n_1 - 1$ degrees of freedom, the respective quantities with subscript 2 are defined similarly, and $\tan\theta = (s_1/\sqrt{n_1})/(s_2/\sqrt{n_2})$ or

$\theta = \tan^{-1}[(s_1/\sqrt{n_1})/(s_2/\sqrt{n_2})]$. The distribution of t' is the Behrens–Fisher distribution. It is, hence, a mixture of the two t distributions.

Under the usual null hypothesis of H_0: $\mu_1 = \mu_2$, the test statistic t', can be obtained and compared with the percentage points of the Behrens–Fisher distribution. Tables for the Behrens–Fisher distribution are available from Fisher and Yates (1957) and Lindley and Scott (1995). The table entries are based on the four numbers: ν_1, ν_2, θ, and the Type I error rate α. For example, Fisher and Yates (1957) presented significance points of the Behrens–Fisher distribution in two tables, one for $\nu_1 = \nu_2 = 8, 12, 24, \infty$, $\theta = 0°, 15°, 30°, 45°, 60°, 75°, 90°$, and $\alpha = 0.05, 0.01$, and the other for ν_1 that is greater than $\nu_2 = 1, 2, 3, 4, 5, 6, 7$, $\theta = 0°, 15°, 30°, 45°, 60°, 75°, 90°$, and $\alpha = 0.10, 0.05, 0.02, 0.01$.

Using the Behrens–Fisher distribution, the $100(1-\alpha)\%$ interval that contains $\mu_1 - \mu_2$ can be constructed with

$$\bar{x}_1 - \bar{x}_2 \pm t'_{\alpha/2}(\nu_1, \nu_2, \theta)\sqrt{s_1^2/n_1 + s_2^2/n_2},$$

where the probability that $t' > t'_{\alpha/2}(\nu_1, \nu_2, \theta)$ is $\alpha/2$ or, equivalently, $\Pr[t' > t'_{\alpha/2}(\nu_1, \nu_2, \theta)] = \alpha/2$.

The Behrens–Fisher t' statistic and the Behrens–Fisher distribution are based on Fisher's (1935) fiducial approach. The approach is to find a fiducial probability distribution that is a probability distribution of a parameter from observed data. Consequently, the interval that involves $t'_{\alpha/2}(\nu_1, \nu_2, \theta)$ is referred to as the $100(1 - \alpha)\%$ fiducial interval.

Example

Driving times from a person's house to work were measured for two different routes with $n_1 = 5$ and $n_2 = 11$ (see Lehmann 1975, p. 83). The ordered data from the first route are 6.5, 6.8, 7.1, 7.3, 10.2 yielding $\bar{x}_1 = 7.580$ and $s_1^2 = 2.237$, and the data from the second route are 5.8, 5.8, 5.9, 6.0, 6.0, 6.0, 6.3, 6.3, 6.4, 6.5, 6.5 yielding $\bar{x}_2 = 6.136$ and $s_2^2 = 0.073$. It is assumed that the two independent samples were drawn from two normal distributions having means μ_1 and μ_2 and variances σ_1^2 and σ_2^2, respectively. A researcher wants to know whether the average driving times differed for the two routes.

The test statistic under the null hypothesis of equal population means is $t' = 2.143$ with $\nu_1 = 4$, $\nu_2 = 10$, and $\theta = 83.078$. The result, $\Pr(t' > 2.143) = 0.049$, indicates the null hypothesis cannot be rejected at $\alpha = 0.05$ when the alternative hypothesis is non-directional, H_a: $\mu_1 \neq \mu_2$, because $p = 0.098$. The corresponding 95% interval for the population mean difference is $[-0.431, 3.308]$.

Other Solutions

The Student's t test (see ▶Student's t-Tests) for independent means can be used when the two population variances are assumed to be equal and $\sigma_1^2 = \sigma_2^2 = \sigma^2$,

$$t = \frac{(\bar{x}_1 - \bar{x}_2) - (\mu_1 - \mu_2)}{\sqrt{s_p^2/n_1 + s_p^2/n_2}},$$

where the pooled variance that provides the estimate of the common population variance σ^2 is defined as $s_p^2 = \left[(n_1 - 1)s_1^2 + (n_2 - 1)s_2^2\right]/(n_1 + n_2 - 2)$. It has a t distribution with $\nu = n_1 + n_2 - 2$ degrees of freedom. The example data yield the Student's $t = 3.220$, $\nu = 14$, the two-tailed $p = 0.006$, and the 95% confidence interval of $[0.482, 2.405]$. The null hypothesis of equal population means is rejected at the nominal $\alpha = 0.05$, and the confidence interval does not contain 0.

When the two variances cannot be assumed to be the same, there are several alternative solutions in addition to use the Behrens–Fisher t' statistic. One simple way to solve this two means problem, called the smaller degrees of freedom t test, is to use the same t' statistic that has a t distribution with different degrees of freedom (e.g., Moore 2007, p. 465):

$$t' \sim t[\min(\nu_1, \nu_2)],$$

where the degrees of freedom is the smaller value of ν_1 or ν_2. Note that this method should be used only if no statistical software is available because it yields a conservative test result and a wider confidence interval. The example data yield $t' = 2.143$, $\nu = 4$, the two-tailed $p = 0.099$, and the 95% confidence interval of $[-0.427, 3.314]$. The null hypothesis of equal population means is not rejected at $\alpha = 0.05$, and the confidence interval contains 0.

Welch (1938)'s approximate t test also uses the same t' statistic that has a t distribution with the approximate degrees of freedom ν' (see Moore 2007, p. 474):

$$t' \sim t(\nu'),$$

where $\nu' = 1/[c^2/\nu_1 + (1 - c)^2/\nu_2]$ with $c = \left(s_1^2/n_1\right)/\left[\left(s_1^2/n_1\right) + \left(s_2^2/n_2\right)\right]$. It can be noted that the equivalent of this Welch's approximate t test was proposed by Smith (1936). Moore (2007) indicated that the approximation is accurate when both sample sizes are 5 or larger. Although there are other solutions, Welch's approximate t test currently seems to be the best practical solution to the Behrens–Fisher problem because of its availability from popular statistical software including SPSS and SAS. The example data yield $t' = 2.143$, $\nu' = 4.118$, the two-tailed $p = 0.097$, and the 95% confidence interval of $[-0.406, 3.293]$. The null hypothesis of equal population means is

not rejected at $\alpha = 0.05$, and the confidence interval contains 0.

In addition to the previous method, Welch (1938, 1947) and Aspin (1948) presented an approximation of the distribution of t' by the method of moments (i.e., Welch-Aspin t test; see Kim and Cohen 1998, for the detailed expansion terms for the approximation). The example data yield $t' = 2.143$ and the critical value under the Welch-Aspin t test for the two-tailed test is 2.715 at $\alpha = 0.05$. The corresponding 95% confidence interval is [−0.386, 3.273]. Again, the null hypothesis of equal population means is not rejected at $\alpha = 0.05$, and the confidence interval contains 0.

The Bayesian solution to the Behrens–Fisher problem was offered by Jeffreys (1940). When uninformative uniform priors are used for the population parameters, the Bayesian solution to the Behrens–Fisher problem is identical to that of Fisher's (1939). The Bayesian highest posterior density interval that contains the population mean difference with the probability of $1 - \alpha$ is identical to the $100(1 - \alpha)\%$ fiducial interval.

There are many solutions to the Behrens–Fisher problem based on the frequentist approach of the Neyman and Pearson (1928) sampling theory. Among the methods, Kim and Cohen (1998) indicated that Welch (1938, 1947), Aspin (1948), and Tsui and Weerahandi (1989) are the most important ones from the frequentist perspective. The critical values and the confidence intervals from various methods under the frequentist approach are in general different from either fiducial or Bayesian approach. For the one-sided alternative hypothesis, however, it is interesting to note that the generalized extreme region to obtain the generalized p by Tsui and Weerahandi (1989) is identical to the extreme area from the Behrens–Fisher t' statistic (see also Weerahandi 1995, pp. 174–181).

For the example data, the smaller degrees of freedom t test yielded the most conservative result with the largest critical value and the widest confidence interval. The Student's t test yielded the smallest critical value and the shortest confidence interval. All other intervals lie between these two intervals. Robinson (1982) pointed out that the differences between many solutions to the Behrens–Fisher problem might be less than their differences from the Student's t test when sample sizes are greater than 10.

The popular statistical software programs SPSS and SAS produce results from the Welch's approximate t test and the Student's t test as well as the respective confidence intervals. It is essential to have a table that contains the percentage points of the Behrens–Fisher distribution or computer programs that can calculate the tail areas and percentage values in order to use the Behrens–Fisher t test or to obtain the fiducial interval. Note that the Welch's approximate t test may not be as effective as the Welch-Aspin t test (Wang 1971). Note also that the sequential testing of the population means based on the result from either Levene's test of the equal population variances from SPSS or the folded F test from SAS is not recommended in general due to the complicated nature of control of the Type I error in the sequential testing.

About the Authors

Dr. Allan S. Cohen is Professor of Research, Evaluation, Measurement, and Statistics Program, Department of Educational Psychology and Instructional Technology, and Director, the Georgia Center for Assessment, both at the University of Georgia. He has authored or co-authored over 70 journal articles, 250 conference papers and technical reports as well as several tests, test manuals, and computer programs. He is an editorial board member of Applied Psychological Measurement and the Journal of Educational Measurement and is a Member of the American Educational Research Association and the National Council on Measurement in Education.

Dr. Seock-Ho Kim is Professor of Research, Evaluation, Measurement, and Statistics Program, Department of Educational Psychology and Instructional Technology, University of Georgia. He has co-authored over 40 papers and several computer programs. He has been the Editorial board member of *Educational and Psychological Measurement*, *Journal of Educational Measurement*, *School Psychology Quarterly*, and *Measurement in Physical Education and Exercise Science*. He has a co-authored book with Frank B. Baker entitled *Item Response Theory: Parameter Estimation Techniques* (2nd edn, Dekker, 2004). He is a Member of the American Statistical Association, Institute of Mathematical Statistics, American Educational Research Association, American Psychological Association, National Council on Measurement in Education, and Psychometric Society. Professor Seock-Ho Kim has served as Vice-President and President of the Korean-American Educational Researchers Association.

Best Linear Unbiased Estimation in Linear Models

Simo Puntanen[1], George P. H. Styan[2]
[1]University of Tampere, Tampere, Finland
[2]McGill University, Montréal, QC, Canada

Introduction

In this article we consider the general linear model

$$\mathbf{y} = \mathbf{X}\boldsymbol{\beta} + \boldsymbol{\varepsilon}, \quad \text{or in short } \mathscr{M} = \{\mathbf{y}, \mathbf{X}\boldsymbol{\beta}, \sigma^2\mathbf{V}\},$$

where $\mathbf{X}$ is a known $n \times p$ model matrix, the vector $\mathbf{y}$ is an observable n-dimensional random vector, $\boldsymbol{\beta}$ is a $p \times 1$ vector of unknown parameters, and $\boldsymbol{\varepsilon}$ is an unobservable vector of random errors with expectation $E(\boldsymbol{\varepsilon}) = \mathbf{0}$, and covariance matrix $cov(\boldsymbol{\varepsilon}) = \sigma^2\mathbf{V}$, where $\sigma^2 > 0$ is an unknown constant. The nonnegative definite (possibly singular) matrix $\mathbf{V}$ is known. In our considerations σ^2 has no role and hence we may put $\sigma^2 = 1$.

As regards the notation, we will use the symbols $\mathbf{A}'$, $\mathbf{A}^-$, $\mathbf{A}^+$, $\mathscr{C}(\mathbf{A})$, $\mathscr{C}(\mathbf{A})^\perp$, and $\mathscr{N}(\mathbf{A})$ to denote, respectively, the transpose, a generalized inverse, the Moore–Penrose inverse, the column space, the orthogonal complement of the column space, and the null space, of the matrix $\mathbf{A}$. By $(\mathbf{A} : \mathbf{B})$ we denote the partitioned matrix with $\mathbf{A}$ and $\mathbf{B}$ as submatrices. By $\mathbf{A}^\perp$ we denote any matrix satisfying $\mathscr{C}(\mathbf{A}^\perp) = \mathscr{N}(\mathbf{A}') = \mathscr{C}(\mathbf{A})^\perp$. Furthermore, we will write $\mathbf{P}_\mathbf{A} = \mathbf{A}\mathbf{A}^+ = \mathbf{A}(\mathbf{A}'\mathbf{A})^-\mathbf{A}'$ to denote the orthogonal projector (with respect to the standard inner product) onto $\mathscr{C}(\mathbf{A})$. In particular, we denote $\mathbf{H} = \mathbf{P}_\mathbf{X}$ and $\mathbf{M} = \mathbf{I}_n - \mathbf{H}$. One choice for $\mathbf{X}^\perp$ is of course the projector $\mathbf{M}$.

Let $\mathbf{K}'\boldsymbol{\beta}$ be a given vector of parametric functions specified by $\mathbf{K}' \in \mathbb{R}^{q\times p}$. Our object is to find a (homogeneous) linear estimator $\mathbf{A}\mathbf{y}$ which would provide an unbiased and in some sense "best" estimator for $\mathbf{K}'\boldsymbol{\beta}$ under the model $\mathscr{M}$. However, not all parametric functions have linear unbiased estimators; those which have are called estimable parametric functions, and then there exists a matrix $\mathbf{A}$ such that

$$\mathrm{E}(\mathbf{A}\mathbf{y}) = \mathbf{A}\mathbf{X}\boldsymbol{\beta} = \mathbf{K}'\boldsymbol{\beta} \quad \text{for all } \boldsymbol{\beta} \in \mathbb{R}^p.$$

Hence $\mathbf{K}'\boldsymbol{\beta}$ is estimable if and only if there exists a matrix $\mathbf{A}$ such that $\mathbf{K}' = \mathbf{A}\mathbf{X}$, i.e., $\mathscr{C}(\mathbf{K}) \subset \mathscr{C}(\mathbf{X}')$.

The ordinary ▶least squares estimator of $\mathbf{K}'\boldsymbol{\beta}$ is defined as $\mathrm{OLSE}(\mathbf{K}'\boldsymbol{\beta}) = \mathbf{K}'\hat{\boldsymbol{\beta}}$, where $\hat{\boldsymbol{\beta}}$ is any solution to the normal equation $\mathbf{X}'\mathbf{X}\hat{\boldsymbol{\beta}} = \mathbf{X}'\mathbf{y}$; hence $\boldsymbol{\beta} = \hat{\boldsymbol{\beta}}$ minimizes $(\mathbf{y} - \mathbf{X}\boldsymbol{\beta})'(\mathbf{y} - \mathbf{X}\boldsymbol{\beta})$ and it can be expressed as $\hat{\boldsymbol{\beta}} = (\mathbf{X}'\mathbf{X})^-\mathbf{X}'\mathbf{y}$, while $\mathbf{X}\hat{\boldsymbol{\beta}} = \mathbf{H}\mathbf{y}$. Now the condition $\mathscr{C}(\mathbf{K}) \subset \mathscr{C}(\mathbf{X}')$ guarantees that $\mathbf{K}'\hat{\boldsymbol{\beta}}$ is unique, even though $\hat{\boldsymbol{\beta}}$ may not be unique.

The Best Linear Unbiased Estimator (BLUE) of $\mathbf{X}\boldsymbol{\beta}$

The expectation $\mathbf{X}\boldsymbol{\beta}$ is trivially estimable and $\mathbf{G}\mathbf{y}$ is unbiased for $\mathbf{X}\boldsymbol{\beta}$ whenever $\mathbf{G}\mathbf{X} = \mathbf{X}$. An unbiased linear estimator $\mathbf{G}\mathbf{y}$ for $\mathbf{X}\boldsymbol{\beta}$ is defined to be the *best* linear unbiased estimator, BLUE, for $\mathbf{X}\boldsymbol{\beta}$ under $\mathscr{M}$ if

$$cov(\mathbf{G}\mathbf{y}) \leq_\mathrm{L} cov(\mathbf{L}\mathbf{y}) \quad \text{for all } \mathbf{L}: \mathbf{L}\mathbf{X} = \mathbf{X},$$

where "$\leq_\mathrm{L}$" refers to the Löwner partial ordering. In other words, $\mathbf{G}\mathbf{y}$ has the smallest covariance matrix (in the Löwner sense) among all linear unbiased estimators. We

denote the BLUE of $\mathbf{X}\boldsymbol{\beta}$ as $\mathrm{BLUE}(\mathbf{X}\boldsymbol{\beta}) = \mathbf{X}\tilde{\boldsymbol{\beta}}$. If $\mathbf{X}$ has full column rank, then $\boldsymbol{\beta}$ is estimable and an unbiased estimator $\mathbf{Ay}$ is the BLUE for $\boldsymbol{\beta}$ if $\mathbf{AVA}' \leq_{\mathrm{L}} \mathbf{BVB}'$ for all $\mathbf{B}$ such that $\mathbf{BX} = \mathbf{I}_p$. The Löwner ordering is a very strong ordering implying for example

$$var(\tilde{\beta}_i) \leq var\left(\beta_i^*\right), \quad i = 1, \ldots, p,$$
$$tracecov(\tilde{\boldsymbol{\beta}}) \leq tracecov(\boldsymbol{\beta}^*), \quad \det cov(\tilde{\boldsymbol{\beta}}) \leq \det cov(\boldsymbol{\beta}^*),$$

for any linear unbiased estimator $\boldsymbol{\beta}^*$ of $\boldsymbol{\beta}$; here "det" denotes determinant.

The following theorem gives the "Fundamental BLUE equation"; see, e.g., Rao (1967), Zyskind (1967) and Puntanen et al. (2000).

Theorem 1 *Consider the general linear model* $\mathscr{M} = \{\boldsymbol{y}, \boldsymbol{X\beta}, \boldsymbol{V}\}$. *Then the estimator* $\boldsymbol{Gy}$ *is the BLUE for* $\boldsymbol{X\beta}$ *if and only if* $\boldsymbol{G}$ *satisfies the equation*

$$\boldsymbol{G}(\boldsymbol{X} : \boldsymbol{VX}^{\perp}) = (\boldsymbol{X} : \boldsymbol{0}). \tag{1}$$

The corresponding condition for $\boldsymbol{Ay}$ *to be the BLUE of an estimable parametric function* $\boldsymbol{K}'\boldsymbol{\beta}$ *is* $\boldsymbol{A}(\boldsymbol{X} : \boldsymbol{VX}^{\perp}) = (\boldsymbol{K}' : \boldsymbol{0})$.

It is sometimes convenient to express (1) in the following form, see Rao (1971).

Theorem 2 (Pandora's Box) *Consider the general linear model* $\mathscr{M} = \{\boldsymbol{y}, \boldsymbol{X\beta}, \boldsymbol{V}\}$. *Then the estimator* $\boldsymbol{Gy}$ *is the BLUE for* $\boldsymbol{X\beta}$ *if and only if there exists a matrix* $\boldsymbol{L} \in \mathbb{R}^{p\times n}$ *so that* $\boldsymbol{G}$ *is a solution to*

$$\begin{pmatrix} \boldsymbol{V} & \boldsymbol{X} \\ \boldsymbol{X}' & \boldsymbol{0} \end{pmatrix} \begin{pmatrix} \boldsymbol{G}' \\ \boldsymbol{L} \end{pmatrix} = \begin{pmatrix} \boldsymbol{0} \\ \boldsymbol{X}' \end{pmatrix}.$$

The equation (1) has a unique solution for $\mathbf{G}$ if and only if $\mathscr{C}(\mathbf{X} : \mathbf{V}) = \mathbb{R}^n$. Notice that under $\mathscr{M}$ we assume that the observed value of $\mathbf{y}$ belongs to the subspace $\mathscr{C}(\mathbf{X} : \mathbf{V})$ with probability 1; this is the consistency condition of the linear model, see, e.g., Baksalary et al. (1992). The consistency condition means, for example, that whenever we have some statements which involve the random vector $\mathbf{y}$, these statements need hold only for those values of $\mathbf{y}$ that belong to $\mathscr{C}(\mathbf{X} : \mathbf{V})$. The general solution for $\mathbf{G}$ can be expressed, for example, in the following ways:

$$\mathbf{G}_1 = \mathbf{X}(\mathbf{X}'\mathbf{W}^{-}\mathbf{X})^{-}\mathbf{X}'\mathbf{W}^{-} + \mathbf{F}_1(\mathbf{I}_n - \mathbf{WW}^{-}),$$

$$\mathbf{G}_2 = \mathbf{H} - \mathbf{HVM}(\mathbf{MVM})^{-}\mathbf{M} + \mathbf{F}_2[\mathbf{I}_n - \mathbf{MVM}(\mathbf{MVM})^{-}]\mathbf{M},$$

where $\mathbf{F}_1$ and $\mathbf{F}_2$ are arbitrary matrices, $\mathbf{W} = \mathbf{V} + \mathbf{XUX}'$ and $\mathbf{U}$ is any arbitrary conformable matrix such that $\mathscr{C}(\mathbf{W}) = \mathscr{C}(\mathbf{X} : \mathbf{V})$. Notice that even though $\mathbf{G}$ may not be unique, the numerical value of $\mathbf{Gy}$ is unique because $\mathbf{y} \in \mathscr{C}(\mathbf{X} : \mathbf{V})$. If $\mathbf{V}$ is positive definite, then $\mathrm{BLUE}(\mathbf{X}\boldsymbol{\beta}) = \mathbf{X}(\mathbf{X}'\mathbf{V}^{-1}\mathbf{X})^{-}\mathbf{X}'\mathbf{V}^{-1}\mathbf{y}$. Clearly $\mathrm{OLSE}(\mathbf{X}\boldsymbol{\beta}) = \mathbf{Hy}$ is the BLUE under $\{\mathbf{y}, \mathbf{X}\boldsymbol{\beta}, \sigma^2\mathbf{I}\}$. It is also worth noting that the matrix $\mathbf{G}$ satisfying (1) can be interpreted as a projector: it is a projector onto $\mathscr{C}(\mathbf{X})$ along $\mathscr{C}(\mathbf{VX}^{\perp})$, see Rao (1974).

OLSE vs. BLUE

Characterizing the equality of the Ordinary Least Squares Estimator (OLSE) and the BLUE has received a lot of attention in the literature, but the major breakthroughs were made by Rao (1967) and Zyskind (1967); for a detailed review, see Puntanen and Styan (1989). We present below six characterizations for the OLSE and the BLUE to be equal (with probability 1).

Theorem 3 (OLSE vs. BLUE) *Consider the general linear model* $\mathscr{M} = \{\boldsymbol{y}, \boldsymbol{X\beta}, \boldsymbol{V}\}$. *Then* $\mathrm{OLSE}(\boldsymbol{X\beta}) = \mathrm{BLUE}(\boldsymbol{X\beta})$ *if and only if any one of the following six equivalent conditions holds.* (*Note:* $\boldsymbol{V}$ *may be replaced by its Moore–Penrose inverse* $\boldsymbol{V}^{+}$ *and* $\boldsymbol{H}$ *and* $\boldsymbol{M} = \boldsymbol{I} - \boldsymbol{H}$ *may be interchanged.*)

1. $\boldsymbol{HV} = \boldsymbol{VH}$,
2. $\boldsymbol{HVM} = \boldsymbol{0}$,
3. $\mathscr{C}(\boldsymbol{VH}) \subset \mathscr{C}(\boldsymbol{H})$,
4. $\mathscr{C}(\boldsymbol{X})$ *has a basis comprising orthonormal eigenvectors of* $\boldsymbol{V}$,
5. $\boldsymbol{V} = \boldsymbol{HAH} + \boldsymbol{MBM}$ *for some* $\boldsymbol{A}$ *and* $\boldsymbol{B}$,
6. $\boldsymbol{V} = \alpha\boldsymbol{I}_n + \boldsymbol{HKH} + \boldsymbol{MLM}$ *for some* $\alpha \in \mathbb{R}$, *and* $\boldsymbol{K}$ *and* $\boldsymbol{L}$.

Two Linear Models

Consider now two linear models $\mathscr{M}_1 = \{\mathbf{y}, \mathbf{X}\boldsymbol{\beta}, \mathbf{V}_1\}$ and $\mathscr{M}_2 = \{\mathbf{y}, \mathbf{X}\boldsymbol{\beta}, \mathbf{V}_2\}$, which differ only in their covariance matrices. For the proof of the following proposition and related discussion, see, e.g., Rao (1971, Theorem 5.2, Theorem 5.5), and Mitra and Moore (1973, Theorem 3.3, Theorems 4.1–4.2).

Theorem 4 *Consider the linear models* $\mathscr{M}_1 = \{\boldsymbol{y}, \boldsymbol{X\beta}, \boldsymbol{V}_1\}$ *and* $\mathscr{M}_2 = \{\boldsymbol{y}, \boldsymbol{X\beta}, \boldsymbol{V}_2\}$, *and let the notation* $\{\, \mathrm{BLUE}(\boldsymbol{X\beta} \mid \mathscr{M}_1) \,\} \subset \{\, \mathrm{BLUE}(\boldsymbol{X\beta} \mid \mathscr{M}_2) \,\}$ *mean that every representation of the BLUE for* $\boldsymbol{X\beta}$ *under* $\mathscr{M}_1$ *remains the BLUE for* $\boldsymbol{X\beta}$ *under* $\mathscr{M}_2$. *Then the following statements are equivalent:*

1. $\{\, \mathrm{BLUE}(\boldsymbol{X\beta} \mid \mathscr{M}_1) \,\} \subset \{\, \mathrm{BLUE}(\boldsymbol{X\beta} \mid \mathscr{M}_2) \,\}$,
2. $\mathscr{C}(\boldsymbol{V}_2\boldsymbol{X}^{\perp}) \subset \mathscr{C}(\boldsymbol{V}_1\boldsymbol{X}^{\perp})$,
3. $\boldsymbol{V}_2 = \boldsymbol{V}_1 + \boldsymbol{XN}_1\boldsymbol{X}' + \boldsymbol{V}_1\boldsymbol{MN}_2\boldsymbol{MV}_1$, *for some* $\boldsymbol{N}_1$ *and* $\boldsymbol{N}_2$,
4. $\boldsymbol{V}_2 = \boldsymbol{XN}_3\boldsymbol{X}' + \boldsymbol{V}_1\boldsymbol{MN}_4\boldsymbol{MV}_1$, *for some* $\boldsymbol{N}_3$ *and* $\boldsymbol{N}_4$.

Notice that obviously

$$\{\,\mathrm{BLUE}(\mathbf{X}\boldsymbol{\beta} \mid \mathscr{M}_1)\,\} = \{\,\mathrm{BLUE}(\mathbf{X}\boldsymbol{\beta} \mid \mathscr{M}_2)\,\} \iff$$
$$\mathscr{C}(\mathbf{V}_2\mathbf{X}^{\perp}) = \mathscr{C}(\mathbf{V}_1\mathbf{X}^{\perp}).$$

For the equality between the BLUEs of $\mathbf{X}_1\boldsymbol{\beta}_1$ under two partitioned models, see Haslett and Puntanen (2010a).

Model with New Observations: Best Linear Unbiased Predictor (BLUP)

Consider the model $\mathscr{M} = \{\mathbf{y}, \mathbf{X}\boldsymbol{\beta}, \mathbf{V}\}$, and let $\mathbf{y}_f$ denote an $m \times 1$ unobservable random vector containing *new observations*. The new observations are assumed to follow the linear model $\mathbf{y}_f = \mathbf{X}_f\boldsymbol{\beta} + \boldsymbol{\varepsilon}_f$, where $\mathbf{X}_f$ is a known $m \times p$ model matrix associated with new observations, $\boldsymbol{\beta}$ is the same vector of unknown parameters as in $\mathscr{M}$, and $\boldsymbol{\varepsilon}_f$ is an $m \times 1$ random error vector associated with new observations. Our goal is to predict the random vector $\mathbf{y}_f$ on the basis of $\mathbf{y}$. The expectation and the covariance matrix are

$$\mathrm{E}\begin{pmatrix}\mathbf{y}\\ \mathbf{y}_f\end{pmatrix} = \begin{pmatrix}\mathbf{X}\boldsymbol{\beta}\\ \mathbf{X}_f\boldsymbol{\beta}\end{pmatrix}, \quad cov\begin{pmatrix}\mathbf{y}\\ \mathbf{y}_f\end{pmatrix} = \begin{pmatrix}\mathbf{V} = \mathbf{V}_{11} & \mathbf{V}_{12}\\ \mathbf{V}_{21} & \mathbf{V}_{22}\end{pmatrix},$$

which we may write as

$$\mathscr{M}_f = \left\{\begin{pmatrix}\mathbf{y}\\ \mathbf{y}_f\end{pmatrix}, \begin{pmatrix}\mathbf{X}\boldsymbol{\beta}\\ \mathbf{X}_f\boldsymbol{\beta}\end{pmatrix}, \begin{pmatrix}\mathbf{V} & \mathbf{V}_{12}\\ \mathbf{V}_{21} & \mathbf{V}_{22}\end{pmatrix}\right\}.$$

A linear predictor $\mathbf{Ay}$ is said to be unbiased for $\mathbf{y}_f$ if $\mathrm{E}(\mathbf{Ay}) = \mathrm{E}(\mathbf{y}_f) = \mathbf{X}_f\boldsymbol{\beta}$ for all $\boldsymbol{\beta} \in \mathbb{R}^p$. Then the random vector $\mathbf{y}_f$ is said to be unbiasedly predictable. Now an unbiased linear predictor $\mathbf{Ay}$ is the best linear unbiased predictor, BLUP, if the Löwner ordering

$$cov(\mathbf{Ay} - \mathbf{y}_f) \le_{\mathrm{L}} cov(\mathbf{By} - \mathbf{y}_f)$$

holds for all $\mathbf{B}$ such that $\mathbf{By}$ is an unbiased linear predictor for $\mathbf{y}_f$.

The following theorem characterizes the BLUP; see, e.g., Christensen (2002, p 283), and Isotalo and Puntanen (2006, p 1015).

Theorem 5 (Fundamental BLUP equation) *Consider the linear model $\mathscr{M}_f$, where $\boldsymbol{X}_f\boldsymbol{\beta}$ is a given estimable parametric function. Then the linear estimator $\boldsymbol{Ay}$ is the best linear unbiased predictor (BLUP) for $\boldsymbol{y}_f$ if and only if $\boldsymbol{A}$ satisfies the equation*

$$\boldsymbol{A}(\boldsymbol{X} : \boldsymbol{V}\boldsymbol{X}^{\perp}) = (\boldsymbol{X}_f : \boldsymbol{V}_{21}\boldsymbol{X}^{\perp}).$$

In terms of Pandora's Box (Theorem 2), $\boldsymbol{Ay}$ is the BLUP for $\boldsymbol{y}_f$ if and only if there exists a matrix $\boldsymbol{L}$ such that $\boldsymbol{A}$ satisfies the equation

$$\begin{pmatrix}\boldsymbol{V} & \boldsymbol{X}\\ \boldsymbol{X}' & \boldsymbol{0}\end{pmatrix}\begin{pmatrix}\boldsymbol{A}'\\ \boldsymbol{L}\end{pmatrix} = \begin{pmatrix}\boldsymbol{V}_{12}\\ \boldsymbol{X}_f'\end{pmatrix}.$$

The Mixed Model

A mixed linear model can be presented as

$$\mathbf{y} = \mathbf{X}\boldsymbol{\beta} + \mathbf{Z}\boldsymbol{\gamma} + \boldsymbol{\varepsilon}, \quad \text{or in short} \quad \mathscr{M}_{\mathrm{mix}} = \{\mathbf{y}, \mathbf{X}\boldsymbol{\beta} + \mathbf{Z}\boldsymbol{\gamma}, \mathbf{D}, \mathbf{R}\},$$

where $\mathbf{X} \in \mathbb{R}^{n\times p}$ and $\mathbf{Z} \in \mathbb{R}^{n\times q}$ are known matrices, $\boldsymbol{\beta} \in \mathbb{R}^p$ is a vector of unknown fixed effects, $\boldsymbol{\gamma}$ is an unobservable vector (q elements) of *random effects* with $cov(\boldsymbol{\gamma}, \boldsymbol{\varepsilon}) = \mathbf{0}_{q\times p}$ and

$$\mathrm{E}(\boldsymbol{\gamma}) = \mathbf{0}_q, \quad cov(\boldsymbol{\gamma}) = \mathbf{D}_{q\times q}, \quad \mathrm{E}(\boldsymbol{\varepsilon}) = \mathbf{0}_n, \quad cov(\boldsymbol{\varepsilon}) = \mathbf{R}_{n\times n}.$$

This leads directly to

Theorem 6 *Consider the mixed model $\mathscr{M}_{mix} = \{\boldsymbol{y}, \boldsymbol{X\beta} + \boldsymbol{Z\gamma}, \boldsymbol{D}, \boldsymbol{R}\}$. Then the linear estimator $\boldsymbol{By}$ is the BLUE for $\boldsymbol{X\beta}$ if and only if*

$$\boldsymbol{B}(\boldsymbol{X} : \boldsymbol{\Sigma}\boldsymbol{X}^{\perp}) = (\boldsymbol{X} : \boldsymbol{0}),$$

where $\boldsymbol{\Sigma} = \boldsymbol{ZDZ}' + \boldsymbol{R}$. Moreover, $\boldsymbol{Ay}$ is the BLUP for $\boldsymbol{\gamma}$ if and only if

$$\boldsymbol{A}(\boldsymbol{X} : \boldsymbol{\Sigma}\boldsymbol{X}^{\perp}) = (\boldsymbol{0} : \boldsymbol{D}\boldsymbol{Z}'\boldsymbol{X}^{\perp}).$$

In terms of Pandora's Box (Theorem 2), $\boldsymbol{Ay} = \mathrm{BLUP}(\boldsymbol{\gamma})$ if and only if there exists a matrix $\boldsymbol{L}$ such that $\boldsymbol{A}$ satisfies the equation

$$\begin{pmatrix}\boldsymbol{\Sigma} & \boldsymbol{X}\\ \boldsymbol{X}' & \boldsymbol{0}\end{pmatrix}\begin{pmatrix}\boldsymbol{A}'\\ \boldsymbol{L}\end{pmatrix} = \begin{pmatrix}\boldsymbol{ZD}\\ \boldsymbol{0}\end{pmatrix}.$$

For the equality between the BLUPs under two mixed models, see Haslett and Puntanen (2010b, 2010c).

Beta Distribution

Arjun K. Gupta
Distinguished University Professor
Bowling Green State University, Bowling Green, OH, USA

A random variable X is said to have the beta distribution with parameters a and b if its probability density function is

$$f_X(x) = \frac{1}{B(a,b)} x^{a-1}(1-x)^{b-1}, \quad 0 < x < 1, \quad a > 0, b > 0 \tag{1}$$

where

$$B(a,b) = \int_0^1 u^{a-1}(1-u)^{b-1} du$$

denotes the beta function. The beta family, whose origin can be traced to 1676. in a letter from Sir Isaac Newton to Henry Oldenberg, has been utilized extensively in statistical theory and practice.

Originally defined on the unit interval, many generalizations of (1) have been proposed in the literature; see Karian and Dudewicz (2000) for a four parameter generalization defined over a finite interval, McDonald and Richards (1987a, b) for a generalization obtained by power transformation of X; Libby and Novick (1982) and Armero and Bayarri (1994) for generalizations obtained by dividing (1) by certain algebraic functions; Gordy (1998) for a generalization obtained by multiplying (1) by an exponential function; and, Nadarajah and Kotz (2003) for a generalization obtained by multiplying (1) by a Gauss hypergeometric function. For further details, the reader is referred to

Chap. 25 in Johnson et al. (1994) and Gupta and Nadarajah (2004).

Some properties of beta distribution (1) are listed here.

1. rth moment about zero

$$\mu'_r = \frac{B(a+r,b)}{B(a,b)} = \frac{\Gamma(a+r)\Gamma(a+b)}{\Gamma(a)\Gamma(a+b+r)}.$$

In particular,

$$E(X) = \frac{a}{a+b},$$

$$Var(X) = \frac{ab}{(a+b+1)(a+b)^2}.$$

2. Characteristic function

$$E\left[e^{itX}\right] = {}_1F_1(a; a+b; it)$$

where ${}_1F_1$ is the confluent hypergeometric function defined by

$${}_1F_1(\alpha;\beta;z) = \sum_{k=0}^{\infty} \frac{(\alpha)_k}{(\beta)_k}\frac{z^k}{k!}.$$

3. The random variable

$$Y = \frac{X}{1-X}$$

has the Pearson type VI distribution defined by

$$f_Y(y) = \frac{1}{B(a,b)}\frac{y^{a-1}}{(1+y)^{a+b}},\ y > 0.$$

About the Author

Professor Gupta is Distinguished University Professor, Department of Mathematics and Statistics Bowling Green State University. He was Chair of the Department (1985–1987). He is Elected Fellow of the Ohio Academy of Science (2001), ASA, ISI and Royal Statistical Society. He was awarded the All India Mathematical Society Golden Jubilee Award (1959). Professor Gupta was editor and associate editor of many international journals. Currently, he is Associate editor for *Communications in Statistics*. He has written or co-authored more than 450 papers and 16 books, including *Handbook of Beta Distribution and Its Applications* (with Saralees Nadarajah, eds., CRC, 2004).

Bias Analysis

Sander Greenland
Professor
University of California-Los Angeles, Los Angeles, CA, USA

Methodological shortcomings of studies can lead to bias, in the sense of systematic (nonrandom) distortion of estimates from the studies. Well-recognized shortcomings (bias sources) include the following: Units may be selected for observation in a nonrandom fashion; stratifying on additional unmeasured covariates U may be essential for the X-Y association to approximate a target causal effect; inappropriate covariates may be entered into the analysis; and components of X or Y or Z may not be adequately measured.

In methodologic modeling or *bias analysis*, one models these shortcomings. In effect, one attempts to model the design and execution of the study, including features (such as selection biases and measurement errors) beyond investigator control. The process is thus a natural extension to imperfect experiments and observational studies of the design-based paradigm in experimental and survey statistics.

Bias analysis well established in engineering and policy research and are covered in many books, albeit in a wide variety of forms and specialized applications. Little and Rubin (2002) focus on missing-data problems; Eddy et al. (1992) focus on medical and health-risk assessment; and Vose (2000) covers general risk assessment. Models for specific biases have a long if scattered history in epidemiology, going back to Berkson (1946) and Cornfield et al. (1959); Greenland and Lash (2008) give a review. Nonetheless, methods for statistical inference from bias models have only recently begun to appear in observational health research (Robins et al. 2000; Graham 2000; Lash and Fink 2003; Lash et al. 2009; Phillips 2003; Greenland 2003a, 2005, 2009a, b; Gustafson 2003, 2005a, b; Fox et al. 2005).

Statistical Formulation

Many of the parameters in realistic bias models will not be *identifiable* (estimable) from the data, necessitating inferential approaches well beyond those of conventional statistics. The simplest approach is to fix those parameters at specific values, estimate effects assuming those values are correct, and see how effect estimates change as those values are varied. This process is an example of ►*sensitivity analysis*. One can also assign the parameters prior probability distributions based on background information, and summarize target estimates over these distributions or over the resulting posterior distribution.

Consider the problem of estimating the effect of X on Y, given a collection of antecedent covariates Z, as common in causal inference (see Causation and Causal Inference). Standard approaches estimate the regression of Y on X and Z, E(Y|x,z), and then taking the fitted (partial) regression of Y on X given Z as the effect of X on Y. Usually a parametric model r(x,z;β) for E(Y|x,z) is fit and the coefficient for X is taken as the effect (this approach is reflected in common terminology that refers to such coefficients as "main effects"); the logistic model for a binary Y is the most common epidemiologic example. Model fitting is almost always done as if

1. Within levels of X and Z, the data are a ►simple random sample and any missingness is completely random.
2. The causal effect of X on Y is accurately reflected by the association of X and Y given Z (i.e., there is no residual confounding – as might be reasonable to assume if X were randomized within levels of Z).
3. X, Y, and Z are measured without error.

In reality, (1) sampling and missing-data probabilities may jointly depend on X, Y, and Z in an unknown fashion, (2) stratifying or adjusting for certain unmeasured (and possibly unknown) covariates U might be essential for the association of X and Y to correspond to a causal effect of X on Y, and (3) some of the X, Y and Z components are mismeasured.

Selection Biases

Let V = (X,Y,Z). One approach to sampling (selection) biases posits a model s(v;σ) for the probability of selection given v, then uses this model in the analysis along with r(x,z;β), e.g., by incorporating s(v;σ) into the likelihood function (Eddy et al. 1992; Little and Rubin 2002; Gelman et al. 2003; Greenland 2009b) or by using $s(v;\sigma)^{-1}$ as a weighting factor (Robins et al. 1994, 2000; Copas and Li 1997; Scharfstein et al. 1999). The parameters β and σ are usually cannot be completely estimated from the data under analysis, so one must either posit various fixed values for σ and estimate β for each chosen σ (sensitivity analysis), or else give β σ a prior distribution and conduct a Bayesian analysis.

A third, somewhat informal approach between sensitivity and Bayesian analysis is Monte-Carlo risk analysis or Monte-Carlo sensitivity analysis (MCSA). This approach repeatedly samples σ from its prior distribution, resamples (bootstraps) the data, and re-estimates β using the sampled σ and data; it then outputs the distribution of results obtained from this repeated sampling-estimation cycle. MCSA can closely approximate Bayesian results under certain (though not all) conditions (Greenland 2001, 2005), most notably when β and σ are *a priori* independent and there is negligible prior information about β. These selection-modeling methods can be generalized (with many technical considerations) to handle arbitrary missing data (Little and Rubin 2002; Robins et al. 1994, 2000).

Confounding

Suppose U is a collection of unmeasured (latent) covariates required for identification of the effect of X on Y. One approach to problem (2) is to model the distribution of U and V with a probability model p(u,v;β,γ) = p(y|u,x,z;β)p(u,x,z;γ). Again, one can estimate β by likelihood-based or by weighting methods, but because U is unmeasured, the parameter (β,γ) will not be fully estimable from the data and so some sort of sensitivity analysis or prior distribution will be needed (e.g., Cornfield et al. 1959; Yanagawa 1984; Robins et al. 2000; Rosenbaum 2002; Greenland 2003a, 2003b, 2005, 2009b). Results will depend heavily on the prior specification given U. For example, U may be a specific unmeasured covariate (e.g., smoking status) with well studied relations to X, Y, and Z,

which affords straightforward Bayesian and MCSA analyzes (Steenland and Greenland 2004). On the other hand, U may represent an unspecified aggregation of latent confounders, in which case the priors and hence inferences are more uncertain (Greenland 2003a).

Measurement Error and Misclassification

Suppose that the collection of "true" values V = (X,Y,Z) has a corresponding collection of measurements or surrogates W (which might include multiple surrogates for X, Y, or Z). The measurement-error problem (problem 3) can then be expressed as follows: For some or all units, at least one of the V components is missing, but the measurements in W that correspond to the missing V components are present. If enough units are observed with both V and W complete, the problem can be handled by standard missing-data methods. For example, given a model for the distribution of V and W one can use likelihood-based methods (Little and Rubin 2002), or impute V components where absent and then fit the model $r(x,z;\beta)$ for $E(Y|x,z)$ to the completed data (Cole et al. 2006), or fit the model to the complete records using weights derived from all records using a model for missing-data patterns (Robins et al. 1994). Direct Bayesian approaches to measurement error are also available (Gustafson 2003; Greenland 2009a, b).

Alternatively, there are many measurement-error correction procedures that adjust the "naïve" β estimates obtained by fitting the regression using W as if it were V. This adjustment is usually accomplished with a model relating V to W fitted to the complete records, as in instrumental-variable (regression calibration) corrections and their extensions (Carroll et al. 2006). Some recent methods are based on assuming various subsamples with information on multiple surrogates are available (so W may be of much higher dimension than V and may have complex missing-data patterns) (e.g., Spiegelman et al. 2005).

All methods assume that missingness in V and W components is random, which is often quite implausible because noncooperation increases with demands on subjects, collection of some components may be demanding (e.g., as when W includes diet diaries or biomarkers), and cooperation may be related to unobserved true values or confounders. Thus selection modeling will be needed along with measurement modeling to account for this nonrandom ("nonignorable") missingness.

Further nonidentified modeling becomes a necessity if a component of V is never observed on any unit (or, more practically, if there are too few complete records to support large-sample missing-data or measurement-error procedures). Latent-variable methods are natural for this situation (Berkane 1997). For example, one could model the distribution of (V,W) or a sufficient factor from that distribution by a parametric model; the unobserved components of V are then the latent variables in the model. As before, the parameters will not be fully identified, making Bayesian methods a natural choice for summary inferences (Gustafson 2003, 2005a, b; Greenland 2005, 2009a, b).

Realistic specification for nonidentified measurement error models can become quite complex, with inferences displaying extreme sensitivity to parameter constraints or prior distributions. Nonetheless, methodologic modeling helps provide an honest accounting for the large uncertainty that can be generated by even modest measurement error.

Bias Correction

Gauss M. Cordeiro
Professor
Universidade Federal Rural de Pernambuco, Recife, Brazil

Introduction

A central object in asymptotic likelihood theory is the calculation of the second-order biases of the maximum likelihood estimates (MLEs). To improve the accuracy of these estimates, substantial effort has gone into computing the cumulants of log-likelihood derivatives which are, however, notoriously cumbersome. The MLEs typically have biases of order $O(n^{-1})$ for large sample size n, which are commonly ignored in practice, the justification being that they are small when compared to the standard errors of the parameter estimates that are of order $O(n^{-1/2})$. For small samples sizes, however, these biases can be appreciable and of the same magnitude as the corresponding standard errors. In such cases, the biases cannot be neglected, and for turning feasible estimation of their size in practical applications, corresponding formulae for their calculation need to be established for a wide range of probability distributions and regression models.

Bias correction has been extensively studied in the statistical literature and there has been considerable interest in finding simple matrix expressions for second-order biases of MLEs in some classes of regression models which do not involve cumulants of log-likelihood derivatives. The methodology has been applied to several regression models. We focus on the following models: normal nonlinear models (Cook et al. 1986), generalized log-gamma regression model (Young and Bakir 1987), ▶generalized linear models (Cordeiro and McCullagh 1991), ARMA models (Cordeiro and Klein 1994), multivariate nonlinear regression models (Cordeiro and Vasconcellos 1997), generalized linear models with dispersion covariates (Botter and Cordeiro 1998), symmetric nonlinear regression models (Cordeiro et al. 2000), Student t regression model with unknown degrees of freedom (Vasconcellos and Silva 2005), beta regression models (Ospina et al. 2006) and a class of multivariate normal model where the mean vector and the covariance matrix have parameters in common (Patriota and Lemonte 2009). In general two parameter continuous distributions, Stósic and Cordeiro (2009) showed how to symbolically compute the biases of the MLEs bypassing the traditional computation of joint cumulants of log-likelihood derivatives.

The bias approximation may be used to produce a bias-corrected estimator by subtracting the bias approximation from the MLE. Alternatively, an examination of the form of the bias may suggest a re-parametrization of the model that results is less biased estimates.

General Formula

Consider that the total log-likelihood function $\ell(\theta)$, based on n observations not necessarily independent and identically distributed, is a function of a $p\times 1$ vector θ of unknown parameters. We assume that $\ell = \ell(\theta)$ is regular (Cox and Hinkley 1974) with respect to all θ derivatives up to and including those of third order. We introduce the following log-likelihood derivatives in which we reserve lower-case subscripts $r, s, t, \ldots$ to denote components of the vector θ: $U_r = \partial l/\partial\theta_r$, $U_{rs} = \partial^2 l/\partial\theta_r\partial\theta_s$, and so on. The standard notation is adopted for the cumulants of log-likelihood derivatives $\kappa_{rs} = E(U_{rs})$, $\kappa_{r,s} = E(U_r U_s)$, $\kappa_{rs,t} = E(U_{rs}U_t)$, etc, where all κ's refer to a total over the sample and are, in general, of order n. The elements of the information matrix K^{-1} are $\kappa_{r,s} = -\kappa_{rs}$ and let $\kappa^{r,s} = -\kappa^{rs}$ denote the corresponding elements of the inverse information matrix K^{-1}, which is of order $O(n^{-1})$.

The MLE $\widehat{\theta}$ of θ can be obtained as a solution of a system of nonlinear equations $\widehat{U}_r = 0$ for $r = 1, \ldots, p$. A general formula for the $O(n^{-1})$ bias of $\widehat{\theta}$ for a regular statistical model with p unknown parameters was given by Cox and Snell (1968) and Cordeiro and McCullagh (1991). Assuming standard regularity conditions (Cox and Hinkley 1974), we can expand $\widehat{U}_r = 0$ to obtain $U_r + \sum_s U_{rs}(\widehat{\theta}_s - \theta_s) + O_p(1) = 0$ and write in matrix notation $U = J(\widehat{\theta} - \theta) + O_p(1)$, where U is the score vector and J is the observed information matrix. Since $J = K + O_p(n^{1/2})$ we have $U = K(\widehat{\theta} - \theta) + O_p(1)$ and

$$\widehat{\theta} - \theta = K^{-1}U + O_p(n^{-1}). \tag{1}$$

Equation 1 is important to provide higher-order moments and cumulants of the estimate $\widehat{\theta}$. If we now expand $\widehat{U}_r$ up to terms of second-order, we obtain

$$U_r + \sum_s U_{rs}(\hat{\theta}_s - \theta_s) + \frac{1}{2}\sum_{s,t} U_{rst}(\hat{\theta}_s - \theta_s)(\hat{\theta}_t - \theta_t) + o_p(1) = 0$$

and then by calculating its expected value

$$\sum_s \kappa_{rs}E(\hat{\theta}_s - \theta_s) + \sum_s \mathrm{Cov}(U_{rs}, \hat{\theta}_s - \theta_s) + \frac{1}{2}\sum_{s,t}\kappa_{rst}(-\kappa^{st}) + o(1) = 0. \tag{2}$$

Up to terms of order $O(n^{-1})$, we can write $\mathrm{Cov}(U_{rs}, \widehat{\theta}_s - \theta_s) = \mathrm{Cov}\left(U_{rs}, -\sum_t \kappa^{st}U_t\right) = -\sum_t \kappa_{rs,t}\kappa^{st}$.

Let $B(\widehat{\theta}_a)$ be the $O(n^{-1})$ bias of the estimate $\widehat{\theta}_a$ for $a = 1, \ldots, p$. Inverting Eq. 2, we can write $B(\widehat{\theta}_a)$ as (Cox and Snell 1968)

$$B(\widehat{\theta}_a) = \sum_{r,s,t}\kappa^{ar}\kappa^{st}\left(\kappa_{rs,t} + \frac{1}{2}\kappa_{rst}\right) = \sum_{r,s,t}\kappa^{ar}\kappa^{st}\left(\kappa_{rs}^{(t)} - \frac{1}{2}\kappa_{rst}\right). \tag{3}$$

We can verify that the two alternative forms for $B(\widehat{\theta}_a)$ are equivalent using Bartlett identity. In general regression models, we can derive matrix expressions for the bias of the estimate $\widehat{\theta}$, say $B(\widehat{\theta})$, from Eq. 3 when the cumulants κ's are invariant under permutations of parameters (see Cordeiro and McCullagh 1991).

The estimate $\widehat{\theta}$ can be inserted in $B(\widehat{\theta})$ to define bias corrected estimate $\widetilde{\theta} = \widehat{\theta} - \widehat{B}(\widehat{\theta})$, where $\widehat{B}(\widehat{\theta})$ is the value of $B(\widehat{\theta})$ at $\widehat{\theta}$. The bias corrected estimate $\widetilde{\theta}$ is expected to have better sampling properties than the classical estimate $\widehat{\theta}$. In fact, several simulations presented in the literature (Botter and Cordeiro 1998; Cordeiro et al. 2000; Vasconcellos and Silva 2005; Ospina et al. 2006; Patriota and Lemonte 2009) have shown that the corrected estimates $\widetilde{\theta}$ have smaller biases than their corresponding uncorrected estimates, thus suggesting that these bias corrections have the effect of shrinking the corrected estimates toward to the true parameter values. However, we can not say that the bias corrected estimates offer always some improvement

over the MLEs, since they can have larger mean squared errors than the uncorrected estimates.

We give a simple example by taking n *iid* observations from a normal distribution $N(\mu, \sigma^2)$, where we are interested to calculate the n^{-1} biases of the MLEs of μ and σ. The elements of the information matrix are: $\kappa_{\mu,\mu} = n/\sigma^2$, $\kappa_{\mu,\sigma} = 0$ and $\kappa_{\sigma,\sigma} = 2n/\sigma^2$. The third cumulantes are easily obtained: $\kappa_{\mu\mu\mu} = \kappa_{\mu,\mu\mu} = \kappa_{\sigma,\mu\mu} = \kappa_{\sigma,\mu\sigma} = \kappa_{\mu,\sigma\sigma} = \kappa_{\mu\sigma\sigma} = 0$, $\kappa_{\mu\mu\sigma} = -\kappa_{\mu,\mu\sigma} = 2n/\sigma^3$, $\kappa_{\sigma,\sigma\sigma} = -6n/\sigma^3$ and $\kappa_{\sigma\sigma\sigma} = 10n/\sigma^3$. Thus, $B(\widehat{\mu}) = 0$ since $\widehat{\mu} = \Sigma y_i/n$ has no bias. Further, after some algebra, $B(\hat{\sigma}) = -3\sigma/4n$. This result is in agreement with the exact bias of $\widehat{\sigma} = \{\Sigma(y_i - \overline{y})^2/n\}^{1/2}$ given by $E(\hat{\sigma}) = \sqrt{\frac{2}{n}}\frac{\Gamma\left(\frac{n-1}{2}\right)}{\Gamma\left(\frac{n}{2}\right)}\sigma$, which is obtained from the χ^2_{n-1} distribution of $(n-1)\hat{\sigma}^2/\sigma^2$. In fact, using Stirling expansion in $E(\hat{\sigma})$ yields $E(\hat{\sigma}) = \sigma\left\{1 - \frac{3}{4n} + O(n^{-2})\right\}$. The corrected estimate of σ is then $\tilde{\sigma} = \left(1 + \frac{3}{4n}\right)\hat{\sigma}$.

For a one-parameter model, the n^{-1} bias of $\widehat{\theta}$ follows from Eq. 3 by setting all parameters equal to θ. We obtain a formula first derived by Bartlett (1953)

$$B(\hat{\theta}) = \kappa^{\theta\theta^2}\left(\kappa_{\theta\theta,\theta} + \frac{1}{2}\kappa_{\theta\theta\theta}\right) = \kappa^{\theta\theta^2}\left(\kappa^{(\theta)}_{\theta\theta} - \frac{1}{2}\kappa_{\theta\theta\theta}\right).$$

Stósic and Cordeiro (2009) presented simple programs (scripts) that may be used with algebraic manipulation software Maple and Mathematica to calculate closed-form analytic expressions for the bias corrections B_μ and B_ϕ of the MLEs of the parameters μ and ϕ for arbitrary two-parameter continuous distributions through a straightforward application of Eq. 3.

While these symbolic computation software packages have currently the ability to deal with analytic expressions of formidable size and complexity, limitations still exist, and it turns out that the complexity of the formulae involved in calculating the cumulants of log-likelihood derivatives for some distributions exceed their capacity. It is precisely for this reason that they presented equivalent scripts for calculating the bias correction terms in both frameworks. For some very rare cases neither Maple nor Mathematica were able to produce closed form expressions, but even for these, the current scripts may be expected to produce results on future versions of the softwares (under the assumption that backward compatibility of the scripting language is maintained). It should be pointed out that the above fact does not diminish the usefulness of either of the software packages (in their current versions), as both have produced closed form expressions in a large majority of the tested continuous density functions. Moreover, in all cases where both packages came up with a closed form expression, the results were found to be identical stressing the extremely high level of confidence that may be attributed to analytic manipulations involved.

For both Maple and Mathematica, after specifying the form and the domain of the density function $f(y;\mu,\phi)$ as well as the assumptions to be made on μ and ϕ (e.g. $\mu \in \mathbb{R}$ or $\mu > 0$), the program first defines and analytically calculates the cumulants (κ's), the second-order cumulants are then subsequently inserted into intermediate expression for the information matrix, in order to find the inverse information matrix, which are then used together with the third-order cumulants to produce the final result from Eq. 3. From now on, we use the notation $\psi'(p)$ and $\psi''(p)$ for the derivatives of the digamma function $\psi(p) = d\log\{\Gamma(p)\}/dp$, $\gamma = 1 - \psi(2)$ for the Euler's constant and $\zeta(p)$ for the Riemann Zeta function. The examples below are obtained using these programs and agree with previously reported results in the literature:

1. Normal distribution with mean μ and variance ϕ^2

$$nB_\mu = 0, \quad nB_\phi = -\frac{3\phi}{4n}.$$

2. Inverse Gaussian distribution with mean μ and precision parameter ϕ

$$nB_\mu = 0, \quad nB_\phi = \frac{3\phi}{n}.$$

3. Gamma distribution with mean μ and shape parameter ϕ

$$B_\mu = 0, \quad B_\phi = -\frac{2 - \phi\psi'(\phi) + \phi^2\psi''(\phi)}{2n\left(\phi\psi'(\phi) - 1\right)^2}.$$

4. Weibull distribution with scale μ and shape ϕ (here $E(y) = \mu\Gamma(1 + 1/\phi)$)

$$B_\mu = \frac{\mu}{2\pi^4\phi^2 n}\left\{\pi^4(1 - 2\phi) + 6\pi^2\left[1 + \gamma^2 + 5\phi - 2\gamma(1 + 2\phi)\right] + 72(\gamma - 1)\phi\zeta(3)\right\},$$
$$B_\phi = \frac{18\phi\left(\pi^2 - 2\zeta(3)\right)}{\pi^4 n}.$$

5. Logistic distribution with mean μ and variance $\pi^2\phi^2/6$

$$B_\mu = 0, \quad B_\phi = -\frac{9}{4n}\frac{\phi\left(4\pi^2 + 3\right)}{\left(\pi^2 + 3\right)^2}.$$

6. Extreme value distribution with mean $\mu + \gamma\,\phi$ and variance $\pi^2\,\phi^2/6$

$$B_\mu = \frac{\phi\left(3\,(-5+4\,\gamma)\,\pi^2+\pi^4-36\,(-1+\gamma)\,\zeta(3)\right)}{4\pi^4},$$
$$B_\phi = \frac{-12\,\phi\,\left(\pi^2-3\,\zeta(3)\right)}{4\pi^4}.$$

7. Beta distribution with parameters μ and ϕ

$$\begin{aligned}B_\mu = {} & \frac{1}{2\left[\psi'(\mu)\,(\psi'(\phi)-\psi'(\mu+\phi))-\psi'(\phi)\,\psi'(\mu+\phi)\right]^2 n}\\ & \times\{-[\psi'(\mu+\phi)\,(\psi'(\mu+\phi)\,(\psi''(\mu)-\psi''(\phi))\\ & +\psi'(\mu)\,\psi''(\phi))]\\ & +\psi'(\phi)^2\,[-\psi''(\mu)+\psi''(\mu+\phi)]\\ & +\psi'(\phi)\,[2\,\psi'(\mu+\phi)\,\psi''(\mu)+\psi'(\mu)\,\psi''(\mu+\phi)]\},\end{aligned}$$

$$\begin{aligned}B_\phi = {} & \frac{1}{2\left[\psi'(\mu)\,(\psi'(\phi)-\psi'(\mu+\phi))-\psi'(\phi)\,\psi'(\mu+\phi)\right]^2 n}\\ & \times\{\psi'(\mu+\phi)^2\,[\psi''(\mu)-\psi''(\phi)]\\ & +2\,\psi'(\mu)\,\psi'(\mu+\phi)\,\psi''(\phi)\\ & +\psi'(\mu)^2\,[-\psi''(\phi)+\psi''(\mu+\phi)]\\ & +\psi'(\phi)\,[-(\psi'(\mu+\phi)\,\psi''(\mu))+\psi'(\mu)\,\psi''(\mu+\phi)]\}.\end{aligned}$$

8. Student t distribution with location parameter μ and dispersion parameter ϕ

$$B_\mu = 0,\quad B_\phi = \frac{-3\left(-3+2\,\nu+\nu^2\right)\phi}{4\,n\,\nu\,(5+\nu)}.$$

When ν tends to infinity, we obtain $B_\phi = -3\phi/(4n)$ as is well known in the normal case.

9. Generalized Rayleigh distribution with mean $\frac{\Gamma\left(\phi+\frac{3}{2}\right)}{\sqrt{\mu}\,\Gamma(\phi+1)}$ and variance $\frac{1}{\mu}\left[1+\phi-\frac{\Gamma\left(\phi+\frac{3}{2}\right)^2}{\Gamma(\phi+1)^2}\right]$

$$B_\mu = \frac{\mu\,[-3\,\psi'(1+\phi)+2\,(1+\phi)\,\psi'(1+\phi)^2-(1+\phi)\,\psi''(1+\phi)]}{2\,[-1+(1+\phi)\,\psi'(1+\phi)]^2},$$
$$B_\phi = \frac{-2+(1+\phi)\,\psi'(1+\phi)-(1+\phi)^2\,\psi''(1+\phi)}{2\,n\,[-1+(1+\phi)\,\psi'(1+\phi)]^2}.$$

10. Type I Gumbel distribution with mean $\frac{\gamma+\log(\phi)}{\mu}$ and variance $\frac{\pi^2}{6\,\mu^2}$

$$B_\mu = \frac{18\,\mu\,\left(\pi^2-2\,\zeta(3)\right)}{\pi^4\,n},$$
$$\begin{aligned}B_\phi = {} & \frac{3\,\phi}{2\,\pi^4\,n}\{2\left(-6+4\,\gamma+\gamma^2\right)\pi^2+\pi^4+2\,\pi^2\log(\phi)^2\\ & +4\log(\phi)\,[(2+\gamma)\,\pi^2-6\,\zeta(3)]\\ & -24\,(-1+\gamma)\,\zeta(3)\}.\end{aligned}$$

11. Type II Gumbel distribution with mean $\phi^{\frac{1}{\mu}}\,\Gamma\left(1-\frac{1}{\mu}\right)$ and variance

$$\phi^{\frac{2}{\mu}}\left[\Gamma\left(1-\frac{2}{\mu}\right)-\Gamma\left(1-\frac{1}{\mu}\right)^2\right]$$

$$B_\mu = \frac{18\,\mu\,\left(\pi^2-2\,\zeta(3)\right)}{\pi^4\,n},$$
$$\begin{aligned}B_\phi = {} & \frac{3\,\phi}{2\,\pi^4\,n}\{2\left(-6+4\,\gamma+\gamma^2\right)\pi^2+\pi^4+2\,\pi^2\log(\phi)^2\\ & +4\log(\phi)\,[(2+\gamma)\,\pi^2-6\,\zeta(3)]\\ & -24\,(-1+\gamma)\,\zeta(3)\}.\end{aligned}$$

12. Fisher-Tippett distribution with mode μ and variance $\pi^2\,\phi^2/6$

$$B_\mu = \frac{\phi\left(3\,(-5+4\,\gamma)\,\pi^2+\pi^4-36\,(-1+\gamma)\,\zeta(3)\right)}{\pi^4\,n},$$
$$B_\phi = \frac{-12\,\phi\,\left(\pi^2-3\,\zeta(3)\right)}{\pi^4\,n}.$$

For these twelve distributions tested, Maple fails to yield closed form analytic expressions for bias corrections B_μ and B_ϕ for the extreme value, Student t, type I Gumbel and Fisher-Tippett distributions, whereas Mathematica fails only for the ▸logistic distribution. Comparing the equations obtained with Maple and Mathematica with some results previously reported in the literature, we note that, in most cases, all of the terms fully agree with the previously reported results, and where discrepancies were observed, it was found that the current results are correct, and errors were identified in the previous publications. This fact builds confidence regarding the correctness of the presented scripts, and the ability of these software for analytic formulae manipulation, so that application of the scripts to other density functions may be expected to produce reliable closed form expressions.

It is worth emphasizing that there are other methods to obtain bias corrected estimates. In regular parametric problems, Firth (1993) developed the so-called "preventive" method, which also allows for the removal of the second-order bias. His method consists of modifying the original score function to remove the first-order term from the asymptotic bias of these estimates. In exponential families with canonical parameterizations, his correction scheme consists in penalizing the likelihood by the Jeffreys invariant priors. This is a preventive approach to bias adjustment which has its merits, but the connections between our results and his work are not pursued here. We should also stress that it is possible to avoid cumbersome and tedious algebra on cumulant calculations by using Efron's bootstrap; see Efron and Tibshirani (1993). We use

the analytical approach here since this leads to a nice formula. Moreover, the application of the analytical bias approximation seems to generally be the most feasible procedure to use and it continues to receive attention in the literature.

Binomial Distribution

Andreas N. Philippou[1], Demetrios L. Antzoulakos[2]
[1]Professor of Probability and Statistics
University of Patras, Patras, Greece
[2]Associate Professor
University of Piraeus, Piraeus, Greece

The binomial distribution is one of the most important distributions in Probability and Statistics and serves as a model for several real life problems. Special cases of it were first derived by Pascal (1679) and Bernoulli (1713).

Definition and genesis. Denote by X the number of successes in a sequence of n (≥ 1) independent trials of an experiment, and assume that each trial results in a *success* (S) or a *failure* (F) with respective probabilities p ($0 < p < 1$) and $q = 1-p$. The random variable (rv) X is said to have the *binomial distribution with parameters n and p*, and it is denoted by $B(n,p)$. The probability mass function (pmf) $f(x)$ of X is given by

$$f(x) = P(X = x) = \binom{n}{x} p^x q^{n-x}, \quad x = 0, 1, 2, \ldots, n, \qquad (1)$$

where $\binom{n}{x} = n!/x!(n-x)!$ for $0 \leq x \leq n$ and 0 otherwise.

In fact a typical element of the event $\{X = x\}$ is a sequence $SSFS \ldots SF$ of x S's and $n - x$ F's, having probability $p^x q^{n-x}$ because of P(S) = p and the independence of the trials. Since there are $\binom{n}{x}$ such distinct allocations of x S's and $n - x$ F's, the result follows.

The name of the distribution is due to the binomial theorem, which implies that $B(n,p)$ is a proper probability distribution, since $f(x) \geq 0$ for $x \in R$ and

$$\sum_{x=0}^{n} f(x) = \sum_{x=0}^{n} \binom{n}{x} p^x q^{n-x} = (q+p)^n = 1. \qquad (2)$$

The cumulative distribution function (cdf) of X is related with the incomplete beta function by the formula

$$F(x) = P(X \leq x) = \sum_{i=0}^{x} \binom{n}{i} p^i q^{n-i}$$
$$= (n-x)\binom{n}{x} \int_0^q t^{n-x-1}(1-t)^x dt, \quad x = 0, 1, 2, \ldots, n. \qquad (3)$$

Its ▶moment generating function (mgf) is

$$M(t) = E(e^{tX}) = \sum_{x=0}^{n} e^{tx}\binom{n}{x}p^x q^{n-x} = (q + pe^t)^n \qquad (4)$$

from which the mean and the variance follow as

$$\mu = E(X) = M'(0) = np, \quad \sigma^2 = Var(X) = E(X^2) - \mu^2 = M''(0) - (M'(0))^2 = npq. \qquad (5)$$

When $n = 1$, the binomial distribution $B(n, p)$ is known as the Bernoulli distribution.

By substitution, we get from (1) the recurrence relation

$$f(x) = \frac{(n - x + 1)p}{xq} f(x - 1), \quad x = 1, 2, \ldots, n, \qquad (6)$$

which along with the initial condition $f(0) = q^n$ is very useful for calculating binomial probabilities. It follows from (6) that if $(n + 1)p$ is not an integer, then $f(x)$ has a unique mode at $x = [(n + 1)p]$. If $(n + 1)p$ is an integer, then $f(x)$ has two modes, one at $x = (n + 1)p$ and one at $x = (n + 1)p - 1$.

The binomial distribution arises whenever a sample of size n is drawn randomly with replacement from a population containing just two types of elements.

Urn models. From an urn containing w white and b black balls, n balls are drawn randomly *with replacement*. Let X be the number of white balls drawn. Then

$$f(x) = P(X = x) = \binom{n}{x}\left(\frac{w}{w+b}\right)^x \left(\frac{b}{w+b}\right)^{n-x}, \quad x = 0, 1, 2, \ldots, n. \qquad (7)$$

In fact considering as a *success S the drawing of a white ball*, and noting that that the n balls are drawn randomly with replacement, it follows that X is the number of successes in a sequence of n independent trials of an experiment with success probability $p = w/(w + b)$. The result then follows from (1).

Assume now that the balls are drawn randomly *without replacement* and denote by Y the number of white balls drawn. The rv Y follows the hypergeometric distribution with pmf

$$g(x) = P(Y = x) = \frac{\binom{w}{x}\binom{b}{n-x}}{\binom{w+b}{n}}, \quad x = 0, 1, 2, \ldots, n. \qquad (8)$$

If, in addition, $w/(w + b) \to p$ $(0 < p < 1)$, as $w \to \infty$ and $b \to \infty$, it follows from (8) that

$$\lim_{w,b\to\infty} g(x) = \binom{n}{x}p^x q^{n-x}, \quad x = 0, 1, 2, \ldots, n. \qquad (9)$$

The last equation practically means that $g(x)$ is approximately equal $(\simeq)$ to the RHS of (7) for large w and b in comparison to n. The approximation is considered adequate if $w + b > 10n$.

The binomial distribution converges to the following distribution named after Poisson.

Poisson convergence (Poisson 1837). Let X_n be a sequence of rv's distributed as $B(n, p_n)$ and assume that as $n \to \infty$, $p_n \to 0$ and $np_n \to \lambda$ (> 0). Then

$$\lim_{n\to\infty}\binom{n}{x}p_n^x(1 - p_n)^{n-x} = e^{-\lambda}\frac{\lambda^x}{x!}, \quad x = 0, 1, 2, \ldots . \qquad (10)$$

In practice, (10) means

$$\binom{n}{x}p^x q^{n-x} \simeq e^{-np}\frac{(np)^x}{x!} \qquad (11)$$

for large n and small p. The approximation is quite accurate if $n \geq 20$ and $p \leq 0.05$ or if $n \geq 100$ and $p \leq 0.1$.

The binomial distribution can be approximated by the normal distribution.

Normal approximation. Let X be a rv distributed as $B(n, p)$. Since X can be viewed as a sum of n independent Bernoulli rv's, a direct application of the Central Limit Theorem yields the following approximation for the cdf of X

$$F(x) = P(X \leq x) \simeq \Phi\left(\frac{x - np}{\sqrt{npq}}\right) \qquad (12)$$

where $\Phi(\cdot)$ denotes the cdf of the standard normal distribution. If a ▶*continuity correction* is used we have the following improved approximation

$$F(x) = P(X \leq x) \simeq \Phi\left(\frac{x + 0.5 - np}{\sqrt{npq}}\right) \qquad (13)$$

The approximation is fairly good provided n and p are such that $npq > 20$.

The approximation of binomial probabilities by the normal distribution was proved by de Moivre (1738) for $p = 1/2$ and for arbitrary values of p by Laplace (1812).

We end this note by the following example.

Example. The manager of Alpha Airlines knows from past data that 10% of the passengers who buy Alpha tickets do not show up for travel. Based on this, Alpha Airlines sell 220 tickets when the available seats in their planes are only 200. Find the probability that each ticket holder showing up will find a seat available and hence there will be no complaints.

Solution. Denote by X the number of ticket holders who do not show up for travel. Then the required probability is $P(X \geq 20) = 1 - P(X \leq 19)$. Assuming that each of the 220 ticket holders has the same probability

$p = 0.1$ of not showing up, independently of the others, we have that X is distributed as $B(220, 0.1)$. Therefore, the *exact probability* of no complaints is $P(X \geq 20) = 1 - \sum_{x=0}^{19} \binom{220}{x} (0.1)^x (0.9)^{220-x} = 0.7057$. The *Poisson approximation* by (11) gives $P(X \geq 20) \simeq 1 - \sum_{x=0}^{19} e^{-22} 22^x / x! = 0.6938$. The *normal approximation* by (12) is $P(X \geq 20) \simeq 1 - \Phi\left((19-22)/\sqrt{19.8}\right) = \Phi(0.6742) = 0.7499$. Finally, the *normal approximation with continuity correction* by (13) is $P(X \geq 20) \simeq 1 - \Phi\left((19+0.5-22)/\sqrt{19.8}\right) = \Phi(0.5618) = 0.7129$.

Bioinformatics

Susan R. Wilson
Professor, Faculty of Medicine, Faculty of Science
University of New South Wales, Sydney, NSW, Australia

Bioinformatics is a relatively young, cross-disciplinary research area at the intersection of the biological sciences with the mathematical, statistical, and physical sciences and chemistry and information technology. In the past decade or so, there has been phenomenal growth of life science databases. For example, the most widely used nucleotide sequence database is Genbank that is maintained by the National Center for Biotechnology Information (NCBI) of the US National Library of Medicine; as of February 2008 it contained approximately 86 billion nucleotides from 83 million sequences. Its size continues to grow exponentially as more genomes are being sequenced. However, there is a very large gap (that will take a long time to fill) between our knowledge of the functioning of the genome and the generation (and storing) of raw genomic data. This overview touches briefly on those aspects of bioinformatics that will be of interest to statisticians.

The stated goal for many researchers is for developments in Bioinformatics to be focused at finding the fundamental laws that govern biological systems, as in physics. However, if such laws exist, they are a long way from being determined for biological systems. Instead the current aim is to find insightful ways to model limited components of biological systems and to create tools which biologists can use to analyze data. Examples include tools for statistical assessment of the similarity between two or more DNA sequences or protein sequences, for finding genes in genomic DNA, for quantitative analysis of functional genomics data, and for estimating differences in how genes are expressed in say different tissues, for analysis and comparison of genomes from different species, for phylogenetic analysis, and for DNA sequence analysis and assembly. Tools such as these involve statistical modeling of biological systems. Although the most reliable way to determine a biological molecule's structure or function is by direct experimentation, there is much that can be achieved *in vitro*, i.e., by obtaining the DNA sequence of the gene corresponding to an RNA or protein and analyzing it, rather than the more laborious finding of its structure or function by direct experimentation.

Much biological data arise from mechanisms that have a substantial probabilistic component, the most significant being the many random processes inherent in biological evolution, and also from randomness in the sampling process used to collect the data. Another source of variability or randomness is introduced by the biotechnological procedures and experiments used to generate the data. So the basic goal is to distinguish the biological "signal" from the "noise". Today, as experimental techniques are being developed for studying genome wide patterns, such as expression arrays, the need to appropriately deal with the inherent variability has been multiplied astronomically. For example, we have progressed from studying one or

a few genes in comparative isolation to being able to evaluate simultaneously thousands of genes. Not only must methodologies be developed which scale up to handle the enormous data sets generated in the post-genomic era, they need to become more sensitive to the underlying biological knowledge and understanding of the mechanisms that generate the data. For statisticians, research has reached an exciting and challenging stage at the interface of computational statistics and biology. The need for novel approaches to handle the new genome-wide data has coincided with a period of dramatic change in approaches to statistical methods and thinking. This "quantum" change has been brought about, or even has been driven by, the potential of ever more increasing computing power. What was thought to be intractable in the past is now feasible, and so new methodologies need to be developed and applied.

Unfortunately too many of the current practices in the biological sciences rely on methods developed when computational resources were very limiting and are often either (a) simple extensions of methods for working with one or a few outcome measures, and do not work well when there are thousands of outcome measures, or (b) ad-hoc methods (that are commonly referred to as "statistical" or "computational", or more recently "data mining"! methods (see ►Data Mining)) that make many assumptions for which there is often no (biological) justification. The challenge now is to creatively combine the power of the computer with relevant biological and stochastic process knowledge to derive novel approaches and models, using minimal assumptions, and which can be applied at genomic wide scales. Such techniques comprise the foundation of bioinformatic methods in the future.

Hidden Markov model (HMMs) is a tool that is popular in bioinformatics. Here, applications of HMMs are related to prediction of protein-coding regions in genome sequences, modeling families of related DNA or protein sequences or prediction of secondary structure elements from protein primary sequences. Biological data are the result of evolution, that is, the result of an incredibly complex, and currently unknown, stochastic process. Very simplified models of this process are often used, particularly for the construction of phylogenetic trees. Such evolutionary models have been developed as both discrete time and continuous time processes. A key requirement of these processes is that they be reversible, since statistical comparisons of, say, two contemporary species, can require one tracing up the tree of evolution to a common ancestor and then down the tree to the other species, and so the stochastic process for tracing must be the same in each direction.

Of recent years, gene expression data have become of increasing interest to statistical scientists. The technology has evolved too. Such data are being generated using technologies like microarrays, and very recently, next-generation sequencing. These data can be thought of as lying in very high dimensional space, and the resultant challenges are at the forefront of modern statistical science.

In the past, biologists looked at genes and proteins one at a time. Now we have the technology to start to look at all the elements – genes, mRNA, proteins, interactions, and so on - in a biological system, and to explore their relationships as the system functions in response to biological, and environmental, perturbations. This is known as systems biology. The long-term goal is to have (mathematical) models to describe the behavior of the system given any kind of perturbation, and then to be able to redesign systems by modifications, such as drugs, to have completely new properties. The key question is whether it is possible to take a systematic approach to mapping pathways. The preliminary step involves building a comprehensive "scaffold" of molecular interactions that broadly covers many aspects of cellular function and physiological responses. At the broad, overall level, statistical data mining approaches are used to search for patterns and relationships between variables, and Bayesian networks model conditional dependencies. At a more detailed level, Markov chains model predictions, loss and interconversion among molecular species and states. Today, systems biology is very much in its infancy, but with a challenging future that will also involve expansion to include many more levels of complexity.

An excellent starting point reference for statisticians is Ewens and Grant (2005). Bioconductor (http://www.bioconductor.org) is an open source and open development software project for the analysis of genomic data.

Ewens WJ, Grant G (2005) Statistical methods in bioinformatics, 2nd edn. Springer, New York

Biopharmaceutical Research, Statistics in

Christy Chuang-Stein
Vice President of the American Statistical Association (2009–2011), Head
Pfizer Inc., Kalamazoo, MI, USA

"*Statistics in Biopharmaceutical Research*" is the title of the on-line journal launched by the American Statistical Association in 2009. There are at least two other international peer-reviewed journals completely dedicated to the use of statistics to support the development of pharmaceutical products. They are *Journal of Biopharmaceutical Statistics* (Taylor and Francis Group) and *Pharmaceutical Statistics* (John Wiley and Sons). There are many books devoted to this area of statistical applications also, e.g., Senn (2008), Dmitrienko et al. (2007) and Dmitrienko et al. (2005). In the United States, pharmaceutical and biotech industries employ thousands of statisticians, either directly or indirectly. These statisticians support the discovery, development and commercialization of valuable medicines, medicines that have made substantial contributions to a longer life expectancy and a better quality of life in the past 50 years.

The development of pharmaceutical products is a long and high risk proposition. It takes an average of 15 years for a new compound to be discovered and eventually submitted to regulators for approval. As of 2008, the cost of developing a new drug is estimated to be between $800 million and $2 billion US dollars (Masia 2008). Biopharmaceutical research begins in the laboratory where chemists synthesize compounds and biologists screen the compounds for activities. Because of the large number of compounds, it is essential to develop an efficient algorithm-based process to conduct high-throughput screening for the maximum yield of promising compounds. Once a compound is judged to meet the level of required potency, it needs to go through formulation development so that the active ingredient could be delivered to the target site of actions in test subjects. The first test subjects are laboratory animals used to evaluate the effect of the compound on cardiovascular function, reproductive function, tumor development and the general wellbeing of offspring born to animals exposed to the compound. Most of the animal experiments are conducted according to the International Conference on Harmonisation (ICH) guidance M3(R2) (2009) on nonclinical safety studies. The need to use the smallest number of animals at this preclinical testing stage has led to the use of efficient experimental designs with repeated measures on each animal. In addition, data mining techniques (see ►Data Mining) are used widely to search for chemical and physical properties that tend to associate with compounds that turn out to be successful.

The majority of statistical support in biopharmaceutical research takes place during the clinical testing in humans. In the United States, this support has grown substantially since the 1962 Kefauver-Harris Amendment (Krantz 1966) that required drug sponsors to prove a product's safety and efficacy in controlled clinical trials before receiving marketing authorization. It is usually thought that the first properly randomized control trial in the twentieth century that was recorded involved the use of streptomycin for the treatment of pulmonary tuberculosis (MRC, 1948). Since that time, the number of clinical trials (both randomized and non-randomized) has skyrocketed as evidenced by the number of trials registered at the www.clinicaltrials.gov site in the United States.

The clinical development of a new treatment is often divided into three phases. All clinical trials need to follow ICH E6 guidance on good clinical practice (1996) and the 1964 Declaration of Helsinki. In Phase 1 trials, healthy volunteers are randomized to receive a single dose or multiple doses of the compound or a placebo to study the tolerance and pharmacokinetics of the new compound. The objective is to decide an acceptable dose range. For cytotoxic agents, Phase 1 trials are conducted in cancer patients with the objective to estimate the maximum tolerated dose. Because of the small number of subjects (e.g., 40–100) at this stage, safety evaluation focuses on identifying common side effects of the new treatment. If the tolerance and pharmacokinetic profiles based on the limited data are judged to be acceptable, testing will proceed to Phase 2.

In Phase 2, treatment using the new compound will be compared against a concurrent comparator (placebo, an approved product or the standard of care) in patients with the target disease. The primary objective is to gather safety and efficacy data in patients. Different dose strengths are typically used in these trials to help estimate the dose–response relationship. The latter often involves fitting an Emax model or logistic model. For oncology trials, Phase 2 studies can be a single arm study using the maximum tolerated dose estimated from Phase 1. Some researchers further divide Phase 2 into Phase 2a proof-of-concept and Phase 2b dose-ranging studies. The former often includes a single dose strength to verify the hypothesized mechanism while the latter uses different dose strengths and clinically relevant endpoints. Phase 1 and Phase 2 trials are designed to help a sponsor learn about the new treatment (Sheiner 1997). They are exploratory in nature and the analysis will focus on estimation instead of hypothesis testing.

This is a critical phase of product development. It is during this stage that important information on dose(s), dosing schedule(s), endpoints and the target population will be evaluated and decided upon. Statistics is heavily used to design trials, to analyze the results and to make Go or No-Go decisions.

If data from the Phase 2 development offer good reasons to believe that the new treatment has a positive benefit to risk balance and can bring value to patients, development will move into the confirmatory stage, or Phase 3. In general, Phase 3 trials are double-blind randomized trials if blinding is at all possible. These trials are typically large (hundreds to thousands of patients) with a longer duration. The primary objective is to confirm the presence of a treatment effect and to collect additional safety information in a more diverse population. In terms of efficacy assessment, it could be either superiority over a comparator or non-inferiority to an active control (ICH E10 2000). For life-threatening conditions, interim analyses are often conducted to stop a trial early for efficacy (positive outcome) or futility (negative outcome) for ethical reasons. Interim analyses are typically conducted by individuals independent of the study and reviewed by an Independent Data Monitoring Committee (FDA DMC guidance 2006). Except for those pre-specified in the protocol as possible mid-trial adaptations, changes are strongly discouraged at this stage. When multiple comparisons (multiple doses, multiple endpoints, multiple subgroups, interim efficacy analysis etc.) are conducted for inferential purposes, the significance levels for comparisons need to be properly adjusted so that the family-wide Type I error rate is strongly controlled. The adjustment method needs to be pre-specified and can't be changed once the trial results become known. In short, the design and analysis of Phase 3 trials need to be carefully planned and rigorously executed. Statistical principles, as articulated in ICH E9 (1998), should be followed with very few deviations. Deviations, when occurring, need to be justified and sensitivity analyses should be conducted to evaluate the impact of the deviations on conclusions. Statistics is the basis for inferential conclusions in these trials.

After a product receives a marketing authorization, testing typically continues for additional uses of the product. A new product could also be included in a head-to-head comparison against another marketed product for differentiation or comparative effectiveness research. Much of the work on comparative effectiveness is to support the valuation of a new product, particularly in regions where a government board decides if a new product is eligible for reimbursement and the price of the product under a national healthcare system. These efforts often involve pooling data from multiple studies and can rely on endpoints different from those used to make marketing authorization decision. The work requires statisticians to collaborate closely with health economists, health care providers, third party payers and patients. Systematic review (including ►meta-analysis) is often an integral part of such efforts.

Following several highly visible product withdrawals, the safety of pharmaceutical products has been a major source of public attention in recent years. Data from clinical trials, spontaneous reports of adverse reactions collected in pharmacovigilance databases and longitudinal patient information from healthcare or claims databases are increasingly used to explore possible product-induced injuries. Statistical techniques, based on the concept of proportionality (Almenoff et al. 2007), have been developed and applied extensively to look for possible safety signals.

The decrease in the overall productivity measured by the number of approved new molecular entities each year has led industry and regulators to look for better ways to conduct biopharmaceutical research. Examples include FDA's Critical Path Initiative (2004, http://www.fda.gov/ScienceResearch/SpecialTopics/CriticalPathInitiative/) and European Union's Innovative Medicines Initiative (2007) (http://www.imi.europa.eu/index_en.html). One outcome from this emphasis is the extensive research on adaptive trial designs over the last 5 years (Gaydos et al. 2009; Bornkamp et al. 2007; Bretz et al. 2006; Gallo et al. 2006 etc.). Research on adaptive design includes designs for dose-ranging studies and confirmatory studies. Central to the concept of adaptive designs is a more efficient use of data and a more agile response to accumulated evidence on the effect of a new treatment.

In biopharmaceutical research, statisticians are at the heart of evidence collection, synthesis and communication. Statisticians have enormous opportunities and face probably an equal number of challenges. We can expect both opportunities and challenges to increase in the twenty-first century. Statisticians need to be in tune with the dynamic environment, to help meet the needs of multiple customers, to cash in on the opportunities and rise to the challenges (Chuang-Stein et al. 2010)!

About the Author

Dr. Christy Chuang-Stein is Head of the Statistical Research and Consulting Center, Pfizer Inc, United States. She is a Vice President of the American Statistical Association (2009–2011) and a past Chair of the Biostatistics and Data Management Technical Group of the Pharmaceutical Research and Manufacturers of America (2003–2004).

She is a Founding Editor (with two others) of the journal *Pharmaceutical Statistics* (2002–2005). She is a Fellow of the American Statistical Association (elected in 1998). She has authored and co-authored more than 120 papers including a book on *Analysis of Clinical Trials Using SAS: A Practical Guide* (2005). She co-edited a book on *Pharmaceutical Statistics Using SAS* (2007). Dr. Chuang-Stein received the Donald E Francke Award for Overall Excellence in Journal Publishing (2001, 2006, 2009) and the Thomas Teal Award for Excellence in Statistics Publishing (2008, 2010) from the Drug Information Association. She also received the Excellence in Continuing Education Award from the American Statistical Association (2005). She has served as an Associate Editor for The *American Statistician* (1993–1999), *Journal of Biopharmaceutical Statistics* (2000–2002), *Wiley Encyclopedia of Clinical Trials* (2005–2008) and *Drug Information Journal* (1996–present).

Biostatistics

Susan R. Wilson
Professor, Faculty of Medicine, Faculty of Science
University of New South Wales, Sydney, NSW, Australia

The term Biostatistics is formed from the words biology and statistics, but these days more commonly refers to a somewhat narrower coverage of statistical methods needed in medicine and public health. In its broadest sense, biostatistics is the science of collecting and analyzing biological data to create knowledge about biological processes. The field of biostatistics (even as the term is generally used today) is wide and in its scope includes applications in clinical medicine, public health, epidemiology, genetics (genomics and all the other 'omics), health services, ►demography, and laboratory research. An essential part of the practice of biostatistics is collaboration between the statistician and the medical scientist or health professional.

To give some insight into the very many facets encompassed by biostatistics we use the five central principles

of applied statistics (of which Biostatistics arguably can be regarded as the largest branch) proposed by Cox (2007).

1. *Formulation of Objectives:* This can vary very widely, dependent on the biological, health and related environmental issues being studied. Such issues range over, for example, calculations of birth and death rates, and life expectancy, finding the genomic and environmental basis of complex disease, evaluating the efficacy of a new treatment/drug, determination of efficacious dose for reliable drug production in pharmaceutical research, improving the delivery of health care. It can be useful to distinguish between decision-making and inference. A Bayesian approach is usually to be preferred for decision making in a narrow sense. Inference of causality is often a major objective and is widely studied, particularly in epidemiology. In the early stage of an investigation, biostatisticians can be important in helping to focus on the specific formulation of concrete objectives.
2. *Study design:* This ranges from observational studies and sample surveys, to secondary analysis of collected data, through to experimental design. Major study types include the ecologic study, the cross-sectional study, the case-control study, the cohort study and clinical trials.
3. *Measurement:* The actual entities being measured depend on the objectives, and specific situation, and range from instrument measurements to quality of life measures. Basic criteria include relevance, precision and minimal (preferably no) bias. Care may be needed to ensure that data quality does not drop if too many measurements are being taken, particularly when dealing with human subjects. One also needs to avoid any confounding effect on the system due to the measurement process itself; a much-studied example is the placebo effect in human studies.
4. *Analysis of Biostatistical Data:* The three basic, common phases in any statistical data analysis are data editing and quality control, preliminary, often exploratory, analysis and graphics, and more detailed analysis. Of recent years there has been an explosion in statistical reasoning and methods for analysis of studies of human health. Examples include developments in epidemiological methods, clinical trials, survival analysis, statistical inference based on likelihood methods, ►statistical genetics. Although much analysis is based on probabilistic models, increasingly purely algorithmic approaches, such as cluster analysis (see ►Cluster Analysis: An Introduction), machine learning and ►bioinformatics, are being used. This is particularly the case in the analyses of extremely large data sets where the current challenge is dealing with the extremely large number of measurements that is many times the number of observations.
5. *Interpretation:* The borderline with analysis is not clear-cut, but it is fundamentally important that biostatisticians present the conclusions in a way that is readily interpretable by the relevant members of the health community.

The human context of biostatistics differentiates it from other areas of applied statistics. In particular, ethical issues may arise, patients often do not make ideal "experimental units" and establishment of causation (as in all areas of biology) can be problematic. To achieve evidence-based medical practice, the Cochrane Collaboration was established in 1993 with the aims of facilitating meta-analyses of randomized clinical trials, to disseminate results effectively, and update these regularly.

Many parts of the global field of biostatistics have become disciplines in their own right, such as statistical genetics, demography, actuarial science, methods for clinical trials, as well as bioassay. Often there is overlap with a part of another scientific area; one such example is the recently emerged discipline of bioinformatics.

Many journals are either entirely devoted to biostatistics (including *Biostatistics*, *Statistics in Medicine*, *Statistical Methods for Medical Research*) or have a substantial part devoted (including *Biometrics*, *Biometrical Journal*). There are specialist journals for specific subareas, (such as *Pharmaceutical Statistics*, *Journal of the Society for Clinical Trials*). Besides specialist societies dealing with a subarea, many of the major statistical societies have a Biostatistics (or ►Medical Statistics) section.

Biostatistical software has been expanding rapidly to handle developments of new methodology, as well as changing to meet the ongoing improvements in computer power and capability. There is an enormous, exponentially growing, number of biostatistics reference and textbooks, aimed at the great variety of backgrounds of those interested in biostatistics.

The *Encyclopedia of Biostatistics* (2005) offers a relatively definitive reference on the development and use of statistical methods for addressing the problems and critical questions that confront scientists, practitioners and policy makers involved in the medical and life sciences. Therein, broad sections of the subject were identified, covering specific biostatistical work (clinical trials, epidemiologic studies, clinical epidemiology, vital and health statistics, health services research, laboratory studies, biological models, health surveys and biomedical experiments), as well as particular branches of statistical methodology of special

biostatistical interest (►categorical data analysis, statistical models, longitudinal data analysis, multivariate analysis, survival analysis, sampling and experimental design, statistical computing), medical specialities with statistical applications, human genetics and genetic epidemiology.

The growing importance and application of ►biostatistics is reflected in the increasing number of statisticians employed in the healthcare sector, pharmaceutical industry and medical schools. The boundaries are vague as the discipline of biostatistics is broad, linking a theoretical discipline, namely mathematical statistics, to a diversity of applied sciences relevant to medicine and human health.

Bivariate Distributions

Colin Rose
Director
Theoretical Research Institute, Sydney, NSW, Australia

Bivariate distributions allow one to model the relationship between two random variables, and thus they raise subject areas such as dependence, correlation and conditional distributions. We consider the continuous and discrete cases, separately.

Continuous Bivariate Distributions

Let (X, Y) denote two random variables defined on a domain of support $\Lambda \subset \mathbb{R}^2$, where we assume Λ is an open set in $\mathbb{R}^2$. Then a function $f : \Lambda \to \mathbb{R}_+$ is a joint bivariate pdf (*probability density function*) if it has the following properties:

$$f(x,y) > 0, \text{ for } (x,y) \in \Lambda$$
$$\int_\Lambda \int f(x,y)dxdy = 1 \quad (1)$$
$$P((X,Y) \in S) = \int_S \int f(x,y)dxdy, \text{ for any } S \subset \Lambda$$

The joint cdf (*cumulative distribution function*) is given by:

$$F(x,y) = P(X \le x, Y \le y) = \int_{-\infty}^{y} \int_{-\infty}^{x} f(v,w)dvdw \quad (2)$$

where $0 \le F(x,y) \le 1$. The probability content of a rectangular region $S = \{(x,y) : a < x < b,\ c < y < d\}$ can be expressed in terms of the cdf $F(x,y)$ as:

$$P(a < X < b,\ c < Y < d) = F(a,c) - F(a,d) - F(b,c) + F(b,d) \quad (3)$$

The *marginal pdf* of X, denoted $f_x(x)$, is:

$$f_x(x) = \int_y f(x,y)dy \quad (4)$$

and similarly, the *marginal pdf* of Y, denoted $f_y(y)$, is:

$$f_y(y) = \int_x f(x,y)dx \quad (5)$$

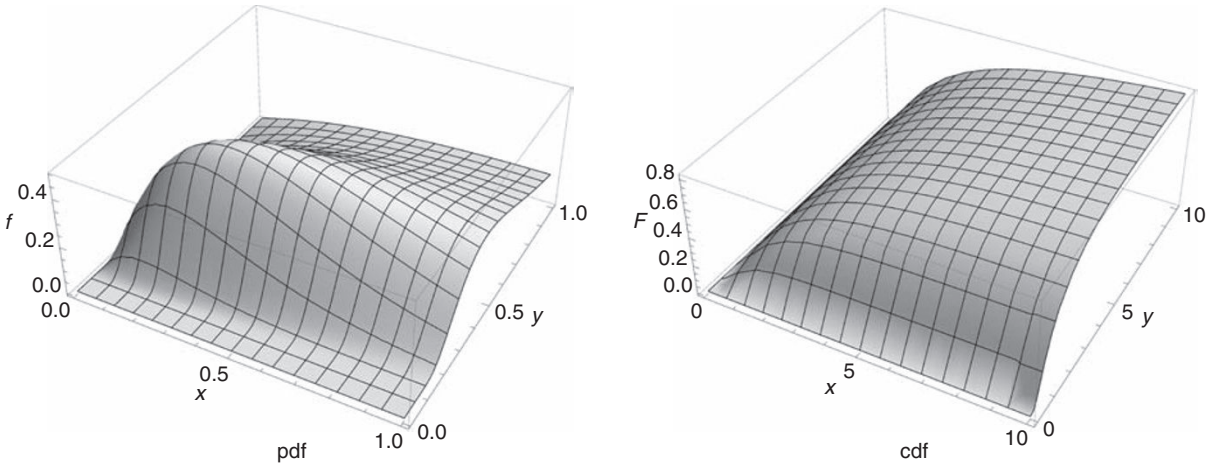
The *conditional pdf* of X given $Y = y$ is denoted by $f(x|Y = y)$ or, for short, $f(x|y)$. It is defined by

$$f(x|y) = \frac{f(x,y)}{f_y(y)}, \quad \text{provided } f_y(y) > 0 \quad (6)$$

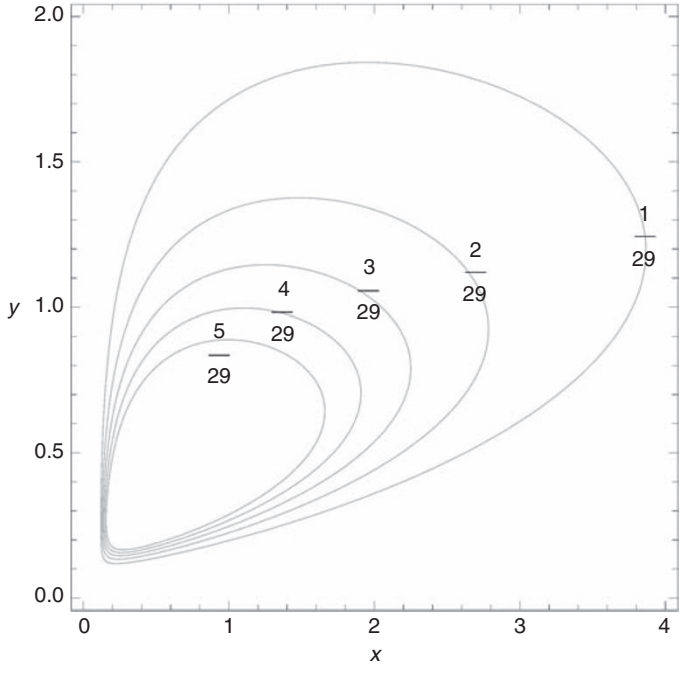
Table 1 lists some well-known bivariate pdf's. Whereas, in a univariate world, one speaks of *the* ►Gamma distribution (one single functional form), by contrast, in a bivariate world, there are a multitude of different bivariate Gamma distributions. This is because the term bivariate Gamma, or bivariate Exponential, or bivariate Uniform etc. is applied to essentially any bivariate distribution whose marginal pdf's are univariate Gamma, Exponential, or Uniform, respectively.

Bivariate Distributions. Table 1 Some bivariate continuous pdf's

Distribution	pdf	Domain	Parameters
Bivariate Normal (standardised)	$f(x,y) = \frac{1}{2\pi\sqrt{1-\rho^2}} \exp\left(-\frac{x^2 - 2\rho xy + y^2}{2(1-\rho^2)}\right)$	$(x,y) \in \mathbb{R}^2$	$-1 < \rho < 1$
Bivariate Normal (general)	$f(x,y) = \frac{1}{2\pi\sigma_x\sigma_y\sqrt{1-\rho^2}} \exp\left(-\frac{\left(\frac{x-\mu_x}{\sigma_x}\right)^2 - 2\rho\left(\frac{x-\mu_x}{\sigma_x}\right)\left(\frac{y-\mu_y}{\sigma_y}\right) + \left(\frac{y-\mu_y}{\sigma_y}\right)^2}{2(1-\rho^2)}\right)$	$(x,y) \in \mathbb{R}^2$	$-1 < \rho < 1$, $\sigma_x > 0, \sigma_y > 0$
Bivariate T (standardised)	$f(x,y) = \frac{1}{2\pi\sqrt{1-\rho^2}} \left(1 + \frac{x^2 - 2\rho xy + y^2}{v(1-\rho^2)}\right)^{-1-\frac{v}{2}}$	$(x,y) \in \mathbb{R}^2$	$-1 < \rho < 1$, $v > 0$
Bivariate Cauchy	$f(x,y) = \frac{1}{2\pi}(1 + x^2 + y^2)^{-3/2}$	$(x,y) \in \mathbb{R}^2$	
Bivariate Exponential (Gumbel Type *I*)	$f(x,y) = e^{-x-y-xy\theta}((1+\theta x)(1+\theta y) - \theta)$	$x > 0,\ y > 0$	$-1 \le \theta \le 1$
Bivariate Exponential (Gumbel Type *II*)	$f(x,y) = \frac{e^{x+y} + \alpha(e^x - 2)(e^y - 2)}{e^{2(x+y)}}$	$x > 0, y > 0$	$-1 < \alpha < 1$
Bivariate Gamma (McKay)	$f(x,y) = \frac{c^{a+b}}{\Gamma[a]\Gamma[b]} x^{a-1}(y-x)^{b-1}e^{-cy}$	$0 < x < y < \infty$	$a, b, c > 0$
Bivariate Logistic (Gumbel)	$f(x,y) = \frac{2e^{-x-y}}{(1+e^{-x}+e^{-y})^3}$	$(x,y) \in \mathbb{R}^2$	
Bivariate Uniform (Morgenstern)	$f(x,y) = 1 + \alpha(2x-1)(2y-1)$	$0 \le x \le 1$, $0 \le y \le 1$	$-1 \le \alpha \le 1$



Bivariate Distributions. Fig. 1 The joint pdf $f(x,y) = \exp[(-1-x)/y]x/y^4$ of Example 1 (left) and the cdf $F(x,y)$ (right)



Bivariate Distributions. Fig. 2 Contours of the joint pdf $f(x,y) = \exp[(-1-x)/y]x/y^4$ of Example 1, illustrated when $f(x,y) = 1/29, 2/29, 3/39, 4/29, 5/29$

Example 1 Joint pdf

Consider the function $f(x,y) = e^{\frac{-1-x}{y}} x/y^4$ with domain of support $\Lambda = \{(x,y) : 0 < x < \infty, 0 < y < \infty\}$. Clearly, f is positive over its domain, and it integrates to unity over the domain. Thus, $f(x,y)$ can represent the joint pdf of a pair of random variables. Figure 1 plots $f(x,y)$ over part of its support, and the cdf over a somewhat wider region of its support …

A contour plot allows one to pick out specific contours along which $z = f(x,y)$ is constant. That is, each

contour joins points on the surface that have the same height z. Figure 2 plots all combinations of x and y such that $f(x,y) = \frac{1}{29}, \frac{2}{29}, \frac{3}{29}, \frac{4}{29}$ and $\frac{5}{29}$.

For extensive detail on continuous bivariate distributions, see Balakrishnan and Lai (2009).

Constructing Continuous Bivariate Distributions: Copulae

Copulae (see ▶Copulas) provide a method for constructing bivariate distributions from known marginal distributions.

Let the continuous random variable X have cdf $\Phi(x)$; similarly, let the continuous random variable Y have cdf $G(y)$. We wish to create a bivariate distribution $H(x,y)$ from these known marginals. The joint distribution function $H(x,y)$ is given by

$$H(x,y) = C(\Phi, G) \tag{7}$$

where C denotes the copula function. Then, the joint pdf $h(x,y)$ is given by

$$h(x,y) = \frac{\partial^2 H(x,y)}{\partial x\, \partial y} \tag{8}$$

Table 2 lists some examples of copulae.

With the exception of the independent case, each copula in Table 2 includes parameter α. This term induces a new parameter into the joint bivariate distribution $h(x,y)$, which gives added flexibility. In each case, setting parameter $\alpha = 0$ (or taking the limit $\alpha \to 0$, in the Frank case) yields the independent copula $C = \Phi G$ as a special case. For more detail on copulae, see, for instance, Nelson (2006). For many alternative ways to construct continuous bivariate distributions, see Balakrishnan and Lai (2009).

Discrete Bivariate Distributions

Let (X,Y) denote two random variables defined on a domain of support $\Lambda \subset \mathbb{R}^2$. Then a function $f : \Lambda \to \mathbb{R}_+$ is a joint pmf (*probability mass function*) if it has the following properties:

$$\begin{aligned} f(x,y) &= P(X = x, Y = y) > 0, \text{ for } (x,y) \in \Lambda \\ \sum_{\Lambda}\sum f(x,y) &= 1 \\ P((X,Y) \in S) &= \sum_{S}\sum f(x,y), \text{ for any } S \subset \Lambda \end{aligned} \tag{9}$$

The joint cdf is:

$$F(x,y) = P(X \le x, Y \le y) = \sum_{v \le x}\sum_{w \le y} f(v,w) \tag{10}$$

The *marginal pmf* of X, denoted $f_x(x)$, is:

$$f_x(x) = \sum_y f(x,y) \tag{11}$$

and similarly, the *marginal pmf* of Y, denoted $f_y(y)$, is:

$$f_y(y) = \sum_x f(x,y) \tag{12}$$

The *conditional pmf* of Y given $X = x$ is denoted by $f(y|X=x)$ or, for short, $f(y|x)$. It is defined by

$$f(y|x) = \frac{f(x,y)}{f_x(x)}, \quad \text{provided } f_x(x) > 0 \tag{13}$$

For extensive detail on discrete bivariate distributions, see Kocherlakota and Kocherlakota (1992).

Given discrete random variables defined on subsets of the non-negative integers $\{0,1,2,\ldots\}$, and $\vec{t} = (t_1, t_2) \in \mathbb{R}^2$, the bivariate *probability generating function* (pgf) is:

$$\Pi\left(\vec{t}\right) = E\left[t_1^X t_2^Y\right] \tag{14}$$

The pgf provides a way to determine the probabilities:

$$P(X = r, Y = s) = \frac{1}{r!s!} \frac{\partial^{r+s}\Pi\left(\vec{t}\right)}{\partial t_1^r \partial t_2^s}\Big|_{\vec{t}=\vec{0}} \tag{15}$$

Example 2 Joint pmf

Let random variables X and Y have joint pmf $f(x,y) = \frac{x+1-y}{54}$ with domain of support $\Lambda = \{(x,y) : x \in \{3,5,7\}, y \in \{0,1,2,3\}\}$, as per Table 3.

This is a well-defined pmf since all the probabilities are positive, and they sum to 1. Figure 3 plots the joint pmf and the joint cdf. For computational details, see Rose and Smith (2002).

Example 3 A bivariate Poisson

Let Z_0, Z_1 and Z_2 be mutually stochastically independent univariate Poisson random variables, with non-negative parameters λ_0, λ_1 and λ_2, respectively, and pmf's $g_i(z_i)$ for $i \in \{0,1,2\}$:

$$g_i(z_i) = \frac{e^{-\lambda_i}\lambda_i^{z_i}}{z_i!} \text{ defined on } z_i \in \{0,1,2,\ldots\} \tag{16}$$

Due to independence, the joint pmf of (Z_0, Z_1, Z_2) is $g_0(z_0)g_1(z_1)g_2(z_2)$. Then, a non-trivial *bivariate Poisson* distribution is obtained as the joint distribution of X and Y where:

$$X = Z_1 + Z_0 \text{ and } Y = Z_2 + Z_0 \tag{17}$$

The joint pmf of X and Y can be found via the method of transformations (see, for instance, Rose and Smith (2002,

Bivariate Distributions. Table 2 Some examples of copulae

Copula	Formula	Restrictions
Independent	$C = \Phi G$	
Morgenstern	$C = \Phi G(1 + \alpha(1-\Phi)(1-G))$	$-1 \le \alpha \le 1$
Ali–Mikhail–Haq	$C = \dfrac{\Phi G}{1-\alpha(1-\Phi)(1-G)}$	$-1 \le \alpha < 1$
Frank	$C = -\dfrac{1}{\alpha}\log\left[1 + \dfrac{\left(e^{-\alpha\Phi}-1\right)\left(e^{-\alpha G}-1\right)}{e^{-\alpha}-1}\right]$	$\alpha \neq 0$

Bivariate Distributions. Table 3 Joint pmf of $h(x,y) = \dfrac{x+1-y}{54}$

	$Y=0$	$Y=1$	$Y=2$	$Y=3$
$X=3$	$\frac{4}{54}$	$\frac{3}{54}$	$\frac{2}{54}$	$\frac{1}{54}$
$X=5$	$\frac{6}{54}$	$\frac{5}{54}$	$\frac{4}{54}$	$\frac{3}{54}$
$X=7$	$\frac{8}{54}$	$\frac{7}{54}$	$\frac{6}{54}$	$\frac{5}{54}$

p. 244)). Doing so yields the bivariate Poisson pmf as:

$$\begin{aligned} f(x,y) &= P(X=x, Y=y) \\ &= e^{(-\lambda_0-\lambda_1-\lambda_2)} \sum_{i=0}^{x} \frac{\lambda_0^i \lambda_1^{x-i} \lambda_2^{y-i}}{i!(x-i)!(y-i)!} \\ &= e^{(-\lambda_0-\lambda_1-\lambda_2)} \lambda_0^x (-\lambda_2)^{-x} \lambda_2^y \frac{U\left(-x, 1-x+y, -\frac{\lambda_1\lambda_2}{\lambda_0}\right)}{x!y!} \end{aligned} \tag{18}$$

with domain of support $\{(x,y) : x \in \{0,1,2,\ldots\}, y \in \{0,1,2,\ldots\}\}$, and where $U(a,b,c)$ denotes the confluent hypergeometric function.

Product Moments

The bivariate *raw moment* $\acute{\mu}_{r,s}$ is defined as:

$$\acute{\mu}_{r,s} = E\left[X^r Y^s\right]. \tag{19}$$

With $s = 0$, $\acute{\mu}_{r,0}$ denotes the r^{th} raw moment of X. Similarly, with $r = 0$, $\acute{\mu}_{0,s}$ denotes the s^{th} raw moment of Y. More generally, $\acute{\mu}_{r,s}$ is known as a *product* raw moment or joint raw moment.

The bivariate *central moment* $\mu_{r,s}$ is defined as

$$\mu_{r,s} = E[(X - E[X])^r (Y - E[Y])^s] \tag{20}$$

The *covariance* of X and Y, denoted $\mathrm{Cov}(X,Y)$, is defined as $\mu_{1,1}$, namely:

$$\mathrm{Cov}(X,Y) = E[(X - E[X])(Y - E[Y])] \tag{21}$$

The *correlation* between X and Y is defined as

$$\rho = \frac{\mathrm{Cov}(X,Y)}{\sqrt{\mathrm{Var}(X)\mathrm{Var}(Y)}} \tag{22}$$

where it can be shown, by the Cauchy–Schwarz inequality, that $-1 \le \rho \le 1$.

Let $\vec{t} = (t_1, t_2) \in \mathbb{R}^2$ denote two dummy variables. Then the bivariate ▶*moment generating function* (mgf) $M_{X,Y}\left(\vec{t}\right)$ is a function of $\vec{t}$, defined by

$$M\left(\vec{t}\right) = E[\exp(t_1 X + t_2 Y)] \tag{23}$$

provided the expectation exists for all $t_i \in (-c, c)$, for some constant $c > 0$, $i = 1, 2$. If it exists, the mgf $M\left(\vec{t}\right)$ can be used to generate the product raw moments $\acute{\mu}_{r,s} = E\left[X^r Y^s\right]$ as follows:

$$\acute{\mu}_{r,s} = E\left[X^r Y^s\right] = \frac{\partial^{r+s} M\left(\vec{t}\right)}{\partial t_1^r \partial t_2^s}\Big|_{\vec{t}=\vec{0}} \tag{24}$$

The *cumulant generating function* is the natural logarithm of the mgf. The bivariate *characteristic function* is similar to (23) and given by

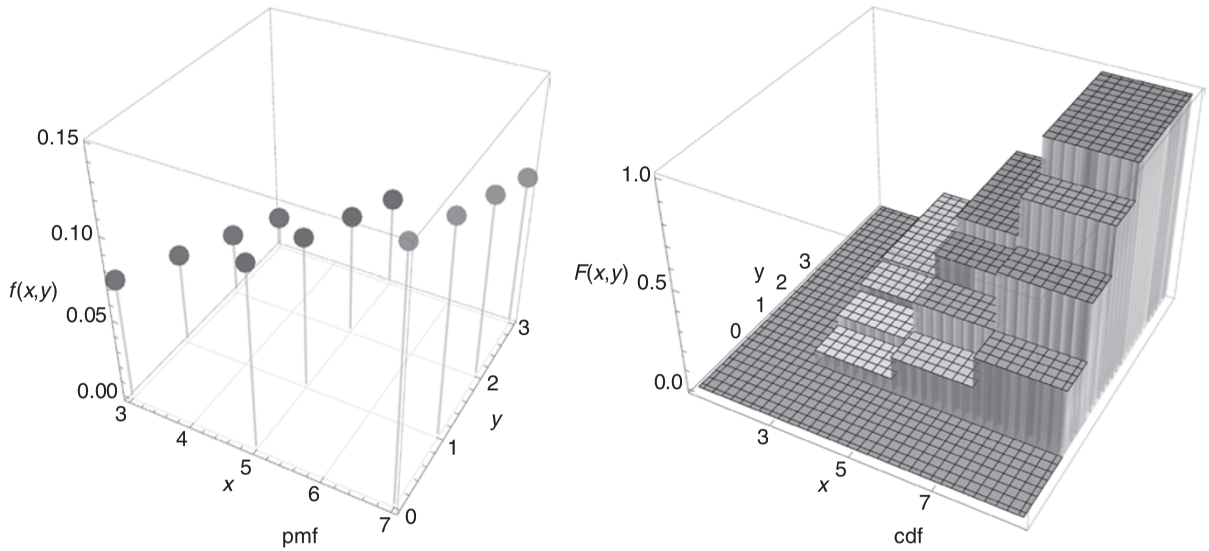
$$C\left(\vec{t}\right) = E[\exp(i\,(t_1 X + t_2 Y))] \tag{25}$$

where i denotes the unit imaginary number.

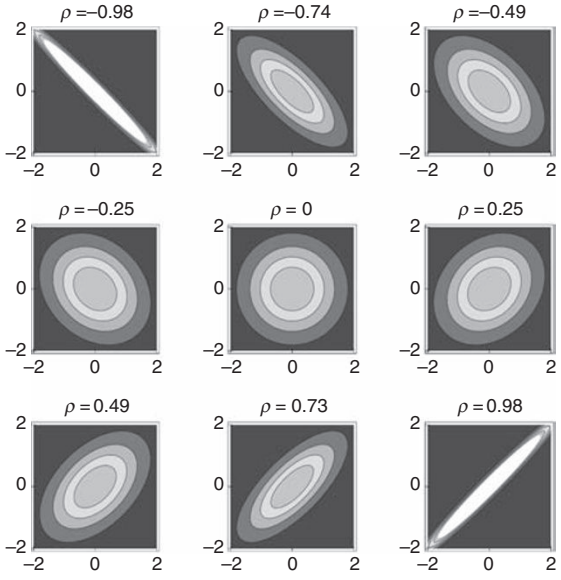
Dependence

Let random variables X and Y have joint pdf $f(x,y)$, with marginal density functions $f_x(x)$ and $f_y(y)$. Then X and Y are said to be *mutually stochastically independent* if and only if

$$f(x,y) = f_x(x) f_y(y) \tag{26}$$



Bivariate Distributions. Fig. 3 Joint pmf of $h(x, y) = \frac{x+1-y}{54}$ of Example 2 (*left*) and the joint cdf (*right*)



Bivariate Distributions. Fig. 4 Contour plots of the bivariate Normal pdf, for different values of ρ

i.e., if and only if the joint pdf is equal to the product of the marginal pdf's. If X and Y are mutually stochastically independent, then, amongst other properties, $\mathrm{Cov}(X, Y) = 0$. Independence implies zero covariance, but the converse is not true: that is, zero covariance does *not* imply that X and Y are independent.

Figure 4 illustrates contour plots for a bivariate Normal pdf with zero means and variance–covariance matrix $\begin{pmatrix} 1 & \rho \\ \rho & 1 \end{pmatrix}$. Here, ρ denotes the correlation coefficient between X and Y. Each plot corresponds to a specific value of ρ. In the top left corner, $\rho = -0.98$ (almost perfect negative correlation), whereas in the bottom right corner, $\rho = 0.98$ (almost perfect positive correlation). The middle plot corresponds to the case of zero correlation. In any given plot, the edge of each shaded region represents the contour line, and each contour is a two-dimensional ellipse along which the bivariate Normal pdf $f(x, y)$ is constant.

Balakrishnan and Lai (2009, Chaps. 3 and 4) provide detail on alternative and more sophisticated concepts of dependence.

About the Author

Dr. Colin Rose is director of the Theoretical Research Institute (Sydney). He is the co-author (with M.D. Smith) of the Springer text *Mathematical Statistics with Mathematica*. His current area of research is exact computational methods in mathematical statistics, in particular, with application to the mathStatica project (winner of the Best Software Contribution at CompStat Berlin). He is an Editor of the *Journal of Statistical Software*, and a recent guest editor of the *Mathematica Journal*.

Bootstrap Asymptotics

Rudolf Beran
Distinguished Professor Emeritus
University of California-Davis, Davis, CA, USA

The bootstrap (see ►Bootstrap Methods), introduced by Efron (1979), merges simulation with formal model-based statistical inference. A statistical model for a sample X_n of size n is a family of distributions $\{P_{\theta,n}: \theta \in \Theta\}$. The parameter space Θ is typically metric, possibly infinite-dimensional. The value of θ that identifies the true distribution from which X_n is drawn is unknown. Suppose that $\hat{\theta}_n = \hat{\theta}_n(X_n)$ is a consistent estimator of θ. The bootstrap idea is

(a) Create an artificial *bootstrap world* in which the true parameter value is $\hat{\theta}_n$ and the sample X_n^* is generated from the fitted model $P_{\hat{\theta}_n,n}$. That is, the conditional distribution of X_n^*, given the data X_n, is $P_{\hat{\theta}_n,n}$.

(b) Act as if a sampling distribution computed in the fully known bootstrap world is a trustworthy approximation to the corresponding, but unknown, sampling distribution in the model world.

For example, consider constructing a confidence set for a parametric function $\tau(\theta)$, whose range is the set T. As in the classical pivotal method, let $R_n(X_n, \tau(\theta))$ be a specified *root*, a real-valued function of the sample and $\tau(\theta)$. Let $H_n(\theta)$ be the sampling distribution of the root under the model. The *bootstrap distribution* of the root is $H_n(\hat{\theta}_n)$, a random probability measure that can also be viewed as the conditional distribution of $R_n\left(X_n^*, \tau(\hat{\theta}_n)\right)$ given the sample X_n. An associated *bootstrap confidence set* for $\tau(\theta)$, of nominal coverage probability β, is then $C_{n,B} = \left\{t \in T: R_n(X_n, t) \le H_n^{-1}(\beta, \hat{\theta}_n)\right\}$. The quantile on the right can be approximated, for instance, by Monte Carlo techniques. The intuitive expectation is that the coverage probability of $C_{n,B}$ will be close to β whenever $\hat{\theta}_n$ is close to θ.

When does the bootstrap approach work? Bootstrap samples are perturbations of the data from which they are generated. If the goal is to probe how a statistical procedure performs on data sets similar to the one at hand, then repeating the statistical procedure on bootstrap samples stands to be instructive. An exploratory rationale for the bootstrap appeals intellectually when empirically supported probability models for the data are lacking. Indeed, the literature on "statistical inference" continues to struggle with an uncritical tendency to view data as a *random* sample from a statistical model *known* to the statistician apart from parameter values. In discussing the history of probability theory, Doob (1972) described the mysterious interplay between probability models and physical phenomena: "But deeper and subtler investigations had to await until the blessing and curse of direct physical significance had been replaced by the bleak reliability of abstract mathematics."

Efron (1979) and most of the subsequent bootstrap literature postulate that the statistical model $\{P_{\theta,n}: \theta \in \Theta\}$ for the data is credible. "The bootstrap works" is taken to mean that bootstrap distributions, and interesting functionals thereof, converge in probability to the correct limits as sample size n increases. The convergence is typically established pointwise for each value of θ in the parameter space Θ. A template argument: Suppose that Θ is metric and that (a) $\hat{\theta}_n \to \theta$ in $P_{\theta,n}$-probability as $n \to \infty$; (b) for any sequence $\{\theta_n \in \Theta\}$ that converges to θ, $H_n(\theta_n) \Rightarrow H(\theta)$. Then $H_n(\hat{\theta}_n) \Rightarrow H(\theta)$ in $P_{\theta,n}$-probability. Moreover, any weakly continuous functional of the bootstrap distribution converges in probability to the value of that functional at the limit distribution.

Such equicontinuity reasoning, in various formulations, is widespread in the literature on bootstrap convergence. For statistical models of practical interest, considerable insight may be needed to devise a metric on Θ such that the template sufficient conditions both hold. Some early papers on bootstrap convergence after Efron (1979) are Bickel and Freedman (1981), Hall (1986), Beran (1987). Broader references are the books and monographs by Hall (1992), Mammen (1992), Efron and Tibshirani (1993), Davison and Hinkley (1997) and the review articles in the bootstrap issue of *Statistical Science* **18** (2003).

These references leave the impression that bootstrap methods often work, in the sense of correct pointwise asymptotic convergence or pointwise second-order accuracy, at every θ in the parameter space Θ. Counterexamples to this impression have prompted further investigations. One line of research has established necessary and sufficient conditions for correct pointwise convergence of bootstrap distributions as n tends to infinity [cf. Beran (1997), van Zwet and Zwet (1999)].

In another direction, Putter (1994) showed: Suppose that the parameter space Θ is complete metric and that (a) $H_n(\theta) \Rightarrow H(\theta)$ for every $\theta \in \Theta$ as $n \to \infty$; (b) $H_n(\theta)$ is continuous in θ, in the topology of weak convergence, for every $n \ge 1$; (c) $\hat{\theta}_n \to \theta$ in $P_{\theta,n}$-probability for every $\theta \in \Theta$ as $n \to \infty$. Then $H_n(\hat{\theta}_n) \Rightarrow H(\theta)$ in $P_{\theta,n}$-probability for "almost all" $\theta \in \Theta$. The technical definition of "almost all" is a set of Baire category II. While "almost all" θ may sound harmless, the failure of bootstrap convergence on a tiny set in the parameter space typically stems from non-uniform convergence of bootstrap distributions over neighborhoods of that set. When that is the case, pointwise limits are highly deceptive.

To see this concretely, let $\hat{\theta}_{n,S}$ denote the ▶James-Stein estimator for an unknown p-dimensional mean vector θ on which we have n i.i.d. observations, each having a $N(0, I_p)$ error. Let $H_n(\theta)$ be the sampling distribution of the root $n^{1/2}(\hat{\theta}_{n,S} - \theta)$ under this model. As n tends to infinity with $p \ge 3$ fixed, we find (cf. Beran (1997)):

(a) The natural bootstrap distribution $H_n(\bar{X}_n)$, where $\bar{X}_n$ is the sample mean vector, converges correctly almost everywhere on the parameter space, except at $\theta = 0$. A similar failure occurs for the bootstrap distribution $H_n(\hat{\theta}_{n,S})$.

(b) The weak convergences of the sampling distribution $H_n(\theta)$ and of the two bootstrap distributions just described are *not* uniform over neighborhoods of the point of bootstrap failure, $\theta = 0$.

(c) The exact quadratic risk of the James-Stein estimator strictly dominates that of $\bar{X}_n$ at *every* θ, especially at $\theta = 0$. If the dimension p is held fixed, the region of substantial dominance in risk shrinks towards $\theta = 0$ as n increases. The asymptotic risk of the James-Stein estimator dominates that of the sample mean only at $\theta = 0$. That the dominance is strict for every finite $n \geq 1$ is missed by the non-uniform limit. Apt in describing non-uniform limits is George Berkeley's celebrated comment on infinitesimals: "ghosts of departed quantities."

In the James-Stein example, correct pointwise convergence of bootstrap distributions as n tends to infinity is an inadequate "bootstrap works" concept, doomed by lack of uniform convergence. The example provides a leading instance of an estimator that dominates classical counterparts in risk and fails to bootstrap naively. The message extends farther. Stein (1956, first section) already noted that multiple shrinkage estimators, which apply different shrinkage factors to the summands in a projective decomposition of the mean vector, are "better for most practical purposes." Stein (1966) developed multiple shrinkage estimators in detail. In recent years, low risk multiple shrinkage estimators have been constructed implicitly through regularization techniques, among them adaptive penalized least squares with quadratic penalties, adaptive submodel selection, or adaptive symmetric linear estimators. Naive bootstrapping of such modern estimators fails as it does in the James-Stein case.

Research into these difficulties has taken two paths: (a) devising bootstrap patches that fix *pointwise* convergence of bootstrap distributions as the number of replications n tends to infinity [cf. Beran (1997) for examples and references to the literature]; (b) studying bootstrap procedures under asymptotics in which the dimension p of the parameter space increases while n is held fixed or increases. Large p bootstrap asymptotics turn out to be uniform over usefully large subsets of the parameter space and yield effective bootstrap confidence sets around the ►James-Stein estimator and other regularization estimators [cf. Beran (1995), Beran and Dümbgen (1998)]. The first section of Stein (1956) foreshadowed the role of large p asymptotics in studies of modern estimators.

About the Author

Rudolf Beran was Department Chair at UC Davis (2003–2007) and at UC Berkeley (1986–1989). He received in 2006 the Memorial Medal of the Faculty of Mathematics and Physics, Charles University, Prague, in recognition of "distinguished and wide-ranging achievements in mathematical statistics, ... devoted service to the international statistical community, and a long-lasting collaboration with Czech statisticians." During 1997–1999 he held an Alexander von Humboldt U.S. Senior Scientist Award at Heidelberg University. He has authored or co-authored over 100 papers in international journals and published lecture notes (with G. R. Ducharme) on *Asymptotic Theory for Bootstrap Methods in Statistics* (Publications CRM, Université de Montréal, 1991).

Introduction

Use of the bootstrap idea goes back at least to Simon (1969) who used it as a tool to teach statistics. But the properties of the bootstrap and its connection to the ▶jackknife and other resampling methods, was not realized until Efron (1979). Similar resampling methods such as the jackknife and subsampling go back to the late 1940s and 1960s respectively (Quenouille (1949) for the jackknife and Hartigan (1969) and McCarthy (1969) for subsampling). In 1979 the impact that the bootstrap would have was not really appreciated and the motivation for Efron's paper was to better understand the jackknife and its properties. But over the past 30 years it has had a major impact on both theoretical and applied statistics with the applications sometimes leading the theory and vice versa. The impact of Efron's work has been so great that he was awarded with the President's Medal of Science by former President George W. Bush and Kotz and Johnson (1992) included the 1979 Annals of Statistics paper in their three volume work on breakthroughs in statistics. After the publication of Efron's paper, Simon's interest in bootstrapping was revitalized and he and Peter Bruce formed the company Resampling Stats which publicized the methodology and provided elementary software for teaching and basic data analysis (see Simon and Bruce (1991)). The bootstrap is not simply another statistical technique but is rather a general approach to statistical inference with very broad applicability and very mild modeling assumptions.

There are now a number of excellent books that specialize in bootstrap or resampling in general. Included in this list are Efron (1982), Efron and Tibshirani (1993), Davison and Hinkley (1997), Chernick (1999, 2007), Hall (1992), Manly (1997), Lunneborg (2000), Politis et al. (1999), Shao and Tu (1995) and Good (1998, 2004). Many other texts devote chapters to the bootstrap including a few introductory statistics texts. There are even a couple of books that cover subcategories of bootstrapping (Westfall and Young (1993) and Lahiri (2003b)).

The Basic Idea

Formally, denote by $\mathbf{X} = (X_1, \ldots, X_n)$ a random sample from X with unknown distribution F and consider a random variable $T = T(X_1, \ldots, X_n; F)$ which may be as simple as $T = \overline{X} - \mu$, with $\mu = \int x dF(x)$, or a more complicated one such as a nonparametric kernel density estimator of the density f given by $T = \hat{f}_h(x) = \frac{1}{nh}\sum_{i=1}^{n} K\left(\frac{x - X_i}{h}\right)$, where h denotes the bandwidth parameter and K is a kernel function. The main goal in statistical inference is to determine the sampling distribution of T, namely $\mathbb{P}_F(T(\mathbf{X}, F) \leq x)$. If F_n denotes the empirical distribution of X, from the sample $\mathbf{X}$, then the bootstrap version of T is given by $T^* = T\left(X_1^*, \ldots, X_n^*; F_n\right)$ where $\mathbf{X}^* = \left(X_1^*, \ldots, X_n^*\right)$ is a random sample from F_n. This is known as the naive bootstrap. We may also replace F by a smoothed version $\tilde{F}_n(x) = \int_{-\infty}^{x} \hat{f}_h(t)dt$ (called the smooth or generalized bootstrap) or by a parametric estimate of F say $F_{\hat{\theta}_n}$ (parametric bootstrap). See Efron (1979, 1982) as introductory references, and Silverman and Young (1987) and Dudewicz (1992) for detailed coverage on the smooth bootstrap.

As it has been said, the main goal is to estimate the sampling distribution of T. The bootstrap estimator of $\mathbb{P}_F(T(\mathbf{X}, F) \leq x)$ is given by $\mathbb{P}_{F_n}(T(\mathbf{X}^*, F_n) \leq x) = \mathbb{P}^*(T(\mathbf{X}^*, F_n) \leq x)$, where $\mathbb{P}^*$ is the associated probability in the bootstrap world (the distribution associated with sampling with replacement from F_n in the naive bootstrap case). Since in most cases this probability cannot be computed, Monte Carlo methods are used in order to obtain an approximation, based on B bootstrap replicates $\mathbf{X}^{*j}$, with $j = 1, \ldots B$. The estimate of $\mathbb{P}^*(T(\mathbf{X}^*, F_n) \leq x)$ is just

$$\widehat{\mathbb{P}^*}(T(\mathbf{X}^*, F_n) \leq x) = \frac{\#\{j; T(\mathbf{X}^{*j}, F_n) \leq x\}}{B},$$

where # denotes the cardinal of the set. Once we have approximated the statistic's distribution, other inference problems such as bias and variance estimation, confidence interval construction or hypothesis testing, etc. can be tackled. With confidence intervals, the variable of interest is usually given by $T = \hat{\theta} - \theta$, where θ is an unknown parameter of the distribution and $\hat{\theta}$ is the corresponding estimator. The simplest case is based on the direct approximation of the distribution of T, known as the percentile method. Several refinements such as bias-corrected percentile, percentile-t (also called bootstrap-t) or other corrections based on Edgeworth expansions (see ▶Edgeworth Expansion), have been proposed. For more complete coverage of bootstrap confidence intervals, see Hall (1988, 1992), Efron and Tibshirani (1993), Chernick (2007) or Davison and Hinkley (1997).

Generally speaking, the bootstrap methodology aims to reproduce from the sample the mechanism generating the data which may be a probability distribution, a regression model, a time series, etc. Nowadays, bootstrap methods have been applied to solve different inference problems, including bandwidth selection in curve estimation (Cao 1993), distribution calibration in ▶empirical processes or empirical regression processes (Stute et al. 1998) or inference for incomplete data detailed below, among others.

Extension to Dependent Data

For the sake of simplicity, we may distinguish two perspectives. First, data involved in the statistic may be directly observed, where the basic bootstrap resampling procedures introduced above can be applied. Secondly, data may exhibit a complex generating mechanism. As a special case, consider a parametric regression model

$$y_i = m_\theta(x_i) + \varepsilon_i, \quad i = 1, \ldots, n,$$

where $m_\theta(\cdot)$ is the regression function and ε_i denotes the associated ith error. For fixed design and parametric regression function, we may proceed by resampling the residuals $e_i = y_i - m_{\hat{\theta}}(x_i)$, where $\hat{\theta}$ is a parameter estimator. Naive bootstrap samples $\tilde{e}_i^*$ drawn from the empirical distribution of the centered residuals $\{e_i - \bar{e}\}$ are used to get the bootstrap regression model $y_i^* = m_{\hat{\theta}}(x_i) + \tilde{e}_i^*$. This approach is called model-based bootstrapping.

Efron also introduced the bootstrap in this context. Each of the bootstrap samples can provide an estimate of the regression parameter (possibly a vector of parameters) following the same estimation procedure that was used with the original fitted model (e.g., ordinary ▶least squares). From all the bootstrap replicates, we get a Monte Carlo approximation to the bootstrap distribution of the regression parameter and this is then used to make inferences about the parameter based on this approximation to the sampling distribution for the parameter estimate. In model-based inference, Paparoditis and Politis (2005) underscored the importance of the choice of residuals. For example, to maximize power in bootstrap-based hypothesis testing, residuals are obtained using a sequence of parameter estimators that converge to the true parameter value under both the null and alternative hypotheses.

Different modifications of this simple idea allow for adapting to random design, heterocedastic models or situations where the regression function is not totally specified or is unknown, such as in nonparametric regression. From the first references, specially in parametric regression, by Bickel and Freedman (1981) and Freedman (1981), several advances have been introduced in this context. For the nonparametric case, see Chap. 14 in Schimek (2000).

Although bootstrap originally started with independent sample observations, just as in the regression models described above, there are extensions to dependent data: ▶time series, ▶spatial statistics, ▶point processes, spatio-temporal models and more. For example, similar to the ideas of bootstrap in regression models, given an explicit dependence structure such an autoregressive model, we may write:

$$y_i = m(y_{i-1}, \ldots, y_{i-p}) + \varepsilon_i$$

and proceed by resampling from the residuals. When an explicit parametric equation is not available, an alternative is block bootstrap, which consists of resampling blocks of subsamples, trying to capture the dependence in the data. Bootstrap replicates obtained by these methods may not be stationary even though the original data came from a stationary process. In order to solve this problem, Politis and Romano (1994a) propose the stationary bootstrap. These bootstrap procedures can be adapted for predicting the future values of the process. An overview of bootstrap methods for estimation and prediction in time series can be found in Cao (1999). The idea of block bootstrap has also been extended to the spatial setting (see Lahiri 2003b)

There is theoretical justification for bootstrapping time series. As an example, Politis and Romano (1994b) established convergence of certain sums of stationary time series that can facilitate bootstrap resampling. The block bootstrap was among the early proposals for time series data. While the method is quite straightforward, there are associated problems like getting independence between blocks while maintaining the dependence structure within the block. The size of the block is a crucial quantity that should be determined to assure success in block bootstrapping. The AR-sieve method was also introduced as a residual-based method similar to the model-based approach. Local bootstrap was also introduced but in the context of a local regression framework (nonparametric) and to account for the nonparametric model, resampling allows the empirical distribution to vary locally in the time series.

Bühlman (2002) compared different methods for time series bootstrapping. The block bootstrap is recognized as the most general and simplest generalization of the original independent resamples but is sometimes criticized for the possible artifacts it may exhibit when blocks are linked together. Blocking can potentially introduce some dependence structure in addition to those naturally existing in the data. The AR-sieve is less sensitive to selection of a

model than the block to the block length. The local bootstrap for ▶nonparametric estimation is observed to yield slower rates of convergence. Generally, the AR-sieve is relatively advantageous among the bootstrap approaches for time series data.

Recently, the bootstrap has been introduced in more complex and complicated models. In modeling non-stationary volatility, Xu (2008) used an autoregression around a polynomial trend with stable autoregressive roots to illustrate how non-stationary volatility affects the consistency, convergence rates and asymptotic distributions of the estimators. Westerlund and Edgerton (2007) proposed a bootstrap test for the null hypothesis of cointegration in ▶panel data. Dumanjug et al. (2009) developed a block bootstrap method in a spatial-temporal model.

Diversity of Applications

The use of bootstrap as a tool for calibrating the distribution of a statistic has been extended to most topics in statistical inference. Not trying to be exhaustive, it is worth it considering the immersion of bootstrap in the following fields of study:

1. Incomplete data. When dealing with censored data, the empirical estimator of the distribution is replaced by the ▶Kaplan-Meier estimator (Efron 1981).
2. Missing information. If some observations are missing or imputed, bootstrap estimators must be suitably adapted (Efron 1994).
3. Hypothesis testing in regression models. When the goal is to check whether a parametric regression model m_θ fits the data, the distribution of a test statistic $T = D(\hat{m}_h, m_{\hat{\theta}})$, where $\hat{m}_h$ is a nonparametric estimator of the regression function m and D is a distance measure, must be calibrated. In this context, a broad literature can be cited, such as Härdle and Mammen (1993) or Cao and González-Manteiga (1993). For a recent review on the topic, see González-Manteiga and Crujeiras (2008).
4. Small area inference. Bootstrap has also shown a great development in finite populations (Shao and Tu 1995), specially in recent years with the appearance of small area models. See Hall and Maiti (2006) and Lahiri (2003a).
5. Bootstrap has also recently been used in learning theory and high dimensional data. As an example, see the application of bootstrap in the regression model with functional data (Ferraty et al. 2009) or the bootstrap for variable choice in regression or classification models (Hall et al. 2009).

The continuing development of bootstrap methods has been motivated by the increasing progress in computational efficiency in recent years. Other computer-intensive methods are the ▶Markov Chain Monte Carlo, usually known as MCMC [see Smith and Roberts (1993), for instance] and subsampling (Politis et al. 1999).

Some Historical Development

The bootstrap's popularity rests in its relaxation of distribution assumptions that can be restrictive and its wide variety of applications as described above. We see that the development of the bootstrap evolved as follows. Efron introduced it in (1979) with some theoretical and heuristic development. Theoretical activity followed quickly with Athreya, Bickel, Freedman, Singh, Beran and Hall providing notable contributions in the early 1980s. Efron realized its practical value early on and efforts to make the scientific community aware of its potential were the Diaconis and Efron (1983) article in Scientific American and the article by Efron and Tibshirani (1986).

So by the early 1990s enough theory and successful applications had developed to lead to an explosion of papers, mostly applied and some extending the theory. The literature was so large that Chernick (1999) contains more than 1,600 references. An excellent and nearly up-to-date survey article on the bootstrap is Lahiri (2006).

When and Why Bootstrap Can Fail to Work

For the bootstrap to *work*, the bootstrap estimates must be consistent. But even when the first results on consistency of the bootstrap estimate of a mean were derived, Bickel, Freedman and others realized that there were cases where the bootstrap is inconsistent. Two notable examples are (1) the sample mean when the population distribution has an infinite variance but the ordinary sample mean appropriately normalized still converges to a stable law and (2) the maximum of a sample when the population distribution is in the domain of attraction of an extreme value distribution. These examples are covered in Chap. 9 of Chernick (2007).

These results on bootstrap inconsistency were already published in the 1980s and led to a concern about what the real limitations of the bootstrap are. The volume edited by LePage and Billard (1992) and the monograph by Mammen (1992) address these concerns. Consistency is one requirement but what about the small sample properties? This was addressed beautifully using simulation as illustrated in Shao and Tu (1995) and Efron (1983). The work of Efron

and others on small sample accuracy of bootstrap estimates of error rates in classification is summarized in Chap. 2 of Chernick (2007).

Remedies for Failure

Efron's bootstrap principle states that the nonparametric bootstrap mimics sampling from a population by letting the empiric distribution F_n play the role of the unknown population distribution F and letting the bootstrap distribution F_n^* play the role of F_n. This is to say in words what was described using formal mathematics earlier in this article.

Efron thought it was natural to take the size of a bootstrap sample to be n but others saw no reason why a value $m < n$ could not be used. For many problems where consistency was shown $m = n$ works fine. Bickel and Ren (1996) introduced a bootstrap approach called the m-out-of-n bootstrap which takes $m < n$ and works well in some problems. A recent advance in bootstrapping was the proof that for the two examples previously described, where the bootstrap is inconsistent when $m = n$, the m-out-of-n bootstrap is consistent provided m tends to infinity at a slower rate than n and slow enough for $m/n \to 0$. Prior to the formal introduction of the m-out-of-n bootstrap, Athreya (1987) showed that for heavy-tailed distributions a trimmed mean could converge to the population mean with the advantage that the sampling distribution of the trimmed mean has second moments. Using this idea he proved consistency of the m-out-of-n bootstrap for the mean in the infinite variance case. Fukuchi (1994) did the same for extremes. Both results require m and n to approach infinity at a rate that would have $m/n \to 0$. The m-out-of-n bootstrap has been further studied by Bickel et al. (1997) and Politis et al. (1999). Zelterman (1993) found a different way to modify the bootstrap to make it consistent for the extreme values. This is all summarized in Chap. 9 of Chernick (2007).

The theoretical developments from 1995 to the present have been in the area of (1) modifying the bootstrap to fix inconsistency in order to widen its applicability and (2) extending the theory to dependent situations (as previously mentioned). Lahiri (2003a) is the ideal reference for a detailed account of these developments with dependent data.

Problems and Refinements for Bootstrap Confidence Intervals

Bootstrap confidence intervals have been a concern and Efron recognized early on that getting the asymptotic coverage nearly correct in small samples required more sophistication than his simple percentile method bootstrap. So the bias corrected bootstrap was developed to do that. However, in Schenker (1985) the example of variance estimation for a particular chi square population distribution showed that even the BC method had coverage problems in small samples. Efron (1987) introduced the BCa method which remedied the problem discovered by Schenker.

However, in recent years variance estimation for other examples with skewed or heavy-tailed distributions has shown all bootstrap confidence interval methods to be problematic in small samples. A large Monte Carlo investigation, Chernick and LaBudde (2010), compares the coverage of various bootstrap confidence intervals for the variance estimate from a variety of population distributions when sample sizes are small. They also provide an idea of rates of convergence by showing how the coverage improves as the sample size gets large. An interesting surprise is that in some situations for small sample sizes the lower order bootstrap work better than the higher order ones. This is because they are simpler and do not involve estimating biases and acceleration constants which depend on third order moments of the distribution. For the lognormal population they show that at the small sample sizes (20–100) the coverage error is shockingly high for all methods.

About the Authors

Dr. Chernick is the author of *Bootstrap Methods: A Practitioner's Guide* (Wiley 1999), with the second edition title *Bootstrap Methods: A Guide for Practitioners and Researchers* (Wiley 2007). He is also the coauthor of *Introductory Biostatistics for the Health Sciences: Modern Methods including Bootstrap* (Wiley 2002). He is currently Manager of Biostatistical Services at the Lankenau Institute for Medical Research. He is the winner of the Jacob Wolfowitz Prize in 1983 and is a past President of the Southern California Chapter of the American Statistical Association. He has taught at California State University and the University of Southern California. He is elected Fellow of the American Statistical Association (2001).

Wenceslao González-Manteiga is a full-time professor and main researcher at the Department of Statistics and Operations Research (University of Santiago de Compostela, Spain). He received his Ph.D. degree in Mathematics at this University. He was Editor-in-Chief of *TEST* for 6 years and the *International Journal of the Spanish Statistical Society*. Over the years, he has collaborated with researchers in many fields, visiting several universities and has published about 140 papers in journals such as *Technometrics, Chemometrics, Journal of the American Statistical Association, Annals of Statistics* and *Computational*

Statistics and Data Analysis. He has also collaborated in several projects in applied statistics.

Rosa M. Crujeiras is an associate professor and the Department of Statistics and Operations Research (University of Santiago de Compostela, Spain). With a dissertation thesis on spectral methods for spatial data, she obtained her Ph.D. degree in Mathematics at this University in January 2007. She has been a post-doctoral researcher at the Université catholique de Louvain (Belgium). She has published several papers in international journals, such as *Environmetrics, Theory of Probability and its Applications* or *Computational Statistics and Data Analysis*.

Dr. Erniel Barrios is a Professor and Dean, School of Statistics, University of the Philippines Diliman He was a board member of the Philippine Statistical Association. He served as visiting researcher at The Ohio State University (USA) and the Asian Development Bank Institute (Japan). He has authored and co-authored over 50 papers and a forthcoming book on small area estimation. He served as Associate Editor of *Social Science Diliman*, a journal published by University of the Philippines Diliman (2001–2002) and is incoming Editor of *The Philippine Statistician* published by the Philippine Statistical Association.

Borel–Cantelli Lemma and Its Generalizations

Tapas Kumar Chandra[1], Fejzi Kolaneci[2]
[1]Professor
Indian Statistical Institute, Calcutta, India
[2]Professor
University of New York, Tirana, Albania

The celebrated Borel–Cantelli Lemma is important and useful for proving the ▶laws of large numbers in the strong form. Consider a sequence of random events $\{A_n\}$ on a probability space (Ω, F, P), and we are interested in the question of whether infinitely many random events occur or if possibly only a finite number of them occur.

The upper limit of the sequence $\{A_n\}$ is the random event defined by

$$\{A_n \; i.o.\} = \limsup_{n\to\infty} A_n = \bigcap_{n=1}^{\infty} \bigcup_{k=n}^{\infty} A_k \,,$$

which occurs if and only if an infinite number of events A_n occur. This i.o. stands for "infinitely often."

Below we shall use the fact that if $\{A_n\}$ is a sequence of random events, then

$$P\left(\bigcup_{n=1}^{\infty} A_n\right) \le \sum_{n=1}^{\infty} P(A_n). \quad (*)$$

The Borel–Cantelli Lemma

Lemma 1 *If* $\sum_{n=1}^{\infty} P(A_n) < \infty$, *then* $P(\limsup_{n\to\infty} A_n) = 0$. *If the random events* $A_1, A_2, \cdots, A_n, \cdots$ *are independent and* $\sum_{n=1}^{\infty} P(A_n) = \infty$, *then* $P(\limsup_{n\to\infty} A_n) = 1$.

Intuitively, $P(\limsup_{n\to\infty} A_n)$ is the probability that the random events A_n occur "infinitely often" and will be denoted by $P(A_n\ i.o.)$.

Proof

First part

Note that $\limsup_{n\to\infty} A_n \subset \bigcup_{k=m}^{\infty} A_k$ for each $m \geq 1$. So for each $m \geq 1$.

$$P\left(\limsup_{n\to\infty} A_n\right) \leq P\left(\bigcup_{k=m}^{\infty} A_k\right) \leq \sum_{k=m}^{\infty} P(A_k) \qquad \text{by } (*).$$

Since $\sum_{n=1}^{\infty} P(A_n)$ is convergent, the tails $\sum_{k=m}^{\infty} P(A_k) \to 0$ as $m \to \infty$. Letting $m \to \infty$, we get $P(\limsup_{n\to\infty} A_n) = 0$.

Second part

We show that

$$1 - P(\limsup_{n\to\infty} A_n) = P((\limsup_{n\to\infty} A_n)') = 0,$$

where A' denotes the complement of A. To this end, it is enough to show that

$$P\left(\bigcap_{k=m}^{\infty} A_k'\right) = 0 \text{ for each } m \geq 1,$$

since then by De Morgan's Rule

$$P\left((\limsup_{n\to\infty} A_n)'\right) = P\left(\bigcup_{n=1}^{\infty}\bigcap_{k=n}^{\infty} A_k'\right) \leq \sum_{n=1}^{\infty} P\left(\bigcap_{k=n}^{\infty} A_k'\right)$$
$$= 0 \text{ by } (*).$$

Fix such an m. Since $1 - x \leq \exp(-x)$ for each real x, we have for each $j \geq 1$

$$P\left(\bigcap_{k=m}^{\infty} A_k'\right) \leq P\left(\bigcap_{k=m}^{m+j} A_k'\right) = \prod_{k=m}^{m+j}(1 - P(A_k))$$
$$\leq \exp\left(-\sum_{k=m}^{m+j} P(A_k)\right).$$

As $\sum_{n=1}^{\infty} P(A_n)$ diverges, so does $\sum_{k=m}^{\infty} P(A_k)$ which implies that $\sum_{k=m}^{m+j} P(A_k) \to \infty$ as $j \to \infty$. As $\lim_{x\to\infty} \exp(-x) = 0$, we get upon letting $j \to \infty$ that

$$P\left(\bigcap_{k=m}^{\infty} A_k'\right) = 0.$$

□

Generalizations

The first part of the Borel-Cantelli Lemma was generalized in Barndorff-Nielsen (1961).

Lemma 2 *Let $\{A_n\}$ be a sequence of random events satisfying the conditions*

$$\lim_{n\to\infty} P(A_n) = 0 \quad \text{and} \quad \sum_{n=1}^{\infty} P(A_n A_{n+1}') < \infty.$$

Then

$$P(\limsup_{n\to\infty} A_n) = 0.$$

Lemma 2 holds true if the random events $A_n' A_{n+1}$ are substituted with $A_n A_{n+1}'$.

It should be noted that the hypothesis in Lemma 2 is weaker than the hypothesis in Lemma 1.

A further generalization of Lemma 2 was obtained in Stepanov (2006).

Lemma 3 *Let $\{A_n\}$ be a sequence of random events satisfying the condition $\lim_{n\to\infty} P(A_n) = 0$. Assume that there exists $m \geq 0$ such that*

$$\sum_{n=1}^{\infty} P(A_n' A_{n+1}' \cdots A_{n+m-1}' A_{n+m}) < \infty.$$

Then

$$P(\limsup_{n\to\infty} A_n) = 0.$$

Observe that the hypothesis in Lemma 3 when $m \geq 2$ is weaker than the hypothesis in Lemma 2.

Many attempts were made in order to weaken the independence condition in the second part of the Borel-Cantelli Lemma. This condition means mutual independence of random events $A_1, A_2, \cdots, A_n$ for every n. Erdös and Rényi (1959) discovered that the independence condition can be replaced by the weaker condition of pairwise independence of the random events $A_1, A_2, \cdots, A_n$ for every n. Indeed they also proved the result which is the special case '$l = 1$' in the following lemma due to Kochen and Stone (1964):

Lemma 4 *If $\{A_n\}$ is a sequence of random events satisfying the conditions*

$$\sum_{n=1}^{\infty} P(A_n) = \infty \quad \text{and} \quad \liminf_{n\to\infty} \frac{\sum_{i,k=1}^{n} P(A_i \cap A_k)}{\left[\sum_{k=1}^{n} P(A_k)\right]^2} = l,$$

then

$$P(\limsup_{n\to\infty} A_n) \geq \frac{1}{l}.$$

A further extension due to Chandra (2008) is given below.

Lemma 5 *Let* $\{A_n\}$ *be a sequence of random events such that* $\sum_{n=1}^{\infty} P(A_n) = \infty$. *Let*

$$\liminf_{n\to\infty} \frac{\sum_{1\le i\le j\le n}(P(A_i \bigcap A_j) - a_{ij})}{(\sum_{1\le k\le n} P(A_k))^2} = L$$

where $a_{ij} = (c_1 P(A_i) + c_2 P(A_j))P(A_{j-i}) + c_3 P(A_i)P(A_j)$ *for* $1 \le i < j$, $c_1 \ge 0, c_2 \ge 0, c_3 \in \mathcal{R}$ *being constants (L may depend on* c_1, c_2, c_3*). Assume that L is finite. Then* $c + 2L \ge 1$ *and*

$$P\left(\limsup_{n\to\infty} A_n\right) \ge (c + 2L)^{-1}$$

where $c = 2(c_1 + c_2) + c_3$.

As a special case of Lemma 5, we have the following result.

Lemma 6 *Let* $\{A_n\}$ *be a sequence of random events such that* $\sum_{n=1}^{\infty} P(A_n) = \infty$. *If for some constants* $c_1 \ge 0, c_2 \ge 0$, *and* $c_3 \in \mathcal{R}$ *there exists an integer* $N \ge 1$ *such the* $P(A_i \bigcap A_j) \le a_{ij}$ *whenever* $N \le i < j$ *where the* a_{ij} *are as in Lemma 5, then* $c \ge 1$ *and* $P(\limsup_{n\to\infty} A_n) \ge 1/c$, *c being as in Lemma 5.*

Petrov (1995) found conditions that are necessary and sufficient for the equality

$$P(\limsup_{n\to\infty} A_n) = p, \quad \text{where } 0 \le p \le 1,$$

as well as for the inequality

$$P(\limsup_{n\to\infty} A_n) \ge p, \quad \text{where } 0 < p \le 1.$$

For a different type of extensions of the Borel-Cantelli lemma, see Chen (1978) and Serfling (1975).

About the Authors

Professor Chandra's area of specialization spans Statistical Inference, Asymptotic Theory of Statistics, Limit Theorems and Large Deviations. He earned Ph.D. degree in Statistics in 1981 from The Indian Statistical Institute. He has published two books and about 40 papers in international journals. One important contribution is the demonstration of the superiority of the Score Test over a large family of tests including the Likelihood Ratio test and Wald's test under local alternatives, thereby settling an old conjecture of Professor C.R. Rao.

Dr. Fejzi Kolaneci is Professor and Chair of the Department of Mathematics, University of New York Tirana, Albania. He is Past Editor-in-Chief of AJNTS, *Albanian Journal of Natural and Technical Sciences*. He has written several textbooks, including *Probability Theory And Statistics*, *Mathematical Analysis*, and *Differential Equations*. Professor Kolaneci is past Secretary of Natural and Technical Sciences of Albanian Academy of Sciences, and past Dean of the Teaching Faculty of University "Fan S. Noli." He is member of London Mathematical Society, and member of Society for Industrial and Applied Mathematics.

Box–Cox Transformation

Takashi Daimon
Hyogo College of Medicine, Hyogo, Japan
Osaka University Hospital, Osaka, Japan

Box and Cox (1964) proposed a family of power transformations in order to improve additivity, normality, and homoscedasticity of observations. The Box–Cox transformation, which was a modification of a family of power transformations introduced by Tukey (1957), was named for their work. For each value of a real or vector valued transformation parameter λ, let $\psi(y, \lambda)$ be a strictly monotone increasing transformation for a positive y in

some interval. Tukey's power transformations takes the following form:

$$\psi(y,\lambda) = \begin{cases} y^{\lambda}, & \lambda \neq 0, \\ \log y, & \lambda = 0. \end{cases}$$

To take account of the discontinuity at $\lambda = 0$ in the above equation, the original form of the Box–Cox transformation takes the following form:

$$\psi^{\mathrm{BC}}(y,\lambda) = \begin{cases} \dfrac{y^{\lambda}-1}{\lambda}, & \lambda \neq 0, \\ \log y, & \lambda = 0. \end{cases}$$

They also proposed an extended form of the Box–Cox transformation, "shifted" power transformation which could deal with situations where y is negative but bounded below:

$$\psi(y,\boldsymbol{\lambda}) = \begin{cases} \dfrac{(y+\lambda_2)^{\lambda_1}-1}{\lambda}, & \lambda_1 \neq 0, \\ \log(y+\lambda_2), & \lambda_1 = 0, \end{cases}$$

where $\boldsymbol{\lambda} = (\lambda_1, \lambda_2)^{\mathrm{T}}$. However, since the range of the distribution is determined by the unknown shift parameter λ_2, the asymptotic results of maximum likelihood theory may not apply. Consequently, there have existed some alternative versions of the Box–Cox transformation which could handle a negative y. For example, Manly (1976) proposed the exponential transformation:

$$\psi(y,\lambda) = \begin{cases} \dfrac{\exp(\lambda y)-1}{\lambda}, & \lambda \neq 0, \\ y, & \lambda = 0. \end{cases}$$

John and Draper (1980) presented the so-called modulus transformation:

$$\psi(y,\boldsymbol{\lambda}) = \begin{cases} \operatorname{sign}(y)\dfrac{(|y|+1)^{\lambda}-1}{\lambda}, & \lambda \neq 0, \\ \operatorname{sign}(y)\log(|y|+1), & \lambda = 0, \end{cases}$$

where

$$\operatorname{sign}(y) = \begin{cases} 1, & y \geq 0, \\ -1, & y < 0. \end{cases}$$

Bickel and Doksum (1981) suggested another modification:

$$\psi(y,\lambda) = \frac{|y|^{\lambda}\operatorname{sign}(y)-1}{\lambda}, \quad \lambda \neq 0.$$

Yeo and Johnson (2000) proposed another power transformation family motivated by the above modified modulus transformation:

$$\psi(y,\lambda) = \begin{cases} \dfrac{(y+1)^{\lambda}-1}{\lambda}, & y \geq 0, \lambda \neq 0, \\ \log(y+1), & y \geq 0, \lambda = 0, \\ -\dfrac{(1-y)^{2-\lambda}-1}{2-\lambda}, & y < 0, \lambda \neq 2, \\ -\log(1-y), & y < 0, \lambda = 2. \end{cases}$$

The main objective in the analysis using Box–Cox transformation is to make inference on the transformation parameter λ. Box and Cox (1964) applied the maximum likelihood as well as Bayesian methods for estimating the transformation parameter, but there have been many approaches to other inferences including hypothesis testing on the transformation parameter (see Sakia 1992 for details, which gave a comprehensive review on the Box–Cox transformation).

The Box–Cox transformation can be applied to a regressor, a combination of regressors, and/or to the response variable in a linear or nonlinear regression. For example let us consider the following linear functional form:

$$\psi^{\mathrm{BC}}(y,\lambda_0) = \beta_0 + \sum_{j=1}^{q}\beta_j\psi^{\mathrm{BC}}(x_j,\lambda_j) + \varepsilon,$$

where $\psi(y,\lambda_0)$ and $\psi(x_j,\lambda_j)$ represent the transformed response variable and explanatory variables, respectively, where λ_j $(j = 0,1,\ldots,p)$ are the transformation parameters, and ε represents the errors. When using such a functional form with the Box–Cox transformation, it is helpful to explore the underlying relationship in cases where the determination of the functional form need not be based on a priori rationale in any research field.

In addition, for example, for nonlinear regressions (See ►Nonlinear Regression) we can consider the following form (see Carroll and Ruppert 1988):

$$\psi^{\mathrm{BC}}(y,\lambda) = \psi^{\mathrm{BC}}(f(x,\beta),\lambda) + \varepsilon,$$

where $f(x,\beta)$ is a functional form (possibly, corresponding to a theoretical model) that has explanatory variables x and is nonlinear with respect to a real or vector valued parameter β. It is noted that the both sides in the above equation have the same Box–Cox transformation. Thus the objective here is to reduce ►heteroscedasticity and autocorrelation of the error structure as well as non-normality of the error (or residual) itself, rather than the determination of the functional form as above mentioned.

The Box–Cox transformation has been widely utilized. However, when using it we note that this transformation seldom fulfills the basic assumptions required for statistical

inference such as linearity, normality and homoscedasticity simultaneously as originally suggested by Box and Cox (1964).

Box–Jenkins Time Series Models

John Boland
Associate Professor
University of South Australia, Adelaide, SA, Australia

Introduction

We are going to examine the Autoregressive Moving Average (ARMA) process for identifying the serial correlation attributes of a stationary time series (see Boland 2008; Box and Jenkins 1970). Another name for the processes that we will undertake is the Box–Jenkins (BJ) Methodology, which describes an iterative process for identifying a model and then using that model for forecasting. The Box–Jenkins methodology comprises four steps:

- Identification of process
- Estimation of parameters
- Verification of model
- Forecasting

Identification of Process

Assume we have a (at least weakly) stationary time series, i.e., no trend, seasonality, and it is homoscedastic (constant variance). Stationarity will be discussed further in section Stationarity. The general form of an ARMA model is

$$X_t - \phi_1 X_{t-1} - \cdots - \phi_p X_{t-p} = Z_t + \theta_1 Z_{t-1} + \cdots + \theta_q Z_{t-q}, \tag{1}$$

where $\{X_t\}$ are identically distributed random variables $\sim(0, \sigma_X^2)$ and $\{Z_t\}$ are white noise, i.e., independent and identically distributed (iid) $\sim(0, \sigma_Z^2)$. ϕ_i and θ_j are the coefficients of polynomials satisfying

$$\begin{aligned} \phi(y) &= 1 - \phi_1 y - \cdots - \phi_p y^p \\ \theta(y) &= 1 + \theta_1 y + \cdots + \theta_q y^q, \end{aligned} \tag{2}$$

where $\phi(y), \theta(y)$ are the autoregressive and moving average polynomials respectively. Define the backward shift operator $B^j X_t = X_{t-j}$, $j = 0, 1, 2, \ldots$ and we may then write (2) in the form

$$\phi(B) X_t = \theta(B) Z_t \tag{3}$$

defining an $ARMA(p, q)$ model. If $\phi(B) = 1$, we then have a moving average model of order q, designated $MA(q)$. Alternatively, if we have $\theta(B) = 1$, we have an autoregressive model of order p, designated $AR(p)$. The question is, how do we identify whether we have an $MA(q), AR(p)$ or $ARMA(p, q)$? To do so, we can examine the behavior of the autocorrelation and partial autocorrelation functions.

Autocorrelation and Partial Autocorrelation Functions

We need some definitions to begin with. Suppose two variables X and Y have means μ_X, μ_Y respectively. Then the covariance of X and Y is defined to be

$$Cov(X, Y) = E\{(X - \mu_X)(Y - \mu_Y)\}. \tag{4}$$

If X and Y are independent, then

$$\begin{aligned} Cov(X, Y) &= E\{(X - \mu_X)(Y - \mu_Y)\} \\ &= E(X - \mu_X) E(Y - \mu_Y) = 0. \end{aligned} \tag{5}$$

If X and Y are not independent, then the covariance may be positive or negative, depending on whether high

values of X tend to happen coincidentally with high or low values of Y. It is usual to standardise the covariance by dividing by the product of their respective standard deviations, creating the correlation coefficient. If X and Y are random variables for the same stochastic process at different times, then the covariance coefficient is called the autocovariance coefficient, and the correlation coefficient is called the autocorrelation coefficient. If the process is stationary, then the standard deviations of X and Y will be the same, and their product will be the variance of either.

Let $\{X_t\}$ be a stationary time series. The *autocovariance function* (ACVF) of $\{X_t\}$ is $\gamma_X(h) = Cov(X_{t+h}, X_t)$, and the *autocorrelation function* (ACF) of $\{X_t\}$ is

$$\rho_X(h) = \frac{\gamma_X(h)}{\gamma_X(0)} = Corr(X_{t+h}, X_t). \tag{6}$$

The autocovariance and autocorrelation functions can be estimated from observations of $X_1, X_2, \ldots, X_n$ to give the sample autocovariance function (SAF) and the sample autocorrelation function (SACF), the latter defined by

$$r_k = \frac{\sum_{t=1}^{n-k}(x_t - \bar{x})(x_{t+k} - \bar{x})}{\sum_{t=1}^{n}(x_t - \bar{x})^2}. \tag{7}$$

Thus the SACF is a measure of the linear relationship between time series separated by some time period, denoted by the lag k. Similar to the correlation coefficient of linear regression, r_k will take a value between +1 and –1, and the closer to ±1, the stronger the relationship. What relationship are we talking about? Consider a lag 1 value close to +1 as an example. This means that there is a strong relationship between X_t and X_{t-1}, X_{t-1} and $X_{t-2}, \ldots, X_{t-k+1}$ and X_{t-k}, and so on. The interesting thing is that what can happen in practice is that because of this serial correlation, it can appear that X_t has a strong relationship with X_{t-k}, k time units away from X_t, when in fact it is only because of this interaction. To sort out this potential problem, one estimates the partial autocorrelation function (PACF). The partial autocorrelation between X_t and X_{t-k} is the correlation between them after their mutual linear dependency on the intervening variables $X_{t-1}, \ldots, X_{t-k+1}$ has been removed. The sample PACF (SPACF) is given by the Yule–Walker equations,

$$\begin{bmatrix} 1 & r_1 & r_2 & \cdots & r_{k-2} & r_{k-1} \\ r_1 & 1 & r_1 & \cdots & r_{k-3} & r_{k-2} \\ . & . & . & \cdots & . & . \\ . & . & . & \cdots & . & . \\ r_{k-1} & r_{k-2} & r_{k-3} & \cdots & r_1 & 1 \end{bmatrix} \begin{bmatrix} \hat{\phi}_{k1} \\ \hat{\phi}_{k2} \\ . \\ . \\ \hat{\phi}_{kk} \end{bmatrix} = \begin{bmatrix} r_1 \\ r_2 \\ . \\ . \\ r_k \end{bmatrix}. \tag{8}$$

The value of $\hat{\phi}_{kk}$ gives the estimate of the PACF at lag k. These equations can be solved using Cramer's Rule to obtain:

$$\hat{\phi}_{mm} = \frac{r_m - \sum_{j=1}^{m-1} \hat{\phi}_{m-1,j} r_{m-j}}{1 - \sum_{j=1}^{m-1} \hat{\phi}_{m-1,j} r_j}. \tag{9}$$

Once we have calculated these estimates for a stationary time series, we can use them to give an indication whether we should fit an $AR(p)$, $MA(q)$, or $ARMA(p,q)$ model. The criteria are in general:

- When the SACF dies down gradually and the SPACF has insignificant spikes at lags greater than p we should fit an $AR(p)$.
- When the SACF has a significant spike at lag q and the SPACF dies down gradually, we should fit an $MA(q)$.
- If both die down gradually, we fit an $ARMA(p,q)$. In this case, we will have to progressively increase p, q until we get a suitable model.

The last point brings up an interesting question; how do we decide between competing models? In fact, the situation is often not as simple as these criteria make it seem. Sometimes it is difficult to decide between for instance, an $AR(3)$ and an $ARMA(1,1)$ model. An aid in identifying the appropriate model comes from the principle of parsimony, using criteria from Information Theory. The ►Akaike's Information Criterion (AIC) is one such measure (Akaike 1973). The goal is to pick the model that minimises

$$AIC = -\frac{2}{T}\{\ln(\text{likelihood}) + l\}. \tag{10}$$

Here, l is the number of parameters fitted and T the number of data values. There is a competing criterion, that penalises the number of parameters fitted even more, called the (Schwarz) Bayesian Information Criterion (BIC) (Schwarz 1978),

$$BIC = -\frac{2}{T}\ln(\text{likelihood}) + \frac{l\ln(T)}{T}. \tag{11}$$

Moving Average Process

In a moving average process $MA(q)$, the present value of the series is written as the weighted sum of past shocks:

$$X_t = Z_t + \theta_1 Z_{t-1} + \theta_2 Z_{t-2} + \cdots + \theta_q Z_{t-q}, \qquad (12)$$

where $Z_t \sim WN(0, \sigma_Z^2)$.

We find immediately that

$$E(X_t) = 0,$$
$$Var(X_t) = \sigma_Z^2 (1 + \sum_{i=1}^{q} {\theta_1}^2). \qquad (13)$$

Autoregressive Process

The general form of an $AR(p)$ process is:

$$\phi(B) X_t = Z_t$$
$$(1 - \phi_1 B - \phi_2 B^2 - \cdots - \phi_p B^p) X_t = Z_t$$
$$X_t = \phi_1 X_{t-1} + \phi_2 X_{t-2} + \cdots + \phi_p X_{t-p} + Z_t.$$

A first order autoregressive process $AR(1)$ is referred to as a Markov Chain (see ▶Markov Chains). It can, through successive substitutions, be written as:

$$\begin{aligned} X_t &= \phi X_{t-1} + Z_t \\ &= \phi(\phi X_{t-2} + Z_{t-1}) + Z_t \\ &= Z_t + \phi Z_{t-1} + \phi^2 Z_{t-2} + \phi^3 Z_{t-3} + \cdots. \end{aligned}$$

From this we write $Var(X_t) = \sigma_Z^2 (1 + \sum_{i=1}^{\infty} \phi^{2i}) = \dfrac{\sigma_Z^2}{1 - \phi^2}$.

Any $AR(p)$ process can be rewritten as an infinite order moving average process.

Stationarity

If neither the mean μ_t nor the autocovariances $\gamma_X(h)$ are dependent on t, then the process is said to be *weakly stationary*. This means that the autocovariances depend only on the length of time separating the observations h. A process is strictly stationary if for any values of $h_1, h_2, \ldots, h_n$, the joint distribution of $(X_t, X_{t+h_1}, X_{t+h_2}, \ldots, X_{t+h_n})$ depends not on t, but only on the time intervals between the variables. A sufficient condition for negating weak stationarity (and thus strict stationarity) is failure of the unit root test. A stochastic process has a unit root if its characteristic equation has 1 as a root.

For $X_t = \phi_1 X_{t-1} + \phi_2 X_{t-2} + \cdots + \phi_p X_{t-p} + Z_t$, the characteristic equation is given by:

$$m^p - \phi_1 m^{p-1} - \phi_2 m^{p-2} - \cdots - \phi_{p-1} m - \phi_p = 0.$$

If $m = 1$ is a root of this characteristic equation, the process has a unit root or is termed integrated of order 1, denoted $I(1)$. A first difference of the time series will be stationary.

If the characteristic equation has a unit root of multiplicity r then the process is integrated of order r, denoted $I(r)$. The time series differenced r times will be stationary. The process defined by $X_t = X_{t-1} + Z_t$ has a unit root and this process defines a ▶random walk. The process is customarily started at zero when $t = 0$, so $X_1 = Z_1$, and $X_t = \sum_{i=1}^{t} Z_i$, so we obtain $Var(X_t) = t\sigma_Z^2$, dependent on t.

Conditional Heteroscedastic Modelling

There is one particular type of non-stationarity that is receiving increasing attention. In financial markets, and other applications such as modelling wind farm output (Boland et al. 2007), a phenomenon has been identified wherein the SACF of Z_t shows no residual autocorrelation, but the SACF of ${Z_t}^2$ does. This property means that the noise is uncorrelated but not independent. This is reflective of a process that retains conditional heteroscedasticity, wherein there is what is termed as volatility clustering. Periods of high volatility can be followed by periods of low volatility. The volatility is generally modelled by Autoregressive Conditional Heteroscedastic (ARCH) or Generalised ARCH (GARCH) models, or utilising a concept called realised volatility (see Tsay 2005 and references therein).

About the Author

Associate Professor John Boland has extensive expertise in environmental modelling, specialising in time series and statistical modelling of climate variables and modelling systems under uncertainty. He has published 70 papers in many areas of environmental modelling and is Associate Editor for two international journals: *Renewable Energy*, and *Case Studies in Business, Industry and Government Statistics*. He, along with colleagues, is present or past holder of three Australian Research Council (ARC) Linkage and three Discovery grants. One Linkage and two Discovery Grants have been in the area of water cycle management. The present one in this area is focusing on using advanced mathematical techniques to better understand the structure of the Murray Darling Basin and its management options. Presently, he holds a Linkage and a Discovery grant in the energy area, focusing on the future of the electricity supply network with significant increases in the penetration of renewable energy into the grid. All these projects focus on stochastic modelling and risk management, particularly utilising conditional value at risk. His expertise in modelling systems under uncertainty has led him to being selected to run a one day Masterclass in Managing Data for Energy Storage and Renewable Energy Supply at the Energy Storage Forum, Beijing, March 2010.

Brownian Motion and the Wiener Process

A small particle (e.g., a pollen corn) suspended in a liquid is subject to infinitely many collisions with atoms, and therefore it is impossible to observe its exact trajectory. With the help of a microscope it is only possible to confirm that the movement of the particle is entirely chaotic. This type of movement, discovered under similar circumstances by the botanist Robert Brown, is called Brownian motion. As its mathematical inventor Einstein already observed, it is necessary to make approximations, in order to describe the process. The formalized mathematical model defined on the basis of these is called a Wiener process. Henceforth, we will limit ourselves to the study of the one-dimensional Wiener process in $\mathbb{R}$, under the assumption that the three components determining its motion in space are independent.

Definition 1 A real-valued process $(W_t)_{t\in\mathbb{R}_+}$ is a *Wiener process* if it satisfies the following conditions:

1. $W_0 = 0$ almost surely.
2. $(W_t)_{t\in\mathbb{R}_+}$ is a process with independent increments.
3. $W_t - W_s$ is normally distributed with $N(0, t-s)$, $(0 \le s < t)$.

Remark 1 From point 3 of Definition 1 it becomes obvious that every Wiener process is time homogeneous.

Proposition 1 *If $(W_t)_{t\in\mathbb{R}_+}$ is a Wiener process, then*

1. $E[W_t] = 0$ *for all* $t \in \mathbb{R}_+$,
2. $K(s,t) = Cov[W_t, W_s] = \min\{s,t\}$, $s,t \in \mathbb{R}_+$.

Proof 1. Fixing $t \in \mathbb{R}$, we observe that $W_t = W_0 + (W_t - W_0)$ and thus $E[W_t] = E[W_0] + E[W_t - W_0] = 0$. The latter is given by the fact that $E[W_0] = 0$ (by 1 of Definition 1) and $E[W_t - W_0] = 0$ (by 3 of Definition 1).

2. Let $s,t \in \mathbb{R}_+$ and $Cov[W_t, W_s] = E[W_t W_s] - E[W_t]E[W_s]$, which (by point 1) gives $Cov[W_t, W_s] = E[W_t W_s]$. For simplicity, if we suppose that $s < t$, then

$$E[W_t W_s] = E[W_s(W_s + (W_t - W_s))] = E\left[W_s^2\right] + E[W_s(W_t - W_s)].$$

Since $(W_t)_{t\in\mathbb{R}_+}$ has independent increments, we obtain

$$E[W_s(W_t - W_s)] = E[W_s]E[W_t - W_s]$$

and by 3 of Definition 1 it follows that this is equal to zero, thus

$$Cov[W_t, W_s] = E\left[W_s^2\right] = Var[W_s].$$

If we now observe that $W_s = W_0 + (W_s - W_0)$ and hence $Var[W_s] = Var[W_0 + (W_s - W_0)]$, then, by the independence of the increments of the process, we get

$$Var[W_0 + (W_s - W_0)] = Var[W_0] + Var[W_s - W_0].$$

Therefore, by points 1 and 3 of Definition 1 it follows that

$$Var[W_s] = s = \inf\{s,t\},$$

which completes the proof. □

Remark 2 By 1 of Definition 1, it follows, for all $t \in \mathbb{R}_+$, $W_t = W_t - W_0$ almost surely and by 3 of the same definition, that W_t is distributed as $N(0,t)$. Thus

$$P(a \le W_t \le b) = \frac{1}{\sqrt{2\pi t}} \int_a^b e^{-\frac{x^2}{2t}} dx, \qquad a \le b.$$

Remark 3 The Wiener process is a Gaussian process. In fact, if $n \in \mathbb{N}^*$, $(t_1, \ldots, t_n) \in \mathbb{R}_+^n$ with $0 = t_0 < t_1 < \ldots < t_n$

and $(a_1, \ldots, a_n) \in \mathbb{R}^n, (b_1, \ldots, b_n) \in \mathbb{R}^n$, such that $a_i \leq b_i, i = 1, 2, \ldots, n$, it can be shown that

$$P(a_1 \leq W_{t_1} \leq b_1, \ldots, a_n \leq W_{t_n} \leq b_n) = \int_{a_1}^{b_1} \cdots \int_{a_n}^{b_n} g(0|x_1, t_1) g(x_1|x_2, t_2 - t_1) \cdots g(x_{n-1}|x_n, t_n - t_{n-1}) dx_n \cdots dx_1, \quad (1)$$

where

$$g(x|y,t) = \frac{e^{-\frac{|x-y|^2}{2t}}}{\sqrt{2\pi t}}.$$

Proposition 2 *If $(W_t)_{t\in\mathbb{R}_+}$ is a Wiener process, then it is also a martingale* (see ▶Martingales).

Proof The proposition follows from the fact that $(W_t)_{t\in\mathbb{R}_+}$ is a zero mean process with independent increments. □

Theorem 1 *Every Wiener process $(W_t)_{t\in\mathbb{R}_+}$ is a Markov process.*

Proof The theorem follows directly from the fact that $(W_t)_{t\in\mathbb{R}_+}$ is a process with independent increments. □

Remark 4 Since Brownian motion is continuous in probability, it admits a separable and progressively measurable modification.

Theorem 2 (Kolmogorov's continuity theorem). *Let $(X_t)_{t\in\mathbb{R}_+}$ be a separable real-valued stochastic process. If there exist positive real numbers r, c, ϵ, δ such that*

$$\forall h < \delta, \forall t \in \mathbb{R}_+, \qquad E[|X_{t+h} - X_t|^r] \leq ch^{1+\epsilon}, \quad (2)$$

then, for almost every $\omega \in \Omega$, the trajectories are continuous in $\mathbb{R}_+$.

Theorem 3 *If $(W_t)_{t\in\mathbb{R}_+}$ is a real-valued Wiener process, then it has continuous trajectories almost surely.*

Proof Let $t \in \mathbb{R}_+$ and $h > 0$. Because $W_{t+h} - W_t$ is normally distributed as $N(0, h)$, putting $Z_{t,h} = \frac{W_{t+h} - W_t}{\sqrt{h}}$, $Z_{t,h}$ has standard normal distribution. Therefore, it is clear that there exists an $r > 2$ such that $E[|Z_{t,h}|^r] > 0$, and thus $E[|W_{t+h} - W_t|^r] = E[|Z_{t,h}|^r] h^{\frac{r}{2}}$. If we write $r = 2(1+\epsilon)$, we obtain $E[|W_{t+h} - W_t|^r] = ch^{1+\epsilon}$, with $c = E[|Z_{t,h}|^r]$. The assertion then follows by Kolmogorov's continuity theorem. □

Theorem 4 *If $(W_t)_{t\in\mathbb{R}_+}$ is a real-valued Wiener process, then*

1. $P(\sup_{t\in\mathbb{R}_+} W_t = +\infty) = 1$
2. $P(\inf_{t\in\mathbb{R}_+} W_t = -\infty) = 1$

Theorem 5 *If $(W_t)_{t\in\mathbb{R}_+}$ is a real-valued Wiener process, then,*

$$\forall h > 0, \qquad P\left(\max_{0\leq s\leq h} W_s > 0\right) = P\left(\min_{0\leq s\leq h} W_s < 0\right) = 1.$$

Moreover, for almost every $\omega \in \Omega$ the process $(W_t)_{t\in\mathbb{R}_+}$ has a zero (i.e., crosses the spatial axis) in $[0, h]$, for all $h > 0$.

Theorem 6 *Almost every trajectory of the Wiener process $(W_t)_{t\in\mathbb{R}_+}$ is differentiable almost nowhere.*

Proposition 3 (scaling property). *Let $(W_t)_{t\in\mathbb{R}_+}$ be a Wiener process. Then the time-scaled process $(\tilde{W}_t)_{t\in\mathbb{R}_+}$ defined by*

$$\tilde{W}_t = tW_{1/t}, \; t > 0, \qquad \tilde{W}_0 = 0$$

is also a Wiener process.

Proposition 4 (Strong law of large numbers). *Let $(W_t)_{t\in\mathbb{R}_+}$ be a Wiener process. Then*

$$\frac{W_t}{t} \to 0, \qquad as \qquad t \to +\infty, \qquad a.s.$$

Proposition 5 (Law of iterated logarithms). *Let $(W_t)_{t\in\mathbb{R}_+}$ be a Wiener process. Then*

$$\limsup_{t\to+\infty} \frac{W_t}{\sqrt{2t \ln\ln t}} = 1, \qquad a.s.,$$
$$\liminf_{t\to+\infty} \frac{W_t}{\sqrt{2t \ln\ln t}} = -1, \qquad a.s.$$

As a consequence, for any $\epsilon > 0$, there exists a $t_0 > 0$, such that for any $t > t_0$ we have

$$-(1+\epsilon)\sqrt{2t \ln\ln t} \leq W_t \leq (1+\epsilon)\sqrt{2t \ln\ln t}, \qquad \text{a.s.}$$

Existence of the Wiener process is guaranteed by the following fundamental theorem (see, e.g., Billingsley 1968).

Theorem 7 (Donsker). *Let $\xi_1, \xi_2, \ldots, \xi_n, \ldots$ be a sequence of independent identically distributed random variables defined on a common probability space $(\Omega, \mathcal{F}, P)$, with mean 0 and finite, positive variance σ^2:*

$$E[\xi_n] = 0, \qquad E\left[\xi_n^2\right] = \sigma^2.$$

Let $S_0 = 0$ and, for any $n \in \mathbb{N} \setminus \{0\}$, let $S_n = \xi_1 + \xi_2 + \cdots + \xi_n$. Then the sequence of random processes defined by

$$X_n(t, \omega) = \frac{1}{\sigma\sqrt{n}} S_{[nt]}(\omega) + (nt - [nt]) \frac{1}{\sigma\sqrt{n}} \xi_{[nt]+1}(\omega)$$

for any $t \in \mathbb{R}_+$, $\omega \in \Omega$, $n \in \mathbb{N}$, weakly converges to a Wiener process.

Diffusion Processes

Markov Processes

Definition 2 *Let $(X_t)_{t\in\mathbb{R}_+}$ be a stochastic process on a probability space, valued in $(E,\mathcal{B})$ and adapted to the increasing family $(\mathcal{F}_t)_{t\in\mathbb{R}_+}$ of σ-algebras of subsets of $\mathcal{F}$. $(X_t)_{t\in\mathbb{R}_+}$ is a* Markov process *with respect to $(\mathcal{F}_t)_{t\in\mathbb{R}_+}$ if the following condition is satisfied:*

$$\forall B\in\mathcal{B},\forall(s,t)\in\mathbb{R}_+\times\mathbb{R}_+, s<t:\quad P(X_t\in B|\mathcal{F}_s)=P(X_t\in B|X_s)\ a.s. \tag{3}$$

Remark 5 If, for all $t\in\mathbb{R}_+$, $\mathcal{F}_t=\sigma(X_r,0\le r\le t)$, then condition (3) becomes

$$P(X_t\in B|X_r,0\le r\le s)=P(X_t\in B|X_s)\ \text{a.s.}$$

for all $B\in\mathcal{B}$, for all $(s,t)\in\mathbb{R}_+\times\mathbb{R}_+$, and $s<t$.

Proposition 6 *Under the assumptions of Definition 2, the following two statements are equivalent:*

1. *For all $B\in\mathcal{B}$ and all $(s,t)\in\mathbb{R}_+\times\mathbb{R}_+, s<t$: $P(X_t\in B|\mathcal{F}_s)=P(X_t\in B|X_s)$ almost surely.*
2. *For all $g:E\to\mathbb{R}$, $\mathcal{B}$-$\mathcal{B}_{\mathbb{R}}$-measurable such that $g(X_t)\in L^1(P)$ for all t, for all $(s,t)\in\mathbb{R}_+^2, s<t$: $E[g(X_t)|\mathcal{F}_s]=E[g(X_t)|X_s]$ almost surely.*

Theorem 8 *Every real stochastic process $(X_t)_{t\in\mathbb{R}_+}$ with independent increments is a Markov process.*

Proposition 7 Consider a real valued Markov process $(X_t)_{t\in\mathbb{R}_+}$, and let

$$p(s,x,t,A)=P(X_t\in A|X_s=x),\quad 0\le s<t<\infty, x\in\mathbb{R}, A\in\mathcal{B}_{\mathbb{R}}.$$

p is a *Markov transition probability function*, i.e., it is a non-negative function defined for $0\le s<t<\infty, x\in\mathbb{R}, A\in\mathcal{B}_{\mathbb{R}}$, which satisfies the following properties

1. For all $0\le s<t<\infty$, for all $A\in\mathcal{B}_{\mathbb{R}}$, $p(s,\cdot,t,A)$ is $\mathcal{B}_{\mathbb{R}}$-measurable.
2. For all $0\le s<t<\infty$, for all $x\in\mathbb{R}$, $p(s,x,t,\cdot)$ is a probability measure on $\mathcal{B}_{\mathbb{R}}$.
3. p satisfies the Chapman–Kolmogorov equation:

$$p(s,x,t,A)=\int_{\mathbb{R}}p(s,x,r,dy)p(r,y,t,A)\quad\forall x\in\mathbb{R}, s<r<t.$$

Definition 3 A Markov process $(X_t)_{t\in[t_0,T]}$ is said to be *homogeneous* if the transition probability functions $p(s,x,t,A)$ depend on t and s only through their difference $t-s$. Therefore, for all $(s,t)\in[t_0,T]^2$, $s<t$, for all $u\in[0,T-t]$, for all $A\in\mathcal{B}_{\mathbb{R}}$, and for all $x\in\mathbb{R}$:

$$p(s,x,t,A)=p(s+u,x,t+u,A)\qquad\text{a.s.}$$

Remark 6 If $(X_t)_{t\in\mathbb{R}_+}$ is a homogeneous Markov process with transition probability function p, then, for all $(s,t)\in\mathbb{R}_+{}^2, s<t$, for all $A\in\mathcal{B}_{\mathbb{R}}$, and for all $x\in\mathbb{R}$, we obtain

$$p(s,x,t,A)=p(0,x,t-s,A)\ \text{a.s.}$$

We may then define a one-parameter transition function

$$p(\tilde{t},x,A):=p(0,x,t-s,A)$$

with $\tilde{t}=(t-s), x\in\mathbb{R}, A\in\mathcal{B}_{\mathbb{R}}$.

Semigroups Associated with Markov Transition Probability Functions

Let $BC(\mathbb{R})$ be the space of all continuous and bounded functions on $\mathbb{R}$, endowed with the norm $\|f\|=\sup_{x\in\mathbb{R}}|f(x)|$ $(<\infty)$, and let $p(s,x,t,A)$ be a transition probability function $(0\le s<t\le T, x\in\mathbb{R}, A\in\mathcal{B}_{\mathbb{R}})$. We consider the operator

$$T_{s,t}:BC(\mathbb{R})\to BC(\mathbb{R}),\qquad 0\le s<t\le T,$$

defined by assigning, for all $f\in BC(\mathbb{R})$,

$$(T_{s,t}f)(x)=\int_{\mathbb{R}}f(y)p(s,x,t,dy).$$

If $s=t$, then

$$p(s,x,s,A)=\begin{cases}1 & \text{if } x\in A,\\ 0 & \text{if } x\notin A.\end{cases}$$

Therefore,

$$T_{t,t}=I\ \text{(identity)}. \tag{4}$$

Moreover, we have that

$$T_{s,t}T_{t,u}=T_{s,u},\qquad 0\le s<t<u. \tag{5}$$

In fact, if $f\in BC(\mathbb{R})$ and $x\in\mathbb{R}$,

$$\begin{aligned}&(T_{s,t}(T_{t,u}f))(x)\\ &=\int_{\mathbb{R}}(T_{t,u}f)(y)p(s,x,t,dy)\\ &=\int\int_{\mathbb{R}^2}f(z)p(t,y,u,dz)p(s,x,t,dy)\\ &=\int_{\mathbb{R}}f(z)\int_{\mathbb{R}}p(t,y,u,dz)p(s,x,t,dy)\\ &\qquad\text{(by Fubini's theorem)}\\ &=\int_{\mathbb{R}}f(z)p(s,x,u,dz)\\ &\qquad\text{(by the Chapman–Kolmogorov equation)}\\ &=(T_{s,u}f)(x).\end{aligned}$$

Definition 4 The family $\{T_{s,t}\}_{0\le s\le t\le T}$ is a *semigroup associated with the transition probability function* $p(s,x,t,A)$ (or with its corresponding Markov process).

Definition 5 If $(X_t)_{t\in\mathbb{R}_+}$ is a Markov process with transition probability function p and associated semigroup $\{T_{s,t}\}$, then the operator

$$\mathcal{A}_s f = \lim_{h\downarrow 0} \frac{T_{s,s+h}f - f}{h}, \qquad s \geq 0, f \in BC(\mathbb{R})$$

is called the *infinitesimal generator of the Markov process* $(X_t)_{t\geq 0}$. Its domain $\mathcal{D}_{\mathcal{A}_s}$ consists of all $f \in BC(\mathbb{R})$ for which the above limit exists uniformly (and therefore in the norm of $BC(\mathbb{R})$) (see, e.g., Feller 1971).

Remark 7 From the preceding definition we observe that

$$(\mathcal{A}_s f)(x) = \lim_{h\downarrow 0} \frac{1}{h} \int_{\mathbb{R}} [f(y) - f(x)] p(s, x, s+h, dy).$$

Definition 6 Let $(X_t)_{t\in\mathbb{R}_+}$ be a Markov process with transition probability function $p(s, x, t, A)$, and $\{T_{s,t}\}$ $(s, t \in \mathbb{R}_+, s \leq t)$ its associated semigroup. If, for all $f \in BC(\mathbb{R})$, the function

$$(t, x) \in \mathbb{R}_+ \times \mathbb{R} \to (T_{t,t+\lambda} f)(x) = \int_{\mathbb{R}} p(t, x, t+\lambda, dy) f(y) \in \mathbb{R}$$

is continuous for all $\lambda > 0$, then we say that the process satisfies the *Feller property*.

Theorem 9 *If $(X_t)_{t\in\mathbb{R}_+}$ is a Markov process with right-continuous trajectories satisfying the Feller property, then, for all $t \in \mathbb{R}_+$, $\mathcal{F}_t = \mathcal{F}_{t^+}$, where $\mathcal{F}_{t^+} = \bigcap_{t'>t} \sigma(X(s), 0 \leq s \leq t')$, and the filtration $(\mathcal{F}_t)_{t\in\mathbb{R}_+}$ is right-continuous.*

Remark 8 It can be shown that $\mathcal{F}_{t^+}$ is a σ-algebra.

Example 1 Wiener processes are processes with the Feller property, or simply *Feller processes*.

If we consider the time-homogeneous case, a Markov process $(X_t)_{t\in\mathbb{R}_+}$ on $(\mathbb{R}, \mathcal{B}_{\mathbb{R}})$, will be defined in terms of a transition kernel $p(t, x, B)$ for $t \in \mathbb{R}_+$, $x \in \mathbb{R}$, $B \in \mathcal{B}_{\mathbb{R}}$, such that

$$p(h, X_t, B) = P(X_{t+h} \in B | \mathcal{F}_t) \qquad \forall t, h \in \mathbb{R}_+, B \in \mathcal{B}_{\mathbb{R}},$$

given that $(\mathcal{F}_t)_{t\in\mathbb{R}_+}$ is the natural filtration of the process. Equivalently, if we denote by $BC(\mathbb{R})$ the space of all continuous and bounded functions on $\mathbb{R}$, endowed with the *sup norm*,

$$E[g(X_{t+h})|\mathcal{F}_t] = \int_E g(y) p(h, X_t, dy) \quad \forall t, h \in \mathbb{R}_+, g \in BC(\mathbb{R}).$$

In this case the transition semigroup of the process is a one-parameter contraction semigroup $(T(t), t \in \mathbb{R}_+)$ on $BC(\mathbb{R})$ defined by

$$T(t)g(x) := \int_E g(y) p(t, x, dy) = E[g(X_t)|X_0 = x], \quad x \in \mathbb{R},$$

for any $g \in BC(\mathbb{R})$. The infinitesimal generator will be time independent. It is defined as

$$\mathcal{A}g = \lim_{t\to 0+} \frac{1}{t}(T(t)g - g)$$

for $g \in \mathcal{D}(\mathcal{A})$, the subset of $BC(\mathbb{R})$ for which the above limit exists, in $BC(\mathbb{R})$, with respect to the sup norm. Given the above definitions, it is obvious that for all $g \in \mathcal{D}(\mathcal{A})$,

$$\mathcal{A}g(x) = \lim_{t\to 0+} \frac{1}{t} E[g(X_t)|X_0 = x], \qquad x \in \mathbb{R}.$$

If $(T(t), t \in \mathbb{R}_+)$ is the contraction semigroup associated with a time-homogeneous Markov process, it is not difficult to show that the mapping $t \to T(t)g$ is right-continuous in $t \in \mathbb{R}_+$ provided that $g \in BC(\mathbb{R})$ is such that the mapping $t \to T(t)g$ is right continuous in $t = 0$. Then, for all $g \in \mathcal{D}(\mathcal{A})$ and $t \in \mathbb{R}_+$,

$$\int_0^t T(s)g\,ds \in \mathcal{D}(\mathcal{A})$$

and

$$T(t)g - g = \mathcal{A} \int_0^t T(s)g\,ds = \int_0^t \mathcal{A}T(s)g\,ds = \int_0^t T(s)\mathcal{A}g\,ds$$

by considering Riemann integrals. The following, so-called *Dynkin's formula*, establishes a fundamental link between ►Markov processes and ►martingales (see Rogers and Williams 1994, p 253).

Theorem 10 *Assume $(X_t)_{t\in\mathbb{R}_+}$ is a time-homogeneous Markov process on $(\mathbb{R}, \mathcal{B}_{\mathbb{R}})$, with transition kernel $p(t, x, B)$, $t \in \mathbb{R}_+$, $x \in \mathbb{R}$, $B \in \mathcal{B}_{\mathbb{R}}$. Let $(T(t), t \in \mathbb{R}_+)$ denote its transition semigroup and $\mathcal{A}$ its infinitesimal generator. Then, for any $g \in \mathcal{D}(\mathcal{A})$, the stochastic process*

$$M(t) := g(X_t) - g(X_0) - \int_0^t \mathcal{A}g(X_s)\,ds$$

is an $\mathcal{F}_t$-martingale.

The next proposition shows that a Markov process is indeed characterized by its infinitesimal generator via a martingale problem (see, e.g., Rogers and Williams 1994, p 253).

Theorem 11 (Martingale problem for Markov processes). *If an RCLL (right continuous with left limits) Markov process $(X_t)_{t\in\mathbb{R}_+}$ is such that*

$$g(X_t) - g(X_0) - \int_0^t \mathcal{A}g(X_s)\,ds$$

is an $\mathcal{F}_t$-martingale for any function $g \in \mathcal{D}(\mathcal{A})$, where $\mathcal{A}$ is the infinitesimal generator of a contraction semigroup on

E, then X_t is equivalent to a Markov process having $\mathcal{A}$ as its infinitesimal generator.

Markov Diffusion Processes

Definition 7 A Markov process on $\mathbb{R}$ with transition probability function $p(s,x,t,A)$ is called a *diffusion process* if

1. For all $\epsilon > 0$, for all $t \geq 0$, and for all $x \in \mathbb{R}$: $\lim_{h\downarrow 0} \frac{1}{h} \int_{|x-y|>\epsilon} p(t,x,t+h,dy) = 0$.
2. There exist $a(t,x)$ and $b(t,x)$ such that, for all $\epsilon > 0$, for all $t \geq 0$, and for all $x \in \mathbb{R}$,

$$\lim_{h\downarrow 0} \frac{1}{h} \int_{|x-y|<\epsilon} (y-x)p(t,x,t+h,dy) = a(t,x),$$
$$\lim_{h\downarrow 0} \frac{1}{h} \int_{|x-y|<\epsilon} (y-x)^2 p(t,x,t+h,dy) = b(t,x).$$

$a(t,x)$ is the *drift coefficient* and $b(t,x)$ the *diffusion coefficient* of the process.

Proposition 8 *If $(X_t)_{t\in\mathbb{R}_+}$ is a diffusion process with transition probability function p and drift and diffusion coefficients $a(x,t)$ and $b(x,t)$, respectively, and if $\mathcal{A}_s$ is the infinitesimal generator associated with p, then we have that*

$$(\mathcal{A}_s f)(x) = \frac{\partial f}{\partial x} a(s,x) + \frac{1}{2}\frac{\partial^2 f}{\partial x^2} b(s,x), \qquad (6)$$

provided that f is bounded and twice continuously differentiable.

Proposition 9 *A Wiener process is a time homogeneous diffusion process, with drift zero and diffusion coefficient equal to* 1.

Its infinitesimal generator is then

$$(\mathcal{A}f)(x) = \frac{1}{2}\frac{\partial^2 f}{\partial x^2}, \qquad (7)$$

Business Forecasting Methods

Rob J. Hyndman
Professor of Statistics
Monash University, Melbourne, VIC, Australia

Forecasting, Planning, and Goals

Forecasting is a common statistical task in business where it helps inform decisions about scheduling of production, transportation and personnel, and provides a guide to long-term strategic planning. However, business forecasting is often done poorly and is frequently confused with planning and goals. They are three different things.

Forecasting is about predicting the future as accurately as possible, given all the information available including historical data and knowledge of any future events that might impact the forecasts.

Goals are what you would like to happen. Goals should be linked to forecasts and plans, but this does not always occur. Too often, goals are set without any plan for how to achieve them, and no forecasts for whether they are realistic.

Planning is a response to forecasts and goals. Planning involves determining the appropriate actions that are required to make your forecasts match your goals.

Forecasting should be an integral part of the decision-making activities of management, as it can play an important role in many areas of a company. Modern organizations require short-, medium-, and long-term forecasts, depending on the specific application.

Short-term forecasts are needed for scheduling of personnel, production, and transportation. As part of the scheduling process, forecasts of demand are often also required.

Medium-term forecasts are needed to determine future resource requirements in order to purchase raw materials, hire personnel, or buy machinery and equipment.

Long-term forecasts are used in strategic planning. Such decisions must take account of market opportunities, environmental factors, and internal resources.

An organization needs to develop a forecasting system involving several approaches to predicting uncertain events. Such forecasting systems require the development of expertise in identifying forecasting problems, applying a range of forecasting methods, selecting appropriate methods for each problem, and evaluating and refining forecasting methods over time. It is also important to have strong organizational support for the use of formal forecasting methods if they are to be used successfully.

Commonly Used Methods

Typically, businesses use relatively simple forecasting methods that are often not based on statistical modelling. However, the use of statistical forecasting is growing and some of the most commonly used methods are listed below.

Time Series Methods

Let the historical time series data be denoted by $y_1, \ldots, y_n$, and the forecast of y_{n+h} be given by $\hat{y}_{n+h|n}$, $h > 0$.

- Naïve forecasting is where the forecasts of all future values of a time series are set to be equal to the last observed value: $\hat{y}_{n+h|n} = y_n$, $h = 1, 2, \ldots$. If the data follow a random walk process ($y_t = y_{t-1} + e_t$ where e_t is white noise – a series of iid random variables with zero mean), then this is the optimal method of forecasting. Consequently, it is popular for stock price and stock index forecasting, and for other time series that measure the behavior of a market that can be assumed to be efficient.
- Simple exponential smoothing was developed in the 1950s (Brown 1959) and has been widely used ever since. Forecasts can be computed recursively as each new data point is observed:

$$\hat{y}_{t+1|t} = \alpha y_t + (1-\alpha)\hat{y}_{t|t-1},$$

where $0 < \alpha < 1$. (Longer-term forecasts are constant: $\hat{y}_{t+h|t} = \hat{y}_{t+1|t}$, $h \geq 2$.) Consequently, only the most recent data point and most recent forecast need to be stored. This was an attractive feature of the method when computer storage was expensive. The method has proved remarkably robust to a wide range of time series, and is optimal for several processes including the ARIMA(0,1,1) process (Chatfield et al. 2001).
- Holt's linear method (Holt 1957) is an extension of simple exponential forecasting that allows a locally linear trend to be extrapolated. Forecasts are given by $\hat{y}_{t+h|t} = \ell_t + hb_t$ where

$$\ell_t = \alpha y_t + (1-\alpha)(\ell_{t-1} + b_{t-1}),$$
$$b_t = \beta(\ell_t - \ell_{t-1}) + (1-\beta)b_{t-1},$$

and the two parameters α and β must lie in $[0,1]$. Here ℓ_t denotes the level of the series and b_t the slope of the trend at time t.
- For seasonal data, a popular method is the Holt–Winters' method, also introduced in Holt (1957), which extends Holt's method to include seasonal terms. Then $\hat{y}_{t+h|t} = \ell_t + hb_t + s_{t-m+h_m^+}$ where

$$\ell_t = \alpha(y_t - s_{t-m}) + (1-\alpha)(\ell_{t-1} + b_{t-1}),$$
$$b_t = \beta(\ell_t - \ell_{t-1}) + (1-\beta)b_{t-1},$$
$$s_t = \gamma(y_t - \ell_t) + (1-\gamma)s_{t-m},$$

$h_m^+ = [(h-1) \mod m] + 1$, and the three parameters α, β and γ all lie in [0,1].

There is also a multiplicative version of the Holt–Winters' method, and damped trend versions of both Holt's linear method and Holt–Winters' method (Makridakis et al. 1998). None of these methods are explicitly based on

underlying time series models, and as a result the estimation of parameters and the computation of prediction intervals is often not done. However, all the above methods have recently been shown to be optimal for some state space models (Hyndman et al. 2008), and maximum likelihood estimation of parameters, statistical model selection and computation of prediction intervals is now becoming more widespread.

Other time series models sometimes used in business forecasting include ARIMA models, GARCH models (especially in finance), structural models and ►neural networks.

Explanatory Models for Forecasting

The use of explanatory models in business forecasting does not have such a long history as the use of time series methods.

- Linear regression modeling (see ►Linear Regression Models) is now widely used (e.g., Pardoe 2006) where a variable to be forecast is modeled as a linear combination of potential input variables:

$$y_t = \sum_{j=1}^{J} c_j x_{j,t} + e_t,$$

where e_t denotes an iid error term with zero mean. An interesting application of regression models to forecasting is given by Byron and Ashenfelter (1995) who use a simple regression models to predict the quality of a Grange wine using simple weather variables. However, it is far more common for regression modelling to be used to explain historical variation than for it to be used for forecasting purposes.

- In some domains, the use of nonparametric additive models for forecasting is growing (e.g., Hyndman and Fan 2010). Here, the model is often of the form

$$y_t = \sum_{j=1}^{J} f_j(x_{j,t}) + e_t,$$

where f_j is a smooth nonlinear function to be estimated nonparametrically.

- In advertising, there is a well-developed culture of using distributed lag regression models (e.g., Hanssens et al. 2001) such as

$$y_t = \sum_{j=1}^{J} \alpha \lambda^j x_{t-j} + e_t,$$

where x_t denotes advertising expenditure in month t, $0 < \lambda < 1$ and $\alpha > 0$.

Data Mining Methods for Business Forecasting

Outside of traditional statistical modelling, an enormous amount of forecasting is done using data mining methods (see ►Data Mining). Most of these methods have no formal statistical model, prediction intervals are not computed, and there is limited model checking. But some of the data-mining methods have proven powerful predictors in some contexts, especially when there is a vast quantity of available data. Predictive methods include neural networks, support vector machines, and regression trees. Many of the best-known business predictive algorithms are based on data-mining methods including the prediction of Netflix ratings (see ►Data Mining Time Series Data, Forecasting Principles).

Business Intelligence

Jasna Soldic-Aleksic, Rade Stankic
Professors, Faculty of Economics
Belgrade University, Belgrade, Serbia

There is no unique definition of the term and concept of Business Intelligence (BI) adopted both in the academic community and commercial business circles. However, there are various short and broad definitions that emphasize some specific aspects of this complex concept. In general, the concept of Business Intelligence refers to in-depth analysis of company data for better decision-making. However, more specifically, the concept may be explained as follows: BI is an umbrella term combining architectures, tools, databases, analytical tools, applications, and methodologies for gathering, storing, analyzing, and providing access to data for improving business performance and helping enterprise users make better business and strategic decisions (Turban et al. 2007).

From a historical point of view, the term business intelligence appeared in the late 1950s, but many years later its usage has been widened to cover the sense it is associated with nowadays. The history of BI concept development is closely connected to the evolution of information systems for enterprise decision support. This is the field in which the roots of the BI concept can be identified, i.e., the Management Information System – MIS reporting systems of the 1970s. These systems were characterized by static reporting features without analytical capabilities. The next generation of information systems – the Executive Information System (EIS) that emerged in the early 1980s provided some additional capabilities, such as: ad-hoc reporting, on-demand reporting, forecasting and prediction, trend analysis, drill-down capability, and critical success factors. These capabilities were essential for computerized support to top-level managers and executives and they were all integrated in the BI system. While the widespread usage of the term and the concept had been recorded in the late 1990s, the rapid growth of BI tools and technologies became evident in 2000s, when many sophisticated data analysis tools were being included in BI enterprise information systems.

Considering the broader scene of the main business and technological trends that had an impact on the development of the BI concept, the following are particularly worth noting: globalization, rapid business growth, strong market competition, data explosion and information overload in all spheres of business and ordinary life, user dissatisfaction with fragmented information systems capabilities, client/server architecture, Enterprise Resource Planning (ERP), Data warehouse (DW) technology, artificial intelligence computing, and web-based technologies and applications. Among all of these technologies, one can be distinguished as the biggest technological catalyst for BI rapid development and success – the DW technology. DW is a repository of subject-oriented, consistent, integrated, historic, and non-volatile collection of data, organized in such way to allow the end-user easy access to data in a form acceptable for analytical processing activities. One of the key features of the DW refers to specific data organization. In contrast to classical data organization approach, with data stored in operational systems (legacy, inventory, shipping, or ERP) and organized according to a concrete business process (purchasing, shipping, billing...), data in DW are organized by subject. Special software, called ETL (Extract, Transform and Load) is responsible for extracting data from different sources, cleaning them up and loading them into a data warehouse. Thanks to this feature, DW provides fast retrieval of historical data (allowing users to analyze time series, trends, and historical patterns) and allows users to analyze broader sets of data. In addition to the *data warehouse*, the architecture of a BI system comprises three other components (Turban et al. 2006): *business analytics* as a collection of tools for data query and reporting, online analytical processing, statistical analysis, prediction, data visualization, ▶data mining, text and web mining; *business performance management* (BPM) used for monitoring and analyzing performance through business performance indicators; and a *user interface* that aims to adequate user communication with the BI system (e.g., dashboard, alerts, and notifications).

For analytical purposes, the BI concept assumes a broad usage of statistical software products and machine learning techniques. The combination of statistics and predictive analytics is recognized as one of the crucial trends in business intelligence. So, it is not unusual to observe some of the most famous statistical software products being incorporated in the integrated predictive analytics technology suits or portfolios. The most impressive examples in this sense are the transformation of two statistical software leaders – SPSS ("*Statistical Package for the Social Sciences*") and SAS ("*Statistical Analysis System*") into remarkable providers of predictive analytics software and services. By using this combined technology, organizations can address their vital BI needs, be it reporting, querying, business visualization, statistics, survey analysis, ▶data mining, text and Web analysis, decision optimization, or, very often, a combination of previous capabilities.

The market of BI products and tools has been on the rise in the last few years and shows a strong tendency for further expansion in the future. According to the Business Intelligence Tools Survey (published in October 2008), the most renowned providers of BI products are: Oracle, SAP, SAS Institute, IBM, EFM Software, Information Builders, Microsoft, QlikTech, Microstrategy, and Actuate.

Business Statistics

Mark L. Berenson
Professor
Montclair State University, Montclair, NJ, USA

An Overview and Definitions

Business statistics can be viewed from two perspectives. One focuses on the use of the statistics themselves. The other sees business statistics as a practitioner-based discipline. To the user, business statistics are intended to be helpful information pertaining to the efficacy of either a company (e.g., financial statements and financial ratios at a particular point in time over several time periods), an industry (e.g., a series of data or an index constructed over time), or the overall economy. The information gleaned is often intended to help the user in making decisions regarding planning, monitoring or investing. To the practitioner, however, business statistics is a particular academic branch of study, similar to other applications-based branches of statistics such as agricultural statistics, ►astrostatistics, ►biostatistics, educational statistics, ►medical statistics, psychological statistics and sociological statistics. The operational definition of business statistics adopted herein is the latter.

Business statistics is an applied branch of mathematics that transforms data into useful information for decision-making purposes (Berenson et al. 2009a). The applications transcend the various functional areas of business – accounting (e.g., auditing), finance (e.g., portfolio development, ►risk analysis, forecasting, econometric modeling), information systems (e.g., database management, e-commerce analysis), management (e.g., project management, quality and productivity management) and marketing (e.g., consumer behavior, sales forecasting, market segmentation, conjoint analysis).

Owing to the wide variety of applications within these areas, business statistics is sometimes referred to as industrial statistics or economic statistics. However, the scope of such nomenclature is too narrow and the more encompassing definition of business statistics is preferred. Industrial statistics typically pertains to quality and productivity whereas economic statistics usually pertains to econometric modeling.

The key feature which distinguishes business statistics as a discipline distinct from other subject area applications of statistics is that in business two types of studies can be conducted, enumerative or analytic, and each has its own methodology. To distinguish between these two types of studies, consider a photograph in a frame versus a motion picture film played on a DVD. Whereas an enumerative study is a "snapshot at a single moment in time," an analytic study is a "motion picture taken over time."

Enumerative studies are common to other application-based branches of statistics and various methodologies employed transcend these statistics disciplines. Enumerative studies involve decision making regarding a population and/or its characteristics at a particular point in time. The sampled data collected can be analyzed descriptively and inferentially provided that appropriate probability sampling methods are used in the data collection stage. Inferences drawn through confidence interval estimation and regression modeling would be considered appropriate for that population at that moment in time. For example, a 95% confidence interval estimate based on a survey conducted today might show that adult males are between 7% and 12% more confident than are adult females that there will be improvements in global economic conditions next year, but who would believe that such opinions would remain static over time as events which led to such opinions change? Decisions made based on inferences drawn from enumerative studies hold true only as long as the population frames from which the samples were drawn remain unchanged.

On the other hand, analytic studies are specifically applicable to industrial or business situations (Deming

1986). Analytic studies involve taking some action on a process to improve future performance (Berenson et al. 2009a; Cryer and Miller 1991; Hoerl and Snee 2002). Data from a process are monitored over time and the focus of the study is to understand process behavior in order to make improvements to the process. Data collected typically constitute samples (i.e., *subgroups*) from some ongoing production process or service process obtained at regular intervals of time. The data can be analyzed descriptively but inferential analysis at this stage is usually limited to studying whether there are recognizable trends or other patterns in some critical-to-quality (*CTQ*) characteristic over time. By monitoring and understanding process variation, once a process is deemed "in-control," the objective is to improve the process either by enhancing the critical-to-quality characteristic's average and/or reducing process variation. This is done through inference – designing appropriate experiments based on the principle of ►randomization (Box et al. 1978). The fields of quality and productivity management, CQI/TQM, and Six-Sigma management have evolved from analytic studies.

A parallel to the analytic study described in managing a manufacturing or service process is time-series analysis (Roberts 1988) which, for many years, was used for either decomposing a series of data into its trend, seasonal or cyclical components in order to compare the series with others in the same industry, across industries or against movements in the overall economy or for forecasting the series into the future (Croxton and Cowden 1955). The fields of econometric modeling and forecasting have evolved from time-series analysis.

Evolution of Business Statistics Education

Through the 1950s teaching emphasis was mainly on descriptive statistical methods along with time series decomposition, forecasting, and index number construction (Croxton and Cowden 1955). Numbers-crunching was typically achieved through the use of desktop calculators. However, in the 1960s, as growth in computer technology permitted the storing of large data sets along with more rapid numbers-crunching capability, research using multivariate analysis methods that were developed in the 1930s through 1950s was finally plausible. Statistical software packages such as SPSS, SAS and BMDP, designed for research in the social sciences, psychology and medicine, were also adopted for use in business, particularly in marketing research and in finance. Thus, from the mid 1960s through the mid 1980s, business statistics education mainly focused on probability (Schlaifer 1961), sampling and, in particular, statistical inference.

In the mid 1980s, sparked by world-wide recognition of the achievements of W. Edwards Deming, the need to distinguish between enumerative and analytic studies in a business environment in which collected data are often longitudinal and not a random sample led to the development of annual MSMESB (Making Statistics More Effective in Schools and Business) conferences and resulted in the infusion of TQM into the business statistics curriculum (Tiao et al. 1986). Probability and inference were deemphasized. Following Deming's death in 1993, the TQM approach, which so successfully developed in Japan, was marred by financial failures and corrupt business practices in that country. Unfortunately, MSMESB was unable to sustain its earlier momentum regarding the importance of TQM in the business statistics course curriculum, particularly after TQM evolved into a Six-Sigma approach (see ►Six Sigma) which B-school faculty considered "too much" to handle in a 1-year, let alone one-semester introductory course.

The late 1990s and the first decade of the new millennium have witnessed an even more rapid expansion of information technology capability. Owing to increased computer literacy and the ability to use computer software to solve larger-scale problems, there has been a reduction in numbers-crunching and more emphasis is now placed on analyzing computer-obtained results. In addition, advances in information technology have led to further advances in the data mining of enormous data bases and emphasis on regression model-building and other analytical tools for evaluating such large data sets is emerging in business statistics education.

The Future of Business Statistics Education

Approximately 20% of all undergraduate students in the US who currently take an introductory statistics course are business majors. Thus, as recognized at the very first MSMESB conference (Tiao et al. 1986) in 1986, it is essential that the course be practical and relevant, demonstrate applications to the functional areas of business, use real data, employ computer information technology rather than "numbers crunching" to get results, emphasize analysis and interpretation of results, and enhance critical thinking and problem-solving skills through written articulation of findings (Berenson et al. 2009b).

In addition, attention must be given to proper tabular and graphic presentation that assist in descriptive analysis and decision making. The importance of probability sampling and randomization in making inferences from sample statistics to population parameters in enumerative studies must be emphasized. And the course must provide an understanding of models useful for prediction and for

forecasting as well as an understanding of process management in analytic studies through control chart monitoring and the use of other quality tools (Berenson et al. 2009a).

Owing to the need for B-schools to produce graduates who will be able to make useful contributions to business in an ever dynamic global environment, the field of business statistics will continue to make important contributions by providing the tools and methods along with enhancing the quantitative and critical thinking skills of the future workforce. With continued advances in IT, and continued developments in data mining and methodology for handling and analyzing enormously large sets of data collected over time, emerging functional area disciplines in business such as business analytics and business informatics will likely subsume business statistics along with the fields of operations research, management information systems and supply chain management. Future students preparing for work in such emerging fields will have a tremendous opportunity to learn and contribute to the world at large.

About the Author

Dr. Mark L. Berenson is Professor, Department of Management and Information Systems, Montclair State University, USA, and Professor Emeritus, Statistics, Zicklin School of Business, Baruch College CUNY, USA. He is also a former President of the New York Metropolitan Area Chapter of the American Statistical Association. Over his academic career Professor Berenson has received several awards for excellence in teaching. He has authored and/or co-authored dozens papers and 11 books, including Basic Business Statistics: Concepts and Applications with David M. Levine and Timothy C. Krehbiel (11th edition, Prentice Hall, 2009), Business Statistics: A First Course with David M. Levine and Timothy C. Krehbiel (5th edition, Prentice Hall, 2010), and Statistics for Managers Using Microsoft Excel with David M. Levine, David F. Stephan and Timothy C. Krehbiel (6th edition, Prentice Hall, 2011).

Business Surveys

Ger Snijkers[1,2], Mojca Bavdaž[3]
[1]Professor in Business Survey Methodology at Utrecht University, Utrecht, The Netherlands
[2]Senior Researcher in Business Survey Data Collection Methodology at Statistics, The Netherlands
[3]Assistant Professor at the Faculty of Economics University of Ljubljana, Ljubljana, Slovenia

The label *business survey* is typically attached to surveys that concern organizations involved in business activities such as manufacturing, commerce, finance, and other services. Business surveys may be considered a subgroup of establishment surveys. Establishment surveys refer to any formal organization engaged in any kind of productive activities, which also includes schools, hospitals, prisons, and other types of institutions that always or prevalently lack a lucrative purpose.

Surveying businesses serves several *aims*. Governments use business surveys to collect data for *economic indicators* within the system of national accounts

(e.g., for gross domestic product) and other areas of economic and ▶business statistics. The collected data are quantitative rather than categorical data, and among the quantitative data the continuous type tends to be more frequent than discrete (Cox and Chinnappa 1995). Some examples are revenues, costs, value of imported and exported goods, number of employees, amount of produced goods, and energy consumption. The most important statistical parameters include totals, structures, and averages, for example, total production or total employment, the structure of businesses by size, and average wages. Changes in these statistics may even be more interesting for the conduct of economic policies (Rivière 2002). This is why panel or longitudinal sampling designs and recurring surveys are often used in such business surveys. In addition, academic researchers use business surveys to collect data for *theoretical models* that often describe complex structures and relationships, for example, organizational structures, the relationship between business innovativeness and revenue growth, the relationship between atmosphere at work and working at home, etc. Chambers of commerce and industry, boards of trade, commodity and industrial boards, and similar organizations representing businesses also use business surveys when they are interested in getting data from their members. Finally, there are business research methods (e.g., Blumberg et al. 2008) that are used by businesses to support their *internal decision making* related to business-to-business relations and their market position.

The *nature of participation* in business surveys depends on their aims. In Europe, business surveys conducted by governmental institutions are typically mandatory, which means that sanctions may be used in case of noncompliance. In the US, this also applies to many but not all business surveys and censuses carried out by the Census Bureau. Mandatory business surveys usually achieve a response rate of 70% or more, often after a series of reminders. Voluntary business surveys not conducted by governmental statistical agencies achieve much lower response rates. These may be slightly higher for academic surveys (e.g., Baruch and Holtom (2008) calculated an average around 35%) compared to commercial surveys.

Business surveys have many unique characteristics given specific characteristics of the business population. The business population is volatile (this is particularly true of small enterprises) and difficult to track due to mergers, acquisitions, numerous forms of linkages, and cooperation. Various business units beyond administrative ones may constitute the most appropriate and meaningful *unit of observation* depending on the survey objectives: an enterprise, a local unit, a kind-of-activity unit etc., but they may not be simple to determine in practice. The choice, definition, and identification of the unit of observation are of paramount importance as they may have a considerable impact on estimates, in particular on breakdowns by activity and region. A public business register can support this complex task and help to construct the survey frame, particularly if it builds on standard statistical units, provides common background variables (at least main economic activity, size indicator, and location), uses standard classifications for these variables (see, for instance, the UN Classifications Registry ▶unstats.un.org/unsd/cr/registry/ and the latest version of the International Standard Industrial Classification of all Economic Activities (ISIC)), and is regularly updated. This reduces frame errors like omissions (e.g., start-ups), erroneous inclusions (e.g., bankrupt companies), duplications (e.g., change of the business name), and misclassifications (e.g., change of the main economic activity). This is why the construction, maintaining, and updating of business registers has traditionally been given a lot of attention in business survey methodology (see, for instance, Cox et al. 1995).

Businesses are also heterogeneous in terms of their activity, behavior, and size. Many variables in business surveys have skewed distributions. Larger businesses in the economy (or in an activity or a region) may therefore be selected in the sample at all times and receive special attention in statistics production. Availability of background variables and a larger weight of some businesses make stratified sampling and probability-proportional-to-size typical *sampling methods* for business surveys (see ▶Sample survey methods).

Questionnaires in business surveys often resemble forms with item labels. Item labels substitute survey questions; they often consist of technical terms, are accompanied by detailed instructions, and request data kept in business records, which all make the response task quite burdensome and time-consuming, and call for self-administered modes of data collection. The trend in governmental business surveys is towards mixed-mode designs in which paper questionnaires are complemented with electronic ones that can either be completed on-line or downloaded to be completed off-line (see ▶Internet survey methodology – recent trends and developments). Both paper and electronic questionnaires should be designed in such a way that it serves the response process within businesses (see e.g., Snijkers et al. 2007).

In business surveys, more than one person may be necessary to reach the decision on survey participation and provide survey answers because authority, capacity, and motivation to respond rarely reside in

one single person within the organization. Organizations have several characteristics that influence their *decision on survey participation* such as centralization of decision making, fragmentation of knowledge through specialization and founding of subsidiaries and branch plants, boundary-spanning roles, environmental dependence, etc. (Tomaskovic-Devey et al. 1994; Snijkers et al. 2007). Some factors influencing this decision are under researchers' control while others are not. The former, for instance, include the selection of the mode, the questionnaire design, and the contact strategies (e.g., introducing the survey, motivating respondents to participate, and respondent chasing); the latter include the selection of the actual respondent(s), internal business factors (e.g., policy not to participate in surveys), and factors in external environment such as survey-taking climate, political and economic climate, and legal and regulatory requirements (Willimack et al. 2002; Snijkers 2008). Paying attention to these factors, even taking the factors that are out of control into account in the survey design, may help prevent or reduce non-response in business surveys.

As in other surveys, the measurement process culminates in the *process of responding* to survey questions. Tourangeau (1984) pointed to four *cognitive components* of this process: understanding of the survey question, retrieval of information from memory, judgment of retrieved pieces of information, and communication of the response (see ►Sample survey methods). While the essence of the response process stays the same also in business surveys, many specifics shape this process considerably. Several people are often involved in the process: in addition to the respondent, also referred to as a reporter or an informant that indeed acts as a business representative or spokesperson, there may be other *business participants* such as gatekeepers (e.g., boundary-spanning units, receptionists), response coordinators, data providers, and authorities who also may serve as gatekeepers. When the required data and/or knowledge to extract them are dispersed across the business, response coordinators organize the survey task. Respondents retrieve the required data themselves or have data providers to retrieve data for them. Authorities have an important role in providing a mandate to work on the ►questionnaire, delegating and scheduling the survey response task and in authorizing the survey response.

Another specific of business surveys is heavy reliance on data stored in business records. When the requested data are not (readily) available in business records, the response burden increases. If the survey design is tailored to internal business processes, the response burden is likely to decrease, which affects the occurrence of non-response and measurement errors (Dale and Haraldsen 2007; Snijkers 2008).

Complexity of data collection in business surveys gave rise to several models of response processes. The latest contributions are the *hybrid model* by Willimack and Nichols (2010), the model introducing the idea of *socially distributed cognition* by Lorenc (2006), the response model focusing on motivating people and influencing their response behavior by Snijkers (2008), and the *multidimensional integral business survey response* (*MIBSR*) *model* by Bavdaž (2010b).

Quality assessment of business surveys may be based on quality frameworks developed by statistical organizations (e.g., IMF, Eurostat, Statistics Canada, Australian Bureau of Statistics, etc.), especially if these surveys provide data for official statistics. None of these frameworks can do without the accuracy of statistical data. Accuracy can be assessed using the concept of the total survey error (see ►Total survey error) even though some specifics may apply especially to non-sampling errors (see ►Non-sampling errors in surveys). Specification errors, for instance, may be quite large because business surveys attempt to measure complex economic phenomena. Frame errors depend on the existence and quality of a business register; these errors do not only refer to under coverage and over coverage but also to duplications and misclassifications. When several units within a business constitute units of observation, businesses may not report data for all of them, which results in within-business non-response; when units of observation differ from existing organisational units, businesses may report data for wrong units, which results in measurement errors. Given the specifics and complexity of the response process in business surveys, sources of measurement errors include all business participants and survey staff involved in the response process, the business environment, the survey instrument, and various survey characteristics and procedures beyond the mode of data collection, in particular the recurrence of the response process (Bavdaž 2010a). For many items in business survey questionnaires, it is difficult to distinguish between item non-response and a valid zero value. Non-response and measurement errors may be reduced in the data editing process. Given the usual abundance of auxiliary information taken from previous data reporting in the same survey, other surveys, or administrative sources, data editing has traditionally been given a lot of attention in business surveys. This is why data processing errors may be relatively small.

Since the 1990s, business survey methodology has been increasingly given a systematic approach in order to solve business surveys' unique problems (Cox et al. 1995). Up

to now, three International Conferences on Establishments Surveys (ICES) have been organized in 1993, 2000 and 2007, and the fourth one is coming up (2012). Other initiatives also serve this goal, for example, the International Workshop on Business Data Collection Methodology (www.ssb.no/bdcmethods) and the European Establishment Statistics Workshop (www.enbes.org). In Europe, Eurostat has started a major program on Modernisation of European Enterprise and Trade Statistics (MEETS; Behrens 2009). These initiatives try to provide a platform for business survey methodologists to discuss their problems, promote exchange of ideas and international collaboration, foster research in this field, and come to current best practices.

C

Calibration

Christos P. Kitsos
Professor and Head
Technological Educational Institute of Athens, Athens, Greece

Various methods and different (linear or not, simple linear, or multivariate) models have been adopted in industry to address the calibration problem. In practice, most of the models attempt to deal with the simple linear calibration technique, mostly applied in chemical applications, especially when some instruments are to be calibrated (examples include pH meters, NIR instruments, and establishing calibration graphs in chromatography).

The early work of Shukla (1972) put forward the problem on the real statistical dimensions, and even early on it was realized that when a non-linear model describes the phenomenon (Schwartz 1978), a linear approximation is eventually adopted. But even so, in the end we come to a nonlinear function to be estimated as best as possible (Kitsos and Muller 1995). When the variance of the measurement is due to many sources of variability, different techniques are used. Statistical calibration has been reviewed by Osborn (1991), who provides a list of pertinent references; when a robust approach might be appropriate, see Kitsos and Muller (1995). Certainly, to consider the variance constant and to follow a statistical quality control method (see ▶Statistical Quality Control), Hochberg and Marom (1983) might be helpful, but not in all cases. For the multivariate case, see the compact book of Brown (1993), Brereton (2000), and for an application Oman and Wax (1984). Moreover, different methods have been used on the development of the calibration problem like cross-validation (see Clark 1980).

Next we briefly introduce the statistical problem and the optimal design approach is adopted in the sequence to tackle the problem.

Consider the simple regression model with

$$n = E(y|u) = \theta_0 + \theta_1 u_1 \quad u_1 \in U = [-1,1]$$

where U is the design space, which can always be transformed to $[-1,1]$. Moreover, the involved error is assumed to be from the normal distribution with mean zero and variance $\sigma^2 > 0$.

The aim is to estimate the value of $u_1 = u_0$ given $n = C$, i.e.,

$$u_0 = (C - \theta_0)/\theta_1$$

which is a nonlinear function of the involved linear parameters, as we have already emphasized above.

The most well-known competitive estimators of u_0 when y_0 is provided are the so-called "*classical predictor*"

$$C(u_0) = \bar{x} + \frac{S_{xx}}{S_{xy}}(\dot{y}_0 - \bar{y})$$

and the "*inverse predictor*"

$$I(u_0) = \bar{u} + \frac{S_{xy}}{S_{yy}}(\dot{y}_0 - \bar{y})$$

with:

$$S_{\text{tr}} = \sum (t_i - \bar{t})(r_i - \bar{r})$$

were by $\dot{y}_0$ we mean the average of the possible k observations taken at the prediction stage (or experimental condition) and $\bar{y}$ as usually the average of the collected values.

The comparison of $C(u_0)$ and $I(u_0)$ is based on the values of the sample size n and the proportion $|\sigma/\theta_1|$ under the assumption that x_0 belongs to the experimenter area.

One of the merits of $C(u_0)$ is that when the usual normal assumption for the errors is imposed, the classical predictor is the maximum likelihood estimator. Moreover, $C(u_0)$ is a consistent estimator while $I(u_0)$ is inconsistent. The $I(u_0)$ estimation is criticized as it provides a confidence interval that might be the whole real line or, in the best case, two disjoint semi-infinite intervals. When $|\sigma/\theta_1|$ is small the asymptotic mse (mean square error) of $C(u_0)$ is smaller than with the use of $I(u_0)$, when x_0 does not lie in the neighborhood of $\bar{u}$.

The main difficulty is the construction of confidence intervals, as the variance of u_0 does not exist. This provides food for thought for an optimal design approach for the calibration problem. To face these difficulties the

Miodrag Lovric (ed.), *International Encyclopedia of Statistical Science*, DOI 10.1007/978-3-642-04898-2,

optimal experimental approach is adopted (see *Optimum Experimental Designs*, also see Kitsos 2002).

For the one-stage design we might use of the criterion function Φ, either D-optimality for (θ_0, θ_1) or c-optimality for estimating u_0. The D-optimal design is of interest because its effectiveness can be investigated, as measured by the c-optimality criterion. Under c-optimality, thanks to Elfving's theorem, locally optimal two-point design can be constructed geometrically. The criterion that experimenters like to use is

$$\min Var(\hat{u}_0).$$

Different approaches have been adopted for this crucial problem: Bayesian, see Chaloner and Verdinelli (1995), Hunter and Lamboy (1981); structural inference, see Kalotay (1971). There is a criticism that structural inference is eventually Bayesian, but this is beyond the scope of this discussion.

When suitable priors for u_0 are chosen the calibrative density functions come from the non-central Student with mean $\mathrm{Ba}(u_0)$ as

$$\mathrm{Ba}(u_0) = \bar{u} + \frac{S_{yy}}{r}(\dot{y}_0 - \bar{y})$$

where $r = S_{yy} + \sum_j^k (y_{0_j} - \bar{y})^2$. When $k = 1$ the Bayesian estimator coincides with the inverse, namely $\mathrm{Ba}(u_0) = I(u_0)$.

The structural approach forms the simple linear model as a "structural model" and obtains a rather complicated model, which, again, with $k = 1$, coincides with the inverse regression.

The nonlinear calibration has attracted classical and Bayesian approaches, both based on the Taylor expansion of the nonlinear model. Therefore, calibration is based on the linear approach of the nonlinear model.

About the Author

Dr. Christos Kitsos is a Professor and Head, Department of Mathematics, of the Technological Educational Institute of Athens, Greece. His first degree is in mathematics, Athens University, his MA degree from the Math and Stat of University of New Brunswick, Canada, while his PhD is from the Glasgow University, UK. He is a member of ISI (and ISI-Committee of Risk Analysis), IEEE and was elected member of IASC, were he is also a member. He has organized a number of statistical conferences in Greece, and has founded the series of International Conference on Cancer Risk Assessment (ICCRA). He has published 88 papers in journals and proceedings volumes, participated in 80 conferences, and published 12 books in Greek (8 are textbooks), and is a coauthor of 5 international books as editor. Professor Kitsos has been the national representative at EUROSTAT and OECD for educational statistics.

Canonical Analysis and Measures of Association

Jacques Dauxois[1], Guy Martial Nkiet[2]

Introduction

The Bravais–Pearson linear correlation coefficient and the Sarmanov maximal coefficient are well known statistical

tools that permit to measure, respectively, correlation (also called linear dependence) and stochastic dependence of two suitable random variables X_1 and X_2 defined on a probability space $(\Omega, \mathcal{A}, P)$. Since these coefficients just are the first canonical coefficients obtained from linear and nonlinear canonical analysis, respectively, it is relevant to improve them by using all the canonical coefficients. In order to give an unified framework for these notions, we introduce the canonical analysis (CA) of two closed subspaces H_1 and H_2 of a Hilbert space H. Then, a class of measures of association that admits the aforementioned coefficients as particular cases can be constructed.

Canonical Analysis

Let H be a separable real Hilbert space with inner product and related norm denoted by $\langle \cdot, \cdot \rangle$ and $\|\cdot\|$ respectively, and H_1 and H_2 be two closed subspaces of H. Then we have the following definition that comes from Dauxois and Pousse (1975).

Definition 1 *The canonical analysis (CA) of H_1 and H_2 is any triple*

$$\left(\{\rho_i\}_{i\in I_0}, \{f\}_{i\in I_1}, \{g\}_{i\in I_2}\right),$$

with $I_\ell \subset \mathbb{N}^*$ for $\ell \in \{0,1,2\}$, that satisfies:

1. *The system $\{f\}_{i\in I_1}$ (resp. $\{g\}_{i\in I_2}$) is an orthonormal basis of H_1 (resp. H_2)*
2. *$\rho_1 = \langle f_1, g_1\rangle = \sup\{\langle f, g\rangle; (f,g) \in H_1 \times H_2,\ \|f\| = \|g\| = 1\}$*
3. *For any $i \in I_0$ such that $i \geq 2$, one has:*

$$\rho_i = \langle f_i, g_i\rangle = \sup\left\{\langle f, g\rangle; (f,g) \in F_i^{\perp} \times G_i^{\perp}, \|f\| = \|g\| = 1\right\}$$

where $F_i = span\{f_1, \cdots, f_{i-1}\}$ and $G_i = span\{g_1, \cdots, g_{i-1}\}$.

Conditions for existence of canonical analysis have been investigated in the aforementioned work. More precisely, denoting by Π_E the orthogonal projector onto the closed subspace E of H, a sufficient condition is the compacity of $T_1 = \Pi_{H_1}\Pi_{H_2|H_1}$ or, equivalently, that of $T_2 = \Pi_{H_2}\Pi_{H_1|H_2}$. In this case, we say that we have a compact CA, and the following proposition holds:

Proposition 1 *Consider a compact CA $\left(\{\rho_i\}_{i\in I_0}, \{f\}_{i\in I_1}, \{g\}_{i\in I_2}\right)$, of H_1 and H_2, where the ρ_i's are arranged in nonincreasing order. Then:*

1. *$\{\rho_i^2\}_{i\in I_0}$ is the noincreasing sequence of eigenvalues of T_1 and T_2 and, for any $i \in I_0$, one has $0 \leq \rho_i \leq 1$.*
2. *$\{f\}_{i\in I_1}$ (resp. $\{g\}_{i\in I_2}$) is an orthonormal basis of H_1 (resp. H_2) such that, for any $i \in I_0$, f_i (resp. g_i) is an eigenvector of T_1 (resp. T_2) associated with ρ_i^2.*
3. *$\forall (i,j) \in (I_0)^2$, $\langle f_i, g_j\rangle = \delta_{ij}\rho_i$, $\Pi_{H_1} f_i = \rho_i g_i$, $\Pi_{H_2} g_i = \rho_i f_i$.*
4. *$\{f\}_{i\in I_1 - I_0}$ (resp. $\{g\}_{i\in I_2 - I_0}$) is an orthonormal basis of $\ker(T_1) = H_1 \cap H_2^{\perp}$ (resp. $\ker(T_2) = H_2 \cap H_1^{\perp}$).*

Remark 1

1. The ρ_i's are termed the *canonical coefficients*. They permit to study the relative postions of each of the preceding subspace with respect to the other. For instance, the nullity of all these coefficients is equivalent to the orthogonality of H_1 and H_2, and if one of these subspaces is included into the other these coefficients are all equal to 1. Note that, in this later case there does not exist a compact CA when the considered subspaces are infinite-dimensional ones. Nevertheless, it is possible to find a triple having the same properties than a compact CA. Such a triple can be given by $\left(\mathbb{1}, (f_i)_{i\in\mathbb{N}^*}, (g_i)_{i\in\mathbb{N}^*}\right)$, where $\mathbb{1}$ is the numerical sequence with all terms equal to 1, $(f_i)_{i\in\mathbb{N}^*}$ is a orthonormal basis of H_1 and $(g_i)_{i\in\mathbb{N}^*}$ is the previous system possibly completed with an orthonormal basis of $\ker T_2 = H_2 \cap H_1^{\perp}$ so as to obtain an orthonormal basis of H_2.
2. From the previous notion of CA it is possible to define a canonical analysis of two subspaces H_1 and H_2 relatively to a third one H_3. It is just the CA of the subspaces $H_{1\cdot 3} := (H_1 \oplus H_3) \cap H_3^{\perp}$ and $H_{2\cdot 3} := (H_2 \oplus H_3) \cap H_3^{\perp}$. This CA leads to interesting properties given in Dauxois et al. (2004a), and is useful in statistics for studying conditional independence between random vectors (see, e.g., Dauxois et al. [2004b]).
3. When $X_1 = \left(X_1^1, \cdots, X_1^{p_1}\right)^T$ and $X_2 = \left(X_2^1, \cdots, X_2^{p_2}\right)^T$ are two random vectors such that any X_i^j belongs to $L^2(P)$, their *Linear Canonical Analysis* (LCA) is the CA of H_1 and H_2 where $H_i = \text{span}\left(X_i^1, \cdots, X_i^{p_i}\right)$. The spectral analysis of T_1 is equivalent to that of $V_1^{-1}V_{12}V_2^{-1}V_{21}$, where V_i (resp. V_{12}; resp. V_{21}) denotes the covariance (resp. cross-covariance) operator of X_i (resp. X_1 and X_2; resp. X_2 and X_1). So, it is just the CA of random vectors introduced by Hotelling (1936). The first canonical coefficient is the Bravais–Pearson linear correlation coefficient.
4. When X_1 and X_2 are arbitrary random variables, their *Nonlinear Canonical Analysis* (NLCA) is the CA of H_1 and H_2 where H_i is the closed subspace of $L^2(P)$ consisting in random variables of the form $\varphi(X_i)$, where φ is a measurable function valued into $\mathbb{R}$. In this case, the first canonical coefficient just is the Sarmanov maximal coefficient.

Measures of Association

Let $\mathcal{C}$ be the set of pairs (H_1, H_2) of closed subspaces of a Hilbert space, having a compact CA or being infinite-dimensional and such that $H_1 \subset H_2$ or $H_2 \subset H_1$. We consider an equivalence relation $\simeq$ defined on $\mathcal{C}$, such that $(H_1, H_2) \simeq (E_1, E_2)$ if there exists a pair (I_1, I_2) of isometries satisfying: $I_1(H_1) = E_1$, $I_2(H_2) = E_2$ and $\forall (x,y) \in H_1 \times H_2$, $< I_1(x), I_2(y) >_E = < x, y >_H$, where

H (resp. E) denotes the separable real Hilbert space which contains H_1 and H_2 (resp. E_1 and E_2). We also consider a preordering relation $\preceq$ on $\mathcal{C}$, such that $(H_1, H_2) \preceq (E_1, E_2)$ if there exists a pair $\left(E_1', E_2'\right)$ of closed subspaces satisfying: $E_1' \subset E_1$, $E_2' \subset E_2$ and $(H_1, H_2) \simeq \left(E_1', E_2'\right)$.

Definition 2 *A measure of association r between Hilbertian subspaces is any map from a subset $\mathcal{C}_r$ of $\mathcal{C}$ into $[0,1]$ such that the following conditions are satisfied:*

$$
\begin{aligned}
r(H_1, H_2) &= r(H_2, H_1);\\
H_1 \perp H_2 &\Leftrightarrow r(H_1, H_2) = 0;\\
H_1 \subset H_2 \quad \text{or} \quad H_1 \subset H_2 &\Rightarrow r(H_1, H_2) = 1;\\
(H_1, H_2) \simeq (E_1, E_2) &\Rightarrow r(H_1, H_2) = r(E_1, E_2);\\
(H_1, H_2) \preceq (E_1, E_2) &\Rightarrow r(H_1, H_2) \leq r(E_1, E_2).
\end{aligned}
$$

Remark 2

1. When $X_1 = \left(X_1^1, \cdots, X_1^{p_1}\right)^T$ and $X_2 = \left(X_2^1, \cdots, X_2^{p_2}\right)^T$ are two random vectors such that any X_i^j belongs to $L^2(P)$, we obtain a measure of linear dependence between X_1 and X_2 by putting $r(X_1, X_2) := r(H_1, H_2)$ with $H_i = \text{span}\left(X_i^1, \cdots, X_i^{p_i}\right)$. Indeed, from second axiom given above, $r(X_1, X_2) = 0$ if and only if X_1 and X_2 are uncorrelated, that is $V_{12} = 0$. From the third one, it is seen that if there exists a linear map A such that $X_1 = AX_2$ then $r(X_1, X_2) = 1$.
2. When X_1 and X_2 are arbitrary random variables, considering $H_i = \{\varphi(X_i) / \mathbb{E}(\varphi(X_i)^2) < +\infty\}$, a measure of stochastic dependence of X_1 and X_2 is obtained by putting $r(X_1, X_2) := r(H_1, H_2)$. In this case, the above axioms are closed to the conditions proposed by Rényi (1959) for good measures of dependence. In particular, the second axiom gives the equivalence between the independence of X_1 and X_2 and the nullity of $r(X_1, X_2)$, and from the third axiom it is seen that for any one to one and bimeasurable functions f and g, one has $r(f(X_1), g(X_2)) = r(X_1, X_2)$.

A class of measures of association can be built by using symmetric non decreasing functions of canonical coefficients. In what follows, $\mathcal{P}(\mathbb{N}^*)$ denotes the set of permutations of $\mathbb{N}^*$. For $\sigma \in \mathcal{P}(\mathbb{N}^*)$ and $x = (x_n)_n \in c_0$, we put $x_\sigma = \left(x_{\sigma(n)}\right)_n$ and $|x| = (|x_n|)_n$. We denote by c_0 the space of numerical sequences $x = (x_n)_n$ such that $\lim_{n\to\infty} x_n = 0$.

Definition 3 *A symmetric nondecreasing function (sndf) is a map Φ from a subset c_Φ of c_0 to $\mathbb{R}_+$ satisfying:*

1. *For all $x \in c_\Phi$ and $\sigma \in \mathcal{P}(\mathbb{N}^*)$, one has $x_\sigma \in c_\Phi$ and $\Phi(|x_\sigma|) = \Phi(x)$.*
2. *For all $(x, y) \in (c_\Phi)^2$, if $\forall n, |x_n| \leq |y_n|$, then $\Phi(x) \leq \Phi(y)$.*
3. *There exists a nondecreasing function f_Φ from $\mathbb{R}$ to $\mathbb{R}$ such that : $f_\Phi(0) = 0$; $\forall u \in \mathbb{R}$, $(u, 0, \cdots) \in c_\Phi$ and $\Phi(u, 0, \cdots) = f_\Phi(|u|)$.*

We denote by Ψ the map from $\mathcal{C}$ to $c_0 \cup \{\mathbb{1}\}$ such that $\Psi(H_1, H_2)$ is the noincreasing sequence of canonical coefficients of H_1 and H_2. Then we have:

Proposition 2 *Let Φ be a sndf with definition domain c_Φ, and such that $\Phi(\mathbb{1}) = 1$. Then, the map $r_\Phi = \Phi \circ \Psi$ is a measure of association defined on the subset $\mathcal{C}_\Phi = \{(H_1, H_2) \in \mathcal{C};\ \Psi(H_1, H_2) \in c_\Phi \cup \{\mathbb{1}\}\}$.*

This proposition means that a measure of association between two subspaces is obtained as a function of the related nonincreasing sequence of canonical coefficients through a sndf. Some examples of such measures are:

$$
\begin{aligned}
r_1(H_1, H_2) &= 1 - \exp\left(-\sum_{i=1}^{+\infty} \rho_i^2,\ r_{2,p}(H_1, H_2)\right)\\
&= \sqrt{\frac{\sum_{i=1}^{+\infty} \rho_i^{2p}}{1 + \sum_{i=1}^{+\infty} \rho_i^{2p}}}\ (p \in \mathbb{N}^*),\ r_3(H_1, H_2)\\
&= \max_{i\geq 1} |\rho_i| = \rho_1.
\end{aligned}
$$

On the one hand, this class of measures of association contains all the measures built by using LCA of random vectors (see Cramer and Nicewander (1979), Lin (1987), Dauxois and Nkiet (1997b)). On the other hand, when H_1 and H_2 are the subspaces considered in the second assertion of Remark 2, r_3 just is the Sarmanov maximal coefficient. In this case, estimation of the coefficients from NLCA and, therefore, the related measures of associations can be obtained from approximation based on step functions or B-spline functions, and from sampling. Using this approach, a class of independence tests that admits the chi-squared test of independence as particular case, have been be proposed (see Dauxois and Nkiet (1998)).

Canonical Correlation Analysis

Tenko Raykov
Professor of Measurement and Quantitative Methods
Michigan State University, East Lansing, MI, USA

Introduction

Canonical correlation analysis (CCA) is one of the most general multivariate statistical analysis methods (see ►Multivariate Statistical Analysis). To introduce CCA, consider two sets of variables, denoted A and B for ease of reference (e.g., Raykov and Marcoulides 2008). Let A consist of p members collected in the vector $\underline{\mathbf{x}}$, and let B consist of q members placed in the vector $\underline{\mathbf{y}}$ $(p > 1, q > 1)$. In an application setting, the variables in either set may or may not be considered response variables (dependent or outcome measures) or alternatively independent variables (predictors, explanatory variables). As an example, A may consist of variables that have to do with socioeconomic status (e.g., income, education, job prestige, etc.), while B may comprise cognitive functioning related variables (e.g., verbal ability, spatial ability, intelligence, etc.).

Consider the correlation matrix R of all variables in A and B taken together, which has $(p + q) \cdot (p + q - 1)/2$ non-duplicated (non-redundant) correlations. Obviously, even for relatively small p and q, there are many non-duplicated elements of R. CCA deals with reducing this potentially quite large number of correlations to a more manageable group of interrelationship indices that represent the ways in which variables in A covary with variables in B, i.e., the interrelationships among these two sets of variables. More specifically, the purpose of CCA is to obtain a small number of derived variables (measures) from those in A on the one hand, and from those in B on the other, which show high correlations across the two sets (e.g., Johnson and Wichern 2002). That is, a main goal of CCA is to "summarize" the correlations between variables in set A and those in set B into a much smaller number of corresponding linear combinations of them, which in a sense are representative of those correlations. With this feature, CCA can be used as a method for (1) examining independence of two sets of variables (viz. A and B), (2) data reduction, and (3) preliminary analyses for a series of subsequent statistical applications.

Achieving this goal is made feasible through the following steps (cf. Raykov and Marcoulides 2008). First, a linear combination Z_1 of the variables $\underline{\mathbf{x}}$ in A is sought, as is a linear combination W_1 of the variables $\underline{\mathbf{y}}$ in B, such that their correlation $\rho_{1,1} = \mathrm{Corr}(Z_1, W_1)$ is the highest possible across all choices of combination weights for W_1 and Z_1 (see next section for further details). Call Z_1 and W_1 the *first pair of canonical variates*, and $\rho_{1,1}$ the *first canonical correlation*. In the next step, another linear combination Z_2 of variables in A is found and a linear combination W_2 of variables in B, with the following property: their correlation $\rho_{2,2} = \mathrm{Corr}(Z_2, W_2)$ is the highest possible under the assumption of Z_2 and W_2 being uncorrelated with the variables in the first combination pair, Z_1 and W_1. Z_2 and W_2 are referred to as the *second pair of canonical variates*, and $\rho_{2,2}$ as the *second canonical correlation*. This process can be continued until t pairs of canonical variates are obtained, where $t = \min(p, q)$ being the smaller of p and q. While in many applications t may be fairly large, it is oftentimes the case that only up to the first two or three pairs of canonical variates are really informative (see following section). If all canonical correlations are then uniformly weak and close to zero, A and B can be considered largely (linearly) unrelated. Otherwise, one could claim that there is some (linear) interrelationship between variables in A with those in B. Individual scores on the canonical variates can next be computed and used as values on new variables in subsequent analyses. These scores may be attractive then, since they capture the essence of the cross-set variable interrelationships.

Procedure

To begin a CCA, two linear combinations $Z_1 = \underline{\mathbf{a}}_1' \underline{\mathbf{x}}$ and $W_1 = \underline{\mathbf{b}}_1' \underline{\mathbf{y}}$ are correspondingly sought from the variables

in A and in B, such that $\rho_{1,1} = \mathrm{Corr}(Z_1, W_1)$ is at its maximal possible value across all possible choices of $\underline{\mathbf{a}}_1$ and $\underline{\mathbf{b}}_1$. Consider the covariance matrix S of the entire set of $p + q$ variables in A and B:

$$S = \begin{bmatrix} S_{11} & S_{12} \\ S_{21} & S_{22} \end{bmatrix},$$

where S_{11} is the covariance matrix of the p variables in A, S_{22} that of the q variables in B, S_{21} that of the q variables in B with the p in A, and S_{12} denotes the covariance matrix of the p variables in A with the q measures in B. It can be shown (e.g., Johnson and Wichern 2002) that this maximum correlation $\rho_{1,1}$ will be achieved if the following holds:

1. $\underline{\mathbf{a}}_1$ is taken as the (generalized) eigenvector pertaining to the largest solution ρ^2 of the equation $\left|S_{12}S_{22}^{-1}S_{21} - \rho^2 S_{11}\right| = 0$, where $|.|$ denotes determinant, that is, $\underline{\mathbf{a}}_1$ fulfils the equation $\left(S_{12}S_{22}^{-1}S_{21} - \rho^2 S_{11}\right)\underline{\mathbf{a}}_1 = \underline{0}$, with ρ^2 being the largest solution of the former equation.
2. $\underline{\mathbf{b}}_1$ is the (generalized) eigenvector pertaining to the largest root of the equation $\left|S_{21}S_{11}^{-1}S_{12} - \pi^2 S_{22}\right| = 0$, that is, $\underline{\mathbf{b}}_1$ fulfils the equation $\left(S_{21}S_{11}^{-1}S_{12} - \pi^2 S_{22}\right)\underline{\mathbf{b}}_1 = \underline{0}$, with the largest π^2 satisfying the former equation.

The solutions of the two involved determinantal equations are identical, that is, $\rho^2 = \pi^2$, and the positive square root of the largest of them equals $\rho_{(1)} = \pi_{(1)} = \rho_{1,1} = \mathrm{Corr}(Z_1, W_1)$, the maximal possible correlation between a linear combination of variables in A with a linear combination of those in B. Then $Z_1 = \underline{\mathbf{a}}_1' \underline{\mathbf{x}}$ and $W_1 = \underline{\mathbf{b}}_1' \underline{\mathbf{y}}$ represent the first canonical variate pair, with this maximal correlation, $\mathrm{Corr}(Z_1, W_1)$, being the first canonical correlation.

As a next step, the second canonical variate pair is furnished as a linear combination of the variables in A, using the eigenvector pertaining to the second largest solution of $\left|S_{12}S_{22}^{-1}S_{21} - \rho^2 S_{11}\right| = 0$ on the one hand, and a linear combination of the B variables using the second largest solution of $\left|S_{21}S_{11}^{-1}S_{12} - \pi^2 S_{22}\right| = 0$ on the other hand; then their correlation is the second canonical correlation. One continues in the same manner until $t = \min(p, q)$ canonical variate pairs are obtained; the corresponding canonical correlations are calculated as their interrelationship indices (correlations). From the construction of the canonical variates follows that they are uncorrelated with one another:

$$\begin{aligned} \mathrm{Cov}(Z_i, Z_j) &= \mathrm{Cov}(W_i, W_j) = \mathrm{Cov}(Z_i, W_j) \\ &= 0 \ (\text{for all } i \neq j;\ i, j = 1, \ldots, t). \end{aligned}$$

Interpretation

Even though there are $t = \min(p, q)$ canonical variate pairs and canonical correlations, oftentimes in applications not all are important for understanding the relationships among variables in A and B. Statistical tests are available which help evaluate the importance of canonical variate pairs and aid a researcher in finding out how many pairs could be retained for further analysis. The tests assume multivariate normality and examine hypotheses of canonical correlations being 0 in a given population. The first test evaluates the null hypothesis that all canonical correlations are 0. If this hypothesis is rejected, at least the first canonical variate pair is of relevance when trying to understand the interrelationship between the variables in A and B; more specifically, at least the first canonical correlation is not zero in the population. Then the second test examines the null hypothesis that apart from the first canonical correlation, all remaining ones are 0; and so on. If the first tested hypothesis is not rejected, it can be concluded that A and B are (linearly) unrelated to one another.

After completing these tests, and in case at least the first canonical correlation is significant, the next question may well be how to interpret the canonical variates. To this end, one can use the correlations of each canonical variate with variables within its pertinent set. That is, when trying to interpret Z_1, one can look at its correlations with the variables in A. Similarly, when trying to interpret W_1, one can examine its correlations with the variables B; and so on for the subsequent canonical variate pairs and their members. The principle to follow thereby, is to interpret each canonical variate as representing the common features of initial variables correlated highly with that variate. Furthermore, for a given canonical correlation $\rho_i = \pi_i$, its square ρ_i^2 can be interpreted as a squared multiple correlation coefficient for the regression relating the ith canonical variate for any of the sets A or B, with the variables of the other set (B or A, respectively; $i = 1, \ldots, t$). With this in mind, ρ_i^2 can be viewed as proportion shared variance between A and B, as captured by the ith canonical variate pair ($i = 1, \ldots, t$); the square of the first canonical correlation is interpretable as a measure of "set overlap."

Similarly to principal components and factors, canonical variates can be used to obtain individual subject scores on them. They can be used in subsequent analyses, e.g., as scores on explanatory variables. Like principal components, the units of a canonical variate may not be meaningful. It is stressed that canonical variates are not latent variables, but instead share the same observed status as manifest (recorded) variables, since they are linear combinations of the latter.

Relationship to Discriminant Function Analysis

It can be shown (Tatsuoka 1971) that with $k > 2$ groups discriminant function analysis (DFA) is identical to CCA using additionally defined variables $D_1, D_2, \ldots, D_{k-1}$ as comprising set A, while the original explanatory (predictor) variables, say $\underline{\mathbf{x}} = (x_1, x_2, \ldots, x_p)'$, are treated as set B. These ▶dummy variables $D_1, D_2, \ldots, D_{k-1}$ are defined in exactly the same way they would be for purposes of regression analysis with categorical predictors. If one then performs a CCA with these sets A and B, the results will be identical to those obtained with a DFA on the original variables $\underline{\mathbf{x}}$. Specifically, the first canonical variate for B will equal the first discriminant function; the second canonical variate for B will equal the second discriminant function, etc. The test for significance of the canonical correlations is then a test for significance of discriminant functions, and the number of significant such functions and of canonical correlations is the same. Further, each consecutive eigenvalue for the discriminant criterion, v_i, is related to a corresponding generalized eigenvalue (determinantal equation root) ρ_i : $v_i = \frac{\rho_i^2}{1-\rho_i^2}$ ($i = 1, 2, \ldots, r$; Johnson and Wichern 2002). Testing the significance of discriminant functions is thus equivalent to testing significance of canonical correlations.

Generality of Canonical Correlation Analysis

CCA is a very general multivariate statistical method that unifies a number of analytic approaches. The canonical correlation concept generalizes the notion of bivariate correlation that is a special case of the former for $p = q = 1$ variables. The multiple correlation coefficient of main relevance in regression analysis is also a special case of canonical correlation, which is obtained when the set A consists of $p = 1$ variable – the response measure – and the set B consists of q variables that are the predictors (explanatory variables) in the pertinent regression model. The multiple correlation coefficient is then identical to the first canonical correlation. Third, since various uni- and multivariate ANOVA designs can be obtained as appropriate special cases of regression analysis, these designs and corresponding ANOVAs can be seen as special cases of canonical correlation analysis. Also, as indicated in the preceding section, discriminant function analysis is a special case of CCA as well. (Since DFA is a "reverse" MANOVA – e.g., Raykov and Marcoulides 2008 – one can alternatively see the latter also as a special case of CCA.) Hence, canonical correlation analysis is a very general multivariate analysis method, which subsumes a number of others that are widely used in statistical applications.

[1]Professor and Chair
University of California-Riverside, Riverside, CA, USA
[2]MARC and Professor Emeritus
Claremont McKenna College, Claremont, CA, USA

Statistics has changed over the last decades from being a discipline that primarily studied ways to characterize randomness and variation to a discipline that emphasizes the importance of data in the explanation of phenomenon and in problem solving. While statisticians routinely use mathematics and computer programming languages as key

tools in their work, they usually also function as an important data-driven decision maker within their application domain. Consequently, a statistician must have a genuine curiosity about the subject domain they work within, and furthermore, must have strong collaborative and communication skills in order successfully interact with the many colleagues they will encounter and rely on for information.

As the world becomes more quantitative through the data revolution, more professions and businesses depend on data and on the understanding and analyses of these data. Data are not simply numbers. Data contain information that needs to be understood and interpreted. As a result, statisticians are much more than bean counters or number crunchers. They possess skills to find needles in haystacks and to separate noise from signal. They are able to translate a problem or question into a framework that enables data collection and data analysis to provide meaningful insights that can lead to practical conclusions.

Loosely speaking there is a spectrum of statisticians that ranges from very applied on one end to very theoretical on the other end. Applied statisticians skillfully select and implement an appropriate statistical methodology to solve a problem. They are a statistician who has a problem and is looking for a solution. Theoretical statisticians are interested in trying to expand the toolkit of applied statisticians by generalizing or creating new methods that are capable of solving new problems or solving existing problems more efficiently. They are statisticians who might get motivated by a problem someone else encountered in practice, but who then abstract the problem as much as possible so that their solution has as broad an impact as possible. Most statisticians are not planted firmly on either end of this spectrum, but instead find themselves moving around and adapting to the particular challenge they are facing.

Another way to loosely categorize statisticians is in terms of industrial (or government) versus academic statisticians. Academic statisticians are primarily involved with innovative research and the teaching of statistics classes. Aside from Statistics departments, there are many alternative departments for academic statisticians including Mathematics, Economics, Business, Sociology and Psychology. Research goals for an academic statistician vary with their interests, and also depend on their emphasis toward either applied or theoretical research. In addition, the University at which they work can emphasize either a teaching or research mission that further dictates the quantity and type of research they engage in. In any case, it is a primary responsibility of an academic statistician to publish papers in leading statistics journals to advance the field. Teaching responsibilities can include introductory Statistics for undergraduate non-majors, core statistical theory and methods classes for Statistics majors and in many cases advanced graduate-level Statistics classes for students pursuing an MS and/or PhD degree in Statistics.

Industrial statisticians are frequently focused on problems that have some bearing on the company's business. In some large companies there may be a fundamental research group that operates more like an academic environment, but in recent years the number and size of these groups are diminishing as corporations are more squarely focused on their bottom lines. Industrial statisticians are expected to assimilate the company culture and add value to the projects they work on that goes well beyond the contributions that their statistical skills alone enable. They might, for example, become project managers and even technical managers where their organizational, motivational, and leadership skills become important assets to the company.

Many statisticians engage in statistical consulting, either as their primary vocation or as a part-time endeavor. Academic statisticians, for example, often have opportunities to lend their data analysis and quantitative problem solving skills to government and industry clients, and can contribute to litigation cases as an expert consultant or even an expert witness. Consultants must have exceptionally strong communication skills to be able to translate the interpretation of their findings into the language of the client. In the same way, they have to be able to elicit information from their clients that will ensure the efficacy of their data analyses. Industrial statisticians often function as internal consultants to the company they work for. This is particularly true in large companies where there can be a group of statisticians that serve as a shared central resource for the entire company.

The following alphabetical list is meant to provide an appreciation of the diversity of fields where statisticians are gainfully employed: Agriculture, Archaeology, Astronomy, Biology, Chemistry, Computer Science, Demography, Economics, Ecology, Education, Engineering, Epidemiology, Finance, Forestry, Genetics, Health Sciences, Insurance, Law, Manufacturing, Medicine, National Defense, Pharmacology, Physics, Psychology, Public Health, Safety, Sociology, Sports, Telecommunications, and Zoology. To be more specific, consider the following brief descriptions of work and employment of statisticians in the following fields:

Medicine

Florence Nightingale was not only a historic figure because of what she brought to the profession of nursing, but she was also a pioneering figure in the use of statistics. Statistical work in medicine involves designing studies

and analyzing their data to determine if new (or existing) drugs, medical procedures and medical devices are safe and effective. Statisticians find careers at pharmaceutical companies, medical research centers and governmental agencies concerned with drugs, public health and medicine.

Ecology

Research laboratories, commercial firms and government environmental agencies employ statisticians to evaluate the environmental impact of air, water and soil pollutants. Statisticians also work with government lawyers to analyze the impact (false positive or false negative) of proposed federal or state pollution tests and regulations.

Market Research

Statisticians analyze consumer demand for products and services, analyze the effectiveness of various types of advertising, and analyze the economic risk of satisfying consumer demand for products and services.

Manufacturing

The success of manufacturing industries such as aerospace, electronics, automobile, chemical or other product producing industries depends, at least in part, on the efficiency of production and the quality and reliability of their products. Statistical techniques and models are used for predicting inventory needs, improving production flow, quality control, reliability prediction and improvement, and development of product warranty plans. The Deming Prize, named after the prolific statistician W. Edwards Deming, was established in 1950 and is annually awarded to companies that make major advances in quality improvement. The Malcolm Baldridge National Quality Award, named after Malcolm Baldridge who served as the United States Secretary of Commerce under President Regan, was established in 1988 and is annually awarded to U.S. organizations for performance excellence.

Actuarial Sciences

Actuarial statisticians use Mathematics and Statistics to assess the risk of insurance and financial portfolios. Statistical methods are used, for example, to determine a wide variety of appropriate insurance premiums (e.g., homeowner, life, automobile, flood, etc.) and to manage investment and pension funds.

Safety

Statisticians are employed by many businesses and agencies to model safety concerns and to estimate and predict the probability of occurrence of these safety concerns. Nuclear power plants, national defense agencies and airlines are just a few of the businesses that statistically analyze safety risks.

Telecommunications

The reliability of voice and data networks is paramount to a telecommunication company's revenue and their brand name image. Statisticians work collaboratively with engineers to model alternative design architectures and choose the most cost-effective design that minimizes customer-perceived downtime. Statisticians working in telecommunication companies frequently shift into new technology areas to keep up with the vastly changing landscape of high-tech companies.

The authors have found that their careers in statistics involve work that is usually very interesting, often involves new ideas and learning experiences, and can definitely bring value to problem solving.

For more information on careers in statistics consult www.amstat.org or e-mail asainfo@amstat.org.

About the Authors

Dr. Daniel R. Jeske is a Professor and Chair, Department of Statistics, University of California – Riverside, CA, and is the first Director of the Statistical Consulting Collaboratory at UCR. He has published over 45 journal articles and over 35 refereed conference papers. Prior to his academic career, he was a Distinguished Member of Technical Staff and a Technical Manager at AT&T Bell Laboratories. Concurrent with that, he was a part-time Visiting Lecturer in the Department of Statistics at Rutgers University. Currently, he is an Associate Editor for The *American Statistician*.

Dr. Janet Myhre is President and Founder of Mathematical Analysis Research Corporation of Claremont, California. She is Professor Emeritus, Honorary Alumna, and Founder of the Reed Institute of Applied Statistics at Claremont McKenna College. She is a Fellow of the American Statistical Association and and has served as an Associate Editor of *Technometrics* and as Chair of the Committee on Careers in Statistics of the American Statistical Association.

Case-Control Studies

Alastair Scott, Chris Wild
Professors
The University of Auckland, Auckland, New Zealand

Introduction

The basic aim of a case-control study is to investigate the association between a disease (or some other condition of interest) and potential risk factors by drawing separate samples of "cases" (people with the disease, say) and "controls" (people at risk of developing the disease). Let Y denote a binary response variable which can take values $Y = 1$, corresponding to a case, or $Y = 0$, corresponding to a control, and let $\boldsymbol{x}$ be a vector of explanatory variables or covariates. Our aim is to fit a binary regression model to explain the probabilistic behavior of Y as a function of the observed values of the explanatory variables recorded in $\boldsymbol{x}$. We focus particularly on the logistic regression model (see ▶Logistic Regression),

$$\begin{aligned}\text{logit}\{\text{pr}(Y \mid \boldsymbol{x};\boldsymbol{\beta})\} &= \log\left\{\frac{\text{pr}(Y=1 \mid \boldsymbol{x};\boldsymbol{\beta})}{\text{pr}(Y=0 \mid \boldsymbol{x};\boldsymbol{\beta})}\right\} \\ &= \beta_0 + \boldsymbol{x}^T\boldsymbol{\beta}_1, \qquad (1)\end{aligned}$$

since this makes the analysis of case-control data particularly simple and is the model of choice in most applications.

In principle, the most straightforward way of obtaining data from which to build regression models for $\text{pr}(Y \mid \boldsymbol{x})$ would be to use a prospective sampling design. Here covariate information is ascertained for a cohort of individuals who are then tracked through time until the end of the study when whether they have contracted the disease ($Y = 1$) or not ($Y = 0$) is recorded. With prospective sampling designs, observation proceeds from covariates (explanatory variables) to response, corresponding to the logic underlying the modelling. With case-control sampling, the order is reversed, with data collection proceeding from response to covariates. The parameter $\boldsymbol{\beta}_1$ in Model (1) can still be estimated, however. Consider the simplest situation of a single binary covariate taking values $x = 0$ or $x = 1$. Using Bayes Theorem, Cornfield (1951) showed that the prospective odds ratio, $\frac{\text{pr}(Y=1|x=1)}{\text{pr}(Y=0|x=1)} / \frac{\text{pr}(Y=1|x=0)}{\text{pr}(Y=0|x=0)}$, can be expressed as $\frac{\text{pr}(x=1|Y=1)}{\text{pr}(x=0|Y=1)} / \frac{\text{pr}(x=1|Y=0)}{\text{pr}(x=0|Y=0)}$, which only involves quantities that can be estimated directly from case-control data. Cornfield also pointed out that the relative risk, $\text{pr}(Y = 1 \mid x = 1)/\text{pr}(Y = 1 \mid x = 0)$, which is usually of more interest, is approximated well by the odds ratio if the disease is rare. If the overall probability of a case can be estimated from other sources, then this can be combined with the relative risk to give estimates of the absolute risk of disease for exposed ($x = 1$) and non-exposed ($x = 0$) groups. All this extends immediately to general $\boldsymbol{\beta}_1$, all of whose components represent individual log odds ratios.

Types of Case-Control Studies

There are two broad types of case-control study, population-based and matched, corresponding to two different ways of controlling for confounding variables. In the simplest form of population-based sampling sampling, random samples are drawn independently from the case- and control-subpopulations of a real, finite target population or cohort. Covariate information, $\boldsymbol{x}$, is then ascertained for sampled individuals. Fitting logistic model (1) is particularly simple here. Following earlier work for discrete covariates, Prentice and Pyke (1979) showed that we can get valid inferences about $\boldsymbol{\beta}_1$ by running the case-control data through a standard logistic regression program designed for prospective data. The intercept β_0, which is needed if we want to estimate the absolute risk for given values of the covariates, is completely confounded with the relative sampling rates of cases and controls but can be recovered using additional information such as the finite population totals of cases and controls.

Prentice and Pyke extended this to stratified case-control sampling, where the target population is first split into strata on the basis of variables known for the whole population and separate case-control samples are drawn from each stratum. Again we get valid inferences about all the other coefficients by running the data through a prospective logistic regression program, **provided** that we introduce a separate intercept for each stratum into our model. Otherwise standard logistic programs need to be modified slightly to produce valid inferences (Scott andh Wild 1997).

In designing a population-based study, it is important to make sure that the controls really are drawn from the same population, using the same protocols, as the cases. Increasingly, controls are selected using modern sample survey techniques, involving multi-stage sampling and varying selection probabilities, to help ensure this. The modifications needed to handle these complications are surveyed in Scott and Wild (2009).

In a matched case-control study, each case is individually matched with one or more controls. This could be regarded as an limiting case of a stratified study with the

strata so finely defined that each stratum includes only a single case. If we introduce an extra intercept for each matched set, then we can no longer use a simple logistic program since the plethora of parameters will lead to inconsistent parameter estimates. Instead we need to carry out a conditional analysis. More specifically, suppose that there are M controls in the *jth* matched set and model (1) is replaced by $\text{logit}\{\text{pr}(Y \mid \boldsymbol{x};\boldsymbol{\beta})\} = \beta_{0j} + \boldsymbol{x}^T\boldsymbol{\beta}_1$ for these observations. Then the conditional probability that the covariates $\boldsymbol{x}_{j0}$ are those of the case and $(\boldsymbol{x}_{j1},\ldots,\boldsymbol{x}_{jM})$ are those of the M controls, given the set of $M+1$ covariates can be expressed in the form $exp\left(\boldsymbol{x}_{j0}^T\boldsymbol{\beta}_1\right) / \sum_{m=0}^{M+1} exp\left(\boldsymbol{x}_{jm}^T\boldsymbol{\beta}_1\right)$, which does not involve the intercept terms. Inferences about $\boldsymbol{\beta}_1$ can then be made from the conditional likelihood obtained when we combine these terms over all matched sets. With pair matching ($M = 1$), this likelihood is identical to a simple logistic regression on the difference between the paired covariates.

More sophisticated designs, including incidence density sampling, nested case-control studies and case-cohort studies, that can handle complications such as time-varying covariates and ►survival data are discussed in other chapters in this volume.

Discussion

Case-control sampling is a cost-reduction device. If we could afford to collect data on the whole finite population or cohort, then we would do so. There many practical difficulties that need to be overcome to run a successful case-control study; a good account of these is given in Breslow (2005). Despite this, the case-control study in its various forms is one of the most common designs in health research. In fact, Breslow and Day (1980) described such studies as "perhaps the dominant form of analytical research in epidemiology" and since that time the rate of appearance of papers reporting on case-control studies has gone up by a factor of more than 20. These designs are also used in other fields, sometimes under other names. In econometrics, for example, the descriptor "choice-based" is used (see Manski and McFadden (1981)).

There are several reasons for the popularity of case-control studies. The first is the simplicity of the logistic analysis outlined above. The other two reasons concern efficiency: time efficiency and statistical efficiency. The former comes from being able to use historical information immediately rather than having to follow individuals through time and then wait to observe an outcome as in a prospective study. The first chapter of Breslow and Day (1980) has a good discussion of the attendant risks. The gain in statistical efficiency can be huge. For example, suppose that we have a condition that affects only 1 individual in 20 on average and we wish to investigate the effect of an exposure that affects 50% of people. In this situation a case-control study with equal numbers of cases and controls has the same power for detecting a small increase in risk as a prospective study with approximately five times as many subjects. If the condition affects only one individual in 100 then the prospective study would need 25 times as many subjects!

About the Authors

Professor Scott is Past President of the New Zealand Statistical Society (1989–1990). He is of one of New Zealand's foremost mathematical scientists. He was founding head of the University of Auckland's Department of Statistics (and previously Head of the Department of Mathematics and Statistics). He is an elected member of the International Statistical Institute, and one of 12 honorary life members of the New Zealand Statistical Association. His 1981 paper with JNK Rao, published in the *Journal of American Statistical Association*, was selected as one of 19 landmark papers in the history of survey sampling for the 2001 centenary volume of the International Association of Survey Statisticians.

Professor Wild is, with Professor Scott, the only statistician in New Zealand that has been elected a Fellow of the American Statistical Association. He is a Past President of the International Association for Statistics Education (2003–2005). He is currently Editor of the *International Statistical Review*.

Categorical Data Analysis

Alan Agresti[1], Maria Kateri[2]
[1]Distinguished Professor Emeritus
University of Florida, Gainesville, FL, USA
[2]Associate Professor
University of Ioannina, Ionnina, Greece

Introduction

A categorical variable consists of a set of non-overlapping categories. Categorical data are counts for those categories. The measurement scale is *ordinal* if the categories exhibit a natural ordering, such as opinion variables with categories from "strongly disagree" to "strongly agree." The measurement scale is *nominal* if there is no ordering. The types of possible analysis depend on the measurement scale.

When the subjects measured are cross-classified on two or more categorical variables, the table of counts for the various combinations of categories is a *contingency table*. The information in a contingency table can be summarized and further analyzed through appropriate *measures of association and models*. A standard reference on association measures is Goodman and Kruskal (1979).

Most studies distinguish between one or more *response variables* and a set of *explanatory variables*. When the main focus is on the association and interaction structure among a set of response variables, such as whether two variables are conditionally independent given values for the other variables, *log-linear models* are useful. More commonly, research questions focus on effects of explanatory variables on a categorical response variable. *Logistic regression models* (see ▶Logistic Regression) are then of particular interest. For *binary* (success-failure) response variables, they describe the *logit,* which is $\log[P(Y=1)/P(Y=2)]$, using

$$\log[P(Y=1)/P(Y=2)] = \alpha + \beta_1 x_1 + \beta_2 x_2 + \cdots + \beta_p x_p$$

where Y is the binary response variable and $x_1, \ldots, x_p$ the set of the explanatory variables. For a nominal response Y with J categories, the model simultaneously describes

$$\log[P(Y=1)/P(Y=J)],$$
$$\log[P(Y=2)/P(Y=J)], \ldots, \log[P(Y=J-1)/P(Y=J)].$$

For ordinal responses, a popular model uses explanatory variables to predict a logit defined in terms of a cumulative probability (McCullagh 1980),

$$\log[P(Y \le j)/P(Y > j)],\ j = 1, 2, \ldots, J-1.$$

For categorical data, the binomial (see ▶Binomial Distribution) and multinomial distributions (see ▶Multinomial Distribution) play the central role that the normal does for quantitative data. Models for categorical data assuming the binomial or multinomial were unified with standard regression and ▶analysis of variance (*ANOVA*) models for quantitative data assuming normality through the introduction by Nelder and Wedderburn (1972) of the *generalized linear model* (*GLM*, see ▶Generalized Linear Models). This very wide class of models can incorporate data assumed to come from any of a variety of standard distributions (such as the normal, binomial, and Poisson). The GLM relates a function of the mean (such as the log or logit of the mean) to explanatory variables with a linear predictor.

Contingency Tables

Two categorical variables are *independent* if the probability of response in any particular category of one variable is the same for each category of the other variable. The most well-known result on two-way contingency tables is the test of the null hypothesis of independence, introduced by Karl Pearson in 1900. If X and Y are two categorical variables with I and J categories respectively, then their cross-classification leads to a $I \times J$ table of observed frequencies $\mathbf{n} = (n_{ij})$. Under this hypothesis, the expected cell frequencies equal $m_{ij} = n\pi_{i\cdot}\pi_{\cdot j}, i = 1, \ldots, I, j = 1, \ldots, J$, where n is the total sample size $\left(n = \sum_{i,j} n_{ij}\right)$ and $\pi_{i\cdot}(\pi_{\cdot j})$ is the ith row (jth column) marginal of the underlying probabilities matrix $\boldsymbol{\pi} = (\pi_{ij})$. Then the corresponding maximum likelihood (ML) estimates equal $\hat{m}_{ij} = np_{i\cdot}p_{\cdot j} = \frac{n_{i\cdot}n_{\cdot j}}{n}$, where p_{ij} denotes the sample proportion in cell (i,j). The hypothesis of independence is tested through Pearson's chi-squared statistic

$$\chi^2 = \frac{\sum_{i,j}(n_{ij} - \hat{m}_{ij})^2}{\hat{m}_{ij}}. \qquad (1)$$

The P-value is the right-tail probability above the observed χ^2 value. The distribution of χ^2 under the null hypothesis is approximated by a $\chi^2_{(I-1)(J-1)}$, provided that the individual expected cell frequencies are not too small. When a contingency table has ordered row or column categories (ordinal variables), specialized methods can take advantage of that ordering.

More generally, models can be formulated that are more complex than independence, and expected frequencies m_{ij} can be estimated under the constraint that the model holds. If $\hat{m}_{ij}$ are the corresponding maximum likelihood estimates, then, to test the hypothesis that the model holds, we can use the Pearson statistic (1) or the statistic that results from the standard statistical approach of

conducting a *likelihood-ratio test,* which has test statistic

$$G^2 = 2\sum_{i,j} n_{ij} \ln\left(\frac{n_{ij}}{\hat{m}_{ij}}\right). \quad (2)$$

Independence between the classification variables X and Y (i.e., $m_{ij} = n\pi_{i\cdot}\pi_{\cdot j}$, for all i and j) can be expressed in terms of a log-linear model as

$$\log(m_{ij}) = \lambda + \lambda_i^X + \lambda_j^Y, \quad i = 1, \ldots, I,\ j = 1, \ldots, J.$$

The more general model that allows association between the variables is

$$\log(m_{ij}) = \lambda + \lambda_i^X + \lambda_j^Y + \lambda_{ij}^{XY}, \quad i = 1, \ldots, I,\ j = 1, \ldots, J. \quad (3)$$

Log-linear models describe the way the categorical variables and their association influence the count in each cell of the contingency table. They can be considered as a discrete analogue of *ANOVA*. The two-factor interaction terms relate to odds ratios describing the association.

Associations can be modeled through simpler *association models*. The simplest such model, the *linear-by-linear association model,* is relevant when both classification variables are ordinal. It replaces the interaction term λ_{ij}^{XY} by the product $\phi\mu_i\nu_j$, where μ_i and ν_j are known scores assigned to the row and column categories respectively. This model is

$$\log(m_{ij}) = \lambda + \lambda_i^X + \lambda_j^Y + \phi\mu_i\nu_j, \quad i = 1, \ldots, I,\ j = 1, \ldots, J. \quad (4)$$

More general models treat one or both sets of scores as parameters.

The special case of square $I \times I$ contingency tables with the same categories for the rows and the columns occurs with matched-pairs data. For example, such tables occur in the study of *rater agreement* and in the analysis of social mobility. A condition of particular interest for such data is *marginal homogeneity,* that $\pi_{i\cdot} = \pi_{\cdot i}, i = 1, \ldots, I$. For the 2×2 case of binary matched pairs, the test comparing the margins using the chi-squared statistic $(n_{12} - n_{21})^2/(n_{12} + n_{21})$ is called *McNemar's test.*

The models for two-way tables extend to higher dimensions. The various models available vary in terms of the complexity of the association and interaction structure.

Inference and Software

Standard statistical packages, such as *SAS*, *R*, and *SPSS*, are well suited for analyzing categorical data, mainly using maximum likelihood for inference. For *SAS*, a variety of codes are presented and discussed in the Appendix of Agresti (2002), and see also Stokes et al. (2000). For *R*, see the on-line manual of Thompson (2008). Bayesian analysis of categorical data can be carried out through WinBUGS (http://wlww.mrc-bsu.cam.ac.uk/bugs/winbugs/contents.shtml).

The standard reference on log-linear models is Bishop et al. (1975). For logistic regression, Hosmer and Lemeshow (2000) is popular. A more comprehensive book dealing with categorical data analysis using various types of models and analyses is Agresti (2002), with Agresti (2010) focusing on ordinal data.

About the Author

Professor Agresti is recipient of the first Herman Callaert Leadership Award in Statistical Education and Dissemination, Hasselt University, Diepenbeek, Belgium (2004), and Statistician of the Year award, Chicago chapter of American Statistical Association (2002–2003). He received an honorary doctorate from De Montfort University in the U.K. in 1999. He has presented invited lectures and short courses for universities and companies in about 30 countries. Professor Agresti is author or coauthor of five textbooks, including the internationally respected text "*Categorical Data Analysis*." Professor Kateri won the Myrto Lefkopoulou award for her Ph.D. thesis in Greece and has since published extensively on methods for categorical data.

Causal Diagrams

Sander Greenland[1], Judea Pearl[2]
[1]Professor
University of California-Los Angeles, Los Angeles, CA, USA
[2]Professor, Director of Cognitive Systems Laboratory
University of California-Los Angeles, Los Angeles, CA, USA

From their inception, causal systems models (more commonly known as structural-equations models) have been accompanied by graphical representations or path diagrams that provide compact summaries of qualitative assumptions made by the models. These diagrams can be reinterpreted as probability models, enabling use of graph theory in probabilistic inference, and allowing easy deduction of independence conditions implied by the assumptions. They can also be used as a formal tool for causal inference, such as predicting the effects of external interventions. Given that the diagram is correct, one can see whether the causal effects of interest (target effects, or causal estimands) can be estimated from available data, or what additional observations are needed to validly estimate those effects. One can also see how to represent the effects as familiar standardized effect measures. The present article gives an overview of: (1) components of causal graph theory; (2) probability interpretations of graphical models; and (3) methodologic implications of the causal and probability structures encoded in the graph, such as sources of bias and the data needed for their control.

Introduction

From their inception in the early twentieth century, causal models (more commonly known as structural-equations models) were accompanied by graphical representations or path diagrams that provided compact summaries of qualitative assumptions made by the models. Figure 1 provides a graph that would correspond to any system of five equations encoding these assumptions:

1. independence of A and B
2. direct dependence of C on A and B
3. direct dependence of E on A and C
4. direct dependence of F on C and
5. direct dependence of D on B, C, and E

The interpretation of "direct dependence" was kept rather informal and usually conveyed by causal intuition, for example, that the entire influence of A on F is "mediated" by C.

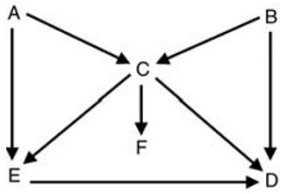
By the 1980s it was recognized that these diagrams could be reinterpreted formally as probability models, enabling use of graph theory in probabilistic inference, and allowing easy deduction of independence conditions implied by the assumptions (Pearl 1988). By the 1990s it was further recognized that these diagrams could also be used as tools for guiding causal and counterfactual inference (Pearl 1995, 2000; Pearl and Robins 1995; Spirtes et al. 2001) and for illustrating sources of bias and their remedy in empirical research (Greenland et al. 1999; Greenland 2000, 2003; Robins 2001; Greenland and Brumback 2002; Cole and Hernán 2002; Hernán et al. 2002; Jewell 2004; Pearl 2009; Glymour and Greenland 2008). Given that the graph is correct, one can see whether the causal effects of interest (target effects, or causal estimands) can be estimated from available data, or what additional observations are needed to validly estimate those effects. One can also see how to represent the effects as familiar standardized effect measures.

The present article gives an overview of: (1) components of causal graph theory; (2) probability interpretations of graphical models; and (3) methodologic implications of the causal and probability structures encoded in the graph, such as sources of bias and the data needed for their control. *See* ▶Causation and Causal Inference for discussion of definitions of causation and statistical models for causal inference.

Graphical Models and Causal Diagrams

Basics of Graph Theory

As befitting a well developed mathematical topic, graph theory has an extensive terminology that, once mastered, provides access to a number of elegant results which may be used to model any system of relations. The term *dependence* in a graph, usually represented by connectivity, may refer to mathematical, causal, or statistical dependencies. The connectives joining variables in the graph are called *arcs, edge,* or *links,* and the variables are also called *nodes* or *vertices*. Two variables connected by an arc are *adjacent* or *neighbors* and arcs that meet at a variable are also adjacent. If the arc is an arrow, the tail (starting) variable is the *parent* and the head (ending) variable is the *child*. In causal diagrams, an arrow represents a "direct effect" of the parent on the child, although this effect is direct only relative



Causal Diagrams. Fig. 1 $E \leftarrow C \rightarrow D$ is open, $E \rightarrow A \rightarrow C \leftarrow B \rightarrow D$ is closed

to a certain level of abstraction, in that the graph omits any variables that might mediate the effect.

A variable that has no parent (such as A and B in Fig. 1) is *exogenous* or *external*, or a *root* or *source* node, and is determined only by forces outside of the graph; otherwise it is *endogenous* or *internal*. A variable with no children (such as D in Fig. 1) is a *sink* or *terminal node*. The set of all parents of a variable X (all variables at the tail of an arrow pointing into X) is denoted $\text{pa}[X]$; in Fig. 1, $\text{pa}[D] = \{B, C, E\}$.

A *path* or *chain* is a sequence of adjacent arcs. A *directed path* is a path traced out entirely along arrows tail-to-head. If there is a directed path from X to Y, X is an *ancestor* of Y and Y is a *descendant* of X. In causal diagrams, directed paths represent causal pathways from the starting variable to the ending variable; a variable is thus often called a cause of its descendants and an effect of its ancestors. In a *directed* graph the only arcs are arrows, and in an *acyclic* graph there is no feedback loop (directed path from a variable back to itself). Therefore, a *directed acyclic graph* or DAG is a graph with only arrows for edges and no feedback loops (i.e., no variable is its own ancestor or its own descendant).

A variable *intercepts* a path if it is in the path (but not at the ends); similarly, a set of variables S intercepts a path if it contains any variable intercepting the path. Variables that intercept directed paths are *intermediates* or *mediators* on the pathway. A variable is a *collider* on the path if the path enters and leaves the variable via arrowheads (a term suggested by the collision of the arrows at the variable). Note that being a collider is relative to a path; for example in Fig. 1, C is a collider on the path $A \rightarrow C \leftarrow B \rightarrow D$ and a noncollider on the path $A \rightarrow C \rightarrow D$. Nonetheless, it is common to refer to a variable as a collider if it is a collider along any path (i.e., if it has more than one parent). A path is *open* or *unblocked* at noncolliders and *closed* or *blocked* at colliders; hence a path with no collider (like $E \leftarrow C \leftarrow B \rightarrow D$) is *open* or *active*, while a path with a collider (like $E \leftarrow A \rightarrow C \leftarrow B \rightarrow D$) is closed or inactive.

Some authors use a bidirectional arc (two-headed arrow, $\leftrightarrow$) to represent the assumption that two variables share ancestors that are not shown in the graph; $A \leftrightarrow B$ then means that there is an unspecified variable U with directed paths to both A and B (e.g., $A \leftarrow U \rightarrow B$).

Interpretations of Graphs

Depending on assumptions used in its construction, graphical relations may be given three distinct levels of interpretation: probabilistic, causal, and functional. We now briefly describe these levels, providing further details in later sections.

The probabilistic interpretation requires the weakest set of assumptions. It treats the diagram as a carrier of conditional independencies constraints on the joint distribution of the variables in the graph. To serve in this capacity, the parents $\text{pa}[X]$ of each variable X in the diagram are chosen so as to render X independent of all its nondescendants, given $\text{pa}[X]$. When this condition holds, we say that the the diagram is *compatible* with the joint distribution. In Fig. 1, for example, variable E is assumed to be independent of its nondescendants $\{B, D, F\}$ given its parents $\text{pa}[E] = \{A, C\}$. We will see that compatibility implies many additional independencies (e.g., E and F are independent given C) that could be read from the diagram by tracing its paths. In real-life problems, compatibility arises if each parent–child family $\{X, \text{pa}[X]\}$ represents a stochastic process by which nature determines the probability of the child X as a function of the parents $\text{pa}[X]$, independently of values previously assigned to variables other than the parents.

To use diagrams for causal inference, we must assume that the direction of the arrows correspond to the structure of the causal processes generating the data. More specifically, the graph becomes a *causal diagram* if it encodes the assumption that for each parent–child family, the conditional probability $\Pr(x|\text{pa}[X])$ would remain the same regardless of whether interventions take place on variables not involving $\{X, \text{pa}[X]\}$, even if they are ancestors or descendants of X. In Fig. 1, for example, the conditional probability $P(C|A, B)$ is assumed to remain invariant under manipulation of the consequences of C, i.e., E, F or D. A causal DAG represents a complete causal structure, in that all sources of causal dependence are explained by causal links; in particular, it is assumed that all common (shared) causes of variables in the graph are also in the graph, so that all exogenous variables (root nodes) are causally independent (although they may be unobserved).

If we assume further that the arrows represent functional relationships, namely processes by which nature assigns a definite value to each internal node, the diagram can then be used to process counterfactual information and display independencies among potential outcomes

(including counterfactual variables) (Pearl 1995, Chap. 7). We will describe such *structural diagrams* and potential outcomes below.

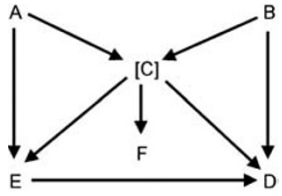
Control: Manipulation Versus Conditioning

The word "control" is used throughout science, but with a variety of meanings that are important to distinguish. In experimental research, to control a variable C usually means to manipulate or set its value. In observational studies, however, to control C (or more precisely, to control for C) more often means to condition on C, usually by stratifying on C or by entering C in a regression model. The two processes are very different physically and have very different representations and implications (Pearl 1995; Greenland et al. 1999).

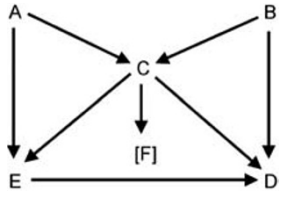
If a variable X is influenced by a researcher, a realistic causal diagram would need an ancestor R of X to represent this influence. In the classical experimental case in which the researcher alone determines X, R and X would be identical. In human trials, however, R more often represents just an *intention* to treat (with the assigned level of X), leaving X to be influenced by other factors that affect compliance with the assigned treatment R. In either case, R might be affected by other variables in the graph. For example, if the researcher uses age to determine assignments (an age-biased allocation), age would be a parent of R. Ordinarily however R would be exogenous, as when R represents a randomized allocation.

In contrast, by definition in an observational study there is no such variable R representing the researcher's influence on X. Conditioning is often used as a substitute for experimental control, in the hopes that with sufficient conditioning, X will be independent of uncontrolled influences. Conditioning on a variable C closes open paths that pass through C. However, if C is a collider, conditioning on C opens paths that were blocked by C or by an ancestral collider A. In particular, conditioning on a variable may open a path even if it is not on the path, as with F in Figs. 1 and 3.

To illustrate conditioning in a graph, we will redraw the graph to surround conditioned variables with square brackets (conditioned variables are often circled instead). We may now graphically determine the status of paths after conditioning by regarding the path open at colliders that are bracketed or have bracketed descendants, open at unbracketed noncolliders, and closed elsewhere. Figure 2 shows Fig. 1 after conditioning on C, from which we see that the $E-D$ paths $E \leftarrow C \leftarrow B \rightarrow D$ and $E \leftarrow A \rightarrow C \rightarrow D$ have been blocked, but the path $E \leftarrow A \rightarrow C \leftarrow B \rightarrow D$ has been opened. Were we to condition on F but not C, no open path would be blocked, but the path $E \leftarrow A \rightarrow C \leftarrow B \rightarrow D$ would again be opened.



Causal Diagrams. Fig. 2 Conditional on C, $E \leftarrow C \rightarrow D$ is closed but $E \rightarrow A \rightarrow C \leftarrow B \rightarrow D$ is open



Causal Diagrams. Fig. 3 Conditional on F, $E \leftarrow C \rightarrow D$ and $E \rightarrow A \rightarrow C \leftarrow B \rightarrow D$ are both open

The opening of paths at conditioned colliders reflect the fact that we should expect two unconditionally independent causes A and B become dependent if we condition on their consequences, which in Fig. 1 are C and F. To illustrate, suppose A and B are binary indicators (i.e., equal to 1 or 0), marginally independent, and $C = A + B$. Then among persons with $C = 1$, some will have $A = 1$, $B = 0$ and some will have $A = 0$, $B = 1$ (because other combinations produce $C \neq 1$). Thus when $C = 1$, A and B will exhibit perfect negative dependence: $A = 1 - B$ for all persons with $C = 1$.

The distinction between manipulation and conditioning is brought to the fore when considering the notion of "holding a variable constant." Conditioning on a variable X means that we choose to narrow the scope of discussion to those situations only where X attains a given value, regardless of how that value is attained. Manipulating X means that we physically intervene and set X to a given value, say $X = x$. The difference can be profound. For example, in cancer screening, conditioning on the absence of lighters and matches in the home lowers dramatically the probability of finding lung cancer, because restricting our attention to those who do not have these tools for smoking is tantamount to examining nonsmokers. In contrast, removing lighters and matches from people's homes during the screening will not lower the probability of finding lung cancer, since any lung cancers present will be unaffected by this act. Likewise, conditional on a low barometer reading we will have a lower probability of rain than

unconditionally, but setting the barometer to a low reading (e.g., by pushing its needle down) will have no effect on the weather.

Graphical Representation of Manipulation

One way of representing manipulation in the graph is to simulate the act of setting X to a constant, or the immediate implications of that act. If prior to intervention the probability of X is influenced by its parents via $P(x|\text{pa}[X])$, such influence no longer exists under an intervention that is made without reference to the parents or other variables. In that case, physically setting X at x dislodges X from the influence of its parents and subjects it to a new influence that keeps its value at $X = x$ regardless of the values taken by other variables. This can be represented by cutting out all arrows pointing to X and thus creating a new graph, in which X is an exogenous (root) node, while keeping the rest of the graph (with its associated conditional probabilities) intact. For example, setting C to a constant in Fig. 1, will render E and D independent, because all $E - D$ paths will be blocked by such intervention, including $E \leftarrow A \rightarrow C \leftarrow B \rightarrow D$, even though the latter path would be opened by conditioning on C. On the other hand, manipulating F but not C would leave all $E - D$ paths intact, and the $E - D$ association will therefore remain unaltered.

Assuming the graph is correct, graphical representation of interventions by deleting arrows enables us to compute post-intervention distributions from pre-intervention distributions (Pearl 1995, 2001, 2009; Spirtes et al. 2001; Lauritzen 2001) for a wide variety of interventions, including those that have side effects or that are conditioned upon other variables in the graph (Pearl 1995, pp. 105, 113). Nonetheless, "holding X constant" does not always correspond to a physically feasible manipulation, not even conceptually. Consider systolic blood pressure (SBP) as a cause of stroke (Y). It is easy to "hold SBP constant" in the sense of conditioning on each of its observed values. But what does it mean to "hold SBP constant" in the manipulative sense? There is only one condition under which SBP is constant: Death, when it stays put at zero. Otherwise, SBP is fluctuating constantly in some strictly positive range in response to posture, activity, and so on. Furthermore, no one knows how to influence SBP except by interventions R which have side effects on stroke (directed paths from R to Y that do not pass through SBP). Yet these side effects vary dramatically with intervention (e.g., there are vast differences between exercise versus medication side effects).

On the other hand, consider the problem of estimating the causal effect of SBP on the rate of blood flow in a given blood vessel. At this physiological level of discussion we can talk about the effect on blood flow of "changing SBP from level s to level s'," without specifying any mechanism for executing that change. We know from basic physics that the blood flow in a vessel depends on blood pressure, vessel diameter, blood viscosity, and so on; and we can ask what the blood flow would be if the blood pressure were to change from s to s' while the other factors remained at their ambient values. Comparing the results from conditioning on SBP $= s$ versus conditioning on SBP $= s'$ would not give us the desired answer because these conditioning events would entail different distributions for the causes (ancestors) of SBP, some of which might also affect those determinants of flow which we wish held constant when comparing.

We may thus conclude that there are contexts in which it makes no practical sense to speak of "holding X constant" via manipulation. In these contexts, manipulation of a given variable X can only be represented realistically by an additional node R representing an actual intervention, which may have side effects other than those intended or desired. On the other hand, such an R node will be redundant if X itself is amenable to direct manipulation. For such an X, manipulation can be represented by removing the arrows ending in X which correspond to effects overridden by the manipulation (Pearl 1995, 2000, 2009; Spirtes et al. 2001; Lauritzen 2001). When X is completely randomized or held constant physically, this corresponds to removing all arrows into X.

The phrase "holding X constant" may also be meaningful when X is not directly manipulable. In these cases, we may still be able to estimate a causal effect of X if we can find an instrumental variable Z (a variable that is associated with X but not with any uncontrolled confounding variable U, and Z has no effect on Y except through X). Although the operational meaning of these effects is not immediately apparent when direct manipulation of X free of side effects is not conceivable, estimation of these effects can help judge proposed interventions that affect Y via effects on X.

Separation

The intuition of closing and opening paths by conditioning is captured by the concept of "separation" which will be defined next. We say that a path is *blocked* by a set S if the path contains either an arrow-emitting node that is in S, or a collider that is outside S and has no descendant in S.

Two variables (or sets of variables) in the graph are *d-separated* (or just separated) by a set S if, after conditioning on S, there is no open path between them. Thus S d-separates X from Y if S blocks all paths from X to Y. In Fig. 1, $\{A, C\}$ d-separates E from B, but $\{C\}$ does

not (because conditioning on C alone results in Fig. 2, in which E and B are connected via the open path A). In a causal DAG, pa$[X]$ d-separates X from every variable that is not affected by X (i.e., not a descendant of X). This feature of DAGs is sometimes called the "Markov condition," expressed by saying the parents of a variable "screen off" the variable from everything but its effects. Thus in Fig. 1 pa$[E] = \{A, C\}$, which d-separates E from B but not from D.

In a probability graph, d-separation of X and Y by S implies that X and Y are independent given S in any distribution compatible with graph. In a causal diagram, d-separation of X and Y by S implies additionally that manipulation of X will not alter the distribution of Y if the variables in S are held constant physically (assuming this can be done). More generally, the distribution of Y will remain unaltered by manipulation of X if we can hold constant physically a set S that intercepts all directed paths from X to Y, even if S does not d-separate X and Y. This is so because only descendants of X can be affected by manipulation of X. In sharp contrast, conditioning on X may change the probabilities of X's ancestors; hence the stronger condition of d-separation by S is required to insure that conditioning on X does not alter the distribution of Y given S.

Statistical Interpretations and Applications

Earlier we defined the notion of compatibility between a joint probability distribution for the variables in a graph and the graph itself. It can be shown that compatibility is logically equivalent to requiring that two sets of variables are independent given S whenever S separates them in the graph. Moreover these conditional independencies constitute the *only* testable implications of a causal model specified by the diagram (Pearl 1988, p. 120). Thus, given compatibility, two sets of variables will be independent in the distribution if there is no open path between them in the graph.

Many special results follow for distributions compatible with a DAG. For example, if in a DAG, X is not an ancestor of any variable in a set T, then T and X will be independent given pa$[X]$. A distribution compatible with a DAG thus can be reduced to a product of factors $\Pr(x|\text{pa}[X])$, with one factor for each variable X in the DAG; this is sometimes called the "Markov factorization" for the DAG. When X is a treatment, this condition implies the probability of treatment is fully determined by the parents of X, pa$[X]$. Algorithms are available for constructing DAGs that are compatible with a given distribution (Pearl 1988, pp. 119–121).

Some of the most important constraints imposed by a graphical model on a compatible distribution correspond to the independencies implied by absence of open paths; e.g., absence of an open path from A to B in Fig. 1 constrains A and B to be marginally independent (i.e., independent if no stratification is done). Nonetheless, the converse does not hold; i.e., presence of an open path allows but does not imply dependency. Independence may arise through cancellation of dependencies; as a consequence even adjacent variables may be marginally independent; e.g., in Fig. 1, A and E could be marginally independent if the dependencies through paths $A \rightarrow E$ and $A \rightarrow C \rightarrow E$ cancelled each other. The assumption of faithfulness, discussed below, is designed to exclude such possibilities.

Bias and Confounding

Usually, the usage of terms like "bias," "confounding" and related concepts refer to dependencies that reflect more than just the effect under study. To capture these notions in a causal graph, we say that an open path between X and Y is a *biasing path* if it is not a directed path. The association of X with Y is then *unbiased* for the effect of X on Y if the only open paths from X to Y are the directed paths. Similarly, the dependence of Y on X is *unbiased given* S if, after conditioning on S, the open paths between X and Y are exactly (only and all) the directed paths in the starting graph. In such a case we say S is sufficient to block bias in the $X - Y$ dependence, and is minimally sufficient if no proper subset of S is sufficient.

Informally, confounding is a source of bias arising from causes of Y that are associated with but not affected by X (*see* ►Confounding). Thus we say an open nondirected path from X to Y is a *confounding path* if it ends with an arrow into Y. Variables that intercept confounding paths between X and Y are *confounders*. If a confounding path is present, we say *confounding* is present and that the dependence of Y on X is *confounded*. If no confounding path is present we say the dependence is *unconfounded*, in which case the only open paths from X to Y through a parent of Y are directed paths. Similarly, the dependence of Y on X is *unconfounded given* S if, after conditioning on S, the only open paths between X and Y through a parent of Y are directed paths.

An unconfounded dependency may still be biased due to nondirected open paths that do not end in an arrow into Y. These paths can be created when one conditions on a descendant of both X and Y, or a descendant of a variable intercepting a directed path from X to Y (Pearl 2000, p. 339). The resulting bias is called *Berksonian bias*, after its discoverer Joseph Berkson (Rothman et al. 2008). Most epidemiologists call this type of bias "selection bias" (Rothman et al. 2008) while computer scientists refer to

it as "explaining away" (Pearl 1988). Nonetheless, some writers (especially in econometrics) use "selection bias" to refer to confounding, while others call any bias created by conditioning "selection bias".

Consider a set of variables S that contains no effect (descendant) of X or Y. S is *sufficient* to block confounding if the dependence of Y on X is unconfounded given S. "No confounding" thus corresponds to sufficiency of the empty set. A sufficient S is called *minimally sufficient* to block confounding if no proper subset of S is sufficient. The initial exclusion from S of descendants of X or Y in these definitions arises first, because conditioning on X-descendants can easily block directed (causal) paths that are part of the effect of interest, and second, because conditioning on X or Y descendants can unblock paths that are not part of the $X - Y$ effect, and thus create new bias.

These considerations lead to a graphical criterion called the *back-door criterion* which identifies sets S that are sufficient to block bias in the $X - Y$ dependence (Pearl 1995, 2000). A *back-door path* from X to Y is a path that begins with a parent of X (i.e., leaves X from a "back door") and ends at Y. A set S then satisfies the back-door criterion with respect to X and Y if S contains no descendant of X and there are no open back-door paths from X to Y after conditioning on S.

In a unconditional DAG, the following properties hold (Pearl 1995, 2000; Spirtes et al. 2001; Glymour and Greenland 2008):

1. All biasing paths are back-door paths.
2. The dependence of Y on X is unbiased whenever there are no open back-door paths from X to Y.
3. If X is exogenous, the dependence of any Y on X is unbiased.
4. All confounders are ancestors of either x or of y.
5. A back-door path is open if and only if it contains a common ancestor of X and Y.
6. If S satisfies the back-door criterion, then S is sufficient to block $X - Y$ confounding.

These conditions do not extend to conditional DAGs like Fig. 2. Also, although pa$[X]$ always satisfies the back-door criterion and hence is sufficient in a DAG, it may be far from minimal sufficient. For example, there is no confounding and hence no need for conditioning whenever X separates pa$[X]$ from Y (i.e., whenever the only open paths from pa$[X]$ to Y are through X).

As a final caution, we note that the biases dealt with by the above concepts are only confounding and selection biases. To describe biases due to measurement error and model-form misspecification, further nodes representing mismeasured or misspecifed variables must be introduced (Glymour and Greenland 2008).

Estimation of Causal Effects

Suppose now we are interested in the effect of X on Y in a causal DAG, and we assume a probability model compatible with the DAG. Then, given a sufficient set S, the only source of association between X and Y within strata of S will be the directed paths from X to Y. Hence the *net effect* of $X = x_1$ vs. $X = x_0$ on Y when $S = s$ is defined as $\Pr(y|x_1, s) - \Pr(y|x_0, s)$, the difference in risks of $Y = y$ at $X = x_1$ and $X = x_0$. Alternatively one may use another effect measure such as the risk ratio $\Pr(y|x_1, s)/\Pr(y|x_0, s)$. A *standardized effect* is a difference or ratio of weighted averages of these stratum-specific $\Pr(y|x, s)$ over S, using a common weighting distribution. The latter definition can be generalized to include intermediate variables in S by allowing the weighting distribution to causally depend on X. Furthermore, given a set Z of intermediates along all directed paths from X to Y and identification of the $X - Z$ and $Z - Y$ effects, one can produce formulas for the $X - Y$ effect as a function of the $X - Z$ and $Z - Y$ effects ("front-door adjustment" (Pearl 1995, 2000)).

The above form of standardized effect is identical to the forms derived under other types of causal models, such as potential-outcome models (*see* ▶Causation and Causal Inference). In those models, the outcome Y of each unit is replaced by a vector of outcomes Y containing components Y_x, where Y_x represents the outcome when $X = x$ is the treatment given. When S is sufficient, some authors (Pearl 2000) go so far as to identify the $\Pr(y|x, s)$ with the distribution of potential outcomes Y_x given S, thereby creating a *structural model* for the potential outcomes. If the graph is based on functional rather than probabilistic relationships between parents and children, this identification can also model unit-based counterfactuals $Y_x(u)$ for any pair (X, Y), where u is a unit index or a vector of exogeneous variables characterizing the units.

There have been objections to this identification on the grounds that not all variables in the graph can be manipulated, and that potential-outcome models do not apply to nonmanipulable variables. The objection loses force when X is an intervention variable, however. In that case, sufficiency of a set S implies that the marginal potential-outcome distribution $\Pr(Y_x = y)$ equals $\sum_s \Pr(y|x, s)\Pr(s)$, which is the risk of $Y = y$ given $X = x$ standardized to the S distribution.

In fact, sufficiency of S implies the stronger condition of *strong ignorability* given S, which says that X and the vector Y of potential outcomes are independent given S. In particular, strong ignorability given S follows if S

satisfies the back-door criterion, or if X is randomized given S. Nonetheless, for the equation $\Pr(Y_x = y) = \sum_s \Pr(y|x,s)\Pr(s)$ it suffices that X be independent of each component potential outcome Y_x given S, a condition sometimes called weak ignorability given S.

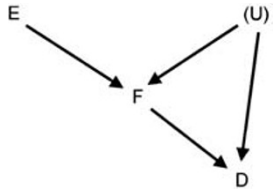
Identification of Effects and Biases

To check sufficiency and identify minimally sufficient sets of variables given a graph of the causal structure, one need only see whether the open paths from X to Y after conditioning are exactly the directed paths from X to Y in the starting graph. Mental effort may then be shifted to evaluating the reasonableness of the causal independencies encoded by the graph, some of which are reflected in conditional independence relations. This property of graphical analysis facilitates the articulation of necessary background knowledge for estimating effects, and eases teaching of algebraically difficult identification conditions.

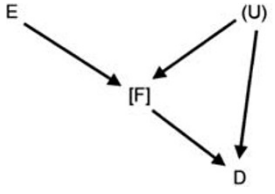
As an example, spurious sample associations may arise if each variable affects selection into the study, even if those selection effects are independent. This phenomenon is a special case of the collider-stratification effect illustrated earlier. Its presence is easily seen by starting with a DAG that includes a selection indicator $F = 1$ for those selected, 0 otherwise, as well as the study variables, then noting that we are always forced to examine associations within the $F = 1$ stratum (i.e., by definition, our observations stratify on selection). Thus, if selection (F) is affected by multiple causal pathways, we should expect selection to create or alter associations among the variables.

Figure 4 displays a situation common in randomized trials, in which the net effect of E on D is unconfounded, despite the presence of an uncontrolled cause U of D. Unfortunately, a common practice in health and social sciences is to stratify on (or otherwise adjust for) an intermediate variable F between a cause E and effect D, and then claim that the estimated (F-residual) association represents that portion of the effect of E on D not mediated through F. In Fig. 4 this would be a claim that, upon stratifying on the collider F, the $E - D$ association represents the direct effect of E on D. Figure 5 however shows the graph conditional on F, in which we see that there is now an open path from E to D through U, and hence the residual $E - D$ association is confounded for the direct effect of E on D.

The $E - D$ confounding by U in Fig. 5 can be seen as arising from the confounding of the $F - D$ association by U in Fig. 4. In a similar fashion, conditioning on C in Fig. 1 opens the confounding path through A, C, and B as seen in Fig. 2; this path can be seen as arising from the confounding of the $C - E$ association by A and the $C - D$ association by B in Fig. 1. In both examples, further stratification on either A or B blocks the created path and thus removes the new confounding.



Causal Diagrams. Fig. 4 $E \to F \to D$ is open, $E \to F \leftarrow U \to D$ is closed



Causal Diagrams. Fig. 5 Conditional on F, $E \to F \to D$ is closed but $E \to F \leftarrow U \to D$ is open

Bias from conditioning on a collider or its descendant has been called "collider bias" (Greenland 2003; Glymour and Greenland 2008). Starting from a DAG, there are two distinct forms of this bias: Confounding induced in the conditional graph (Figs. 2, 3, and 5), and Berksonian bias from conditioning on an effect of X and Y. Both biases can in principle be removed by further conditioning on certain variables along the biasing paths from X to Y in the conditional graph. Nonetheless, the starting DAG will always display ancestors of X or Y that, if known, could be used remove confounding; in contrast, no variable need appear or even exist that could be used to remove Berksonian bias.

Figure 4 also provides a schematic for estimating the $F - D$ effect, as in randomized trials in which E represents assignment to or encouragement toward treatment F. In this case E acts as an *instrumental variable* (or instrument), a variable associated with F such that every open path from E to D includes an arrow pointing into F (Pearl 2000; Greenland 2000; Glymour and Greenland 2008). Although the $F - D$ effect is not generally estimable, using the instrument E one can put bounds on confounding of the $F - D$ association, or use additional assumptions that render the effect of F on D estimable.

Questions of Discovery

While deriving statistical implications of graphical models is uncontroversial, algorithms that claim to discover causal (graphical) structures from observational data have been

subject to strong criticism (Freedman and Humphreys 1999; Robins and Wasserman 1999). A key assumption in certain "discovery" algorithms is a converse of compatibility called *faithfulness* Spirtes et al. 2001. A compatible distribution is *faithful* to the graph (or *stable* Pearl (2000)) if for all X, Y, and S, X and Y are independent given S **only** when S separates X and Y (i.e., the distribution contains no independencies other than those implied by graphical separation). Faithfulness implies that minimal sufficient sets in the graph will also be minimal for consistent estimation of effects. Nonetheless, there are real examples of near cancellation (e.g., when confounding obscures a real effect), which make faithfulness questionable as a routine assumption. Fortunately, faithfulness is not needed for the uses of graphical models discussed here.

Whether or not one assumes faithfulness, the generality of graphical models is purchased with limitations on their informativeness. Causal diagrams show whether the effects can be estimated from the given information, and can be extended to indicate effect direction when that is monotone VanderWeele and Robins 2010;. Nonetheless, the nonparametric nature of the graphs implies that parametric concepts like effect-measure modification (heterogeneity of arbitrary effect measures) cannot be displayed by the basic graphical theory. Similarly, the graphs may imply that several distinct conditionings are minimal sufficient (e.g., both $\{A, C\}$ and $\{B, C\}$ are sufficient for the *ED* effect in Fig. 1), but offer no further guidance on which to use. Open paths may suggest the presence of an association, but that association may be negligible even if nonzero. Because association transmitted by an open path may become attenuated as the length of the path increases, there is often good reason to expect certain phenomena (such as the conditional $E - D$ confounding shown in Figs. 2, 3 and 5) to be small in practical terms.

Further Readings

Full technical details of causal diagrams and their relation to causal inference can be found in the books by Pearl (2000) and Spirtes et al. (2001). A compact survey is given in Pearl (2009). Less technical reviews geared toward health scientists include Greenland et al. (2002), Greenland and Brumback (2008), and Glymour and Greenland (1999).

About the Authors

For Dr. Greenland's biography *see* the entry ►Confounding and Confounder Control.

Dr. Pearl is Professor of Computer Science at the University of California in Los Angeles, and Director of UCLA's Cognitive Systems Laboratory. He is one of the pioneers of Bayesian networks and the probabilistic approach to artificial intelligence. He is a member National Academy of Engineering (1995) and Corresponding Member, Spanish Academy of Engineering (2002). Professor Pearl was awarded the Lakatos Award, London School of Economics and Political Science for "an outstanding contribution to the philosophy of science" (2001); the ACM Allen Newell Award for "groundbreaking contributions that have changed the scientific world beyond computer science and engineering. Dr. Pearl made seminal contributions to the field of artificial intelligence that extend to philosophy, psychology, medicine, statistics, econometrics, epidemiology and social science."; the Benjamin Franklin Medal in Computers and Cognitive Science for "creating the first general algorithms for computing and reasoning with uncertain evidence, allowing computers to uncover associations and causal connections hidden within millions of observations. His work has had a profound impact on artificial intelligence and statistics, and on the application of these fields to a wide range of problems in science and engineering" (2008). He has written three fundamental books in artificial intelligence: *Heuristics: Intelligent Search Strategies for Computer Problem Solving* (Addison-Wesley, 1984), *Probabilistic Reasoning in Intelligent Systems: Networks of Plausible Inference* (Morgan-Kaufmann, 1988) and *Causality: Models, Reasoning, and Inference* (Cambridge University Press, 2000). Profeshhhhsor Pearl holds two Honorary Doctorates.

Causation and Causal Inference

Sander Greenland
Professor
University of California-Los Angeles, Los Angeles, CA, USA

In the health sciences, definitions of cause and effect have not been tightly bound with methods for studying causation. Indeed,many approaches to causal inference require no definition, leaving users to imagine causality however they prefer. As Sir Austin Bradford Hill said in his famous article on causation: "I have no wish…to embark upon a philosophical discussion of the meaning of 'causation'" (Hill 1965). Without a formal definition of causation, an association is distinguished as causal only by having been identified as such based on external and largely subject-matter considerations, such as those Hill put forth.

Nonetheless, beneath most treatments of causation in the health sciences, one may discern a class of definitions built around the ideas of counterfactuals or potential outcomes. These ideas have a very long history and form the foundation of most current statistical methods for causal inference. Thus, the present article will begin with these definitions and the methods they entail. It will then turn methods that explicitly presume no definition of causation but rather begin with an idea of what a causal association should look like (perhaps derived from subject-matter judgments, including consideration of possible counterfactuals), and employ statistical methods to estimate those associations.

Counterfactuals and Potential Outcomes

Skeptical that induction in general and causal inference in particular could be given a sound logical basis, David Hume nonetheless captured the foundation of the potential-outcome approach when he wrote

> We may define a cause to be an object, followed by another, … where, if the first object had not been, the second had never existed.
>
> (Hume 1748, p. 115)

A key aspect of this view of causation is its *counterfactual* element: It refers to how a certain outcome event (the "second object," or effect) would not have occurred if, *contrary to fact*, an earlier event (the "first object," or cause) had not occurred. In this regard, it is no different from conventional statistics, which refers to samples that might have occurred, but did not. This counterfactual view of causation was adopted by numerous philosophers and scientists after Hume (e.g., Mill 1843; Fisher 1918; Cox 1958; Simon and Rescher 1966; MacMahon and Pugh 1967; Stalnaker 1968; Lewis 1973).

The development of this view into a statistical theory with methods for causal inference is recounted by Rubin (1990), Greenland et al. (1999), Greenland (2004), and Pearl (2009). The earliest such theories were developed in the 1920s by Fisher, Neyman, and others for the analysis of randomized experiments and are today widely recognized under the heading of *potential-outcome models* of causation (also known in engineering as *destructive-testing* models). Suppose we wish to study the effect of an intervention variable X on a subsequent outcome variable Y defined on an observational unit or a population; for example, X could be the daily dose regimen for a drug in a clinical trial, and Y could be survival time. Given X has potential values $x_1, \ldots, x_J$ (e.g., drug doses), we suppose that there is a list of *potential outcomes* $\mathbf{y} = (y(x_1), \ldots, y(x_J))'$ such that if $X = x_j$ then $Y = y(x_j)$. The list $\mathbf{y}$ thus exhibits

the correspondence between treatments, interventions, or actions (the X values) and outcomes or responses (the Y values) for the unit, and so is sometimes called a *response schedule* (Berk 2004). A simpler and common notation has $\mathbf{y} = (y_1, \ldots, y_J)'$, with Y_j denoting the random variable "outcome when treated with $X = x_j$."

Under this model, assignment of a unit to a treatment level x_j is a choice of which potential outcome $y(x_j)$ from the list $\mathbf{y}$ to attempt to observe. It is ordinarily assumed that the assignments made for other units do not affect the outcomes of another unit, although there are extensions of the model to include between-unit interactions, as in contagious outcomes (Halloran and Struchiner 1995). Regardless of the X assignment, the remaining potential outcomes are treated as existing pre-treatment covariates on which data are missing (Rubin 1978, 1991). Because at most one of the J potential outcomes is observed per unit, the remaining potential outcomes can be viewed as missing data, and causal inference can thus be seen as a special case of inference with missing data.

To say that intervention x_i causally affects Y relative to intervention x_j means that $y(x_i) \neq y(x_j)$, i.e., X "matters" for Y for the unit. The *sharp* (or strong) null hypothesis is that $y(x)$ is constant over x within units. This hypothesis states that changing X would not affect the Y of any unit, i.e., $y(x_i) = y(x_j)$ for every unit and every x_i and x_j; it forms the basis of exact ►permutation tests such as ►Fisher's exact test (Greenland 1991). The effect of intervention x_i relative to x_j on a unit may be measured by the difference in potential outcomes $y(x_i) - y(x_j)$. If the outcome is strictly positive (like life expectancy or mortality risk), it could instead be measured by the ratio $y(x_i)/y(x_j)$.

Because we never observe two potential outcomes on a unit, we can only estimate population averages of the potential outcomes. We do this by observing average outcomes in differently exposed groups and substituting those observations for the average potential outcomes in the group of interest – a perilous process whenever the observed exposure groups are atypical of the population of interest with respect to other risk factors for the outcome (Maldonado and Greenland 2002) (see Confounding and Confounder Control).

A more subtle problem is that only for difference measures will the population effect (the difference of average potential outcomes) equal the population average effect (the average difference of potential outcomes). Hence the average of the differences $y(x_i) - y(x_j)$ in the population is often called the *average causal effect* (ACE) (Angrist et al. 1996). For some popular measures of effect, such as rate ratios and odds ratios, the population effect may not even equal any average of individual effects (Greenland 1987, 1996; Greenland et al. 1999).

The theory extends to probabilistic outcomes by replacing the $y(x_j)$ by probability functions $p_j(y)$ (Greenland 1987; Robins 1988; Greenland et al. 1999). The theory also extends to continuous X by allowing the potential-outcome list $\mathbf{y}$ to contain the potential outcome $y(x)$ or $p_x(y)$ for every possible value x of X. Both extensions are embodied in Pearl's notation for intervention effects, in which $p_x(y)$ becomes $P(Y = y|\text{set}[X = x])$ or $P(Y = y|\text{do}[X = x])$ (Pearl 1995, 2009). Finally, the theory extends to complex longitudinal data structures by allowing the treatments to be different event histories or processes (Robins 1987, 1997).

From Randomized to Observational Inference

Potential outcomes were developed part of a design-based strategy for causal inference in which ►randomization provided the foundation for inference. Indeed, before the 1980s, the model was often referred to as "the randomization model," even though the causal concepts within it do not hinge on randomization (e.g., Wilk 1955; Copas 1973). It thus seems that the early strong linkage of potential outcomes to randomized designs deflected consideration of the model for observational research. In the 1960s, however, a number of philosophers used counterfactuals to build general foundations for causal analysis (e.g., Simon and Rescher 1966; Stalnaker 1968; Lewis 1973). Similar informal ideas can be found among epidemiologists of the era (e.g., MacMahon and Pugh 1967), and conceptual models subsuming counterfactuals began to appear shortly thereafter (e.g., Miettinen 1972; Rothman 1976; Hamilton 1979).

The didactic value of these models was quickly apparent in the clarification they brought to ideas of strength of effect, synergy, and antagonism (MacMahon and Pugh 1967; Rothman 1976; see also Rothman et al. 2008, Chaps. 2 and 5). Most importantly, the models make clear distinctions between causal and statistical relations: Causal relations refer to relations of treatments to potential outcomes *within* treated units, whereas statistical relations refer associations of treatments with actual outcomes *across* units (Rothman et al. 2008, Chap. 4). Consequently, the models have aided in distinguishing confounding from collapsibility (Greenland and Robins 1986; Greenland et al. 1999), synergy from statistical interaction (Greenland and Poole 1988), and causation probabilities from attributable fractions (Greenland et al. 1999; Greenland and Robins 2000).

The conceptual clarification also stimulated development of statistical methods for observational studies. Rubin (1974, 1978) and his colleagues extended statistical machinery based on potential outcomes from

the experimental setting to observational data analysis, leading, for example, to propensity-scoring and inverse-probability-of-treatment methods for confounder adjustment (Rosenbaum 2002; Hirano et al. 2003), as well as new insights into analysis of trials with noncompliance (Angrist et al. 1996) and separation of direct and indirect effects (Robins and Greenland 1992, 1994; Frangakis and Rubin 2002; Kaufman et al. 2004). In many cases, such insights have led to methodologic refinements and better-informed choices among existing methods. In the longitudinal-data setting, potential-outcome modeling has led to entirely new methodologies for analysis of time-varying covariates and outcomes, including g-estimation and marginal structural modeling (Robins 1987, 1998; Robins et al. 1992, 1999, 2000).

A serious caution arises, however, when it is not clear that the counterfactual values for X (treatments other than the actual one) represent physical possibilities or even unambiguous states of nature. A classic example is gender (biological sex). Although people speak freely of gender (male vs. female) as cause of heart disease, given a particular man, it is not clear what it would mean for that man to have been a woman instead. Do we mean that the man cross-dressed and lived with a female identity his entire life? Or that he received a sex-change operation after birth? Or that the zygote from which he developed had its male chromosome replaced by a female chromosome?

Potential-outcome models bring to light such ambiguities in everyday causal language but do not resolve them (Greenland 2005a; Hernán 2005). Some authors appear to insist that use of the models be restricted to situations in which ambiguities are resolved, so that X must represent an intervention variable, i.e., a precise choice among treatment actions or decisions (Holland 1986). Many applications do not meet this restriction, however, and some go so far as to confuse outcomes (Y) with treatments (X), which can lead to nonsense results. Examples include estimates of mortality after "cause removal," e.g., removal of all lung-cancer deaths. Sensible interpretation of any effect estimate requires asking what intervention on a unit could have given the unit a value of X (here, lung-cancer death) other than the one that was observed, and what the side effects that intervention would have. One cannot remove all lung-cancer deaths by smoking cessation. A treatment with a 100% cure rate might do so but need not guarantee the same subsequent lifespan as if the cancer never occurred. If such questions cannot be given at least a speculative answer, the estimates of the impact of cause removal cannot be expected to provide valid information for intervention and policy purposes (Greenland 2005a).

More sweeping criticisms of potential-outcome models are given by Dawid (2000), for example, that the distribution of the full potential-outcome vector $\mathbf{Y}$ (i.e., the joint distribution of the $Y(x_1), \ldots, Y(x_J)$) cannot be nonparametrically identified by randomized experiments. Nonetheless, as the discussants point out, the practical implication of these criticisms are not clear, because the marginal distributions of the separate potential outcomes $Y(x_j)$ are nonparametrically identifiable, and known mechanisms of action may lead to identification of their joint distribution as well.

Canonical Inference

Before the extension of potential outcomes to observational inference, the only systematic approach to causal inference in epidemiology was the informal comparison of observations to characteristics expected of causal relations. Perhaps, the most widely cited of such approach is based on Hill's considerations (Hill 1965), which are discussed critically in numerous sources (e.g., Koepsell and Weiss 2003; Phillips and Goodman 2004; Rothman et al. 2008, Chap. 2) as well as by Hill himself.

The canonical approach usually leaves terms like "cause" and "effect" as undefined concepts around which the self-evident canons are built, much like axioms are built around concepts like "set" and "is an element of" in mathematics. Only proper temporal sequence (cause must precede effect) is a necessary condition for a cause–effect relation to hold. The remaining considerations are more akin to diagnostic symptoms or signs of causation – that is, they are properties an association is assumed more likely to exhibit if it is causal than if it is not (Hill 1965; Susser 1988, 1991). Furthermore, some of these properties (like specificity and dose response) apply only under specific causal models (Weiss 1981, 2002).

Thus, the canonical approach makes causal inference more closely resemble clinical judgment than experimental science, although experimental evidence is listed among the considerations (Hill 1965; Rothman et al. 2008, Chap. 2; Susser 1991). Some of the considerations (such as temporal sequence, association, dose response or predicted gradient, and specificity) are empirical signs and thus subject to conventional statistical analysis. Others (such as plausibility) refer to prior belief, and thus (as with disease symptoms) require elicitation, the same process used to construct priors for Bayesian analysis.

The canonical approach is widely accepted in health sciences, subject to many variations in detail. Nonetheless, it has been criticized for its incompleteness and informality, and the consequent poor fit it affords to the deductive

or mathematical approaches familiar to classic science and statistics (Rothman et al. 2008, Chap. 2). Although there have been some interesting attempts to reinforce or reinterpret certain canons as empirical predictions of causal hypotheses (e.g., Susser 1988; Weed 1986; Weiss 1981, 2002; Rosenbaum 2002), there is no generally accepted mapping of the entire canonical approach into a coherent statistical methodology; one simply uses standard statistical techniques to test whether empirical canons are violated. For example, if the causal hypothesis linking X to Y predicts a strictly increasing trend in Y with X, a test of this statistical prediction may serve as a statistical criterion for determining whether the hypothesis fails the dose-response canon. Such usage falls squarely in the falsificationist/frequentist tradition of the twentieth-century statistics, but leaves unanswered most of the policy questions that drive causal research; this gap led to the development of methodologic modeling or *bias analysis*.

Bias Analysis

In the second half of the twentieth-century, a more rigorous approach to observational studies emerged in the wake of major policy controversies such as those concerning cigarette smoking and lung cancer (e.g., Cornfield et al. 1959). This approach begins with the idea that, conditional on some sufficient set of confounders Z, there is a population association or relation between X and Y that is the target of inference. In other words, the Z-stratified associations are presumed to accurately reflect the effect of X on Y in that population stratum, however "effect" may be defined. Estimates of this presumably causal association are then the effect estimates.

Observational and analytic shortcomings bias or distort these estimates: Units may be selected for observation in a nonrandom fashion; stratifying on additional unmeasured covariates U may be essential for the X-Y association to approximate a causal effect; inappropriate covariates may be entered into the analysis; components of X or Y or Z may not be adequately measured; and so on. In methodologic modeling or *bias analysis*, one models these shortcomings. In effect, one attempts to model the design and execution of the study, including features (such as selection biases and measurement errors) beyond investigator control. The process is thus a natural extension to observational studies of the design-based paradigm in experimental and survey statistics. For further details, see BIAS MODELING or the overviews by Greenland (2005b, 2009).

Structural Equations and Causal Diagrams

Paralleling the development of potential-outcome models, an entirely different approach causal analysis arose in observational research in economics and related fields. Like methodologic modeling, this *structural-equations* approach does not begin with a formal definition of cause and effect, but instead develops models to reflect assumed causal associations, from which empirical (and hence testable) associations may be derived. Like most of statistics before the 1980s, structural-equations methods were largely limited to normal linear models to derive statistical inferences. Because these models bear no resemblance to typical epidemiologic data, this limitation may in part explain the near absence of structural equations from epidemiology, despite their ubiquity in social-science methodology. From their inception, however, causal system models have been accompanied by graphical representations or path diagrams that provided compact summaries of qualitative assumptions made by the structural model; see ►Causal Diagrams for a review.

Conclusion

Different approaches to causal inference represent separate historical streams rather than distinct methodologies, and can be blended in various ways. The result of any modeling exercise is simply one more input to informal judgments about causal relations, which may be guided by canonical considerations. Insights and innovations in any approach can thus benefit the entire process of causal inference, especially when that process is seen as part of a larger context. Other traditions or approaches (some perhaps yet to be imagined) may contribute to the process. It thus seems safe to say that no one approach or blend is a complete solution to the problem of causal inference, and that the topic remains one rich with open problems and opportunities for innovation.

Basic Concepts on Censored Data

In industrial and clinical experiments, there are many situations in which units (or subjects) are lost or removed from experimentation before the event of interest occurs. The experimenter may not always obtain complete information on the time to the event of interest for all experimental units or subjects. Data obtained from such experiments are called *censored data*. Censoring is one of the distinguishing features of lifetime data. Censoring can be either unintentional due to accidental breakage or an individual under study drops out or intentional in which the removal of units or subjects is pre-planned, or both. Censoring restricts our ability to observe the time-to-event and it is a source of difficulty in statistical analysis.

Censoring can occur at either end (single censoring) or at both ends (double censoring). If the event of interest is only known to be occured before a certain time, it is called *left censoring*. The term "left censored" implies that the event of interest is to the left of the observed time point. The most common case of censoring is *right censoring*, in which the exact time to the event of interest is not observed and it is only known to be occured after a certain time. Different types of right censoring schemes are discussed in the subsequent section. For *interval censoring*, the event of interest is only known to be occurred in a given time interval. This type of data frequently comes from experiments where the items under test are not constantly monitored, for example, the patients in a clinical trial have periodic follow-up and events of interest occur in between two consecutive follow-ups. Note that left censoring is a special case of interval censoring where the starting time for the interval is zero.

For life-testing experiments where the event of interest is the failure of the item on test, two common reasons for pre-planned censoring are saving the total time on test and reducing the cost associated with the experiment because failure implies unit's destruction which can be costly. When budget and/or facility constraints are in place, suitable censoring scheme can be used to control the time spent and the cost of the experiment. Nevertheless, censored data usually will reduce the efficient of statistical inference compare to complete data. Therefore, it is desirable to develop censoring scheme which can balance between (i) total time spent for the experiment; (ii) number of units used in the experiment; and (iii) the efficient of statistical inference based on the results of the experiment.

Different Types of Censoring Schemes

Suppose n units are placed on a life-testing experiment. Further, suppose $X_1, X_2, \cdots, X_n$ denote the lifetimes of these n units taken from a population with lifetime distribution function $F(x;\theta)$ and density function $f(x;\theta)$, where θ is an unknown parameter(s) of interest. Let $X_{1:n} \le \cdots \le X_{n:n}$ denote the corresponding ordered lifetimes observed from the life-test. Some commonly used censoring schemes are discussed in the following.

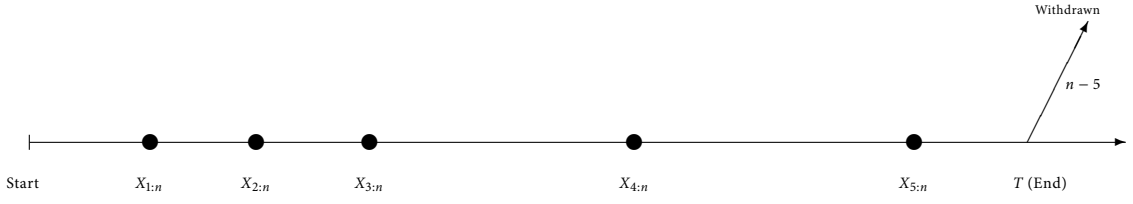
Type-I Censoring

Suppose it is planned that the life-testing experiment will be terminated at a pre-fixed time T. Then, only the failures until time T will be observed. The data obtained from such a restrained life-test will be referred to as a *Type-I censored sample*. It is also called time-censoring since the experimental time is fixed. Note that the number of failures observed here is random and, in fact, has a *Binomial*$(n, F(T;\theta))$ distribution. Figure 1 shows a schematic representation of a Type-I censored life-test with $m = 7$. Inferential procedures based on Type-I censored samples have been discussed extensively in the literature; see, for example, Cohen (1991) and Balakrishnan and Cohen (1991).

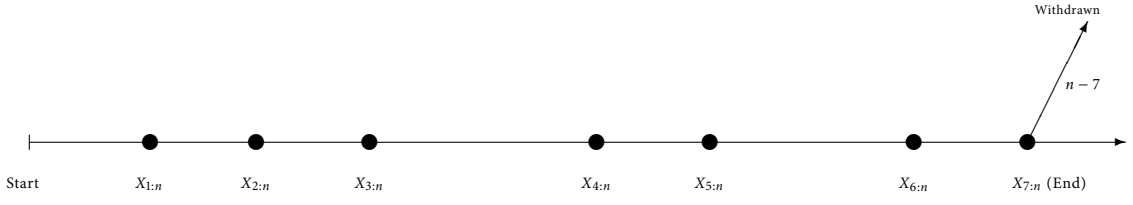
Type-I censoring scheme has the advantage that the experimental time is controlled to be at most T while it has the disadvantage that the effective sample size can turn out to be a very small number (even equal to zero) so that usual statistical inference procedures will not be applicable or they will have low efficiency.

Type-II Censoring

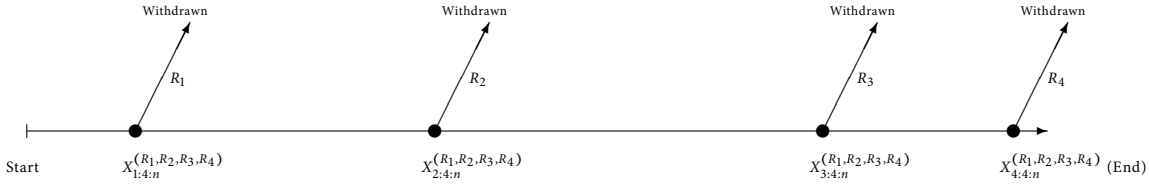
Suppose it is planned that the life-testing experiment will be terminated as soon as the mth (where m is pre-fixed) failure is observed. Then, only the first m failures out of n units under test will be observed. The data obtained from such a restrained life-test will be referred to as a *Type-II censored sample*. In contrast to Type-I censoring, the number of failures observed is fixed (viz., m) while the duration of the experiment is random (viz., $X_{m:n}$). Figure 2 shows a schematic representation of a Type-II censored life-test with m = 7. Inferential procedures based on Type-II censored samples have been discussed extensively in the



Censoring Methodology. Fig. 1 Schematic representation of a Type-I censored life-test



Censoring Methodology. Fig. 2 Schematic representation of a Type-II censored life-test



Censoring Methodology. Fig. 3 Schematic representation of a progressively Type-II censored life-test

literature; see, for example, Nelson (1982), Cohen (1991), and Balakrishnan and Cohen (1991).

Type-II censoring scheme has the advantage that the number of observed failures is fixed to be m which ensure reasonable information is available for statistical inference. However, it has the disadvantage that the experimental time is random and it can be large.

Progressive Censoring

Both the conventional Type-I and Type-II censoring schemes do not have the flexibility of allowing removal of units at points other than the terminal point of the experiment. This restricts our ability to observe extreme failures which may lead to inefficient statistical inference if we are interested in the behavior of the upper tail of the lifetime distribution. For this reason, a more general censoring scheme called *progressive censoring* has been introduced. The censored life-testing experiments described above can be extended to situations wherein censoring occurs in multiple stages. Data arising from such life-tests are referred to as *progressively censored data*. Naturally, progressive censoring can be introduced in both Type-I and Type-II forms.

For example, a progressive Type-II censored life-testing experiment will be carried out in the following manner. Prior to the experiment, a number $m < n$ is determined and the censoring scheme $(R_1, R_2, \ldots, R_m)$ with $R_j > 0$ and $\sum_{j=1}^{m} R_j + m = n$ is specified. During the experiment, j-th failure is observed and immediately after the failure, R_j functioning items are removed from the test. We denote the m completely observed (ordered) lifetimes by $X_{j:m:n}^{(R_1,R_2,\ldots,R_m)}$, $j = 1, 2, \ldots, m$, which are the observed progressively Type-II right censored sample. Figure 3 shows a schematic representation of a progressively Type-II censored life-test with $m = 4$. Notice that the conventional Type-II censoring scheme is a special case of a progressive Type-II censoring scheme when $R_i = 0$, for $i = 1, \ldots, m-1$ and $R_m = n-m$. Similarly, progressive Type-I censoring scheme can be introduced in a similar manner. Inferential procedures based on progressively Type-II censored samples have been discussed in the literature; see, for example, Balakrishnan and Aggarwala (2000) and Balakrishnan (2007) for excellent reviews on the literatures on this topic.

Hybrid Censoring

As mentioned previously, both Type-I and Type-II censoring schemes have some shortcomings. To keep away from these shortcomings, hybrid censoring schemes combining Type-I and Type-II censoring schemes have been proposed. Specifically, if the experiment is terminated at $T^* = \min\{X_{m:n}, T\}$, where m and T are pre-fixed prior to the experiment, then the censoring scheme is called *Type-I hybrid censoring scheme*; if the experiment is terminated at $T^* = \max\{X_{m:n}, T\}$, then the censoring scheme is called *Type-II hybrid censoring scheme*. We can see that both Type-I and Type-II hybrid censoring schemes try to balance between the advantages and disadvantages of conventional Type-I and Type-II censoring schemes. Hybrid censoring schemes has been studied extensively in the literature, one may refer Epstein (1954), Draper and Guttman (1987), Gupta and Kundu (1998), and Childs et al. (2003, 2008), Kundu (2007) for details. In recent years, the idea of hybrid censoring has been generalized to progressive censoring, for discussions on different types of hybrid progressive censoring schemes, see, for example, Kundu and Joarder (2006), Banerjee and Kundu (2008), Ng et al. (2009) and Lin et al. (2009).

About the Author

H. K. T. Ng is an Associate Professor in the Department of Statistical Science at Southern Methodist University. Census

Margo J. Anderson
Professor of History and Urban Studies
University of Wisconsin–Milwaukee, Milwaukee, WI, USA

Introduction

A census usually refers to a complete count by a national government of the population, with the population further defined by demographic, social or economic characteristics, for example, age, sex, ethnic background, marital status, and income. National governments also conduct other types of censuses, particularly of economic activity. An economic census collects information on the number and characteristics of farms, factories, mines, or businesses.

Most countries of the world conduct population censuses at regular intervals. By comparing the results of successive censuses, analysts can see whether the population is growing, stable, or declining, both in the country as a whole and in particular geographic regions. They can also identify general trends in the characteristics of the population. Because censuses aim to count the entire population of a country, they are very expensive and elaborate administrative operations and thus are conducted relatively infrequently. The United States and the United Kingdom, for example, conduct a population census every 10 years (a *decennial* census), and Canada conducts one every 5 years (a *quinquennial* census). Economic censuses are generally conducted on a different schedule from the population census.

Censuses of population usually try to count everyone in the country as of a fixed date, often known as Census Day. Generally, governments collect the information by sending a ►questionnaire in the mail or a census taker to every household or residential address in the country. The recipients are instructed to complete the questionnaire and send it back to the government, which processes the answers. Trained interviewers visit households that do not respond to the questionnaire and individuals without mail service, such as the homeless or those living in remote areas.

History

Censuses have been taken since ancient times by emperors and kings trying to assess the size and strength of their realms. These early censuses were conducted sporadically, generally to levy taxes or for military conscription. Clay tablet fragments from ancient Babylon indicate that a census was taken there as early as 3800 BCE to estimate forthcoming tax revenues. The ancient Chinese, Hebrews, Egyptians, and Greeks also conducted censuses. However, enumerations did not take place at regular intervals until the Romans began to count of the population in the Republic and later the empire. Among the Romans the census was usually a count of the male population and assessment of property value. It was used mainly for drafting men into military service and for taxing property.

After the fall of the Roman Empire in the fifth century CE, census taking disappeared for several hundred years in the West. The small feudal communities of the Middle

Ages had neither the mechanisms nor the need for censuses. However, in 1086 William the Conqueror ordered the compilation of the census-like Domesday Book, a record of English landowners and their holdings. From the data given in this survey, which was made to determine revenues due to the king, historians have reconstructed the social and economic conditions of the times.

The modern census dates from the seventeenth century, when European powers wanted to determine the success of their overseas colonies. Thus the British crown and the British Board of Trade ordered repeated counts of the colonial American population in the seventeenth and eighteenth centuries, starting in the 1620s in Virginia. The first true census in modern times was taken in New France, France's North American empire, beginning in 1665. The rise of democratic governments resulted in a new feature of the census process: The 1790 census of the United States was the first to have its Constitution require a census and periodic reapportionment of its House of Representatives on the basis of the decennial census results. Sweden began to conduct censuses in the mid-eighteenth century, and England and Wales instituted a regular decennial census in 1801. During the nineteenth century and the first half of the twentieth century, the practice of census taking spread throughout the world. India conducted its first national census in 1871, under British rule. China's first modern census, in 1953, counted 583 million people.

The United Nations encourages all countries to conduct a population count through a census or population registration system. It also promotes adoption of uniform standards and census procedures. The United Nations Statistical Office compiles reports on worldwide population.

Uses of Census Information

Governments use census information in almost all aspects of public policy. In some countries, the population census is used to determine the number of representatives each area within the country is legally entitled to elect to the national legislature. The Constitution of the United States, for example, provides that seats in the House of Representatives should be apportioned to the states according to the number of their inhabitants. Each decade, Congress uses the population count to determine how many seats each state should have in the House and in the electoral college, the body that nominally elects the president and vice president of the United States. This process is known as *reapportionment.* States frequently use population census figures as a basis for allocating delegates to the state legislatures and for redrawing district boundaries for seats in the House, in state legislatures, and in local legislative districts. In Canada, census population data are similarly used to apportion seats among the provinces and territories in the House of Commons and to draw electoral districts.

Governments at all levels – such as cities, counties, provinces, and states – find population census information of great value in planning public services because the census tells how many people of each age live in different areas. These governments use census data to determine how many children an educational system must serve, to allocate funds for public buildings such as schools and libraries, and to plan public transportation systems. They can also determine the best locations for new roads, bridges, police departments, fire departments, and services for the elderly.

Besides governments, many others use census data. Private businesses analyze population and economic census data to determine where to locate new factories, shopping malls, or banks; to decide where to advertise particular products; or to compare their own production or sales against the rest of their industry. Community organizations use census information to develop social service programs and child-care centers. Censuses make a huge variety of general statistical information about society available to researchers, journalists, educators, and the general public.

Conducting a Census

Most nations create a permanent national statistical agency to take the census. In the United States, the Bureau of the Census (Census Bureau), an agency of the Department of Commerce, conducts the national population census and most economic censuses. In Canada, the Census Division of Statistics Canada is responsible for taking censuses.

Conducting a census involves four major stages. First, the census agency plans for the census and determines what information it will collect. Next, it collects the information by mailing questionnaires and conducting personal interviews. Then the agency processes and analyzes the data. Finally, the agency publishes the results to make them available to the public and other government agencies.

Planning the Census

Census agencies must begin planning for a census years in advance. One of the most important tasks is to determine what questions will appear on the census questionnaire. Census agencies usually undertake a lengthy public review process to determine the questions to be asked. They conduct public meetings, consider letters and requests from the general public, and consult with other government agencies and special advisory committees. In the United States, census questions must be approved by Congress and

the Office of Management and Budget. In Canada, questions must be approved by the governor-general on the recommendations of the Cabinet.

The questions included on census forms vary from nation to nation depending on the country's particular political and social history and current conditions. Most censuses request basic demographic information, such as the person's name, age, sex, educational background, occupation, and marital status. Many censuses also include questions about a person's race, ethnic or national origin, and religion. Further questions may ask the person's place of birth; relationship to the head of the household; citizenship status; the individual's or the family's income; the type of dwelling the household occupies; and the language spoken in the household.

Questions that are routine in one nation may be seen as quite controversial in another, depending on the history of the country. The United States census does not ask about religious affiliation because such a question is considered a violation of the First Amendment right to freedom of religion or an invasion of privacy. Other nations, such as India, do collect such information. Questions on the number of children born to a woman were quite controversial in China in recent years because of government efforts to limit families to having only one child. In the United States, asking a question on income was considered controversial in 1940 when it was first asked. It is no longer considered as objectionable. Questions change in response to public debate about the state of society. For example, Americans wanted to know which households had radios in 1930, and the census introduced questions on housing quality in 1940. Canadians have recently begun to ask census questions on disability status and on the unpaid work done in the home.

Besides determining the content of the census, census agencies must make many other preparations. Staffing is a major concern for census agencies because censuses in most countries require a huge number of temporary workers to collect and process data. Consequently, census agencies must begin recruiting and training workers months or years in advance. For example, the U.S. Census Bureau had to fill 850,000 temporary, short-term positions to conduct the 2000 census. In order to hire and retain enough staff, it had to recruit nearly three million job applicants. The majority of temporary workers are hired to go door-to-door to interview households that do not respond to the census questionnaire. In some countries, government employees at a local level, such as schoolteachers, are asked to help conduct the count.

Prior to any census, a census agency must develop an accurate list of addresses and maps to ensure that everyone is counted. The U.S. Census Bureau obtains addresses primarily from the United States Postal Service and from previous census address lists. It also works closely with state, local, and tribal governments to compile accurate lists. Finally, census agencies often conduct an extensive marketing campaign before Census Day to remind the general population about the importance of responding to the census. This campaign may involve paid advertising, distributing materials by direct mail, promotional events, and encouraging media coverage of the census.

Collecting the Information

Until relatively recently, population censuses were taken exclusively through personal interviews. The government sent *enumerators* (interviewers) to each household in the country. The enumerators asked the head of the household questions about each member of the household and entered the person's responses on the census questionnaire. The enumerator then returned the responses to the government. Today, many censuses are conducted primarily through *self-enumeration,* which means that people complete their own census questionnaire. Self-enumeration reduces the cost of a census to the government because fewer enumerators are needed to conduct interviews. In addition, the procedure provides greater privacy to the public and generally improves the accuracy of responses, because household members can take more time to think over the questions and consult their personal records.

Nevertheless, census operations still require hiring very large numbers of temporary enumerators to conduct address canvassing in advance of a mail census and to retrieve forms from non responding households and check on vacant units. Other nations continue to conduct censuses partially or totally through direct enumeration. Some, such as Turkey, require people to stay home on Census Day to await the census taker.

Census agencies make a special effort to count people who may not receive a questionnaire by mail or who have no permanent address. For example, the U.S. Census Bureau sends census takers to interview people at homeless shelters, soup kitchens, mobile food vans, campgrounds, fairs, and carnivals. It consults with experts to find migrant and seasonal farmworkers. Finally, the agency distributes census questionnaires to people living in group quarters, such as college dormitories, nursing homes, hospitals, prisons and jails, halfway houses, youth hostels, convents and monasteries, and women's shelters.

The level of detail on the complete count census varies by country, particularly after the development of probability survey techniques in the 1940s. In the United States, for example, until the 2010 census, most households received a "short form," a brief set of questions on basic

characteristics such as name, age, sex, racial or ethnic background, marital status, and relationship to the household head. But from the mid-twentieth century until 2000, a smaller sample of households received the "long form," with many additional detailed questions. These included questions about the individual's educational background, income, occupation, language knowledge, veteran status, and disability status as well as housing-related questions about the value of the individual's home, the number of rooms and bedrooms in it, and the year the structure was built. These "long form" questions have been collected in the American Community Survey since the early 2000s, and thus are no longer asked on the U.S. Census in 2010.

Processing and Analysis of Data

For most of the 19th century in the United States and Canada, census data were tabulated and compiled by hand, without the aid of machines. Manual processing was very slow, and some figures were obsolete by the time they were published. The invention of mechanical tabulating devices in the late nineteenth century made processing of the data much faster and improved the accuracy of the results. For example, in 2010, the U.S. Census Bureau will scan the data from 100 + million paper questionnaires, and capture the responses using optical character recognition software. Once in electronic form, the data can be analyzed and turned into statistics. Unreadable or ambiguous responses are checked by census clerks and manually keyed into the computer.

Publication of Results

U.S. and Canadian censuses publish only general statistical information and keep individual responses confidential. By law, the U.S. Census Bureau and Statistics Canada are prohibited from releasing individual responses to any other government agency or to any individual or business. Census workers in both countries must swear under oath that they will keep individual responses confidential. Employees who violate this policy face a monetary fine and possible prison term. If an individual's personal data were not kept confidential, people might refuse to participate in the census for fear that their personal information would be made public or used by the government to track their activities. In the United States, individual census responses are stored at the National Archives. After 72 years, the original forms are declassified and opened to the public. These original responses are frequently used by people researching the history of their families or constructing genealogies. In Canada, census responses from 1906 and later are stored at Statistics Canada. Microfilmed records of census responses from 1911 and earlier are stored at the National Archives of Canada; these are the only individual census responses currently available for public use.

Until the 1980s, census agencies published their results in large volumes of numeric tables – sometimes numbering in the hundreds of volumes. Today, the majority of census data is distributed electronically, both in tabulated form, and through anonymized public use microdata samples.

Problems in Census Taking and Issues for the Future

Censuses provide important information about the population of a country. But they can become embroiled in political or social controversy simply by reporting information. Complaints about the census generally involve concerns about the accuracy of the count, the propriety of particular questions, and the uses to which the data are put.

All censuses contain errors of various kinds. Some people and addresses are missed. People may misunderstand a question or fail to answer all the questions. Census officials have developed elaborate procedures to catch and correct errors as the data are collected, but some errors remain. For example, the 1990 U.S. census missed 8.4 million people and mistakenly counted 4.4 million people, according to Census Bureau estimates. The latter figure included people counted more than once, fictitious people listed on forms, and fabrications by enumerators. Such errors undermine the credibility of the census as a mechanism for allocating seats in legislative bodies and government funds.

In recent years, developments in statistical analysis have made it possible to measure the accuracy of censuses. Census results may be compared with population information from other sources, such as the records of births, deaths, and marriages in vital statistics. Census officials can also determine the level of accuracy of the count by conducting a second, sample count called a *post-enumeration survey* or *post-censal survey*. In this technique, census staff knock on the door of each housing unit in selected blocks around the country, regardless of whether the housing unit was on the master address list. The staff member determines whether the household was counted in the census. By comparing the results from this survey with the census records, census officials can estimate how many people from each geographic region were missed in the original census count. Some nations, such as Canada and Australia, have begun to adjust the census results for omissions and other errors.

Concerns about the confidentiality of the census represent another source of data error. Censuses require public understanding, support, and cooperation to be successful. Concerns about government interference with private life

can prevent people from cooperating with what is essentially a voluntary counting process. People may be suspicious of giving information to a government agency or may object that particular census questions invade their privacy. When public trust is lacking, people may not participate. In some nations, past census controversies have led to the elimination of the national census. During World War II (1939–1945), for example, the German Nazi forces occupying The Netherlands used the country's census records and population registration data to identify Jews for detention, removal, and extermination. This use ultimately undermined the legitimacy of the census after World War II. In The Netherlands, the legacy of the Nazi era was one of the major justifications to end census taking. The Netherlands took its last regular census in 1971 and now collects population information through other mechanisms.

Many nations are currently exploring alternatives to or major modernizations of the traditional population census. France, for example, has recently implemented a continuous measurement population counting system. The United States is exploring the use of administrative records and electronic methods of data collection to replace the mail enumeration in 2020.

About the Author

Dr. Margo J. Anderson is Professor of History and Urban Studies, University of Wisconsin–Milwaukee. She specializes in the social history of the United States in the nineteenth and twentieth centuries. She was Chair, History Department (1992–1995). She was a member of the National Academy of Sciences' Panel on Census Requirements for the Year 2000 and Beyond. Dr. Anderson was Vice President (2005), and President, Social Science History Association (2006). She is a Fellow, American Statistical Association (ASA) (1998), and was Chair, Social Statistics Section of ASA (1998). Currently, she is ASA Chair, Committee on Committees. She has authored and coauthored numerous papers and several books including, *The American Census: A Social History* (New Haven: Yale University Press, 1988), and *Who Counts? The Politics of Census-Taking in Contemporary America* (with Stephen E. Fienberg, Russell Sage, 1999, revised and updated 2001), named as one of Choice Magazine's Outstanding Academic Books of 2000. She was Editor-in-Chief of the *Encyclopedia of the U.S. Census* (Washington, D.C.: CQ Press, 2000). Professor Anderson is widely regarded as the leading scholar on the history of the U.S. census, and has made distinguished contributions to research in American social science.

Introduction

One of the objectives of statistical inference is to draw conclusions about some parameter, like the mean or the variance of a (possibly conceptual) population of interest based

on the information obtained in a sample conveniently selected therefrom. For practical purposes, estimates of these parameters must be coupled with statistical properties and except in the most simple cases, exact properties are difficult to obtain and one must rely on approximations. It is quite natural to expect estimators to be consistent, but it is even more important that their (usually mathematically complex) exact sampling distribution be adequately approximated by a simpler one, such as the normal or the χ^2 distribution, for which tables or computational algorithms are available. Here we are not concerned with the convergence of the actual sequence of statistics $\{T_n\}$ to some constant or random variable T as $n \to \infty$, but with the convergence of the corresponding distribution functions $\{G_n\}$ to some specific distribution function F. This is known as weak convergence and for simplicity, we write $T_n \xrightarrow{D} F$. Although this is the weakest mode of stochastic convergence, it is very important for statistical applications, since the related limiting distribution function F may generally be employed in the construction of approximate confidence intervals for and significance tests about the parameters of interest. In this context, central limit theorems (CLT) are used to show that statistics expressed as sums of the underlying random variables, conveniently standardized, are asymptotically normally distributed, i.e., converge weakly to the normal distribution. They may be proved under different assumptions regarding the original distributions.

The simplest CLT states that the (sampling) distribution of the sample mean of independent and identically distributed (*i.i.d*) random variables with finite second moments may be approximated by a normal distribution. Although the limiting distribution is continuous, the underlying distribution may even be discrete. CLT are also available for independent, but not identically distributed (e.g., with different means and variances) underlying random variables, provided some (relatively mild) assumptions hold for their moments. The Liapounov CLT and the Lindeberg-Feller CLT are useful examples. Further extensions cover cases of dependent random underlying variables; in particular, the Hájek-Šidak CLT is extremely useful in regression analysis, where as the sample size increases, the response variables form a triangular array in which for each row (i.e., for given n), they are independent but this is not true among rows (i.e., for different values of n). Extensions to cover cases where the underlying random variables have more complex (e.g., martingale-type) dependence structures are also available. When dealing with partial sum or empirical distributional processes, we must go beyond the finite-dimensional case and assume some *compactness* conditions to obtain suitable results, wherein the so-called *weak invariance principles* play an important role.

Different Versions of the Central Limit Theorem

We now present (without proofs) the most commonly used versions of the CLT. Details and a list of related references may be obtained in Sen et al. (2010).

Theorem 1 *(Classical CLT) Let* $\{X_k, k \geq 1\}$ *be a sequence of i.i.d. random variables such that*

1. $\mathbb{E}(X_k) = \mu$.
2. $\mathbb{V}ar(X_k) = \sigma^2 < \infty$.

Also, let $Z_n = (T_n - n\mu)/(\sigma\sqrt{n})$ *where* $T_n = \sum_{k=1}^n X_k$. *Then,* $Z_n \xrightarrow{D} \mathcal{N}(0,1)$.

In practice, this result implies that for large n, the distribution of the sample mean $\overline{X}_n = T_n/n$ may be approximated by a normal distribution with mean μ and variance σ^2/n. An interesting special case occurs when the underlying variables X_k have Bernoulli distributions with probability of success π. Here the expected value and the variance of X_k are π and $\pi(1-\pi)$, respectively. It follows that the large-sample distribution of the sample proportion, $p_n = T_n/n$ may be approximated by a $\mathcal{N}[\pi, \pi(1-\pi)/n]$ distribution. This result is known as the *De Moivre–Laplace CLT*.

An extension of Theorem 1 to cover the case of sums of independent, but not identically distributed random variables requires additional assumptions on the moments of the underling distributions. In this direction, we consider the following result.

Theorem 2 *(Liapounov CLT) Let* $\{X_k, k \geq 1\}$ *be a sequence of independent random variables such that*

1. $\mathbb{E}(X_k) = \mu_k$.
2. $\nu_{2+\delta}^{(k)} = \mathbb{E}(|X_k - \mu_k|^{2+\delta}) < \infty, \quad k \geq 1$ *for some* $0 < \delta \leq 1$.

Also let $T_n = \sum_{k=1}^n X_k$, $\mathbb{V}ar(X_k) = \sigma_k^2$, $\tau_n^2 = \sum_{k=1}^n \sigma_k^2$, $Z_n = (T_n - \sum_{k=1}^n \mu_k)/\tau_n$ *and* $\rho_n = \tau_n^{-(2+\delta)} \sum_{k=1}^n \nu_{2+\delta}^{(k)}$. *Then, if* $\lim_{n\to\infty} \rho_n = 0$, *it follows that* $Z_n \xrightarrow{D} \mathcal{N}(0,1)$.

This as well as other versions of the CLT may also be extended to the multivariate case by referring to the *Cramér-Wold Theorem*, which essentially states that the asymptotic distribution of the multivariate statistic under

investigation may be obtained by showing that every linear combination of its components follows an asymptotic normal distribution. Given a sequence $\{\boldsymbol{X}_n, n \geq 1\}$ of random vectors in $\mathbb{R}^p$, with mean vectors $\boldsymbol{\mu}_n$ and covariance matrices $\boldsymbol{\Sigma}_n$, $n \geq 1$, to show that $n^{-1/2}\sum_{i=1}^{n}(\boldsymbol{X}_i - \boldsymbol{\mu}_i) \xrightarrow{D} \mathcal{N}_p(\boldsymbol{0}, \boldsymbol{\Sigma})$ with $\boldsymbol{\Sigma} = \lim_{n\to\infty} n^{-1}\sum_{i=1}^{n}\boldsymbol{\Sigma}_i$, one generally proceeds according to the following strategy:

1. Use one of the univariate CLT to show that for every fixed $\boldsymbol{\lambda} \in \mathbb{R}^p$, $n^{-1/2}\sum_{i=1}^{n}\boldsymbol{\lambda}'(\boldsymbol{X}_i - \boldsymbol{\mu}_i) \xrightarrow{D} \mathcal{N}(0, \gamma^2)$ with $\gamma^2 = \lim_{n\to\infty} n^{-1}\boldsymbol{\lambda}'\left(\sum_{i=1}^{n}\boldsymbol{\Sigma}_i\right)\boldsymbol{\lambda}$.
2. Use the Cramér-Wold Theorem to complete the proof.

As an example we have:

Theorem 3 *(Multivariate version of the Liapounov CLT) Let $\{\boldsymbol{X}_n, n \geq 1\}$ be a sequence of random vectors in $\mathbb{R}^p$ with mean vectors $\boldsymbol{\mu}_n$ and finite covariance matrices $\boldsymbol{\Sigma}_n, n \geq 1$, such that $\max_{1\leq i\leq n}\max_{1\leq j\leq p}\mathbb{E}(|X_{ij} - \mu_{ij}|^{2+\delta}) < \infty$ for some $0 < \delta < 1$, and $\boldsymbol{\Sigma} = \lim_{n\to\infty} n^{-1}\sum_{i=1}^{n}\boldsymbol{\Sigma}_i$ exists. Then $n^{-1/2}\sum_{i=1}^{n}(\boldsymbol{X}_i - \boldsymbol{\mu}_i) \xrightarrow{D} \mathcal{N}_p(\boldsymbol{0}, \boldsymbol{\Sigma})$.*

In the original formulation, Liapounov used $\delta = 1$, but even the existence of $v_{2+\delta}^{(k)}$, $0 < \delta \leq 1$ is not a necessary condition, as we may see from the following theorem.

Theorem 4 *(Lindeberg-Feller CLT) Let $\{X_k, k \geq 1\}$ be a sequence of independent random variables satisfying*

1. $\mathbb{E}(X_k) = \mu_k$.
2. $\mathbb{V}ar(X_k) = \sigma_k^2 < \infty$.

Also, let $T_n = \sum_{k=1}^{n}X_k$, $\tau_n^2 = \sum_{k=1}^{n}\sigma_k^2$ and $Z_n = \sum_{k=1}^{n}Y_{nk}$ where $Y_{nk} = (X_k - \mu_k)/\tau_n$ and consider the following additional conditions:

1. *Uniform asymptotic negligibility (UAN):* $\max_{1\leq k\leq n}\left(\sigma_k^2/\tau_n^2\right) \to 0$ *as* $n \to \infty$.
2. *Asymptotic normality:* $Z_n \xrightarrow{D} \mathcal{N}(0,1)$.
3. *Lindeberg-Feller (uniform integrability):*

$$\forall \varepsilon > 0, \frac{1}{\tau_n^2}\sum_{k=1}^{n}\mathbb{E}\left[(X_k - \mu_k)^2 I(|X_k - \mu_k| > \varepsilon\tau_n)\right] \to 0 \text{ as } n \to \infty,$$

where $I(A)$ denotes the indicator function.

Then, (A) and (B) hold simultaneously if and only if (C) holds.

Condition (A) implies that the random variables Y_{nk} are *infinitesimal*, i.e., that $\max_{1\leq k\leq n}P(|Y_{nk}| > \varepsilon) \to 0$ as $n \to \infty$ for every $\varepsilon > 0$, or, in other words, that the random variables Y_{nk}, $1 \leq k \leq n$, are uniformly in k, asymptotically in n, negligible.

When the underlying random variables under consideration are bounded, i.e., when $P(a \leq X_k \leq b) = 1$ for some finite scalars $a < b$, it follows that a necessary and sufficient condition for $Z_n \xrightarrow{D} \mathcal{N}(0,1)$ is that $\tau_n \to \infty$ as $n \to \infty$.

Up to this point we have devoted attention to the weak convergence of sequences of statistics $\{T_n, n \geq 1\}$ constructed from independent underlying random variables $X_1, X_2, \ldots$. We consider now some extensions of the CLT where such restriction may be relaxed. The first of such extensions holds for sequences of (possibly dependent) random variables which may be structured as a *double array* of the form

$$\begin{pmatrix} X_{11}, & X_{12}, & \cdots, & X_{1k_1} \\ X_{21}, & X_{22}, & \cdots, & X_{2k_2} \\ \vdots & \vdots & \ddots & \vdots \\ X_{n1}, & X_{n2}, & \cdots, & X_{nk_n} \end{pmatrix}$$

where the X_{nk} are row-wise independent. The case where $k_n = n$, $n \geq 1$, is usually termed a *triangular array* of random variables. This result is very useful in the field of ▶order statistics.

Theorem 5 *(Double array CLT) Let the random variables $\{Y_{nk}, 1 \leq k \leq k_n, n \geq 1\}$ where $k_n \to \infty$ as $n \to \infty$ be such that for each n, $\{Y_{nk}, 1 \leq k \leq k_n\}$ are independent. Then*

1. *$\{Y_{nk}, 1 \leq k \leq k_n, n \geq 1\}$ is an infinitesimal system of random variables, i.e., satisfies the UAN condition.*
2. *$Z_n = \sum_{k=1}^{k_n}Y_{nk} \xrightarrow{D} \mathcal{N}(0,1)$.*

hold simultaneously, if and only if, for every $\varepsilon > 0$, as $n \to \infty$ the following two conditions hold

1. $\sum_{k=1}^{k_n}P(|Y_{nk}| > \varepsilon) \to 0$.
2. $\sum_{k=1}^{k_n}\left\{\int_{\{|y|\leq\varepsilon\}} y^2 dP(Y_{nk} \leq y) - \left[\int_{\{|y|\leq\varepsilon\}} y dP(Y_{nk} \leq x)\right]^2\right\} \to 1$.

Linear regression and related models pose special problems since the underlying random variables are not identically distributed and in many cases, the exact functional form of their distributions is not completely specified. Least-squares methods (see ▶Least Squares) are attractive under these conditions, since they may be employed in a rather general setup. In this context, the following CLT specifies sufficient conditions on the explanatory variables such that the distributions of the least squares estimators of the regression parameters may be approximated by normal distributions.

Theorem 6 *(Hájek-Šidak CLT) Let* $\{Y_n, n \geq 1\}$ *be a sequence of i.i.d. random variables with mean* μ *and finite variance* σ^2*; let* $\{\boldsymbol{x}_n, n \geq 1\}$ *be a sequence of real vectors* $\boldsymbol{x}_n = (x_{n1}, \ldots, x_{nn})'$*. Then if Noether's condition holds, i.e., if*

$$\max_{1 \leq i \leq n} \left[x_{ni}^2 \Big/ \sum_{i=1}^{n} x_{ni}^2 \right] \to 0 \quad as \quad n \to \infty,$$

holds, it follows that

$$Z_n = \left[\sum_{i=1}^{n} x_{ni}(Y_{ni} - \mu) \right] \Big/ \left[\sigma^2 \sum_{i=1}^{n} x_{ni}^2 \right]^{1/2} \xrightarrow{D} \mathcal{N}(0,1).$$

As an illustration, consider the simple linear regression model (see ▶Simple Linear Regression)

$$y_{ni} = \alpha + \beta x_{ni} + e_{ni}, \; i = 1, \ldots, n,$$

where y_{ni} and x_{ni} represent observations of the response and explanatory variables, respectively, α and β are the parameters of interest and the e_{ni} correspond to uncorrelated random errors with mean 0 and variance σ^2. The least squares estimators of β and α are respectively $\widehat{\beta}_n = \sum_{i=1}^{n}(x_{ni} - \bar{x}_n)(y_{ni} - \bar{y}_n) / \sum_{i=1}^{n}(x_{ni} - \bar{x}_n)^2$ and $\widehat{\alpha}_n = \bar{y}_n - \widehat{\beta}_n \bar{x}_n$ where $\bar{x}_n$ and $\bar{y}_n$ correspond to the sample means of the explanatory and response variables. Irrespectively of the form of underlying distribution of e_{ni}, we may use standard results to show that $\widehat{\alpha}_n$ and $\widehat{\beta}_n$ are unbiased and have variances given by $\sigma^2 \left[\sum_{i=1}^{n} x_{ni}^2 / \sum_{i=1}^{n}(x_{ni} - \bar{x}_n)^2 \right]$ and $\sigma^2 \left[\sum_{i=1}^{n}(x_{ni} - \bar{x}_n)^2 \right]^{-1}$, respectively. Furthermore, the covariance between $\widehat{\alpha}_n$ and $\widehat{\beta}_n$ is $-\sigma^2 \bar{x}_n / \sum_{i=1}^{n}(x_{ni} - \bar{x}_n)^2$. When the underlying distribution of e_{ni} is normal, we may show that $(\widehat{\alpha}_n, \widehat{\beta}_n)$ follows a bivariate normal distribution. If Noether's condition holds and both $\bar{x}_n$ and $n^{-1} \sum_{i=1}^{n}(x_{ni} - \bar{x}_n)^2$ converge to finite constants as $n \to \infty$, we may use the Hájek-Šidak CLT and the Cramér-Wold Theorem to conclude that the same bivariate normal distribution specified above serves as an approximation of the true distribution of $(\widehat{\alpha}_n, \widehat{\beta}_n)$, whatever the form of the distribution of e_{ni}, provided that n is sufficiently large.

The results may also be generalized to cover alternative estimators obtained by means of generalized and weighted least-squares procedures as well as via robust M-estimation procedures. They may also be extended to generalized linear and nonlinear models. Details may be obtained in Sen et al. (2010), for example.

It is still possible to relax further the independence assumption on the underlying random variables. The following theorems constitute examples of CLT for dependent random variables having a martingale (or reverse martingale) structure. For further details, the reader is referred to Loynes (1970), Brown (1971), Dvoretzky (1971), or McLeish (1974).

Theorem 7 *(Martingale CLT) Consider a sequence* $\{X_k, k \geq 1\}$ *of random variables satisfying*

1. $\mathbb{E}(X_k) = 0$.
2. $\mathbb{E}\left(X_k^2\right) = \sigma_k^2 < \infty$.
3. $\mathbb{E}\{X_k | X_1, \ldots, X_{k-1}\} = 0$, $X_0 = 0$.

Also let $T_n = \sum_{k=1}^{n} X_k$, $\tau_n^2 = \sum_{k=1}^{n} \sigma_k^2$, $v_k^2 = \mathbb{E}\left(X_k^2 | X_1, \ldots, X_{k-1}\right)$ *and* $w_n^2 = \sum_{k=1}^{n} v_k^2$*. If*

1. $w_n^2 / \tau_n^2 \xrightarrow{P} 1$ *as* $n \to \infty$.
2. $\forall \varepsilon > 0$, $\tau_n^{-2} \sum_{k=1}^{n} \mathbb{E}\left[X_k^2 I(|X_k| > \varepsilon \tau_n) \right] \to 0$ *as* $n \to \infty$ *(Lindeberg-Feller condition),*

then the sequence $\{X_k, k \geq 1\}$ *is infinitesimal and* $Z_n = T_n / \tau_n \xrightarrow{D} \mathcal{N}(0,1)$.

Note that the terms v_k^2 are random variables since they depend on $X_1, \ldots, X_{k-1}$; condition (A) essentially states that all the information about the variability in the X_k is contained in $X_1, \ldots, X_{k-1}$. Also note that $\{T_n, n \geq 1\}$ is a *zero mean martingale* (See also ▶Martingale Central Limit Theorem.)

Theorem 8 *(Reverse Martingale CLT) Consider a sequence* $\{T_k, k \geq 1\}$ *of random variables such that*

$$\mathbb{E}(T_n | T_{n+1}, T_{n+2}, \ldots) = T_{n+1} \quad and \quad \mathbb{E}(T_n) = 0,$$

i.e., $\{T_k, k \geq 1\}$ *is a zero mean reverse martingale. Assume that* $\mathbb{E}\left(T_n^2\right) < \infty$ *and let* $Y_k = T_k - T_{k+1}, k \geq 1$, $v_k^2 = \mathbb{E}\left(Y_k^2 | T_{k+1}, T_{k+2}, \ldots\right)$ *and* $w_n^2 = \sum_{k=n}^{\infty} v_k^2$*. If*

1. $w_n^2 / \mathbb{E}\left(w_n^2\right) \xrightarrow{a.s.} 1$.
2. $w_n^{-2} \sum_{k=n}^{\infty} \mathbb{E}\left[Y_k^2 I(|Y_k| > \varepsilon w_n) \middle| T_{k+1}, T_{k+2}, \ldots \right] \xrightarrow{P} 0$, $\varepsilon > 0$ *or* $w_n^{-2} \sum_{k=n}^{\infty} Y_k^2 \xrightarrow{a.s.} 1$,

it follows that $T_n / \sqrt{\mathbb{E}\left(w_n^2\right)} \xrightarrow{D} \mathcal{N}(0,1)$.

Rates of Convergence to Normality

In the general context discussed above, a question of both theoretical and practical interest concerns the speed with which the convergence to the limiting normal distribution takes place. Although there are no simple answers to this question, the following result may be useful.

Theorem 9 *(Berry-Esséen) Let* $\{X_n, n \geq 1\}$ *be a sequence of i.i.d. random variables with* $\mathbb{E}(X_1) = \mu$, $\mathbb{V}ar(X_1) = \sigma^2$ *and suppose that* $\mathbb{E}(|X_1 - \mu|^{2+\delta}) = \nu_{2+\delta} < \infty$ *for*

some $0 < \delta \leq 1$. *Also let* $T_n = \sum_{i=1}^{n} X_i$ *and* $F_{(n)}(x) = P\left[(T_n - n\mu)/\left(\sigma\sqrt{n}\right) \leq x\right]$, $x \in \mathbb{R}$. *Then there exist a constant* C *such that*

$$\Delta_n = \sup_{x\in\mathbb{R}} |F_{(n)}(x) - \Phi(x)| \leq C\frac{\nu_{2+\delta} n^{-\delta/2}}{\sigma^{2+\delta}}$$

where Φ *denotes the standard normal distribution function.*

The reader is referred to Feller (1971) for details. Berry (1941) proved the result for $\delta = 1$ and Esséen (1956) showed that $C \geq 0.4097$. Although the exact value of the constant C is not known, many authors have proposed upper bounds. In particular, van Beeck (1972) showed that $C \leq 0.7975$ and more recently, Shevtsova (2007) concluded that $C \leq 0.7056$. The usefulness of the theorem, however, is limited, since the rates of convergence attained are not very sharp.

Alternatively, the rates of convergence of the sequence of distribution functions $F_{(n)}$ to Φ or of the density functions $f_{(n)}$ (when they exist) to φ (the density function of the standard normal distribution) may be assessed by *Gram-Charlier* or *Edgeworth expansions* as discussed in Cramér (1946), for example. Although this second approach might offer a better insight to the problem of evaluating the rate of convergence to normality than that provided by the former, it requires the knowledge of the moments of the parent distribution and, thus, is less useful in practical applications.

Convergence of Moments

Given that weak convergence has been established, a question of interest is whether the moments (e.g., mean and variance) of the statistics under investigation converge to the moments of the limiting distribution. Although the answer is negative in general, an important theorem, due to Cramér, indicates conditions under which the result is true. The reader is referred to Sen et al. (2010) for details.

Asymptotic Distributions of Statistics not Expressible as Sums of Random Variables

The *Slustky theorem* is a handy tool to prove weak convergence of statistics that may be expressed as the sum, product or ratio of two terms, the first known to converge weakly to some distribution and the second known to converge in probability to some constant. As an example, consider independent and identically distributed random variables $Y_1, \ldots, Y_n$ with mean μ and variance σ^2. Since the corresponding sample standard deviation S converges in probability to σ and the distribution of $\overline{Y}$ may be approximated by a $\mathcal{N}(\mu, \sigma^2/n)$ distribution, we may apply Slutsky's theorem to show that the large-sample distribution of $\sqrt{n}\,\overline{Y}/S = \left(\sqrt{n}\,\overline{Y}/\sigma\right) \times (\sigma/S)$ may be approximated by a $\mathcal{N}(\mu, 1)$ distribution. This allows us to construct approximate confidence intervals for and tests of hypotheses about μ using the standard normal distribution. A similar approach may be employed to the Bernoulli example by noting that p_n is a consistent estimator of π.

An important application of Slutky's Theorem relates to statistics that can be decomposed as a sum of a term for which some CLT holds and a term that converges in probability to 0. Assume, for example, that the variables Y_i have a finite fourth central moment γ and write the sample variance as

$$S^2 = [n/(n-1)]\left\{n^{-1}\sum_{i=1}^{n}[(Y_i - \mu)^2 - \sigma^2/n] + \left[\sigma^2 - \sum_{i=1}^{n}(\overline{Y} - \mu)^2\right]\right\}.$$

Since the first term within the $\{\}$ brackets is known to converge weakly to a normal distribution by the CLT and the second term converges in probability to 0, we conclude that the distribution of S^2 may be approximated by a $\mathcal{N}(\sigma^2, \gamma/n)$ distribution. This is the basis of the projection results suggested by Hoeffding (1948) and extensively explored by Jurečkova and Sen (1996) to obtain large-sample properties of ▶*U*-statistics as well as of more general classes of estimators.

Another convenient technique to obtain the asymptotic distributions of many (smooth) functions of asymptotically normal statistics is the *Delta-method*: if g is a locally differentiable function of a statistic T_n whose distribution may be approximated (for large samples) by a $\mathcal{N}(\mu, \tau^2)$ distribution, then the distribution of the statistic $g(T_n)$ may be approximated by a $\mathcal{N}\{g(\mu), [g'(\mu)]^2\tau^2\}$ distribution, where $g'(\mu)$ denotes the first derivative of g computed at μ. Suppose that we are interested in estimating the odds of a failed versus pass response, i.e., $\pi/(1-\pi)$ in an exam based on a sample of n students. A straightforward application of the De Moivre Laplace CLT may be used to show that the estimator of π, namely, k/n, where k is the number of students that failed the exam, follows an approximate $\mathcal{N}[\pi, \pi(1-\pi)/n]$ distribution. Taking $g(x) = x/(1-x)$, we may use the Delta-method to show that the distribution of the sample odds $k/(n-k)$ may be approximated by a $\mathcal{N}\{\pi/(1-\pi), \pi/[n(1-\pi)^3]\}$ distribution. This type of result has further applications in variance-stabilizing transformations used in cases (as the above example) where the variance of the original statistic depends on the parameter it is set to estimate.

For some important cases, like the Pearson χ^2-statistic or more general quadratic forms $\boldsymbol{Q} = \boldsymbol{Q}(\boldsymbol{\mu}) = (\mathbf{Y} - \boldsymbol{\mu})^t \boldsymbol{A}(\mathbf{Y} - \boldsymbol{\mu})$ where $\mathbf{Y}$ is a p-dimensional random vector with mean vector $\boldsymbol{\mu}$ and covariance matrix $\mathbf{V}$ and $\mathbf{A}$ is a p-dimensional square matrix of full rank, the (multivariate) Delta-method may not be employed because the derivative of Q computed at $\boldsymbol{\mu}$ is null. If $\mathbf{A}$ converges to an inverse of $\mathbf{V}$, a useful result known as the *Cochran theorem*, states that the distribution of Q may be approximated by a χ^2 instead of a normal distribution. In fact, the theorem holds even if $\mathbf{A}$ is not of full rank, but converges to a generalized inverse of $\mathbf{V}$. This is important for applications in categorical data.

The CLT also does not hold for extreme order statistics like the sample minimum or maximum; depending on some regularity conditions on the underlying random variables, the distribution of such statistics, conveniently normalized, may be approximated by one of three types of distributions, namely the extreme value distributions of the first, second or third type, which, in this context, are the only possible limiting distributions as shown by Gnedenko (1943).

Central Limit Theorems for Stochastic Processes

Empirical distribution functions and ▶order statistics have important applications in nonparametric regression models, resampling methods like the ▶*jackknife* and *bootstrap* (see ▶Bootstrap Methods), sequential testing as well as in Survival and Reliability analysis. In particular it serves as the basis for the well known goodness-of-fit *Kolmogorov-Smirnov* and *Cramér-von Mises statistics* and for *L*- and *R-estimators* like *trimmed* or *Winsorized means*. Given the sample observations $Y_1, \ldots, Y_n$ assumed to follow some distribution function F and a real number y, the empirical distribution function is defined as

$$F_n(y) = n^{-1} \sum_{i=1}^{n} I(Y_i \le y)$$

where $I(Y_i \le y)$ is an indicator function assuming the value 1 if $Y_i \le y$ and 0, otherwise. It is intimately related to the order statistics, $Y_{n:1} \le Y_{n:2} \le \ldots \le Y_{n:n}$ where $Y_{n:1}$ is the smallest among $Y_1, \ldots, Y_n$, $Y_{n:2}$ is the second smallest and so on. For each fixed sample, F_n is a distribution function when considered as a function of y. For every fixed y, when considered as a function of $Y_1, \ldots, Y_n$, $F_n(y)$ is a random variable; in this context, since the $I(Y_i \le y), i = 1, \ldots, n$, are independent and identically distributed zero-one valued random variables, we may apply the classical CLT to conclude that for each fixed y the distribution of $F_n(y)$ may be approximated by a $\mathcal{N}\{F(y), F(y)[1-F(y)]/n\}$ distribution provided that n is sufficiently large. In fact, using standard asymptotic results, we may show that given any finite number m of points $y_1, \ldots, y_m$, the distribution function of the vector $[F_n(y_1), \ldots, F_n(y_m)]$ may be approximated by a multivariate normal distribution function. This property is known as *convergence of finite-dimensional distributions*.

On the other hand, $F_n - F = \{F_n(y) - F(y) : y \in \mathbb{R}\}$ is a random function defined on the set of real numbers, and, hence, to study its various properties we may need more than the results considered so far. Note that as the sample size n increases, so does the cardinality of the set of order statistics used to define the empirical distribution function and we may not be able to approximate this n-dimensional joint distribution by an m-dimensional one unless some further *tightness* or *compactness* conditions are imposed on the underlying distributions. This is the basis of the weak invariance principles necessary to show the convergence of empirical and other ▶stochastic processes to *Brownian bridge* or *Brownian motion* processes. An outline of the rationale underlying these results follows.

Let $t = F(y)$ and $W_n^0(t) = \sqrt{n}[G_n(t) - t]$, $t \in (0,1)$ where $G_n(t) = F_n[F^{-1}(t)] = F_n(y)$ with $F^{-1}(x) = \inf\{y : F(y) > x\}$, so that $\{W_n^0(t),\ t \in (0,1)\}$ is a stochastic process with $\mathbb{E}[W_n^0(t)] = 0$ and $\mathbb{E}[W_n^0(s)W_n^0(t)] = \min(s,t) - st$, $0 \le s,t \le 1$. Using the multivariate version of the CLT we may show that as $n \to \infty$, for all $m \ge 1$, given $0 \le t_1 \le \ldots \le t_m \le 1$, the vector $\boldsymbol{W}_{nm}^0 = [W_n^0(t_1), \ldots, W_n^0(t_m)] \xrightarrow{D} [W^0(t_1), \ldots, W^0(t_m)] = \boldsymbol{W}_m^0$ where $\boldsymbol{W}_m^0$ follows a $\mathcal{N}_m(\mathbf{0}, \boldsymbol{\Gamma}_m)$ distribution with $\boldsymbol{\Gamma}_m$ denoting a positive definite matrix with elements $\min(t_i, t_j) - t_i t_j$, $i,j = 1, \ldots, m$.

Now, define a stochastic process $\{Z(t),\ t \in (0,1)\}$ with independent and homogeneous increments such that, for every $0 \le s < t \le 1$, the difference $Z(t) - Z(s)$ follows a $\mathcal{N}(0, t-s)$ distribution. Then, it follows that $\mathbb{E}[Z(s)Z(t)] = \min(s,t)$. This process is known as a *standard Brownian motion* or *standard Wiener process*. Furthermore, letting $W^0(t) = Z(t) - tZ(1)$, $0 \le t \le 1$, it follows that $\{W^0(t),\ t \in (0,1)\}$ is also a Gaussian stochastic process such that $\mathbb{E}[W^0(t)] = 0$ and $\mathbb{E}[W^0(s)W^0(t)] = \min(s,t) - st$, $0 \le s,t \le 1$. Then for all $m \ge 1$, given $0 \le t_1 \le \ldots \le t_m \le 1$, the vector $\boldsymbol{W}_m^0 = [W^0(t_1), \ldots, W^0(t_m)]$ also follows a $\mathcal{N}_m(\mathbf{0}, \boldsymbol{\Gamma}_m)$ distribution. Since $W^0(0) = W^0(1) = 0$ with probability 1, this process is called a *tied down Wiener process* or *Brownian bridge*.

Using *the Kolmogorov maximal inequality*, we may show that $\{W_n^0(t),\ t \in (0,1)\}$ is *tight* and referring to standard results in weak convergence of probability measures, we may conclude that $\{W_n^0(t),\ t \in (0,1)\} \xrightarrow{D}$

$\{W^0(t),\ t \in (0,1)\}$. Details and extensions to statistical functionals may be obtained in Jurečkova and Sen (1996) among others.

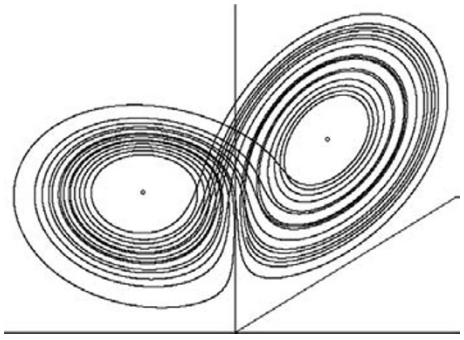
Chaotic Modelling

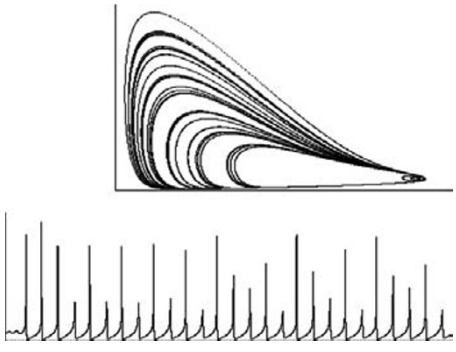
Christos H. Skiadas
Professor, Director of the Data Analysis and Forecasting Laboratory
Technical University of Crete, Chania, Greece

Chaotic modeling is a term used to express the representation of the state of a system or a process by using chaotic models or tools developed in the chaotic literature and the related scientific context. In the following we present the main elements of the chaotic modeling including chaotic terms, differential and difference equations and main theorems (Skiadas 2009).

Chaos is a relatively new science mainly developed during last decades with the use of computers and supercomputers. It touches almost all the scientific fields. However, the basic elements can be found at the end of the nineteenth century and the attempts to solve the famous three-body problem by Henri Poincaré (1890). Although he succeeded to solve only the special case when the three bodies move in the same plane, he could explore the main characteristics of the general three-body problem and to see the unpredictability of the resulting paths in space. In other words he could realize the main characteristic of



Chaotic Modelling. Fig. 1 The Lorenz attractor (xyz view)



Chaotic Modelling. Fig. 2 Autocatalytic attractor and chaotic oscillations

a chaotic process that very small changes in initial conditions have significant impact to the future states of a system.

This was verified by Edwin Lorenz in 1963 with his work on modeling the atmospheric changes. He reduced the Navier-Stokes equations, used to express fluid flows, to a system of three nonlinear coupling differential equations and performed simulations in a computer trying to model the weather changes. He surprisingly found that the system was very sensitive to small changes of initial conditions thus making the forecasts of the future weather unpredictable. Famous are the forms of his simulated paths that look like a butterfly with open wings. The three-dimensional model which he proposed has the form (σ, r and b are parameters):

$$\dot{x} = -\sigma x + \sigma y,\ \dot{y} = -xz + rx - y,\ \dot{z} = xy - bz.$$

The famous Lorenz attractor also known as the butterfly attractor is illustrated in Fig. 1.

Several years later Rössler (1976) proposed a simpler three-dimensional model including only one nonlinear term thus verifying the assumption that a set of simple differential equations with only one nonlinear term may express chaotic behavior. The Rössler system is the following (e, f and m are parameters):

$$\dot{x} = -y - z,\ \dot{y} = x - ez,\ \dot{z} = f + xz - mz.$$

It can be verified that the number of chaotic parameters is equal to the number of the equations.

Chemical chaotic oscillations where observed by Belousov (1959) and later on by Zhabotinsky (1964) when they where working with chemical autocatalytic reactions. The Nobel Prize in chemistry (1977) was awarded to Prigogine for his work on dynamics of dissipative systems (see Prigogine 1961) including the mathematical representation of autocatalytic reactions. A simple autocatalytic reaction is expressed by the following set of three differential equations:

$$\dot{x} = \left(\frac{1}{1+k} + m\right)(k+z) - xy^2 - x,\ \dot{y} = \frac{xy^2 + x - y}{e}, \dot{z} = y - z$$

This model is illustrated in Fig. 2; the parameters set are: $e = 0.013, k = 2.5, m = 0.017$.

The use of computing power gave rise to the exploration of chaos in astronomy and astrophysics. A paper that influenced much the future developments of the chaotic applications was due to Hénon and Heiles in 1964. They had predicted chaos in Hamiltonian systems that could apply to astronomy and astrophysics. Few years before George Contopoulos (1958) had also found chaotic behavior when he explored the paths of stars in a galaxy. That it was most important was that they had shown that the computer experiments had much more to show than simply verify the results coming from the mathematical formulations. Hidden and unexplored scientific fields would emerge by the use of computers.

It was found that chaos could emerge from a system of three or more differential equations with at list one nonlinear term. This comes from the Poincaré–Bendixson theorem which states that a two dimensional system of nonlinear equations may have a regular behavior.

Another theorem is the famous *KAM* theorem from the initials of the names of Kolmogorov, Arnold and Moser. This theorem applies to dynamical systems and may explain the stability or not of these systems to small perturbations. It is interesting that the chaotic forms could be quite stable as it happens for vortex and tornados.

However, the main scientific discovery on chaos came only in 1978 by Michel Feigenbaum when he found that the simple logistic map could produce a chaotic sequence. Feigenbaum tried a difference equation instead of the differential equations that where used in the previous works on chaos. That is different is that chaos can emerge even

from only one difference equation with at list one nonlinear term. This is because a difference equation defines a recurrence scheme which is a set of numerous equations in which every equation uses the outcomes from the preceding one. The complexity resulting from a nonlinear difference equation is large and it can be measured with a power law of the number of iterations.

In the logistic model a mapping into itself is defined by the difference equation and gives rise to period doubling bifurcations and chaos for a specific range of the chaotic parameter. The logistic map is of the form: $x_{n+1} = bx_n(1 - x_n)$, where b is the chaotic parameter and x_n is the chaotic function (see a (x_{n+1}, x_n) diagram of the Logistic model in Fig. 3; $b = 2.9$).

For the logistic map as also for other maps there exists the bifurcation diagram. This is a diagram, usually two dimensional, defining the bifurcation points with respect to the chaotic parameter or parameters (see Fig. 4).

The chaotic modeling has also to do with *strange attractors* by means forms in space that have a great detail and complexity. These forms can arise in nature and also can be simulated from chaotic equations. A very interesting future of a chaotic attractor is that for a variety of initial conditions the chaotic system leads the final results or solutions to a specific area, the strange or chaotic attractor.

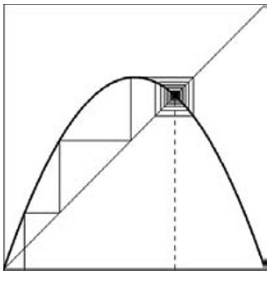
Chaos may also arise from a set of two or more difference equations with at least one nonlinear term. The most popular model is the Hénon (1976) model given by:

$$x_{n+1} = y_n + 1 - ax_n^2,\ y_{n+1} = bx_n.$$

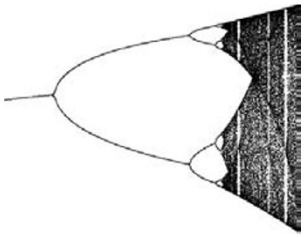
The Jacobian determinant of this model is:

$$\det J = \begin{vmatrix} \frac{\partial x_{n+1}}{\partial x_n} & \frac{\partial y_{n+1}}{\partial x_n} \\ \frac{\partial x_{n+1}}{\partial y_n} & \frac{\partial y_{n+1}}{\partial y_n} \end{vmatrix} = -b.$$

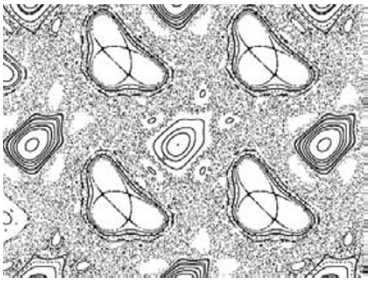
The system is stable for $0 < b < 1$. When $b = 1$ the system is area preserving, but it is unstable.



Chaotic Modelling. Fig. 3 The logistic model



Chaotic Modelling. Fig. 4 The bifurcation diagram



Chaotic Modelling. Fig. 5 A carpet-like form

An alternative of the Hénon map is provided by the following cosine model:
$x_{n+1} = by_n + 2a\cos(x_n) - 2a + 1,\ y_{n+1} = x_n$. This map provides a carpet-like form (see Fig. 5) for $b = -1$ and $a = -0.6$.

Very many cases in nature have to do with delays. This mathematically can be modeled by a delay differential or difference equation. Simpler is to use difference equations to express delay cases. An example is the transformation of the previous Hénon map to the corresponding delay difference equation of the form:

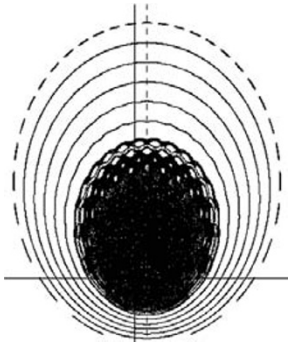
$$x_{n+1} = bx_{n-1} + 1 - ax_n^2.$$

This delay differential equation has the same properties of the Hénon map. In general modeling delays leads to differential or difference equations which produce oscillations and may produce chaos for appropriate selection of the parameters. One of the first proposed chaotic models including delays is the famous Mackey-Glass (1977) model regarding oscillation and chaos in physiological control systems.

Ikeda found his famous attractor in 1979 (see Fig. 6; parameters $a = 1, b = 0.83, c = 0.4$ and $d = 6$) when he was experimenting on the light transmitted by a ring cavity system. The equations' set is:

$$x_{n+1} = a + b(x_n\cos(\varphi_n) - y_n\sin(\varphi_n)),$$
$$y_{n+1} = b(x_n\sin(\varphi_n) + y_n\cos(\varphi_n)),$$

Chaotic Modelling. Fig. 6 The Ikeda attractor



Chaotic Modelling. Fig. 7 Chaotic rotating forms

where the rotation angle is: $\varphi_n = c - \dfrac{d}{1 + x_n^2 + y_n^2}$

The last form of difference equations express a rotation-translation phenomenon and can give very interesting chaotic forms (see Skiadas 2009). Figure 7 illustrates such a case where the rotation angle follows an inverse low regarding the distance r from the origin: $\varphi_n = \dfrac{c}{\sqrt{x_n^2 + y_n^2}} = \dfrac{c}{r}$. A chaotic bulge is located in the central part followed by elliptic trajectories in the outer part (the parameters are: $a = 0.6$ and $b = c = 1$).

Other interesting aspects of chaotic modeling are found in numerous publications regarding control of chaos with applications in various fields.

Chaotic mixing and chaotic advection have also studied with chaotic models as well as economic and social systems.

About the Author

Christos H. Skiadas is the Founder and Director of the Data Analysis and Forecasting Laboratory, Technical University of Crete (TUC). He was Vice-Rector of the Technical University of Crete (1997–1999), Chairman of the Production Engineering and Management Department, TUC (1995–1997) and participated in many committees and served as a consultant in various firms while he directed several scientific and applied projects. He was a visiting fellow in the University of Exeter, UK (1986) and Université Libre de Bruxelles, Belgium (1993–1994). He has been the guest-editor of the journals *Communications in Statistics*, *Methodology and Computing in Applied Probability* (MCAP) and *Applied Stochastic Models and Data Analysis*. He is a member of the Committee and Secretary of ASMDA International Society and was the Chair or co-chair of the International Conferences: 6th ASMDA 1993, 12th ASMDA 2007. As a member of the Greek Statistical Institute he organised and co-chaired two Annual National Conferences of the Institute (11th Chania 1998 and 22nd Chania 2009). Professor Skiadas contributions mainly are directed to the modeling and simulation of innovation diffusion and application of the findings in various fields as finance and insurance, energy consumption, forecasting and modeling. The related publications include more than 90 papers and 10 books, including *Chaotic Modelling and Simulation: Analysis of Chaotic Models, Attractors and Forms* (with Charilaos Skiadas, Chapman and Hall/CRC Press, 2009).

Characteristic Functions

Miljenko Huzak
University of Zagreb, Zagreb, Croatia

Characteristic functions play an outstanding role in the theory of probability and mathematical statistics (Ushakov 1999). The characteristic function (c.f.) of a probability distribution function (d.f.) is the Fourier–Stieltjes transform of the d.f. More precisely, if F is a probability d.f. on d-dimensional real space R^d ($d \geq 1$), then its c.f. is a complex function $\phi : \mathrm{R}^d \to \mathrm{C}$ such that for any $\mathbf{t} = (t_1, \ldots, t_d) \in \mathrm{R}^d$,

$$\begin{aligned}\phi(\mathbf{t}) &= \int_{\mathrm{R}^d} e^{i\sum_{j=1}^d t_j x_j}\, dF(x_1, \ldots, x_d) := \\ &= \int_{\mathrm{R}^d} \cos\left(\sum_{j=1}^d t_j x_j\right) dF(x_1, \ldots, x_d) \\ &\quad + i \int_{\mathrm{R}^d} \sin\left(\sum_{j=1}^d t_j x_j\right) dF(x_1, \ldots, x_d),\end{aligned}$$

where the integrals are Lebesgue–Stieltjes integrals with respect to d.f. F.

If $\mathbf{X} = (X_1, \ldots, X_d)$ is a d-dimensional random vector, then c.f. $\phi = \phi_{\mathbf{X}}$ associated to $\mathbf{X}$ is the c.f. of its d.f. $F = F_{\mathbf{X}}$. Hence

$$\phi_{\mathbf{X}}(\mathbf{t}) = \mathbb{E}\left[e^{i\sum_{j=1}^d t_j X_j}\right], \quad \mathbf{t} = (t_1, \ldots, t_d) \in \mathrm{R}^d. \tag{1}$$

Particularly, c.f. $\phi = \phi_X : \mathrm{R} \to \mathrm{C}$ of a random variable (r.v.) X is equal to

$$\phi(t) = \mathbb{E}[e^{itX}], \quad t \in \mathrm{R}.$$

Examples of c.f.s of some r.v.s are in Table 1.

C.f.s have many good properties (see Table 2). One of the most important properties of c.f.s is that there is a one-to-one correspondence between d.f.s and their c.f.s, which is a consequence of the *Lévy inversion formula* (see Chow and Teicher 1988 or Feller 1971). Since it is usually simpler to manipulate with c.f.s than with corresponding d.f.s, this property makes c.f.s useful in proving many theorems on probability distributions. For example, it can be proved that the components of a random vector $\mathbf{X} = (X_1, \ldots, X_d)$ are independent r.v.s if and only if

$$\begin{aligned}&(\forall t_1, \ldots, t_d \in \mathrm{R}) \;\; \phi_{\mathbf{X}}(t_1, \ldots, t_d) \\ &= \phi_{X_1}(t_1) \cdot \phi_{X_2}(t_2) \ldots \phi_{X_d}(t_d).\end{aligned}$$

Moreover, since for any independent r.v.s $X_1, X_2, \ldots, X_n$, c.f. of their sum $S_n = X_1 + \ldots + X_n$ is equal to the product of their c.f.s, to obtain the d.f. of S_n, it is usually easier

Characteristic Functions. Table 1 Characteristic functions of some univariate probability distributions

Characteristic Functions. Table 2 List of properties of characteristic functions $\phi_{\mathbf{X}}(\mathbf{t})$ given by (1) (the list follows one from Ferguson (1996))

(1)	$\phi_{\mathbf{X}}(\mathbf{t})$ exists for all $\mathbf{t} \in \mathrm{R}^d$ and is continuous.
(2)	$\phi_{\mathbf{X}}(\mathbf{0}) = 1$ and $\lvert\phi_{\mathbf{X}}(\mathbf{t})\rvert \leq 1$ for all $\mathbf{t} \in \mathrm{R}^d$.
(3)	For a scalar a, $\phi_{a\mathbf{X}}(\mathbf{t}) = \phi_{\mathbf{X}}(a\mathbf{t})$.
(4)	For a matrix A and a vector $\mathbf{c}$, $\phi_{A\mathbf{X}+\mathbf{c}}(\mathbf{t}) = e^{i\mathbf{t}^\tau \mathbf{c}} \cdot \phi_{\mathbf{X}}(A^\tau \mathbf{t})$.
(5)	For $\mathbf{X}$ and $\mathbf{Y}$ independent, $\phi_{\mathbf{X}+\mathbf{Y}}(\mathbf{t}) = \phi_{\mathbf{X}}(\mathbf{t})\phi_{\mathbf{Y}}(\mathbf{t})$.
(6)	If $\mathbb{E}\lvert\mathbf{X}\rvert < \infty$, $\dot{\phi}_{\mathbf{X}}(\mathbf{t})$ exists and is continuous and $\dot{\phi}_{\mathbf{X}}(\mathbf{0}) = i\,\mathbb{E}\,\mathbf{X}^\tau$.
(7)	If $\mathbb{E}[\lvert\mathbf{X}\rvert^2] < \infty$, $\ddot{\phi}_{\mathbf{X}}(\mathbf{t})$ exists and is continuous and $\ddot{\phi}_{\mathbf{X}}(\mathbf{0}) = -\mathbb{E}[\mathbf{X}\mathbf{X}^\tau]$.
(8)	If $P(\mathbf{X} = \mathbf{c}) = 1$ for a vector $\mathbf{c}$, $\phi_{\mathbf{X}}(\mathbf{t}) = e^{i\mathbf{t}^\tau \mathbf{c}}$.
(9)	If $\mathbf{X}$ is normal r. vec. with $\boldsymbol{\mu} = \mathbb{E}\,\mathbf{X}$ and $\mathrm{cov}(\mathbf{X}) = \Sigma$, $\phi_{\mathbf{X}}(\mathbf{t}) = \exp\left\{i\mathbf{t}^\tau \boldsymbol{\mu} - \frac{1}{2}\mathbf{t}^\tau \Sigma \mathbf{t}\right\}$.

to find the c.f. of their sum and to apply the Lévy inversion formula than to find the convolution of their d.f.s.

Another very important property of c.f.s comes from the *continuity theorem* (see Chow and Teicher 1988 or Feller 1971): r.v.s X_n, $n \geq 1$, with corresponding c.f.s ϕ_n, $n \geq 1$, converge in law to a r.v. X with c.f. ϕ if and only if c.f.s ϕ_n, $n \geq 1$, converge to ϕ pointwise. For example, this property makes proving ►central limit theorems easier if not only possible.

C.f.s have been important tools in developing theories of infinite divisible and particularly stable distributions (e.g., see Feller 1971; Chow and Teicher 1988).

Chebyshev's Inequality

Gerold Alsmeyer
Professor
Institut für Mathematische Statistik, Münster, Germany

Chebyshev's inequality is one of the most common inequalities used in probability theory to bound the tail probabilities of a random variable X having finite variance $\sigma^2 = \mathrm{Var}X$. It states that

$$\mathbb{P}(|X-\mu| \geq t) \leq \frac{\sigma^2}{t^2} \quad \text{for all } t>0, \tag{1}$$

where $\mu = \mathbb{E}X$ denotes the mean of X. Of course, the given bound is of use only if t is bigger than the standard deviation σ. Instead of proving (1) we will give a proof of the more general *Markov's inequality* which states that for any nondecreasing function $g : [0,\infty) \to [0,\infty)$ and any nonnegative random variable Y

$$\mathbb{P}(Y \geq t) \leq \frac{\mathbb{E}g(Y)}{g(t)} \quad \text{for all } t>0. \tag{2}$$

Indeed, choosing $Y = |X-\mu|$ and $g(x) = x^2$ gives (1). The proof of Markov's inequality is very easy: For any $t > 0$,

$$\mathbb{P}(Y \geq t) = \int 1_{\{Y\geq t\}} d\mathbb{P} \leq \int_{\{Y\geq t\}} \frac{g(Y)}{g(t)} d\mathbb{P} \leq \frac{\mathbb{E}g(X)}{g(t)}.$$

Plainly, (1) provides us with the same bound $\sigma^2 t^{-2}$ for the one-sided tail probability $\mathbb{P}(X-\mu > t)$, but in this case an improvement is obtained by the following consideration: For any $c \geq 0$, we infer from Markov's inequality with $g(x) = x^2$

$$\mathbb{P}(X-\mu \geq t) = \mathbb{P}(X-\mu+c \geq t+c) \leq \frac{\mathbb{E}(X-\mu+c)^2}{(t+c)^2} = \frac{\sigma^2+c^2}{(t+c)^2}.$$

The right-hand side becomes minimal at $c = \sigma^2/t$ giving the one-sided tail bound

$$\mathbb{P}(X-\mu > t) \leq \frac{\sigma^2}{\sigma^2+t^2} \quad \text{for all } t>0, \tag{3}$$

sometimes called *Cantelli's inequality*.

Although Chebyshev's inequality may produce only a rather crude bound its advantage lies in the fact that it applies to any random variable with finite variance. Moreover, within the class of all such random variables the bound is indeed tight because, if X has a symmetric distribution on $\{-a,0,a\}$ with $\mathbb{P}(X = \pm a) = 1/(2a^2)$ and $\mathbb{P}(X=0) = 1-1/a^2$ for some $a > 1$, then $\mu = 0$, $\sigma^2 = 1$ and

$$\mathbb{P}(|X| \geq a) = \mathbb{P}(|X| = a) = \frac{1}{a^2},$$

which means that equality holds in (1) for $t = a$.

On the other hand, tighter bounds can be obtained when imposing additional conditions on the considered distributions. On such example is the following *Vysočanskiĭ-Petunīn inequality* for random variables X with an unimodal distribution:

$$\mathbb{P}(|X-\mu| \geq t) \leq \frac{4\sigma^2}{9t^2} \quad \text{for all } t > \sqrt{3/8}\,\sigma, \tag{4}$$

This improves (1) by a factor 4/9 for sufficiently large t.

One of the most common applications of Chebyshev's inequality is the weak law of large numbers (WLLN). Suppose we are given a sequence $(S_n)_{n\geq 1}$ of real-valued random variables with independent increments $X_1, X_2, \ldots$ such that $\mu_n := \mathbb{E}X_n$ and $\sigma_n^2 := \mathrm{Var}X_n$ are finite for all $n \geq 1$. Defining

$$m_n := \mathbb{E}S_n = \sum_{k=1}^n \mu_k \quad \text{and} \quad s_n^2 := \mathrm{Var}S_n = \sum_{k=1}^n \sigma_k^2$$

and assuming *Markov's condition*

$$\lim_{n\to\infty} \frac{s_n^2}{n^2} = 0 \tag{5}$$

we infer by making use of (1) that, for any $\epsilon > 0$,

$$\mathbb{P}\left(\left|\frac{S_n - m_n}{n}\right| \geq \epsilon\right) \leq \frac{s_n^2}{\epsilon^2 n^2} \to 0 \quad \text{as } n \to \infty$$

and therefore

$$\frac{S_n - m_n}{n} \to 0 \quad \text{in probability.} \tag{WLLN}$$

This result applies particularly to the case of i.i.d. $X_1, X_2, \ldots$ Then $m_n = n\mu$ and $s_n^2 = n\sigma^2$ where $\mu := \mathbb{E}X_1$ and $\sigma^2 := \mathrm{Var}X_1$. In this case, Chebyshev's inequality further gives, for all $\epsilon, \beta > 0$, that

$$\sum_{n\geq 1} \mathbb{P}\left(\left|\frac{S_n - n\mu}{n}\right| \geq \epsilon \log^\beta n\right) \leq \sum_{n\geq 1} \frac{\sigma^2}{\epsilon^2 n \log^{2\beta} n} < \infty$$

and thus, by invoking the Borel-Cantelli lemma (see ►Borel–Cantelli Lemma and Its Generalizations),

$$\frac{S_n - n\mu}{n \log^\beta n} \to 0 \quad \text{a.s. for all } \beta > 0 \tag{6}$$

This is not quite the strong law of large numbers ($\beta = 0$) but gets close to it. In fact, in order for this to derive, a stronger variant of Chebyshev's inequality, called *Kolmogorov's inequality*, may be employed which states that

$$\mathbb{P}\left(\max_{1\leq k\leq n} |S_k - m_k| \geq t\right) \leq \frac{s_n^2}{t^2} \quad \text{for all } t > 0$$

under the same independence assumptions stated above for the WLLN. Notice the similarity to Chebyshev's inequality in that only $S_n - m_n$ has been replaced with $\max_{1\leq k\leq n}(S_k - m_k)$ while retaining the bound.

Let us finally note that, if X has mean μ, median m and finite variance σ^2, then the one-sided version (3) of Chebyshev's inequality shows that

$$\mathbb{P}(X - \mu \geq \sigma) \leq \frac{1}{2} \quad \text{and} \quad \mathbb{P}(X - \mu \leq -\sigma) \leq \frac{1}{2},$$

in other words, the median of X is always with one standard deviation of it mean.

Bibliographical notes: (1) dates back to Chebyshev's original work (Chebyshev 1867), but is nowadays found in any standard textbook on probability theory, like (Feller 1971). The latter contains also a proof of the one-sided version (3) which differs from the one given here. (4) for unimodal distributions is taken from Vysočanskiĭ and Petunĭn (1979), see also Sellke and Sellke (1997). For multivariate extensions of Chebyshev's inequality see Olkin and Pratt (1958) and Monhor (2007).

About the Author

Dr. Alsmeyer is Professor at the Department of Mathematics and Computer Science of the University of Münster and was the Chairman from 2000 till 2008. He has written more than 50 research articles and one book. He has supervised eight Ph.D. students.

Chemometrics

Rolf Sundberg
Professor of Mathematical Statistics
Stockholm University, Stockholm, Sweden

The role of statistics in chemistry is over a century old, going back to the Guinness brewery chemist and experimenter Gosset, more well-known under the pseudonym "Student." For his applications, he was in need of small-sample statistical methods. Until the 1970s, chemistry methods and instruments were typically univariate, but in that decade analytical chemistry and some other branches of chemistry had to start handling data of multivariate character. For example, instead of measuring light intensity at only a single selected wavelength, instruments became available that could measure intensities at several different wavelengths at the same time. The instrumental capacity rapidly increased, and the multivariate spectral dimension soon exceeded the number of chemical samples analysed (the "$n < p$" problem). In parallel, other chemists worked with Quantitative Structure–Activity Relationships (QSAR), where they tried to explain and predict biological activity or similar properties of a molecule from

a large number of structural physical-chemical characteristics of the molecule, but having an empirical data set of only a moderate number of different molecules. Generally, as soon as multivariate data are of high dimension, we must expect near collinearities among the variables, and when $n < p$, there are necessarily exact collinearities. These were some of the problems faced, long before statisticians got used to $n < p$ in genomics, proteomics etc. This was the birth of the field of chemometrics, a name coined by Svante Wold to characterize these research and application activities.

A standard definition of *Chemometrics* would be of type "The development and use of mathematical and statistical methods for applications in chemistry," with more weight on statistical than mathematical. Another characterization, formulated by Wold, is that the aim of chemometrics is to provide methods for

- How to get chemically relevant information out of measured chemical data
- How to get it into data
- How to represent and display this information

and that in order to achieve this, chemometrics is heavily dependent on statistics, mathematics and computer science. The first task is much concerned with analysis of dependencies and relationships (regression, calibration, discrimination, etc.) within a multivariate framework, because complex chemical systems are by necessity multidimensional. The second task is largely represented by experimental design, both classical and newer, where chemometrics has contributed the idea of design in latent factors (principal variates). For representation of high-dimensional data, projection on a low-dimensional latent variable space is the principal tool. Using diagrams in latent factors from PCA or other dimension-reducing methods is also a way of displaying the information found.

Another type of definition, often quoted, is that "Chemometrics is what chemometricians do." This is not only to laugh at. A vital part of chemometrics is connected with chemistry, but the methods developed might be and are applied in quite different fields, where the data analysis problems are similar, such as metabolomics, food science, sensometrics, and image analysis. This could motivate to distinguish chemometrics and chemometric methods, where the latter could as well be described as statistical methods originally inspired by problems in chemistry.

A statistician's look at the contents of *Journal of Chemometrics* for the period 2003–2005 (150 papers) showed that regression and calibration dominated, covering a third of the contents. Much of this was on regularized regression methods, such as PCR (Principal Components Regression) and PLSR (Partial Least Squares Regression). Other statistical areas represented were multiway methods (where each observation is a matrix or an even higher-dimensional array, see Smilde et al. 2004), classification (discrimination and clustering), multivariate statistical process control, and occasionally other areas, for example experimental design, wavelets, genetic algorithms.

A difference between chemometrics and biometrics (►biostatistics) is that chemometricians are mostly chemists by principal education, with more or less of additional statistical education, whereas biometricians are typically statisticians by education. This has had several consequences for chemometrics. Statistical methods are sometimes reinvented. Metods are sometimes proposed without a theoretical underpinning. The popular method of partial least squares (see ►Partial Least Squares Regression Versus Other Methods) is a good such example, nowadays relatively well understood, but proposed and advocated as a computational algorithm, that was widely regarded with suspicion among statisticians. Thus there is often a role for theoretical statistical studies to achieve a deeper understanding of the chemometric methods and their properties, not least to reveal how various suggested methods relate to each others.

About the Author

Professor Sundberg is Past President of the Swedish Statistical Association (1979–1981). He is an Elected member of the International Statistical Institute (1984). He was an Associate editor for *Scandinavian Journal of Statistics* (1987–1994). In 2004 he was awarded (with Marie Linder) the Kowalski prize for best theoretical paper in *Journal of Chemometrics* (2002–2003).

Chernoff Bound

Herman Chernoff
Professor Emeritus
Harvard University, Cambridge, MA, USA

The Chernoff Bound, due to Herman Rubin, states that if $\overline{X}$ is the average of n independent observations on a random variable X with mean $\mu < a$ then, for all t,

$$P(\overline{X} > a) \le \left[E(e^{t(X-a)})\right]^n.$$

The proof which follows shortly is a simple application of the Markov inequality that states that for a positive random variable $Y, P(Y \ge b) \le E(Y)/b$, for $b > 0$. The Chernoff bound was a step in the early development of the important field "Large Deviation Theory." It became prominent among computer scientists because of its usefulness in Information Theory.

The Markov inequality is derived from the fact that for $b > 0$,

$$E(Y) = \int ydF(Y) \ge \int_b^\infty ydF(y) \ge bP(Y \ge b)$$

where F is the cumulative distribution of Y.

We observe that

$$E(e^{nt(\overline{X}-a)}) = \left[E(e^{t(X-a)})\right]^n$$

and hence $P(e^{nt(\overline{X}-a)} \ge 1)$ is less than or equal to the bound. This implies the Chernoff bound for $t > 0$. For $t \le 0$ the inequality is automatically satisfied because the bound is at least one. That follows form the fact that the ►moment generating function $M(t) = E(e^{tZ})$ is convex with $M(0) = 1, M'(0) = E(Z)$ and $E(X - a) < 0$.

The prominence of the bound is due to a natural inclination to extend beyond its proper range of applicability. The Central Limit Theorem (see ►Central Limit Theorems), for which an informal statement is that $\overline{X}$ is approximately normally distributed with mean $\mu = E(X)$ and variance σ^2/n where σ is the standard deviation of X. For large deviations (see ►Large Deviations and Applications), or many standard deviations from the mean, the theorem implies that the probability of exceeding a would approach zero, but a naive interpretation would state that this probability would be approximately $\exp(-na^2/2)(2\pi na)^{-1/2}$ and could be seriously wrong.

In 1951, for a special problem of testing a simple hypothesis versus a simple alternative using a statistic of the form $\overline{X}$ where X could take on a few integer values, I realized that the normal approximation was inappropriate. I derived (Chernoff 1952), for $a > E(X)$,

$$n^{-1} \log P(\overline{X} > a) \to \inf_t E(e^{t(X-a)})$$

which was, as far as I know, the first application of Large Deviation Theory to Statistical Inference. This result was used to define a measure of information useful for experimental design and to show that the Kullback-Leibler information numbers (Kullback and Leibler 1951; Chernoff 1956) measure the exponential rate at which one error probability approaches zero when the other is held constant.

At the time I was informed of Cramér's (1938) earlier elegant derivation of more encompassing results, using exponentially tilted distributions. Cramér dealt with deviations which were not limited to those of order square root of n standard deviations, but required a condition that excluded the case which I needed, where the range of X was a multiple of the integers. Blackwell and Hodges (1959) later dealt with that case.

One of my colleagues, Herman Rubin, claimed that he could derive my results more simply, and when I challenged him, he produced the upper bound that I included in my manuscript. At the time the proof seemed so trivial, that I did not mention that it was his. I made two serious errors. First, the inequality is stronger than the upper limit implied by my result, and therefore deserves mention of authorship even though the derivation is simple. Second, because I was primarily interested in the exponential rate at which the probability approached zero, it did not occur to me that this trivially derived bound could become prominent.

Chernoff Faces

Herman Chernoff
Professor Emeritus
Harvard University, Cambridge, MA, USA

The graphical representation of two dimensional variables is rather straightforward. Three dimensional variables presents more of a challenge, but dealing with higher dimensions is much more difficult. Two methods using profiles and stars suffers from a confusion of which variable is represented when the dimensionality is greater than six.

The method called "Chernoff Faces" (Chernoff 1973) involves a computer program which draws a caricature of a face when given 18 numbers between 0 and 1. These numbers correspond to features of the face. Thus one may represent the length of the nose, another curvature of the mouth, and a third the size of the eyes. If we have 12 dimensional data, we can adjoin 6 constants to get points in 18 dimensional space, each represented by a face. As the point moves in 18 dimensional space the face changes.

The method was developed in response to a problem in cluster analysis (see ►Cluster Analysis: An Introduction). There are many methods proposed to do clustering. It seems that an appropriate method should depend on the nature of the data, which is difficult to comprehend without visualization. The grouping of faces which look alike serves as a preliminary method of clustering and of recognizing which features are important in the clustering.

In the two original applications of the method, the scientists involved claimed that the implementation was lucky because the features which were most important were represented respectively by the size of the eyes and the shape of the face, both of which are prominent features. I claimed that it did not matter which features were selected for the various variables and challenged the scientists to select an alternative choice of features for the variables to degrade the effect of the faces. Their candidate choices had little degradation effect.

To test the conjecture that the choice of variables would have no effect, Rizvi and I carried out an experiment (Chernoff and Rizvi 1975). Of course it is clear that the conjecture cannot be absolutely sound, since the position of the pupils in the eyes cannot be detected if the eyes are small and other features interact similarly. However we set up an experiment where subjects were supposed to cluster 36 faces into two groups of approximately 18 each. The faces were generated from two six dimensional ►multivariate normal distributions with means δ units apart, in Mahalanobis distance, and identity covariance matrix. These data were then subjected to a linear transformation to an 18-dimensional space, and 12 feature selections were made at random. The subjects were given three clustering problem. For the first δ was so large that there was no problem recognizing the clusters. That was a practice problem to train the students in the experiment. For the other two problems two choices of δ were made to establish greater difficulty in separating the two distributions. The result of this experiment was that when the error rate in clustering varies from 8% to 22%, the typical random permutations could change the error rate by a proportion which decreases from 45% to 18%.

Originally, Faces were designed to serve to understand which variables were important and which interacted with each other. Once such relations are understood, analytic methods could be used to probe further. In many applications, Faces could also be used to comprehend data where the roles of the various factors were well understood. For example, in business applications, a smiling face could indicate that some aspect of the business was doing well. With training of the users, such applications could be useful in providing a quick and easy comprehension of a moderately complicated system. For example, one could use a face to represent the many meters an airplane pilot watches, so that he could be alerted when the face begins to look strange. The method of stars could also serve such a function.

Jacob (1978) used faces to represent five particular scales of the Minnesota Multiphasic Personality Inventory (MMPI). The scales represented Hypochondriasis, Depression, Paranoia, Schizophrenia and Hypomania. Realizing that training a psychologist to recognize a smiling face as belonging to a depressed patient would be difficult, he developed an innovative approach to selecting features for the five scales. He presented a random selection of faces

to some psychologists and asked them to rate these faces on the MMPI scales. Then he used regression techniques to decide how the numerical values of an MMPI scale should be translated into features of the face, so that the face presented to a psychologist would resemble that of a person with those scaled values. This would facilitate the process of training psychologists to interpret the faces.

The method of Faces handles many dimensions well. For more than 18 variables, one could use a pair of faces. It does not deal so well with a large number of faces unless we have a time series in which they appear in succession. In that case they can be used to detect changes in characteristics of important complicated systems.

It seems that face recognition among humans is handled by a different part of the brain than that handling other geometrical data and humans are sensitive to very small changes in faces. Also, it seems that cartoons and caricatures of faces are better remembered than realistic representations.

Before the computer revolution, graphical representations, such as nomograms, could be used to substitute for accurate calculations. The Faces are unlikely to be useful for calculation purposes.

Chernoff-Savage Theorem

Herman Chernoff
Professor Emeritus
Harvard University, Cambridge, MA, USA

Hodges and Lehmann (1956) conjectured in 1956 that the nonparametric competitor to the t-test, the Fisher-Yates-Terry-Hoeffding or c_1 test (Terry 1952), was as efficient as the t-test for normal alternatives and more efficient for nonnormal alternatives.

To be more precise, we assume that we have two large samples, of sizes m and n with $N = m + n$, from two distributions which are the same except for a translation parameter which differs by an amount δ. To test the hypothesis that $\delta = 0$ against one sided alternatives, we use a test statistic of the form

$$T_N = m^{-1} \sum_{i=1}^{N} E_{Ni} z_{Ni}$$

where z_{Ni} is one or zero depending on whether the ith smallest of the N observations is from the first or the second sample. For example the Wilcoxon test is of the above form with $E_{Ni} = i/N$. It was more convenient to represent the test in the form

$$T_N = \int_{-\infty}^{\infty} J_N[H_N(x)]\, dF_m(x).$$

where F_m and G_n are the two sample cdf's, $\lambda_N = m/N$ and $H_N = \lambda_N F_m + (1 - \lambda_N) G_n$. These two forms are equivalent when $E_{Ni} = J_N(i/N)$.

The proof of the conjecture required two arguments. One was the ▶asymptotic normality of T when $\delta \neq 0$. The Chernoff-Savage theorem (Chernoff and Savage 1958) establishes the asymptotic normality, under appropriate regularity conditions on J_N, satisfied by c_1, using an argument where F_m and G_n are approximated by continuous time ▶Gaussian Processes, and the errors due to the approximation are shown to be relatively small.

The second argument required a variational result using the Pitman measure of local efficacy of the test of $\delta = 0$, which may be calculated as a function of the underlying distribution. For distributions with variance 1, the efficiency of the test relative to the t-test is minimized with a value of 1 for the normal distribution. It follows that the c_1 test is as efficient as the t-test for normal translation alternatives and more efficient for nonnormal translation alternatives.

About the Author

Dr. Herman Chernoff (born in New York City on July 1, 1923) is Professor Emeritus of Statistics at Harvard University and Emeritus Professor at M.I.T. He received a PhD in Applied Mathematics at Brown University in 1948 under the supervision of Abraham Wald (at Columbia University). Dr. Chernoff worked for the Cowles Commission at the University of Chicago and then spent three years in the Mathematics Department at the University of Illinois before joining the Department of Statistics at Stanford University in 1952, where he remained for 22 years.

He moved to M.I.T. in 1974, where he founded the Statistics Center. Since 1985 he has been in the Department of Statistics at Harvard. He retired from Harvard in 1997. Professor Chernoff was President of the Institute of Mathematical Statistics (1967–1968) and is an Elected member of both the American Academy of Arts and Sciences and the National Academy of Sciences. He has been honored for his contributions in many ways. He is a recipient of the Townsend Harris Medal and Samuel S. Wilks Medal "for outstanding research in large sample theory and sequential analysis, for extensive service to scholarly societies and on government panels, for effectiveness and popularity as a teacher, and for his continuing impact on the theory of statistics and its applications in diverse disciplines" (1987). He was named Statistician of the Year, Boston Chapter of the ASA (1991). He holds four honorary doctorates. Professor Chernoff is the co-author, with Lincoln Moses, of a classic text, now a Dover Reprint, entitled *Elementary Decision Theory*. He is also the author of the SIAM monograph 8 entitled *Sequential Analysis and Optimal Design*. The book *Recent Advances in Statistics* (MH Rizvi, J Rustagi and D Siegmund (Eds.), Academic Press, New York, 1983) published in honor of his 60th birthday in 1983 contained papers in the fields where his influence as a researcher and teacher has been strong: design and sequential analysis, optimization and control, nonparametrics, large sample theory and statistical graphics.

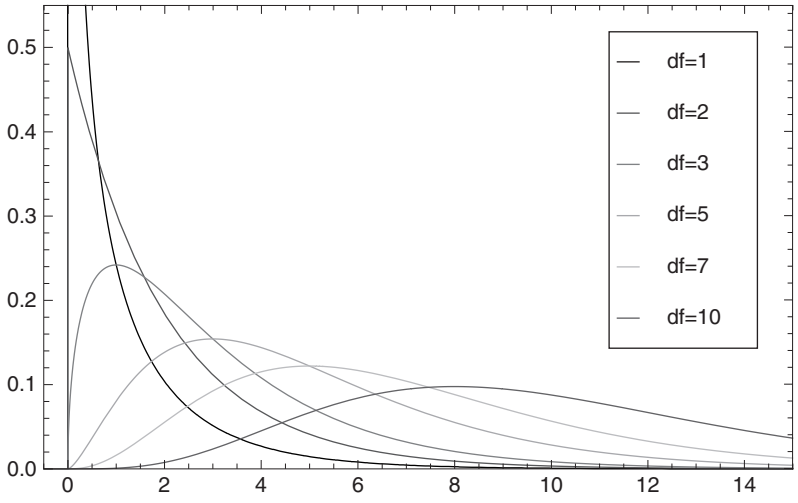
Chi-Square Distribution

Miljenko Huzak
University of Zagreb, Zagreb, Croatia

The chi-square distribution is one of the most important continuous probability distributions with many uses in statistical theory and inference. According to O. Sheynin (1971), Ernst Karl Abbe obtained it in 1863, Maxwell formulated it for three degrees of freedom in 1860, and Boltzman discovered the general expression in 1881. Lancaster (1966) ascertained that Bienaymé derived it as early as in 1838. However, their derivations "had no impact on the progress of the mainstream statistics" (R. L. Plackett 1983, p. 68)



Chi-Square Distribution. Fig. 1 Densities of χ^2 -distributions with 1, 2, 3, 5, 7, and 10 degrees of freedom (df)

since chi-square is not only a distribution, but also a statistic and a test procedure, all of which arrived simultaneously in the seminal paper written by Karl Pearson in 1900.

Let $n \geq 1$ be a positive integer. We say that a random variable (r.v.) has χ^2 (*chi-square*, χ is pronounced ki as in kind) *distribution with n degrees of freedom* (d.f.) if it is absolutely continuous with respect to the Lebesgue measure with density:

$$f(x) = \begin{cases} 0 & \text{if } x \leq 0 \\ \Gamma\left(\frac{n}{2}\right)^{-1} 2^{-n/2} x^{n/2-1} e^{-x/2} & \text{if } x > 0 \end{cases}$$

where Γ denotes the Gamma function.

Figure 1 shows some of the densities.

Hence, the χ^2-distribution (with n d.f.) is equal to the Γ - distribution with the parameters $(n/2, 2)$, that is, with the mean and variance equal to n and $2n$ respectively.

The χ^2-distribution is closely connected with the normal distribution. It turns out that the sample variance S^2 of a random sample from a normally distributed population has, up to the constant, the χ^2 – sample distribution. More precisely, if $X_1, \ldots, X_n$ are independent and identically distributed normal r.v.s with the population variance σ^2, then

$$\frac{n-1}{\sigma^2} \cdot S^2 = \frac{1}{\sigma^2}\left((X_1 - \overline{X})^2 + \ldots + (X_n - \overline{X})^2\right) = \frac{1}{\sigma^2}\left(X_1^2 + X_2^2 + \cdots + X_n^2 - n\overline{X}^2\right)$$

is a χ^2-distributed r.v. with $n - 1$ d.f. (see e.g., Shorack 2000). This is a consequence of a more general property of the normality (Feller 1971). For example, let $\mathbf{X}$ be an n-dimensional standard normal vector, that is, a random vector $\mathbf{X} = (X_1, \ldots, X_n)$ such that its components $X_1, \ldots, X_n$ are independent and normally distributed with mean and variance equal to 0 and 1 respectively. Then the square of the Euclidean norm of $\mathbf{X}$, $|\mathbf{X}|^2 = X_1^2 + \ldots + X_n^2$, is χ^2-distributed with n d.f. If means of the components of $\mathbf{X}$ are non-zero, then $|\mathbf{X}|^2$ has *non-central* χ^2-distribution with n d.f. and *non-centrality* parameter equal to the square of the mean of $\mathbf{X}$. In this generality, χ^2-distribution is the *central* χ^2-distribution, that is, a χ^2-distribution with non-centrality parameter equal to 0.

In statistics, many test statistics have a χ^2 or asymptotic χ^2-distribution. For example, goodness of fit χ^2-tests are based on the so-called Pearson's χ^2-statistics or general χ^2-statistics that have, under appropriate null-hypothesis, asymptotic χ^2-distributions; The Friedman test statistic and likelihood ratio tests are also based on asymptotically χ^2-distributed test statistic (see Ferguson 1996). Generally, appropriately normalized quadratic forms of normal (and asymptotic normal) statistics have χ^2 (and asymptotic χ^2) distributions.

Non-central χ^2-distributions are used for calculating the power function of tests based on quadratic forms of normal or asymptotic normal statistics.

Chi-Square Goodness-of-Fit Tests: Drawbacks and Improvements

Vassiliy Voinov[1], Mikhail Nikulin[2]
[1]Professor
Kazakhstan Institute of Management, Economics and Strategic Research, Almaty, Kazakhstan
[2]Professor
University of Victor Segalen, Bordeaux, France

The famous chi-squared goodness-of-fit test was discovered by Karl Pearson in 1900. If the partition of a sample space is such that observations are grouped over r disjoined

intervals Δ_i, and denoting ν_i observed frequencies and $np_i(\theta)$ expected that correspond to a multinomial scheme, the Pearson's sum is written

$$\chi^2 = X_n^2(\theta) = \sum_{i=1}^{r} \frac{(\nu_i - np_i(\theta))^2}{np_i(\theta)} = \mathbf{V}^T(\theta)\mathbf{V}(\theta), \quad (1)$$

where $\mathbf{V}(\theta)$ is a vector with components $v_i(\theta)=(\nu_i - np_i(\theta))(np_i(\theta))^{-1/2}$, $i=1,\ldots,r$. If the number of observations $n \to \infty$, the statistic (1) for a simple null hypothesis, specifying the true value of θ, will follow chi-squared probability distribution with $r-1$ degrees of freedom.

Until 1934, Pearson believed that the limit distribution of his chi-squared statistic would be the same if unknown parameters of the null hypothesis were replaced by estimates based on a sample (Stigler (2008), p. 266). Stigler noted that this major error of Pearson "has left a positive and lasting impression upon the statistical world." It would be better to rephrase this sentence as follows: "has left a positive (because it inspired the further development of the theory of chi-squared test) and lasting 'negative' impression". Fisher (1924) clearly showed that the number of degrees of freedom of the Pearson's test must be reduced by the number of parameters estimated by a sample. The Fisher's result is true if and only if parameters are estimated by grouped data (minimizing Pearson's chi-squared sum, using multinomial maximum likelihood estimates (MLEs) for grouped data, or by any other asymptotically equivalent procedure).

Nowadays, the Pearson's test with unknown parameters replaced by grouped data estimates $\hat{\theta}_n$ is known as Pearson-Fisher test $X_n^2(\hat{\theta}_n)$. Chernoff and Lehmann (1954) showed that replacing unknown parameters in (1) by their maximum likelihood estimates based on non-grouped data would dramatically change the limit distribution. In this case, it will follow a distribution that in general depends on unknown parameters and, hence, cannot be used for testing. What is difficult to understand for those who apply chi-squared tests is that an estimate is a realization of a random variable with its own probability distribution and that a particular estimate can be too far from the actual unknown value of a parameter or parameters. This misunderstanding is rather typical for those who apply both parametric and non-parametric tests for compound hypotheses.

Roy (1956) extended Chernoff and Lehmann's result to the case of random grouping intervals. Molinari (1977) derived the limit distribution of Pearson's sum if moment type estimates (MMEs) based on raw data are used. Like the case of MLEs it depends on unknown parameters. Thus, a problem of deriving a test statistic, where limiting distribution will not depend on parameters, is aroused. Dahiya and Gurland (1972) showed that for location and scale families with properly chosen random cells, the limit distribution of Pearson's sum may not depend on unknown parameters but on the null hypothesis. Being distribution-free, such tests can be used in practice, but for each specific null distribution one has to evaluate corresponding critical values. So, two ways of constructing distribution-free Pearson's type tests are to use proper estimates of unknown parameters (e.g., based on grouped data), or to use specially constructed grouping intervals. Another possible way is to modify the Pearson's sum such that its limit probability distribution would not depend on unknowns. Nikulin (1973), using a very general theoretical approach (nowadays known as Wald's method (see Moore 1977)), solved the problem in full for any continuous probability distribution if one will use random cells based on predetermined probabilities to fall into a cell with random boundaries depending on efficient estimates (MLEs or best asymptotically normal (BAN) estimates) of unknown parameters. Rao and Robson (1974), using a much less general heuristic approach, confirmed the result of Nikulin for a particular case of exponential family of distributions. Formally their result fully coincides with that of Nikulin (1973)

$$Y1_n^2(\hat{\theta}_n) = X_n^2(\hat{\theta}_n) + \mathbf{V}^T(\hat{\theta}_n)\mathbf{B}(\mathbf{J} - \mathbf{J}_g)^{-1}\mathbf{B}^T\mathbf{V}(\hat{\theta}_n), \quad (2)$$

where $\mathbf{J}$ and $\mathbf{J}_g = \mathbf{B}^T\mathbf{B}$ are Fisher information matrices for non-grouped and grouped data correspondingly, and $\mathbf{B}$ is a matrix with elements $b_{ij} = \frac{1}{\sqrt{p_i(\theta)}}\frac{\partial p_i(\theta)}{\partial \theta_j}$, $i = 1,\ldots,r$, $j = 1,\ldots,s$. The statistic (2) can be presented also as (Moore and Spruill (1975))

$$Y1_n^2(\hat{\theta}_n) = \mathbf{V}^T(\hat{\theta}_n)(\mathbf{I} - \mathbf{B}\mathbf{J}^{-1}\mathbf{B}^T)^{-1}\mathbf{V}(\hat{\theta}_n). \quad (3)$$

The statistic (2) or (3), suggested first by Nikulin (1973a) for testing the normality, will be referred to subsequently as Nikulin-Rao-Robson (NRR) test. Nikulin (1973) assumed that only asymptotically efficient estimates of unknown parameters (e.g., MLEs based on non-grouped data or BAN estimates) are used for testing. Singh (1987), Spruill (1976), and Lemeshko et al. (2001) showed that the NRR test is asymptotically optimal in some sense. This optimality is not surprising because the second term of (2) depends on the difference between Fisher's matrices for grouped and non-grouped data that possibly takes the information lost in full (Voinov (2006)). Dzhaparidze and Nikulin (1992) generalized Fisher's idea to improve any $\sqrt{n}$- consistent estimator to make it asymptotically as efficient as

MLE. This gives the following way of chi-squared test modification: improve an estimator first and then use the NRR statistic. Since this way is not simple computationally, it is worth considering other modifications. At this point it is important to note that the NRR test is very suitable for describing censored data (Habib and Thomas (1986)).

Dzhaparidze and Nikulin (1974) proposed a modification of the standard Pearson's statistic valid for any square root of n consistent estimate $\tilde{\theta}_n$ of an unknown parameter $U_n^2(\tilde{\theta}_n) = \mathbf{V}^T(\tilde{\theta}_n)\mathbf{B}(\mathbf{B}^T\mathbf{B})^{-1}\mathbf{B}^T\mathbf{V}(\tilde{\theta}_n)$. This test (the DN test), like the asymptotically equivalent Pearson-Fisher one, is not powerful for equiprobable cells (McCulloch (1985), Voinov et al. (2009)) but it can be rather powerful if an alternative hypothesis is specified and one uses the Neyman-Pearson classes for data grouping. Having generalized the idea of Dzhaparidze and Nikulin (1974), Singh (1987) suggested a generalization of the RRN test (3) valid for any $\sqrt{n}$ - consistent estimator $\tilde{\theta}_n$ of an unknown parameter $Q_s^2(\tilde{\theta}_n) = \mathbf{V}_*^T(\tilde{\theta}_n)(\mathbf{I} - \mathbf{B}\mathbf{J}^{-1}\mathbf{B}^T)^{-1}\mathbf{V}_*(\tilde{\theta}_n)$, where $\mathbf{V}_*(\tilde{\theta}_n) = \mathbf{V}(\tilde{\theta}_n) - \mathbf{B}\mathbf{J}^{-1}\mathbf{W}(\tilde{\theta}_n)$, and $\mathbf{W}(\tilde{\theta}_n) = \frac{1}{\sqrt{n}}\sum_{i=1}^{n}\frac{\partial \ln f(X_i,\theta)}{\partial\theta}|_{\theta=\tilde{\theta}_n}$.

A unified large-sample theory of general chi-squared statistics for tests of fit was developed by Moore and Spruill (1975). Moore (1977), based upon Wald's approach, formulated a general recipe for constructing modified chi-squared tests for any square root of n consistent estimator that actually is a generalization of Nikulin's idea. He was first to show that a resulting Wald's quadratic form does not depend on the way of limit covariance matrix of generalized frequencies inverting.

Hsuan and Robson (1976) showed that a modified statistic will not be the same as (3) in the case of moment type estimates (MMEs) of unknown parameters. They succeeded in deriving the limit covariance matrix for generalized frequencies and proved the theorem that a corresponding Wald's quadratic form will follow in the limit the chi-squared distribution. Hsuan and Robson provided the test statistic explicitly for the exponential family of distributions, when MMEs coincide with MLEs, thus confirming the already known result of Nikulin (1973). Hsuan and Robson have not derived the general modified test based on MMEs $\bar{\theta}_n$ explicitly. This was done later by Mirvaliev (2001). Taking into account the input of Hsuan and Robson, and Mirvaliev, this test will be referred to subsequently as the Hsuan-Robson-Mirvaliev (HRM) statistic

$$Y2_n^2(\bar{\theta}_n) = X_n^2(\bar{\theta}_n) + R_n^2(\bar{\theta}_n) - Q_n^2(\bar{\theta}_n). \qquad (4)$$

Explicit expressions for quadratic forms $R_n^2(\bar{\theta}_n)$ and $Q_n^2(\bar{\theta}_n)$ are given, e.g., in Voinov et al. (2009). The approach, based on Wald's transformation, was also used by Bol'shev and Mirvaliev (1978), Nikulin and Voinov (1989), Voinov and Nikulin (1994), and by Chichagov (2006) for minimum variance unbiased estimators (MVUEs).

It is important to mention two types of decompositions of classical and modified chi-squared tests. The first way decomposes a modified test on a sum of the classical Pearson's test and a correcting term that makes the test chi-squared distributed being distribution free in the limit (Nikulin (1973)). A much more important decomposition was first suggested by McCulloch (1985) (see also Mirvaliev (2001)). This is a decomposition of a test on a sum of the DN statistic and an additional quadratic form being asymptotically independent on the DN statistic. Denoting $W_n^2(\theta) = \mathbf{V}^T(\theta)\mathbf{B}(\mathbf{B}^T\mathbf{B})^{-1}\mathbf{B}^T\mathbf{V}(\theta)$ and $P_n^2(\theta) = \mathbf{V}^T(\theta)\mathbf{B}(\mathbf{J} - \mathbf{J}_g)^{-1}\mathbf{B}^T\mathbf{V}(\theta)$ the decomposition of the NRR statistic (2) in case of MLEs will be $Y1_n^2(\hat{\theta}_n) = U_n^2(\hat{\theta}_n) + \left(W_n^2(\hat{\theta}) + P_n^2(\hat{\theta}_n)\right)$, where $U_n^2(\hat{\theta}_n)$ is asymptotically independent on $\left(W_n^2(\hat{\theta}) + P_n^2(\hat{\theta}_n)\right)$, and on $W_n^2(\hat{\theta})$. The decomposition of the HRM statistic (4) is $Y2_n^2(\bar{\theta}_n) = U_n^2(\bar{\theta}_n) + \left(W_n^2(\bar{\theta}) + R_n^2(\bar{\theta}_n) - Q_n^2(\bar{\theta}_n)\right)$, where $U_n^2(\bar{\theta}_n)$ is asymptotically independent on $\left(W_n^2(\bar{\theta}) + R_n^2(\bar{\theta}_n) - Q_n^2(\bar{\theta}_n)\right)$, but is asymptotically correlated with $W_n^2(\bar{\theta})$.

The decomposition of a modified chi-squared test on a sum of the DN statistic and an additional term is of importance because the DN test based on non-grouped data is asymptotically equivalent to the Pearson-Fisher's (PF) statistic for grouped data. Hence, that additional term takes into account the Fisher's information lost due to grouping. Later it was shown (Voinov et al. (2009)) that the DN part, like the PF test, is (for equiprobable cells, for example) insensitive to some alternative hypothesis in case of equiprobable cells (fixed or random) and would be sensitive to it for, e.g., non-equiprobable two Neyman-Pearson classes. For equiprobable cells this suggests using the difference between the modified statistic and the DN part that will be the most powerful statistic in case of equiprobable cells (McCulloch (1985), Voinov et al. (2009)). It became clear that the way of sample space partitioning essentially influences power of a test.

Ronald Fisher (1925) was the first to note that "in some cases it is possible to separate the contributions to χ^2 made by the individual degrees of freedom, and so to test the separate components of a discrepancy." Cochran (1954) wrote "that the usual χ^2 tests are often insensitive, and do not indicate significant results when the null hypothesis is actually false" and suggested to "use a single degree of freedom, or a group of degrees of freedom, from the total χ^2," to obtain more powerful and appropriate test. The

problem of implementing the idea of Fisher and Cochran was that decompositions of Pearson's sum and modified test statistics were not known at that time. Anderson (1994) (see also Boero et al. (2004)) was possibly the first who to decompose the Pearson's χ^2 for a simple null hypothesis into a sum of independent χ^2_1 random variables in case of equiprobable grouping cells. A parametric decomposition of Pearson's χ^2 in case of non-equiprobable cells based on ideas of Mirvaliev (2001) was obtained by Voinov et al. (2008) in an explicit form. At the same time Voinov et al. (2008) presented parametric decompositions of NRR and HRM statistics. Voinov (2010) and Voinov and Pya (2010) introduced vector-valued goodness-of-fit tests that, in some cases, can provide a gain in power for specified alternatives.

About the Authors

Vassiliy Voinov is a Professor of the Operations Management and Information Systems Department, Kazakhstan Institute of Management, Economics and Strategic Research (KIMEP). He received his engineering diploma at Tomsk State University; Candidate of Science degree in Kazakh Academy of Science; Doctor of Science degree in Joint Institute for Nuclear Research, Dubna, Moscow region; Professor degree in Kazakh State Polytechnic University, and also in 1998 received a Professor's degree in KIMEP. He has professional experience as an invited professor in statistics at the University Victor Segalen Bordeaux, France. Vassiliy Voinov participated in many international conferences and has more than 120 research papers and books, including: *Unbiased Estimators and Their Applications*, Volume 1: *Univariate Case*, and Volume 2: *Multivariate Case* (with M. Nikulin, Kluwer Academic Publishers: Dordrecht, 1993 and 1996).

Mikhail S. Nikulin (Nikouline) is Professor of Statistics at the University Victor Segalen, Bordeaux 2. He earned his doctorate in the Theory of Probability and Mathematical Statistics from the Steklov Mathematical Institute in Moscow in 1973, under supervision of Professor L. N. Bol'shev. He was Dean of the the Faculty l'UFR "Sciences and Modélisation", the University Victor Segalen (1996–2001) and Head of the Laboratory EA 2961 "Mathematical Statistics and its Applications" (1999–2007). Professor Nikulin has (co-)authored over 250 papers, 28 edited volumes and 13 books, including *A Guide to Chi-Squared Testing* (with P.E. Greenwood, Wiley, 2004), *Probability, Statistics and Modelling in Public Health* (with D. Commenges, Springer, 2005), and was the editor of the volume *Advances in Degradation Modeling: Applications to Reliability, Survival Analysis and Finance* (with N. Balakrishnan, W. Kahle, N. Limnios and C. Huber-Carol, Birkhäuser, 2009). His name is associated with several statistics terms: Dzhaparidze-Nikulin statistic, Rao-Robson-Nikulin statistic, Bagdonavičius-Nikulin model, and Bagdonavičius-Nikulin estimator.

Chi-Square Test: Analysis of Contingency Tables

David C. Howell
Professor Emeritus
University of Vermont, Burlington, VT, USA

The term "chi-square" refers both to a statistical distribution and to a hypothesis testing procedure that produces a statistic that is approximately distributed as the ▶chi-square distribution. In this entry the term is used in its second sense.

Pearson's Chi-Square

The original chi-square test, often known as Pearson's chi-square, dates from papers by Karl Pearson in the earlier 1900s. The test serves both as a "goodness-of-fit" test, where the data are categorized along one dimension, and as a test for the more common "contingency table," in which categorization is across two or more dimensions. Voinov and Nikulin, this volume, discuss the controversy over the correct form for the goodness of fit test. This entry will focus on the lack of agreement about tests on contingency tables.

In 2000 the Vermont State legislature approved a bill authorizing civil unions. The vote can be broken down by gender to produce the following table, with the expected frequencies given in parentheses. The expected frequencies are computed as $R_i \times C_j/N$, where R_i and C_j represent row and column marginal totals and N is the grand total.

	Vote		
	Yes	No	Total
Women	35 (28.83)	9 (15.17)	44
Men	60 (66.17)	41 (34.83)	101
Total	95	50	145

The standard Pearson chi-square statistic is defined as

$$\chi^2 = \sum\sum \frac{(O_{ij} - E_{ij})^2}{E_{ij}} = \frac{(35 - 28.83)^2}{28.83} + \cdots + \frac{(41 - 34.83)^2}{34.83} = 5.50$$

where i and j index the rows and columns of the table. (For the goodness-of-fit test we simply drop the subscript j.) The resulting test statistic from the formula on the left is approximately distributed as χ^2 on $(r-1)(c-1)$ degrees of freedom. The probability of $\chi^2 \geq 5.50$ on 1 df = 0.019, so we can reject the null hypothesis that voting behavior is independent of gender. (Pearson originally misidentified the degrees of freedom, Fisher corrected him, though Pearson long refused to recognize the error, and Pearson and Fisher were enemies for the rest of their lives.)

Likelihood Ratio Chi-Square

Pearson's chi-square statistic is not the only chi-square test that we have. The likelihood ratio chi-square builds on the likelihood of the data under the null hypothesis relative to the maximum likelihood. It is defined as

$$G^2 = 2\sum O_{ij} \log\left(\frac{O_{ij}}{E_{ij}}\right) = 2\left[35\ln\left(\frac{35}{28.83}\right) + 9\ln\left(\frac{9}{15.17}\right) + 60\ln\left(\frac{60}{66.17}\right) + 41\ln\left(\frac{41}{34.83}\right)\right] = 5.81$$

This result is slightly larger than the Pearson chi-square of 5.50. One advantage of the likelihood ratio chi-square is that G^2 for a large dimensional table can be neatly decomposed into smaller components. This cannot be done exactly with Pearson's chi-square, and G^2 is the usual statistic for log-linear analyses. As sample sizes increase the two chi-square statistics converge.

Small Expected Frequencies

Probably no one would object to the use of the Pearson or likelihood ratio chi-square tests for our example. However, the chi-square statistic is only approximated by the chi-square distribution, and that approximation worsens with small expected frequencies. When we have very small expected frequencies, the possible values of the chi-square statistic are quite discrete. For example, for a table with only four observations in each row and column, the only possible values of chi-square are 8, 2, and 0. It should be clear that a continuous chi-square distribution is not a good match for a discrete distribution having only three values. The general rule is that the smallest expected frequency should be at least five. However Cochran (1952), who is generally considered the source of this rule, acknowledged that the number "5" seems to be chosen arbitrarily.

Yates proposed a correction to the formula for chi-square to bring it more in line with the true probability. However, given modern computing alternatives, Yates' correction is much less necessary and should be replaced by more exact methods.

For situations in which we do not satisfy Cochran's rule about small expected frequencies, the obvious question concerns what we should do instead. This is an issue over which there has been considerable debate. One of the most common alternatives is Fisher's Exact Test (see below), but even that is controversial for many designs.

Alternative Research Designs

There are at least four different research designs that will lead to data forming a contingency table. One design assumes that all marginal totals are fixed. Fisher's famous "tea-tasting" study had four cups of tea with milk added first and four with milk added second (row totals are fixed). The taster had to assign four cups to each guessed order of pouring, fixing the column totals. The underlying probability model is hypergeometric, and Fisher's exact test (1934) is ideally suited to this design and gives an exact probability. This test is reported by most software for 2×2 tables, though it is not restricted to the 2×2 case.

Alternatively we could fix only one set of marginals, as in our earlier example. Every replication of that experiment would include 44 women and 101 men, although the vote totals could vary. This design is exactly equivalent to comparing the proportion of "yes" votes for men and women, and it is based on the ▶binomial distribution. The square of a z-test on proportions would be exactly equal to the resulting chi-square statistic. One alternative analysis for this design would be to generate all possible tables with those row marginals and compute the percentage of obtained chi-square statistics that are as extreme as the statistic obtained from the actual data. Alternatively, some authorities recommend the use of a mid-p value, which sums the probability of all tables less likely than the one we obtained, plus half of the probability of the table we actually obtained.

For a different design, suppose that we had asked 145 Vermont citizens to record their opinion on civil unions. In this case neither the Gender nor Vote totals would be fixed, only the total sample size. The underlying probability model would be multinomial. Pearson's chi-square test would be appropriate, but a more exact test would be obtained by taking all possible tables (or, more likely, a very large number of randomly generated tables) with 145 observations and calculating chi-square for each. Again the probability value would be the proportion of tables with more extreme outcomes than the actual table. And, again, we could compute a mid-p probability instead.

Finally, suppose that we went into college classrooms and asked the students to vote. In this case not even the total sample size is fixed. The underlying probability model here is Poisson.

Computer scripts written in R are available for each model with a fixed total sample size at http://www.uvm.edu/~dhowell/StatPages/chi-square-alternatives.html

Summary

Based on a large number of studies of the analysis of contingency tables, the current recommendation would be to continue to use the standard Pearson chi-square test whenever the expected cell frequencies are sufficiently large. There seems to be no problem defining large as "at least 5." With small expected frequencies ▶Fisher's Exact Test seems to perform well regardless of the sampling plan, but ▶randomization tests adapted for the actual research design, as described above, will give a somewhat more exact solution. Recently Campbell (2007) carried out a very large sampling study on 2×2 tables comparing different chi-square statistics under different sample sizes and different underlying designs. He found that across all sampling designs, a statistic suggested by Karl Pearson's son Egon Pearson worked best in most situations. The statistic is defined as $\chi^2 \frac{N}{N-1}$. (For the justification for that adjustment see Campbell's paper.) Campbell found that as

long as the smallest expected frequency was at least one, the adjusted chi-square held the Type I error rate at very nearly α. When the smallest expected frequency fell below 1, Fisher's Exact Test did best.

About the Author

David Howell is a Professor Emeritus (since 2002), and former chair of the Psychology department at the University of Vermont (1987–1992) and (2000–2002). Professor Howell's primary area of research is in statistics and experimental methods. He has authored well known texts: *Statistical Methods for Psychology* (Wadsworth Publishing, 7*th* ed., 2009), *Fundamental Statistics for Behavioral Sciences* (Wadsworth Publishing, 7*th* ed., 2010), and is a coauthor (with Brian Everitt) of a four volume *Encyclopedia of Statistics in Behavior Science* (Wiley & Sons, 2005).

Chi-Square Tests

Karl L. Wuensch
Professor
East Carolina University, Greenville, NC, USA

The χ^2 statistic was developed by Karl Pearson (1900) as a means to compare an obtained distribution of scores with a theoretical distribution of scores. While it is sometimes still employed as a univariate goodness of fit test, other statistics, such as the ►Kolmogorov–Smirnov test and, where the theoretical distribution is normal, the Shapiro–Wilk test, are now more often used for that purpose.

The chi-square statistic on n degrees of freedom is defined as

$$\chi_n^2 = \sum_{i=1}^{n} z_i^2 = \sum \frac{(Y-\mu)^2}{\sigma^2},$$

where z_i is normally distributed with mean zero and standard deviation one (Winkler and Hayes 1975, pp. 375–380). If one were repeatedly to draw samples of one Y score from a normally distributed population, transform that score to a standard z score, and then square that z score, the resulting distribution of squared z scores would be a χ^2 distribution on one degree of freedom. If one were repeatedly to draw samples of three scores, standardize, square, and sum them, the resulting distribution would be χ^2 on three degrees of freedom. Because the χ^2 statistic is so closely related to the normal distribution, it is also closely related to other statistics that are related to the normal distribution, such as t and F.

One simple application of the χ^2 statistic is to test the null hypothesis that the variance of a population has a specified value (Winkler and Hayes 1975, pp. 453–455; Wuensch 2009). From the definition of the sample variance, $s^2 = \frac{\sum(Y-M)^2}{N-1}$, where Y is a score, M is the sample mean, and N is the sample size, the corrected sum of squares $\sum(Y-M)^2 = (N-1)s^2$. Substituting this expression for $\sum(Y-\mu)^2$ in the defining formula yields $\chi^2 = \frac{(N-1)s^2}{\sigma^2}$. To test the hypothesis that an observed sample came from a population with a particular variance, one simply divides the sample sum of squares, $(N-1)s^2$, by the hypothesized variance. The resulting χ^2 is evaluated on $N-1$ degrees of freedom, with a two-tailed p value for nondirectional hypotheses and a one-tailed p for directional hypotheses.

One can also compute a confidence interval for the population variance (Winkler and Hayes 1975, pp. 383–385; Wuensch 2009). For a $100(1-\alpha)\%$ confidence interval for the population variance, compute:

$$\frac{(N-1)s^2}{b} \quad \text{and} \quad \frac{(N-1)s^2}{a}$$

where a and b are the $\alpha/2$ and $(1-\alpha/2)$ fractiles of the chi square distribution on $(N-1)df$. It should be noted that these procedures are not very robust to their assumption that the population is normally distributed.

When one states that he or she has conducted a "chi-square test," that test is most often a "one-way chi-square test" or a "two-way chi-square test" (Howell 2010, pp. 141–151). The one-way test is a univariate goodness of fit test. For each of k groups one has an observed frequency (O) and a theoretical frequency (E), the latter being derived from the theoretical model being tested. The test

statistic is $\chi^2 = \sum \frac{(O-E)^2}{E}$ on $k-1$ degrees of freedom. The appropriate p value is one-tailed, upper-tailed, for nondirectional hypotheses. When $k = 2$, one should make a "correction for continuity":

$$\chi^2 = \sum \frac{(|O-E| - .5)^2}{E}.$$

The two-way chi-square test is employed to test the null hypothesis that two categorical variables are independent of one another. The data may be represented as an $r \times c$ contingency table, where r is the number of rows (levels of one categorical variable) and c is the number of columns (levels of the other categorical variable). For each cell in this table two frequencies are obtained, the observed frequency (O) and the expected frequency (E). The expected frequencies are those which would be expected given the marginal frequencies if the row variable and the column variable were independent of each other. These expected frequencies are easily calculated from the multiplication rule of probability under the assumption of independence. For each cell, the expected frequency is $(R_i C_j / N)$, where R_i is the marginal total for all cells in the same row, C_j is the marginal total for all cells in the same column, and N is the total sample size. The χ^2 is computed exactly as with the one-way chi-square and is evaluated on $(r-1)(c-1)$ degrees of freedom, with an upper-tailed p value for nondirectional hypotheses. Although statistical software often provides a χ^2 with a correction for continuity when there are only two rows and two columns, almost always the uncorrected χ^2 is more appropriate (Camilli and Hopkins 1978).

It is not unusual to see the two-way chi-square inappropriately employed (Howell 2010, pp. 152–153). Most often this is a result of having counted some observations more than once or having not counted some observations at all. Each case should be counted once and only one. Statistical software will often provide a warning if one or more of the cells has a low expected frequency. The primary consequence of low expected frequencies is low power. Even with quite small expected frequencies, actual Type I error rates do not deviate much from the nominal level of alpha (Camilli and Hopkins 1978).

The results of a two-way chi-square test are commonly accompanied by an estimate of the magnitude of the association between the two categorical variables. When the contingency table is 2 × 2, an odds ratio and/or the phi coefficient (Pearson r between the two dichotomous variables) may be useful. With larger contingency tables Cramer's phi statistic may be useful.

The chi-square statistic is also employed in many other statistical procedures, only a few of which will be mentioned here. The Cochran-Mantel-Haenszel χ^2 is employed to test the hypothesis that there is no relationship between rows and columns when you average across two or more levels of a third variable. The Breslow-Day χ^2 is employed to test the hypothesis that the odds ratios do not differ across levels of a third variable. Likelihood ratio chi-square is employed in the log-linear analysis of multidimensional contingency tables, where it can be employed to test the difference between two models, where one is nested within the other. Likewise, in ►logistic regression, chi-square can be employed to test the effect of removing one or more of the predictors from the model. In discriminant function analysis, chi-square may be employed to approximate the p value associated with the obtained value of Wilks' lambda. A chi-square statistic can be employed to test the null hypothesis that k Pearson correlation coefficients are identical. Chi-square is also used to approximate the p value in the Kruskal-Wallis ANOVA and the Friedman ANOVA. Many more uses of the chi-square statistic could be cited.

Clinical Trials, History of

Toshimitsu Hamasaki
Associate Professor
Osaka University Graduate School of Medicine, Osaka, Japan

In recent years, in addition to advances in methodology, the number of clinical trials conducted and published has greatly increased. Clinical trials, in particular, *blinded, randomized, controlled* comparative clinical trials, are widely recognized as the most scientific and reliable method for evaluating the effectiveness of therapies and promoting a culture of evidence-based medicine (Tukey 1977; Byar et al. 1976; Zelen 1979; Cowan 1981; Byar 1991; Royall 1991; Smith 1998).

The first modern clinical trial is generally considered to be the treatment of pulmonary tuberculosis with streptomycin conducted by the UK Medical Research Council (MRC) and published in *British Medical Journal* in 1948 (MRC 1948; Pocock 1984; Ederer 2005; Day 2006). However, there is still some controversy surrounding this claim as some authors refer to the study with the common cold vaccine conducted by Diehl et al. (1938) as the first modern trial (Hart 1972, 1996; Gill 1996). The design of the streptomycin trial included blinding, ►randomization, and control groups as fundamental elements of the clinical trial. The trial included a total of 107 patients from seven centers, who were assigned to either "streptomycin and bed-rest" (S case) or "bed-rest" (C case) groups, by a process involving a statistical series based on random sampling numbers drawn up for each sex and each center and sealed envelopes. The efficacy of streptomycin was evaluated based upon the examination of patient X-ray films by three experts consisting of one clinician and two radiologists. The decision of whether or not the treatment was effective was made by the majority based on independently reached conclusions by each expert, who were also blinded as to which treatment the patient had received. The streptomycin trial also included Sir Austin Bradford Hill who served as the trial statistician. Hill was recognized as the world's leading medical statistician and popularized the use of statistical methods in clinical trials, and who also attempted to improve the quality of their implementation and evaluation by publishing a series of 17 articles in *The Lancet* in 1937 (Hill et al. 2000).

With the success of the streptomycin trial, the MRC and Hill continued with further blinded, randomized, controlled comparative clinical trials (Ederer 2005; Days 2006): for example, chemotherapy of pulmonary tuberculosis in young adults (MRC 1952), an antihistaminic drug in the prevention and treatment of the common cold (MRC 1950), the use of cortisone and aspirin in the treatment of early cases of rheumatoid arthritis (MRC 1954, 1955), and an anticoagulant to treat cerebrovascular disease (Hill et al. 1960). In United States, the first randomized controlled trail started in 1951 and was the US National Institute of Health study of the adrenocorticotropic hormone, cortisone and aspirin in the treatment of rheumatic heart disease in children (Rheumatics Fever Working Party 1960). Presently, a huge number of randomized controlled clinical trials are being conducted worldwide, with the number of clinical trials steadily increasing each year.

Although now commonplace, the fundamental elements of clinical trials, such as blinding, randomization, and control groups, did not just suddenly appear in the second quarter of the twentieth century. Evidence exists that a comparative concept for evaluating therapeutic efficacy with control groups has been known since ancient times (Ederer 2005; Day 2006). For example, Lilienfeld (1949) and Slotki (1951) cited the description of a nutritional experiment using a control group in the Book of Daniel from the Old Testament:

> **1.6**: Among these were some from Judah: Daniel, Hananiah, Mishael and Azariah. . . **1.8**: But Daniel resolved not to defile himself with the royal food and wine, and he asked the chief official for permission not to defile himself this way. . . . **1.11**: Daniel then said to the guard whom the chief official had appointed over Daniel, Hananiah, Mishael and Azariah. **1.12**: Please test your servants for ten days; Give us nothing but vegetables to eat and water to drink. **1.13**: Then compare our appearance with that of the young men who eat the royal food, and treat your servants in accordance with what you see. **1.14**: So he agreed to this and tested them for ten days. **1.15**: At the end of the ten days they looked healthier and better nourished than any of the young men who ate the royal food. **1.16** So the guard took away their choice food and the wine they were to drink and gave them vegetables instead.

The above description is part of a story dating from approximately 800 BC when Daniel was taken captive by the ruler of Babylonia, Nebuchadnezzar. In order to refrain from eating royal meals containing meat (perhaps pork) and wine offered by Nebuchadnezzar, Daniel proposed a comparative evaluation and was rewarded when his test group fared better than the royal food group. Although it is difficult to confirm the accuracy of the account, it is clear that the comparative concept already existed when the Book of Daniel was written around 150 BC. In particular, it is

remarkable that the passage from the Book of Daniel mentioned not only the *choice of a control group* but the *use of a concurrent control group*. Unfortunately, this fundamental concept was not widely practiced until the latter half of the twentieth century (Ederer 2005; Day 2006).

Much later than the Book of Daniel, in the eighteenth and nineteenth centuries, there were some epoch-making clinical researches that formed the basis of the methodology used in current clinical trials. Before the modern clinical trial of the treatment of pulmonary tuberculosis with streptomycin mentioned above (Pocock 1984; Ederer 2005; Day 2006), the most famous historical example of a planned, controlled clinical trial involved six dietary treatments for scurvy on board a British ship. The trial was conducted by the ship's surgeon, James Lind, who was appalled by the ravages of scurvy which had claimed the lives of three quarters of the crew during the circumnavigation of the world by British admiral, George Anson (Lind 1753; Bull 1959; Pocock 1984; Mosteller 1981; Ederer 2005; Day 2006). In 1947, Lind conducted a comparative trial to establish the most promising "cure" for patients with scurvy using twelve individuals who had very similar symptoms on board the Salisbury. In addition to one common dietary supplement given to all of the patients, he assigned each of six pairs one of the following six dietary supplements:

1. Six spoonfuls of vinegar
2. A half-pint of sea water
3. A quart of cider
4. Seventy-five drops of vitriol elixir
5. Two oranges and one lemon
6. Nutmeg

Those patients who received the two oranges and one lemon were cured within approximately 6 days and were able to help nurse the other patients. Apart from the patients who improved somewhat after receiving the cider, Lind observed that the other remedies were ineffective. The reason for the success of Lind's trial was likely due to his knowledge of previous work by James Lancaster (Purchas 1625), who had served three teaspoons of lemon juice each day to sailors suffering from scurvy during the first expedition to India sent by the East India Company in 1601 (Mosteller 1981). Unfortunately, however, the British Navy did not supply lemon juice to its sailors until 1975, although conclusive results concerning the efficacy of such treatment had already been obtained much earlier (Bull 1959; Mosteller 1981).

The use of statistical concepts in clinical trials was also advocated earlier than the streptomycin trials. For example, Pierre Simon Laplace, a French mathematician and astronomer, mentioned the use of probability theory to determine the best treatment for the cure of a disease (Laplace 1814; Hill et al. 2000). Also, Pierre-Charles-Alexandre Louis, a French physician and pathologist, discussed the use of a "numerical method" for the assessment of treatments by constructing comparable groups of patients with similar degrees of a disease, i.e., to compare "like with like" (Louis 1837; Ederer 2005; Day 2006). Unfortunately, these suggestions were not earnestly acted upon until the streptomycin trial because in the eighteenth and nineteenth centuries, the investigators were more involved with the practice of medicine and less versed in the use of probability theory since saving patients' life was considered more important rather than collecting data from the aspect of ethics (Bull 1959; Hill et al. 2000).

Here, the history and development of clinical trials was very briefly traced. More detailed aspects of the history of clinical trials can be found in articles by Bull (1959), Armitage (1972, 1991), Lilienfeld (1982), Pocock (1984), Meinert (1986), Gail (1996), Ederer (2005) and Day (2006).

Clinical Trials: An Overview

Hiroyuki Uesaka
Osaka University, Osaka, Japan

A clinical trial is one type of clinical research where a procedure or drug is intentionally administered outside the realm of standard medical practice to human subjects with the aim of studying its effect on the human body. This includes medications, operations, psychotherapy, physiotherapy, rehabilitation, nursing, restricted diets, and the use of medical devices. The comparative study of two or more treatments, involving the random assignment of treatments to patients, is considered a clinical trial even if the study includes approved drugs or medical devices. This means that a clinical trial is an experiment which includes human subjects. It is necessary to distinguish clinical trials from observational studies which collect outcomes when executing a study treatment as an ordinary treatment.

Since clinical trials include human subjects, the ethical aspects, i.e., the rights, safety and well-being of individual research subjects, should take precedence over all other interests at all stages, from the planning of clinical trials to the reporting of results. Such ethical principles for clinical research are in accordance with the Declaration of Helsinki, "Ethical Principles for Medical Research Involving Human Subjects," issued by the World Medical Association (1964). In conducting a clinical trial, the study protocol should clearly describe the plan and content of the trial. The protocol must also be reviewed and approved by the ethics committee. Furthermore, the Declaration of Helsinki states: The protocol should contain a statement of the ethical considerations involved and indicate how the principles in the above declaration have been addressed. To protect the safety, well-being and rights of the human subjects participating in the trial, the Declaration indicates that potential subjects must be adequately informed of all

relevant aspects of the study which include aims, methods, the anticipated benefits and potential risks of the study and any discomfort that participation may entail. And it states: The potential subjects must be informed of their right to refuse to participate in the study or to withdraw consent to participate at any time without reprisal. The voluntary agreement of a subject to participate after sufficient details have been provided is called informed consent. It is also recommended that the clinical trial be registered in a publicly accessible database, and the results from the trial should be made publicly available, regardless of whether the results are positive or negative.

Clinical trials for a new drug application, when they are conducted in the EU, Japan and/or the United States of America, must meet the requirements of the "Good Clinical Practice" (GCP) guideline (ICH Steering Committee 1996). The GCP guideline is a unified standard provided by the Europe, Japan and the United States in the framework of the International Conference on Harmonization of Technical Requirements for Registration of Pharmaceuticals for Human Use [http://www.ich.org/]. The GCP guideline provides protection for the safety, well-being and human rights of subjects in clinical trials in accordance with the Declaration of Helsinki. The GCP guideline also requires that people appointed by the sponsor, the so-called monitors, verify that the rights and well-being of all human subjects are being protected, that the reported trial data are accurate, complete, and verifiable from source documents, and that the conduct of the trial is in compliance with the currently approved protocol/amendment(s), with the GCP, and with the applicable regulatory requirement(s). This is referred to as trial monitoring in the GCP.

In planning a clinical trial, a protocol must be prepared, including descriptions of the trial justification, trial objectives, study treatments, the population to be studied as defined by the study inclusion and exclusion criteria, test treatments and treatment procedures, observed variables and observation procedures, specification of variables to assess treatment effect, collection of safety information, prohibited concomitant medications, discontinuation criteria for individual subjects, the number of subjects planned to be enrolled and the justification for such, statistical methods to be employed, data collection, quality control and quality assurance (ICH Steering Committee 1997). A case report form (CRF) should be prepared as well. The CRF is a document designed to record all of the required information to be reported according to the protocol. After a trial, a so-called clinical study report is prepared (ICH Steering Committee 1995). This is a document which contains clinical and statistical descriptions of the methods, rationale, results and analyzes of a specific clinical trial fully integrated into a single report. Clinical trials are conducted as collaborative activities involving many specialists, such as investigators, nurses, diagnostic testing specialists and other collaborators. Furthermore, regulators are involved in new drug applications. Therefore, the protocol, CRF and clinical study report should be clearly and accurately documented to be easily understood by those involved in the trial and by those who will make use of the trial results.

Clinical trials can be classified into several types depending on various features (ICH Steering Committee 1998; ICH Steering Committee 2000). First, a trail can be controlled or uncontrolled, this being determined by the presence of a control group. A controlled trial is a trial to compare the study treatment(s) with a control treatment that is either the current standard treatment, best supportive care, placebo, or some other treatment; an uncontrolled trial involves giving the same treatment to all of the subjects participating in the trial. The second feature involves the objective of a trial, either exploratory or confirmatory. A clinical trial that aims to generate or identify a research topic, or provide information to determine the specifics of a trial method is called an exploratory trial. A confirmatory trial is defined as an adequately controlled trial where hypotheses which were derived from earlier research or theoretical considerations are stated in advance and evaluated. Furthermore, a confirmatory trial generally includes three types of comparisons: a superiority trial, a non-inferiority trial, and an equivalence trial. A superiority trial is used to show the superiority of a test treatment over a control. A non-inferiority trial is designed to show that the efficacy or safety of the study treatment is no worse than that of the control. An equivalence trial serves to demonstrate that the test treatment is neither better nor worse than the control. The third aspect involves distinguishing between a pragmatic and an explanatory trial (Gent and Sackett 1979; Schwartz and Lellouch 1967). The objective of a pragmatic trial is to confirm effectiveness of the test treatment for those subjects who are assigned to the test treatment. An explanatory trial serves to establish a biological action for the treatment. Finally, the fourth characteristic focuses on the difference between a single- and a multi-center trial. The single-center trial is conducted by a single investigator, and the multi-center trial is co-conducted by multiple investigators at multiple study sites. Recently, many multi-center trials have been planned and conducted across not only a single country but also two or more countries. Such a multi-center trial is called a multinational trial.

The clinical development of a new drug advances in stages (ICH Steering Committee 1997). A safety trial is executed first to determine the maximum dose that can be safely administered to a subject. In most safety trials of the first use of a new drug in humans, the subjects are healthy volunteers. Administration of the study treatment begins from a dosage expected to be safe enough for normal healthy volunteers, and then the dosage is increased in stages. The pharmacokinetic profile is usually examined in the same trial. Pharmacokinetics investigates the process of drug disposition which usually consists of absorption, distribution, metabolism and excretion. This stage is called Phase I. The next stage is to determine the dosage range that can be safely administered to patients and at which sufficient effectiveness can be expected. The dosage that will be used in clinical treatment as well as the dose intervals are also clarified at this stage. This is called the Phase II. In the third stage, the efficacy and safety of the study treatment is confirmed in the target patient population. This stage is referred to as Phase III. The dose and dosage regimen which are confirmed to be efficacious and safe in phase III are then submitted to the regulatory authority to obtain marketing authorization of the new drug. After marketing authorization is obtained, the drug becomes widely used for clinical treatment. This stage is called Phase IV. During the phase III trials many restrictions are imposed to ensure the safety of the participating subjects. These include the necessity of physical examinations, collection of patient anamneses, regulation of concomitant medications, and clearly defined test treatment administration periods. However, in phase IV such restrictions are relaxed and the approved study treatment can be used by various patients under diverse conditions. Therefore, because the number of patients who are administered the newly approved drug increases rapidly, with patients often using the drug for very long times according to their disease condition, there is a real concern about harmful effects that have not been anticipated. Therefore, an investigation to clarify the safety and effectiveness of the treatment in daily life, an observational study, a large-scale trial, or a long-term trial, is conducted. Moreover, a clinical trial to compare the newly approved drug with other medicines that have been approved for the same indication may also be conducted.

The result of the trial should be scientifically valid. Clinical trial results are intended to be applied to a target population defined by inclusion and exclusion criteria for a given trial. The enrolled subjects should be a random sample from the target population so that the trial results can be applied to the target population. However a trial is conducted in a limited number of medical sites, and not all candidate subjects give informed consent. Therefore, whether or not the trial result can be generalized to the target population will depend on the study protocol and the actual execution procedure. Accordingly, it is preferable to execute the trial in a variety of medical institutions with a wide range of patients corresponding to the diversity of the target population to improve the possibility of generalizing to the target population. A controlled trial usually estimates the difference in response to treatments between treatment groups. As described above, the clinical trial participants are not a random sample of the target population. Therefore the true mean difference in the study population (all subjects who participate in the trial) will be estimated. This is accomplished by dividing the study population into two or more treatment groups which are assigned to different treatments, and then comparing the means of response to treatment between groups. The estimated mean difference is usually different from this true value. When random allocation of treatment to subjects is used, it is assumed that the departure from the true difference is probabilistic or random error. However, there is the possibility of systematic error due to the execution procedure of the trial. This systematic error is called bias (ICH Steering Committee 1998). The execution of treatment, evaluation of results, and/or subjects' reactions can be influenced if the people involved in a trial, such as investigators, relevant clinical staff or subjects, are aware of which treatment is assigned to subjects. Therefore, masking (blinding) and randomization are used to prevent participants from knowing which treatment is being allocated to which subjects. There are several levels of blinding: double-blind, single-blind, observer-blind and open-label. In a double-blind study neither the subjects, nor the investigator, nor any of the relevant clinical trial staff know who belongs to which treatment group. In a single-blind study only treatment assignments are unknown to the subjects or investigator and relevant clinical staff. In an observer-blind study treatment assignments are unknown to the observers who assess the subjects' conditions. In an open-label study treatment assignments are known to both investigators and subjects.

One of the typical methods of treatment assignment is to assign only one treatment to each subject, and then to compare the effects of the treatments between subject groups. This method is referred to as parallel group design. The other typical method is the cross-over design where one subject receives two or more treatments and an intra-subject comparison of treatments is done. It is necessary to select an appropriate design because bias can be caused by the design itself.

A clinical trial is an experiment with human beings as subjects. It is preferable that the number of subjects be as small as possible to protect the rights, health and welfare

of the subjects included in the trial. However, if the objective of the trial is not achieved, the reason for executing the trial is lost. Therefore, based on the estimated difference between the treatments, the trial should be designed to have sufficient precision to either detect such a difference if it truly exists, or to conclude that the difference is below a definite value based on concrete evidence. For this purpose, it is necessary to maintain high accuracy and precision in trials. To ensure the precision of a trial, it is important to consider the stratification of the study population, to make precise observations, and to secure a sufficient number of subjects.

The objective of these trials is to estimate beneficial and adverse effects, and to confirm a hypothesis about the effect of the study treatment. Even if the effect size of the test treatment is assumed to be of a given size, the true effect size may be less than assumed. When the gap between the actual and the assumed value is large, the planned number of subjects might be insufficient and, in some cases, many more subjects than originally planned will be needed. In such cases, a sequential design (Jennison and Turnbull 2000) and a more advanced adaptive design (Bretz et al. 2009) would be proposed.

About the Author

Dr. Hiroyuki Uesaka is a specially appointed Professor of The Center for Advanced Medical Engineering and Informatics, Osaka University, Suita, Japan. He has been working for pharmaceutical companies for about 40 years as a statistical expert of clinical trials. He authored more than 20 original statistical papers, and authored, coauthored and contributed to 6 books written in Japanese (including *Design and Analysis of Clinical Trials for Clinical Drug Development* (Asakura-Shoten, 2006) and *Handbook of Clinical Trials* (jointly edited with Dr. Toshiro Tango, Asakura-Shoten, 2006).

Clinical Trials: Some Aspects of Public Interest

Jagdish N. Srivastava
CNS Research Professor Emeritus
Colorado State University, Fort Collins, CO, USA

Medical experiments, often called "clinical trials," are obviously extremely important for the human race. Here, we shall briefly talk, in layman's language, about some important aspects of the same which are of great public interest.

Side Effect of Drugs

The side effects of allopathic drugs are notorious; death is often included in the same. For degenerative diseases (as opposed to infectious diseases, as in epidemics) it is not clear to the author whether any serious effort is being made by the pharmaceutical companies to develop drugs

which actually cure diseases; the trend seems to be at best to maintain people on drugs for a long time (even for the whole life). Mostly, people live under varying forms of painkiller-surgery regimes.

However, in many institutions (for example, departments doing research on nutrition) there are people who are genuinely interested in finding cures, though often they do not possess the resources they need. Many things, considered true by the public, are not quite so. Consider preservatives and other food additives that are legal. They are found in varying quantities in most foods, and many people do not pay attention to this at all, and consume unknown amounts each day. The thought that they have no side effects is based on relatively (time-wise) small experiments and extrapolations there from. It is probably true that if some food with a particular preservative or a (combination of the same with others) is consumed, it may not have any noticeable effect within a short period. But, the worry that many thinkers have is whether consuming food (all the time ignoring preservatives that it may contain) will have a disastrous effect (like producing cancer, heart attack, diabetes, stroke, etc.) 20, 30, 40, or 50 years earlier than it would have been expected for an additives-free diet. (The fact that, now, teenagers and young ones in their twenties are developing such diseases which, in an earlier age, were found mainly among seniors only, is alarming.) A full scale clinical trial (to study the long term effect of preservatives etc.) will take more than a century, and has not been done. Thus, extrapolations proclaiming that such additives are safe are based on guess work only, and are not necessarily scientifically sound. We live in an age when shelf life has become more important than human life.

It is not even clear whether the damage done from side effects and the painkiller-surgery policies is limited to the increase in the periods of sickness of people, the intensities of such sickness, and the reduction in the age at death. The bigger question is whether there is an effect on the progeny, and for how many generations. We recall that in the processes of natural selection in the theory of evolution, only the fittest may survive. Clearly, for the human race, only the policy that promotes the good of the general public corresponds to being fit for survival.

Contradictory Statements by Opposing Camps of Medical Researchers

Often, seemingly good scientists are found to be contradicting each other. For example, there may be a substance (say, an extract from some herbs) which may be claimed by some nature-cure scientists (based on their experiments) to positively affect some disease (relative to a placebo). However, some pharmaceutical scientists may claim that their experiments show that the drug is no better than the placebo. This is to say that, often in such cases, a close look may reveal that the two sets of experiments are not referring to the same situation. To illustrate, the subjects (people, on whom an experiment is done) in the first group may be people who just contracted the disease, these people being randomly assigned the drug or the placebo. In the second case, the subjects may be people who have had the disease for some time and have been taking painkillers. Now, the herbal drug may be quite effective on a body which is in a more primeval and natural state, and yet not work well in a body which has been corrupted by the chemicals in the painkiller. Clearly, that would explain the discrepancy and support the use of the herbal drug soon after the disease begins, simultaneously discouraging the use of painkillers etc. whose primary effect is to temporarily fool the mind into thinking that one is feeling better. Thus, it is necessary to examine a clinical trial closely rather than take its results on face value.

Large Clinical Trials: Meta-analysis

"Large" clinical trials are often touted as being very "informative." To illustrate, take the simple case of comparing two drugs *A* and *B* with respect to a placebo *C*. Now, how effective a drug is for a person may depend upon his or her constitution. On some people, *A* may be the best, on some *B*, and on others, all the three may be essentially useless. For me, even though I may not know the reality, suppose the reality is that *B* would be very effective with little negative side effect, *A* would be only somewhat effective but with a large negative side effect, and the effect of *C* would be small (being somewhat positive or somewhat negative depending on environmental factors). Suppose a trial is done in Arizona, involving 6,000 patients randomly divided into three equal groups, the result being that *A* is effective in 45% (cases in its group), *B* in 35%, and *C* in 5% cases. Clearly, here, the drug *A* wins. But, for me, what is the value of this information? I really need to know which drug would be best for me.

Now suppose a similar trial is done in Idaho and in California, the result for *A*, *B*, and *C* being 33%, 42%, 7%, and 54%, 52%, and 30% respectively in the two states. Does this help me in some way or does it simply add to the confusion? The drugs manufacturer, Mr. Gaines, would like "meta–analysis" (whose purpose is to combine the results in a legitimate and meaningful way), because his interest is in seeing the overall picture so that he can formulate an appropriate manufacturing policy for his company. However, the interest of the general public is different from that of Gaines, because each individual needs to know what is good for him or her personally. The individual's interest, in a sense, runs counter to ►meta–analysis; he or she would be more interested in knowing what aspects of a person's

health make him or her more receptive to *A* or *B*. Instead of combining the data, more delineation needs to be done. In other words, one needs to connect the results with various features of the subjects and other related factors. Then we may gain knowledge not only on what proportion of subjects are positively affected by a drug, but what bodily features of people (or the food that they eat, or their lifestyle, or the environment around them, etc.) lead to this positive effect.

For example, in the above (artificial) data, it seems that *A* is better in a warm climate and *B* in cold. Where the climate is mild, all of them do well, and many people may recover without much of drugs. If I have been more used to a cold climate, *B* may be more effective on me. With this knowledge, even though *A* may turn out to be much better than *B* in the area where I live, *B* may be better for me individually.

(This leads us to the *philosophy* of statistical inference. Not only do we need to plan our experiments or investigations properly, we need to be careful in drawing inferences from the data obtained from them. According to the author, trying to find what a bunch of data "says" must involve in a relevant way the space of applications where such a finding will be made use of. Many scholars believe that, given a set of data, the "information" that the data contains is a fixed attribute of the data, and the purpose of inference is to bring out this attribute accurately. The author believes that the reason why the inference is sought (in particular, to what use or application the inference will be put) is also important, and should have a bearing on the inference drawn. This policy will give insight into the kind of information we need, what should receive more emphasis, etc. Clinical trials would really gain from this approach.)

Reducing Side Effects of Drugs

Studies are usually done using a "loss function" which tells how much "loss" shall we incur by adopting each of a set of policies. For example, we may have many drugs, several possible doses of a drug per day, many possible durations of time over which a drug is to be continued, etc. For each combination of these factors, the "loss" may be "the total time of absence from work," or "the total financial loss incurred because of sickness," or "the amount of fever," or "the blood pressure," etc. If the loss function involves only one variable (like "blood pressure"), it is "uni-dimensional." But if, many variables are involved simultaneously (like "blood pressure," "fever," "financial loss"), then it is called multi-dimensional. Usually, only one dimension is used or emphasized (like, "intensity of fever"). More theory needs to be developed on how to work with multi-dimensional loss functions.

Besides theory, we also need to develop good quantitative criteria for measuring "healthfulness." There can be various sectors. For example, we can have one criterion for the sector of upper digestive track, one for the middle, one for the colon, one for the respiratory system, one for bone diseases, one for the joints, one for nerves, one for cancerous growth, and so on. For each sector, the corresponding criterion will provide a measure of how healthy that sector is. Suppose we decided to have 25 such sectors. Then the loss function will be 25-dimensional. The drugs will be evaluated in each dimension, and the results will also be combined in various ways. The side effect of a drug in a particular sector will be caught more easily. When the drug is marketed, an assessment for each sector can be provided. Drugs with large effect in any sector can be rejected.

Experiments with Many Factors: Interactions

We make some technical remarks here. A large part of the field of statistical design of multi-factorial scientific experiments is concerned with the simplistic situation when there are either no interactions or the set of non-negligible interactions is essentially known (though the values of these interactions and the main effects are not known). However, in medical experiments, we can have interactions of even very high orders. Thus, for the field of multifactor clinical trials, we have to go beyond Plackett–Burman designs, and orthogonal arrays of small strength (such as 2). There is work available on search theory by the author and others, which would help. However, further work is needed in that field. Indeed, for vigorous full fledged research on how to cure diseases, the statistical theory of the design and analysis of multifactor multi-response experiments need to be developed much further beyond its current levels. However, the basics of the same are available in books such as Roy et al. (1970). For the reader who wishes to go deeper in the field of this article, some further references are provided below.

About the Author

Jagdish N. Srivastava is now CNS Research Professor Emeritus at Colorado State University, where he worked during 1966–2004 as Full Professor, and where he also once held a joint appointment in Philosophy. He was born in Lucknow, India on 20 June 1933. He did his Ph.D. in 1961 (at the University of North Carolina, Chapel Hill, NC, USA). He was President (Indian Society of Agricultural Statistics, 1977 Session; International Indian Statistical Association (IISA) (1993–1997); Forum for Interdisciplinary Mathematics (1994–1996). He visited institutions all over the world. His honors include the Fellowship of the American Statistical Association, Institute of Mathematical Statistics,

Institute of Combinatorial Mathematics and its Applications, IISA (Honorary), International Statistical Institute, and TWAS (The World Academy of Science for developing countries). He is the founder (1975) and Editor-in-Chief of the monthly *Journal of Statistical Planning and Inference*. Two volumes containing papers by experts from all over the world were published in honor of his 65th birthday. He discovered, among other results, the "Srivastava Codes," the "Srivastava Estimators," and the Bose-Srivastava Algebras. He has been interested in, and has contributed to, Science and Spirituality, and is a major researcher in Consciousness and the "Foundations of Reality" (including, in particular, "Quantum Reality").

Cluster Analysis: An Introduction

H. Charles Romesburg
Professor
Utah State University, Logan, UT, USA

Cluster analysis is the generic name for a variety of mathematical methods for appraising similarities among a set of objects, where each object is described by measurements made on its attributes. The input to a cluster analysis is a *data matrix* having t columns, one for each object, and n rows, one for each attribute. The (i, j)th element of the data matrix is the measurement of the ith attribute for the jth object. The output from a cluster analysis identifies groups of similar objects called *clusters*. A cluster may contain as few as one object, because an object is similar to itself.

Applications of cluster analysis are widespread because the need to assess similarities and dissimilarities among objects is basic to fields as diverse as agriculture, geology, market research, medicine, sociology, and zoology. For example, a hydrologist considers as the objects a set of streams, and for attributes describes each stream with a list of water quality measures. A cluster analysis of the data matrix identifies clusters of streams. The streams within a given cluster are similar, and any stream in one cluster is dissimilar to any stream in another cluster.

There are two types of cluster analysis. *Hierarchical cluster analysis* is the name of the collection of methods that produce a hierarchy of clusters in the form of a *tree*. The other type, *nonhierarchical cluster analysis*, is the name of the collection of methods that produce the number of clusters that the user specifies. For both types, computer software packages containing programs for the methods are available.

Let us illustrate the main features of hierarchical cluster analysis with an example where the calculations can be done by hand because the data matrix is small, five objects and two attributes, consisting of made-up data:

Data matrix						
		Object				
		1	2	3	4	5
Attribute	1	10	20	30	30	5
	2	5	20	10	15	10

To perform a hierarchical cluster analysis, we must specify: (1) a coefficient for assessing the similarity between any two objects, j and k; and (2) a clustering method for forming clusters.

For the first, let us choose the "Euclidean distance coefficient," e_{jk}. The smaller its value is, the more similar objects j and k are. If the value is zero, they are identical, i.e., maximally similar. For our example with $n = 2$ attributes, e_{jk} is the distance between object j and object k computed with the Pythagorean theorem. And for the clustering method, let us choose the "UPGMA method," standing for "unweighted pair-group method using arithmetic averages."

At the start of the cluster analysis, each object is considered to be a separate cluster. Thus with five objects, there are five clusters. For the five we compute the $5(5-1)/2 = 10$

values of e_{jk}. To demonstrate the calculation of one of these values, consider object 1 and object 5. The Euclidean distance e_{15} is

$$e_{15} = [(10-5)^2 + (5-10)^2]^{1/2} = 7.07.$$

In this manner, we compute the other values and put the ten in a list, from smallest, indicating the most similar pair of clusters (objects), to largest, indicating the least similar pair: $e_{34} = 5.0$, $e_{15} = 7.07$, $e_{24} = 11.2$, $e_{23} = 14.1$, $e_{12} = 18.0$, $e_{25} = 18.0$, $e_{13} = 20.6$, $e_{14} = 22.4$, $e_{35} = 25.0$, $e_{45} = 25.5$.

The two most similar clusters, 3 and 4, head the list, as the Euclidean distance between them is the smallest. Therefore,

Step 1 Merge clusters 3 and 4, giving 1, 2, (34), and 5 at the value of $e_{34} = 5.0$.

Next, for the four clusters – 1, 2, (34), and 5 – we obtain the $4(4-1)/2 = 6$ values of e_{jk}. Three of these values are unchanged by the clustering at step 1 and can be transcribed from the above list. The other three have to be computed according to the guiding principle of the UPGMA clustering method. It requires that we average the values of e_{jk} between clusters, like this:

$$e_{1(34)} = \tfrac{1}{2}(e_{13} + e_{14}) = \tfrac{1}{2}(20.6 + 22.4) = 21.5;$$
$$e_{2(34)} = \tfrac{1}{2}(e_{23} + e_{24}) = \tfrac{1}{2}(14.1 + 11.2) = 12.7;$$
$$e_{5(34)} = \tfrac{1}{2}(e_{35} + e_{45}) = \tfrac{1}{2}(25.0 + 25.5) = 25.3.$$

So, the six e_{jk} values listed in order of increasing distance are: $e_{15} = 7.07$, $e_{2(34)} = 12.7$, $e_{12} = 18.0$, $e_{25} = 18.0$, $e_{1(34)} = 21.5$, $e_{5(34)} = 25.3$. It follows that the two most similar clusters are 1 and 5, since the Euclidean distance between them is the smallest. Therefore,

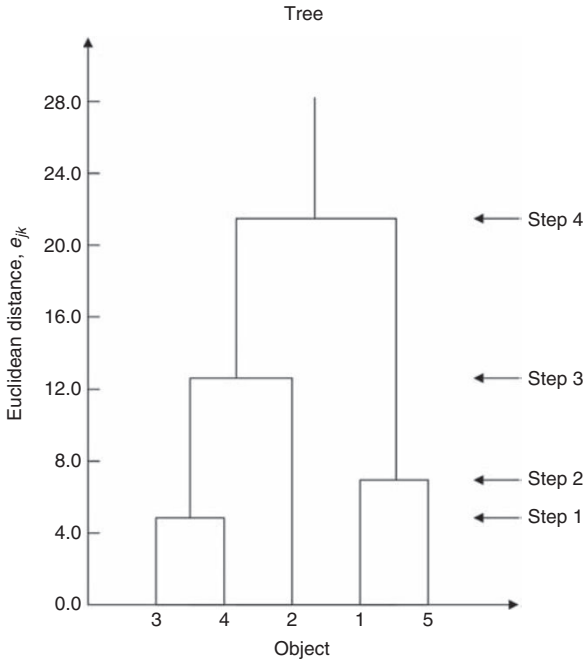
Step 2 Merge clusters 1 and 5, giving 2, (34), and (15) at the value of $e_{15} = 7.07$.

Before going to the next clustering step, we note that step 2 left the distance between clusters 2 and (34) unchanged at $e_{2(34)} = 12.7$. The two remaining distances are calculated according to the UPGMA clustering method by averaging the values of e_{jk} as follows:

$$e_{2(15)} = \tfrac{1}{2}(e_{12} + e_{25}) = \tfrac{1}{2}(18.0 + 18.0) = 18.0;$$
$$e_{(15)(34)} = \tfrac{1}{4}(e_{13} + e_{14} + e_{35} + e_{45}) = \tfrac{1}{4}(20.6 + 22.4 + 25.0 + 25.5) = 23.4.$$

The list of e_{jk} in increasing distance is now: $e_{2(34)} = 12.7$, $e_{2(15)} = 18.0$, $e_{(15)(34)} = 23.4$. The two most similar clusters, 2 and (34) head the list. Therefore,

Step 3 Merge clusters 2 and (34), giving (15) and (234) at the value of $e_{2(34)} = 12.7$.



Cluster Analysis: An Introduction. Fig. 1 Tree showing the hierarchy of similarities between the five objects specified by the data matrix in the text

At this point there are two clusters: (15) and (234). The average Euclidean distance between them is:

$$e_{(15)(234)} = \tfrac{1}{6}(e_{12} + e_{13} + e_{14} + e_{25} + e_{35} + e_{45}) = \tfrac{1}{6}(18.0 + 20.6 + 22.4 + 18.0 + 25.0 + 25.5) = 21.6.$$

The list of e_{jk} has only one value: $e_{(15)(245)} = 21.6$. Therefore,

Step 4 Merge clusters (15) and (234), giving (12345) at the value of $e_{(15)(234)} = 21.6$.

The calculations are finished. With each step, the tree (Fig. 1) has been growing. It summarizes the clustering steps, e.g., showing that the branches containing cluster (34) and cluster 2 join at an Euclidean distance value of 12.7.

The tree is a hierarchical ordering of similarities that begins at the tree's bottom where each object is separate, its own cluster. As we move to higher levels of e_{jk}, we become more tolerant and allow clusters to hold more than one object. When we reach the tree's top we are completely tolerant of the differences between objects, and all objects are considered as one cluster.

Suppose we took the five objects in the data matrix and plotted them on a graph with attribute 1 as one axis and

attribute 2 as the other. We would see that the distances between the objects suggest clusters that nearly match those in the tree. However, real applications typically have many attributes, often more than a hundred. In such cases, the researcher cannot grasp the inter-object similarities by plotting the objects in the high-dimension attribute space. Yet cluster analysis will produce a tree that approximates the inter-object similarities.

A tree is an old and intuitive way of showing a hierarchy. Witness the tree of life forms, the Linnaean classification system. At its bottom is the level of Species, at the next higher hierarchical level is the Genus, consecutively followed by levels of Order, Class, Phylum, and Kingdom.

A widely practiced way of creating a classification of objects is to perform a hierarchical cluster analysis of the objects. On the tree, draw a line perpendicular across the tree's axis, cutting it into branches, i.e., clusters. The objects in the clusters define the classes. Details may be found in Romesburg (2004) and in Sneath and Sokal (1973).

There are several general points to note about hierarchical cluster analysis:

1. There are various coefficients that can be used to assess the similarity between clusters. Of these, there are two types: dissimilarity coefficients and similarity coefficients. With a dissimilarity coefficient (as the Euclidean distance coefficient is), the smaller its value is, the more similar the two clusters are. Whereas with a similarity coefficient, the larger its value is, the more similar the two clusters are. An example of a similarity coefficient is the Pearson product moment correlation coefficient. But whether a dissimilarity coefficient or a similarity coefficient is used, a clustering method at each step merges the two clusters that are most similar.
2. Although the UPGMA clustering method (also called "average linkage clustering method") is perhaps most often used in practice, there are other clustering methods. UPGMA forms clusters based on the average value of similarity between the two clusters being merged. Another is the SLINK clustering method, short for "single linkage" clustering method, and sometimes called "nearest neighbor" clustering method. When two clusters are joined by it, their similarity is that of their most similar pair of objects, one in each cluster. Another is the CLINK clustering method, short for "complete linkage" clustering method, and sometimes called "furthest neighbor" clustering method. When two clusters are joined by it, their similarity is that of the most dissimilar pair of objects, one in each cluster. Another is Ward's clustering method, which assigns objects to clusters in such a way that a sum-of-squares index is minimized.
3. The data in the data matrix may be measured on a continuous scale (e.g., temperature), an ordinal scale (e.g., people's ranked preference for products), or on a nominal scale for unordered classes (e.g., people's sex coded as 1 = female, 0 = male).

   For an illustration of nominal scale measurement, suppose a military researcher takes a set of aircraft as the objects, and for their attributes records whether or not an aircraft can perform various functions. If the jth aircraft is able to perform the ith function, the (i, j)th element of the data matrix is coded with a "1"; if it is unable to perform the ith function, it is coded with a "0." In this way, the data matrix consists of zeroes and ones. A similarity coefficient, such as the one named "the simple matching coefficient," gives a numerical value for the similarity between any two aircraft. The cluster analysis produces a tree which shows which of the aircraft are functionally similar (belong to the same cluster) and which are functionally dissimilar (belong to different clusters).
4. Whenever the attributes of the data matrix are measured on a continuous scale, it is sometimes desired to standardize the data matrix. Standardizing recasts the units of measurement of the attributes as dimensionless units. Then the cluster analysis is performed on the standardized data matrix rather than on the data matrix. There are several alternative ways of standardizing (Romesburg 2004).
5. Commercial software packages for performing hierarchical cluster analysis include SPSS, SAS, CLUSTAN, and STATISTICA. Of these, SPSS is representative, allowing the user a choice of about 35 similarity/dissimilarity coefficients and seven clustering methods.
6. In the literature of cluster analysis, certain terms have synonyms. Among other names for the objects to be clustered are "cases," "individuals," "subjects," "entities," "observations," "data units," and "OTU's" (for "operational taxonomic units"). Among other names for the attributes are "variables," "features," "descriptors," "characters," "characteristics," and "properties." And among other names for the tree are the "dendrogram" and the "phenogram."

In contrast to hierarchical cluster analysis, nonhierarchical cluster analysis includes those clustering methods that do not produce a tree. The software packages mentioned above have programs for nonhierarchical cluster analysis. Perhaps the most-used nonhierarchical method is *K-means cluster analysis*. For it, the user specifies k, the number of clusters wanted, where k is an integer less than t, the number of objects. Software programs for K-means

cluster analysis usually differ a bit in their details, but they execute an iterative process to find clusters, which typically goes like this:

To begin the first iteration, the program selects k objects from the data matrix and uses them as k cluster seeds. The selection is made so that the Euclidean distances between the cluster seeds is large, which helps insure that the seeds cover all regions of the attribute space in which the objects reside.

Next, the program forms tentative clusters by sequentially assigning each remaining object to whichever cluster seed it is nearest to. As objects are assigned, the cluster seeds are recomputed and made to have the attribute values that are the average of those of the objects in the clusters. Hence, cluster seeds generally change as objects are tentatively assigned to clusters.

When the first iteration is finished, the resulting cluster seeds are taken as the k initial seeds to start the second iteration. Then the process is repeated, sequentially assigning the objects to their nearest cluster seed, and updating the seeds as the process moves along.

Finally, after a number of iterations, when the change in the cluster seeds is tolerably small from one iteration to the next, the program terminates. The k final clusters are composed of the objects associated with the k cluster seeds from the final iteration.

We now turn to the question, "Which is the better method for finding clusters – hierarchical cluster analysis or nonhierarchical cluster analysis?" The answer depends. Broadly speaking, researchers like having a choice of a large variety of similarity/dissimilarity coefficients, and like having the similarities among clusters displayed as a hierarchy in the form of a tree – two features that hierarchical methods offer but nonhierarchical methods do not. However, for hierarchical methods the amount of computation increases exponentially with the number of objects. Whereas for nonhierarchical methods the amount of computation increases less than exponentially because the methods do not require the calculation of similarities between all pairs of objects. In any event, all of the software packages mentioned above can handle very large data matrices for hierarchical methods and for nonhierarchical methods. For instance, according to the literature that accompanies CLUSTAN's hierarchical cluster analysis program, the limit to the size of a data matrix that at present can be processed in a reasonable time on a basic PC is in the neighborhood of 16,000 objects and 1,000 attributes. For more objects than that, CLUSTAN's nonhierarchical K-means program can handle as many as a million objects.

Books that provide detailed accounts of hierarchical cluster analysis and nonhierarchical cluster analysis include those by Aldenderfer and Blashfield (1984), Everitt (1993), and Romesburg (2004).

About the Author

Dr. H. Charles Romesburg is Professor of Environment and Society at Utah State University and holds degrees in Operations Research and Biostatistics, Nuclear Engineering, and Mechanical Engineering. He is the author of four books, including *Cluster Analysis for Researchers* (North Carolina: Lulu, 2004) and *Best Research Practices* (North Carolina: Lulu, 2009). He is an active and prolific researcher with numerous scientific articles to his credit. His publications in which he is the sole author have been cited more than 1,000 times. The Wildlife Society has awarded him its Wildlife Publication Award for his article "Wildlife Science: Gaining Reliable Knowledge."

Cluster Sampling

Janusz Wywial
Professor
Katowice University of Economics, Katowice, Poland

The quality of statistical inference is dependent not only on, for example, estimator construction but on the structure of a population and a sampling scheme too. For example, let the estimation of total wheat production in a population of farms be considered. The population of farms is divided into clusters corresponding to villages. This estimation can be based on the ordinary simple sample or on the cluster sample. Population units can be selected to the sample by means of

several sampling schemes. The units (i.e., farms) can be selected to the ordinary sample, or clusters of the units (i.e., villages) can be drawn to the cluster sample. The accuracy of the estimation depends on the sampling scheme and on the intraclass spread of a variable under study (wheat production). When should the ordinary simple sample be used and when should the cluster one?

Let us consider a fixed and finite population case. The fixed and finite population of the size N is denoted by $\Omega = \{\omega_1, \ldots, \omega_N\}$, where ω_k is an element (unit) of the population U. Let us assume that Ω is divided into G mutually disjoint clusters Ω_k $(k = 1, \ldots, G)$ such that $\bigcup_{k=1}^{G} \Omega_k = \Omega$. The size of a cluster Ω_k is denoted by N_k. So, $0 \le N_k \le N$ and $\bigcup_{k=1}^{G} N_k = N$. Let $U = \{\Omega_1, \ldots, \Omega_G\}$ be the set of all clusters. The clusters are called units (elements) of the set U. The cluster sample is selected from the set U and it is denoted by $s = \{\Omega_{i_1}, \ldots, \Omega_{i_n}\}$. The size of s is denoted by n, where $0 \le n \le G$. Let $\mathbf{S}$ be the set (space) of samples. The cluster sample is a random one if it is selected from U according to some sampling design denoted by $P(s)$, where $P(s) \ge 0$ for $s \in \mathbf{S}$ and $\sum_{s \in S} P(s) = 1$. Let the inclusion probability of the first order be denoted by $\pi_k = \sum_{\{s: k \in s\}} P(s)$, $k = 1, \ldots, G$. A random sample is selected from a population by means of the so-called sampling scheme, which fulfills the appropriate sampling design. It is well known that a sample can be selected according to previously determined inclusion probabilities of the first order without any explicit definition of the sampling design. This inference simplifies our practical research. Frequently, the inclusion probabilities are determined as proportional to cluster sizes, so $\pi_k \propto N_k$ for $k = 1, \ldots, G$. In general, $\pi_k \propto x_k$, where $x_k > 0$ is the value of an auxiliary variable.

Let us note that it is possible to show that the well-known systematic sampling design is a particular case of the cluster sampling design. Moreover, the cluster sampling design is a particular case of two (or more) stage sampling designs.

In general, all known sampling designs and schemes can be applied to the cluster case. The examples of sampling designs and schemes are as follows: the simple cluster sample of fixed size n, drawn without replacement, is selected according to the following sampling design: $P(s) = 1/\binom{G}{g}$ for $s \in \mathbf{S}$. The inclusion probability of the first order is $\pi_k = \frac{g}{G}$. The sampling scheme fulfilling that sampling design is as follows: The first element (unit) of the set U is selected to the sample with the probability $1/G$, the next one with the probability $1/(G-1)$, the kth element with the probability $1/(G - k + 1)$, and so on until the nth element of the sample.

The sampling scheme selecting with replacement units to the sample of fixed size n is as follows: Each element of U is selected with probabilities equal to p_k, where, for example, $p_k = x_k / \sum_{i \in U} x_i$. So, elements are independently drawn to the sample n times. In this case, the sampling design is defined in a straightforward manner. Particularly, if $p_k = 1/G$ for all $k = 1, \ldots, G$, the simple cluster sample drawn with replacement is selected according to the sampling design $P(s) = 1/G^n$. In this case, each element of U is selected with the probability $1/G$ to the sample of size n.

The so-called Poisson without replacement sampling scheme is as follows: The kth unit is selected with the probability p_k, $0 < p_k \le 1$, $k = 1, \ldots, G$. In this case, the sample size is not fixed because $0 \le n \le G$. There exists the so-called conditional without replacement sampling design of a fixed sample size, but unfortunately its sampling schemes are complicated, see, for example, Tillé (2006). Additionally, let us note that the cluster sample can be useful in the case of estimating the population mean.

It is well known that the precision of a population mean estimation, performed on the basis of the simple cluster sample, depends on the so-called intraclass (intracluster) correlation coefficient, see, for example, Hansen et al. (1953) or Cochran (1963).

Let us assume that sizes of clusters are the same and equal to M and $N = GM$. The ordinary variance of the variable is defined by $v = \frac{1}{N} \sum_{k=1}^{G} \sum_{j \in \Omega_k} (y_{kj} - \bar{y})^2$, where $\bar{y}_k = \frac{1}{N} \sum_{k=1}^{G} \sum_{j \in \Omega_k} y_{kj}$ is the cluster sample. The intraclass and the betweenclass variances are given by the expressions: $v_w = \frac{1}{G(M-1)} \sum_{k=1}^{G} \sum_{j \in \Omega_k} (y_{kj} - \bar{y}_k)^2$ and $v_b = \frac{1}{G-1} \sum_{k=1}^{G} (\bar{y}_k - \bar{y})^2$, respectively, where $\bar{y}_k = \frac{1}{M} \sum_{j \in \Omega_k} y_{kj}$. The intraclass correlation coefficient is defined by the following expression: $r_I = \frac{2}{N^2 v} \sum_{k=1}^{G} \sum_{i \ne j \in \Omega_k} \sum (y_{ki} - \bar{y})(y_{kj} - \bar{y})$. The coefficient ρ takes its value from the closed interval $[-1/(M-1), 1]$. The coefficient r_I can be rewritten in the following forms: $r_I = (v_b - v_w/M)/v$, $r_I = 1 - v_w/v$ or $r_I = (Mv_m/v - 1)/(M-1)$. The expressions lead to the conclusion that the intraclaas correlation coefficient is negative (positive) when the ordinary variance is smaller (larger) than the intraclass variance or equivalent if the ordinary variance is larger (smaller) than the betweenclass variance divided by M.

Let us note that it is well known that the simple *cluster sample* mean is a more accurate estimator of the population mean than the simple sample mean when the

intraclass correlation coefficient is negative. So, this leads to the conclusion that, if only possible, a population should be clustered in such a way that the intraclass correlation coefficient takes the smallest negative value. A more complicated case of unequal cluster sizes was considered, for example, by Konijn (1973). In this case, Särndal et al. (1992) considered the so-called homogeneity coefficient, which is the function of the intraclass variance. On the basis of the cluster sample, not only the estimation of population parameters is performed but also testing statistical hypothesis, see, for example, Rao and Scott (1981).

Coefficient of Variation

Czesław Stępniak
Professor
Maria Curie-Skłodowska University, Lublin, Poland
University of Rzeszów, Rzeszów, Poland

Coefficient of variation is a relative measure of dispersion and it may be considered in three different contexts: in probability, in a data set or in a sample.

In the first context it refers to distribution of a random variable X and is defined by the ratio

$$v = \frac{\sigma}{\mu} \tag{1}$$

where $\mu = EX$ and $\sigma = \sqrt{E(X - EX)^2}$. It is well defined if $EX > 0$. Moreover it is scale-invariant in the sense that cX has the same v for all positive c.

Data series $x = (x_1, \ldots, x_n)$ corresponds to distribution of a random variable X taking values x_i with probabilities $p_i = \frac{k_i}{n}$, for $i = 1, \ldots, n$, where k_i is the number of appearance of x_i in the series. In this case the formula (1) remains valid if we replace μ by $\overline{x} = \frac{1}{n}\sum_i x_i$ and σ by $\sqrt{\frac{1}{n}\sum(x_i - \overline{x})^2}$.

If $x = (x_1, \ldots, x_n)$ is a sample from a population, then the coefficient may be treated as a potential estimator of the coefficient of variation v in the whole population. Since $\frac{1}{n}\sum(x_i - \overline{x})^2$ is biased estimator of σ^2 in order to eliminate this bias we use the sample coefficient of variance in the form

$$\mathrm{v} = \frac{s}{\overline{x}}, \tag{2}$$

where $s = \sqrt{\frac{1}{n-1}\sum(x_i - \overline{x})^2}$.

One can ask whether v is normalized, i.e., whether it takes values in the interval $[0, 1]$.

In spite of that v is well defined providing $\overline{x} > 0$ it seems reasonable to restrict oneself to the nonnegative samples x, i.e., satisfying the condition $x_i \geq 0$ for all i and $\sum_i x_i > 0$. Under this assumption the sample coefficient (2) of variance in the sample takes values in the interval $[0, \sqrt{n}]$ and the lower and upper bound is attained. Therefore it is not normalized.

Collapsibility

Sander Greenland
Professor
University of California-Los Angeles, Los Angeles, CA, USA

Collapsibility in Contingency Tables

Consider the I by J by K contingency table representing the joint distribution of three discrete variables X, Y, Z, the I by J marginal table representing the joint distribution of X and Y, and the set of conditional I by J subtables (strata) representing the joint distributions of X and Y within levels

Collapsibility. Table 1 Trivariate distribution with (a) strict collapsibility of $Y|X$ risk differences over Z, (b) collapsibility of $Y|X$ risk ratios when standardized over the Z margin, and (c) noncollapsibility of $Y|X$ odds ratios over Z. Table entries are cell probabilities

	$Z = 1$		$Z = 0$		Collapsed over Z	
	$X = 1$	$X = 0$	$X = 1$	$X = 0$	$X = 1$	$X = 0$
$Y = 1$	0.20	0.15	0.10	0.05	0.30	0.20
$Y = 0$	0.05	0.10	0.15	0.20	0.20	0.30
Risks[a]	0.80	0.60	0.40	0.20	0.60	0.40
Differences	0.20		0.20		0.20	
Ratios	1.33		2.00		1.50	
Odds ratios	2.67		2.67		2.25	

[a]Probabilities of $Y = 1$ in column

of Z. A measure of association of X and Y is *strictly collapsible* across Z if it is constant across the strata (subtables) and this constant value equals the value obtained from the marginal table.

Noncollapsibility (violation of collapsibility) is sometimes referred to as ►Simpson's paradox, after a celebrated article by Simpson (1951). This phenomenon had however been discussed by earlier authors, including Yule (1903); see also Cohen and Nagel (1934). Some statisticians reserve the term Simpson's paradox to refer to the special case of noncollapsibility in which the conditional and marginal associations are in opposite directions, as in Simpson's numerical examples. Simpson's algebra and discussion, however, dealt with the general case of inequality. The term "collapsibility" seems to have arisen in later work; see Bishop et al. (1975).

Table 1 provides some simple examples. The difference of probabilities that $Y = 1$ (the risk difference) is strictly collapsible. Nonetheless, the ratio of probabilities that $Y = 1$ (the risk ratio) is not strictly collapsible because the risk ratio varies across the Z strata, and the odds ratio is not at all collapsible because its marginal value does not equal the constant conditional (stratum-specific) value. Thus, collapsibility depends on the chosen measure of association.

Now suppose that a measure is not constant across the strata, but that a particular summary of the conditional measures does equal the marginal measure. This summary is then said to be *collapsible* across Z. As an example, in Table 1 the ratio of risks averaged over (standardized to) the marginal distribution of Z is

$$\Sigma_z P(Y = 1|X = 1, Z = z)P(Z = z)/\Sigma_z P(Y = 1|X = 0, Z = z)$$
$$P(Z = z) = \{-0.8(0.5) + 0.4(0.5)\}/\{-0.6(0.5) + 0.2(0.5)\} = 1.50,$$

which is equal to the marginal (crude) risk ratio. Thus, the risk ratio in Table 1 is collapsible under this particular weighting (standardization) scheme for the risks.

Various tests of collapsibility and strict collapsibility have been developed (e.g., Whittemore 1978; Asmussen and Edwards 1983; Ducharme and LePage 1986; Greenland and Mickey 1988; Geng 1989) as well as generalizations to partial collapsibility. The literature on graphical probability models distinguishes other types of collapsibility; see Frydenberg (1990), Whittaker (1990, Sect. 12.5) and Lauritzen (1996, Sect. 46.1) for examples. Both definitions given above are special cases of parametric collapsibility (Whittaker 1990).

Collapsibility in Regression Models

The above definition of strict collapsibility extends to regression contexts. Consider a generalized linear model (see ►Generalized Linear Models) for the regression of Y on three vectors w, x, z:

$$g[E(Y|w, x, z)] = \alpha + w\beta + x\gamma + z\delta.$$

This regression is said to be collapsible for β over z if $\beta^* = \beta$ in the regression omitting z,

$$g[E(Y|w, x)] = \alpha^* + w\beta^* + x\gamma^*$$

and is noncollapsible otherwise. Thus, if the regression is collapsible for β over Z and β is the parameter of interest, Z need not be measured to estimate β. If Z is measured, however, tests of $\beta^* = \beta$ can be constructed (Hausman 1978; Clogg et al. 1995).

The preceding definition generalizes the original contingency-table definition to arbitrary variables. There is a technical problem with the above regression definition,

however: If the first (full) model is correct, it is unlikely that the second (reduced) regression will follow the given form; that is, most families of regression models are not closed under deletion of Z. For example, suppose Y is Bernoulli with mean p and g is the logit link function $\ln[p/(1-p)]$, so that the full regression is first-order logistic. Then the reduced regression will not follow a first-order logistic model except in special cases. One way around this dilemma (and the fact that neither of the models is likely to be exactly correct) is to define the model parameters as the asymptotic means of the maximum-likelihood estimators. These means are well-defined and interpretable even if the models are not correct (White 1994).

If the full model is correct, $\delta = 0$ implies collapsibility for β and γ over Z. Nonetheless, if neither β nor δ is zero, marginal independence of the regressors does not ensure collapsibility for β over Z except when g is the identity or log link (Gail et al. 1984; Gail 1986). Conversely, collapsibility can occur even if the regressors are associated (Whittemore 1978; Greenland et al. 1999). Thus, it is not generally correct to equate collapsibility over Z with simple independence conditions, although useful results are available for the important special cases of linear, log-linear, and logistic models (e.g., see Gail 1986; Wermuth 1987, 1989; Robinson and Jewell 1991; Geng 1992; Guo and Geng 1995).

Confounding Versus Noncollapsibility

Much of the statistics literature does not distinguish between the concept of confounding as a bias in effect estimation and the concept of noncollapsibility; for example, Becher (1992) defines confounding as $\beta^* \neq \beta$ in the regression models given above, in which case the elements of Z are called confounders. Similarly, Guo and Geng (1995) define Z to be a nonconfounder if $\beta^* = \beta$. Nonetheless, confounding as defined in the causal-modeling literature (*See* ►Confounding) may occur with or without noncollapsibility, and noncollapsibility may occur with or without confounding; see Greenland (1987, 1996) and Greenland et al. (1999) for examples. Mathematically identical conclusions have been reached by other authors, albeit with different terminology in which noncollapsibility is called "bias" and confounding corresponds to "covariate imbalance" (Gail 1986; Hauck et al. 1991).

Comparability of Statistics

Peter Hackl
Professor
Vienna University of Business and Economics, Vienna, Austria

Comparison is the cognitive function that is basis for any measuring process and a frequent activity in everyday human life. Nowadays, comparisons of statistics over time and, even more demanding, cross-national and multilateral comparisons are a central element of economic and social analyzes. For politics and administration, for business and media, and for each citizen, comparisons are means to understand and assess the political, economic, and social processes of this world. This situation raises questions: Under which conditions are statistics comparable? Under which conditions is a comparison valid and leads to reliable results? What conclusions may be drawn and what are the risks implied by such conclusions?

Comparability: Definition and Assessment

Rathsmann-Sponsel and Sponsel (2001) describe "comparison" as a 7-digit relation $f(P, S, Z, K, V, A, B)$; P represents the comparing person, S and Z describe the comparing situation and the purpose of comparison, respectively; vector K stands for a number of criteria, V for a number of procedures, and A and B represent the characteristics of the objects to be compared, respectively. This rather formal view of psychologists indicates the complexity of the interaction between the individual and the objects to be compared. More visible becomes this complexity when the definition is applied to real situations, e.g., comparing the employment rates of two countries.

The employment rate is the number of persons aged 15–64 in employment as the share of the total population of the same age group. Obviously, the definition of "being in employment" and the exact meaning of "persons aged 15–64" are crucial for the value that is obtained for the employment rate. In addition, the statistical value is affected by the sampling design and other aspects of the data collection.

In general, statistics are based on concepts and definitions, and the value of a statistic is the result of a complex measurement process; *comparability is affected* by all these factors and, consequently, a wide range of facts must be considered. Moreover, the relevance of these facts depends on the purpose of comparison, the comparing situation, and other aspects of the comparison process. E.g., if the comparison of the employment rates of two countries is the basis for a decision on the allocation of subsidies for structural development, comparability is a more serious issue than in the case where the result of the comparisons does not have such consequences. These – and many other – characteristics must be taken into consideration when assessing differences between two employment rates.

Assessment of comparability has to take into account the multi-dimensionality of the conditions for comparability. Many aspects to be considered are qualitative, so that the corresponding dimensions cannot be measured on a metric scale. Moreover, important characteristics of the statistical products or the underlying measurement processes are often not available or uncertain.

Hence, in general, it is not feasible to give a comprehensive picture of comparability by means of a few metric measures. Alternatives are

- An indicator in form of a number between zero and one that indicates the degree of comparability, a one indicating perfect comparability.
- A rating of comparisons on an ordinal rating scale with a small number of points, a high value representing good comparability.

An example for a rating scale is the three point scale that is used for the "Overall assessment of accuracy and comparability" of indicators – such as the employment rate – within the Eurostat Quality Profiles; see Jouhette and Sproge (2005). This overall assessment is rated from "A" to "C". Grad "A" indicates that

- Data is collected from reliable sources applying high standards with regard to methodology/accuracy and is well documented in line with Eurostat metadata standard.
- The underlying data is collected on the basis of a common methodology for the European Union and,

where applicable, data for US and Japan can be considered comparable; major differences being assessed and documented.
- Data are comparable over time; impact of procedural or conceptual changes being documented.

This example illustrates:

- That the rating process reduces a high-dimensional information to a single digit.
- Where the characteristics of the statistics to be compared, the underlying measurement processes, and also conditions of the comparison process are crucial input elements for the rating of comparability.
- That the rating outcome has only the character of a label which the user might trust but which only reflects – perhaps vaguely – the result of a complex and subjective assessment process.
- That the rating outcome may miss to give appropriate weight to aspects that are important for a certain user.

A rating of the comparability on an ordinal rating scale has the advantage that it allows an easy communication about comparability.

The professional assessment of comparability requires:

- An adequate *competence of the scrutinizer*
- A careful *documentation of all characteristics* of the statistical products that are relevant for assessing the comparability

Generally, the scrutinizer will be different from the producer of a statistical product. This certainly will be the case in respect of cross-national comparisons. The producer has to provide a comprehensive set of metadata that documents all characteristics which are relevant for assessing the comparability. The outcome of this exercise might be an indicator of the types that are described above.

For the non-expert user, the assessment of the comparability of statistical products is hardly possible even when a well-designed set of all metadata is available that are relevant for assessing the comparability. Most users of the statistical products will have to rely on the professional assessment of the experts.

Comparability in Official Statistics

The integration of societies and the globalization of economies have the consequence that not only comparisons over time but especially cross-regional comparisons of statistical products are of increasing interest and importance. Political planning and decisions of supranational bodies need information that encompasses all involved nations. Multi-national enterprises and globally acting companies face the same problem.

Of even higher relevance for the need of comparability is the fact that statistical products are more and more used for *operational purposes*. Within the European Union, the process of integration of the member states into a community of states requires political measures in many areas. National statistical indicators are the basis for allocating a part of the common budget to member states, for administrating the regional and structural funds, for assessing the national performances with respect to the pact for stability and growth, and for various other purposes. It is in particular the European version of the System of National Accounts (SNA) ESA that plays such an operational role in various administrative processes of the European Union. The Millennium Development Goals and the Kyoto Protocol are other examples for the use of statistical indicators in defining political aims and assessing the corresponding progress. In all these cases, the comparability of the relevant statistical products is a core issue.

In the cross-national context, the responsibility for harmonizing cross-national concepts, definitions, and methodological aspects must be assigned to an authority with *supra-national competence*. Organizations like the UN, OECD, and Eurostat are engaged in the compilation of standards and the editing of recommendations, guidelines, handbooks, and training manuals, important means to harmonize statistical products and improve their comparability. Examples of standards are the Statistical Classifications of Economic Activities (ISIC) and the International Statistical Classification of Diseases (ICD). Principles and Recommendations for Population and Housing Censuses adopted by the Statistical Commission of the UN is an example for a standard methodology. Examples of standards on the European level are the NACE and CPA.

Within the European Union, standards and methods are laid down in regulations which are *legally binding* for the member states. E.g., the ESA 95 was approved as a Council Regulation in June 1996 and stipulates the member states to apply the SNA in a very concrete form. In working groups, experts from the member states are dealing with the preparation and implementation of such regulations; the harmonization of national statistical products is a central concern of these activities.

The important role that is attributed to statistical comparability within the ESS is stressed by the fact that the European Statistics Code of Practice (2005) contains Coherence and Comparability as one of its 15 principles. The corresponding indicators refer mainly to national aspects but also to the European dimension.

To assess the comparability of statistical products, national reports are essential that provide *metadata* for all related aspects of the statistical product. Standard formats for the documentation of metadata have been suggested by the International Monetary Fund in form of the General Data Dissemination Standard (GDDS) and the Special Data Dissemination Standard (SDDS).

It should be mentioned that standardizing concepts, definitions, and methods also has unfavorable effects; *comparability has a price*. An important means for improving harmonization are standards; however, they are never perfect and tend to get outdated over time. In particular the adaptation of standards to methodological progress might be a time-consuming task. Generally, standardization reduces flexibility and makes adaptations to new developments, especially of methodological alternatives, more difficult. This is especially true if standards are put into the form of regulations. It is even truer if such standards are implemented in order to ease the use for operational purposes, as it is the case in the ESS.

Conclusions

Lack of comparability may lead to erroneous results when statistical products are compared. The need for cross-national comparability is even more pronounced if statistical results are used for operational purposes as it is the case, e.g., in the European Union. Hence, comparability is an important quality aspect of statistical products. It is affected by the involved concepts and definitions, the measurement processes, and comparability may also depend on conditions of the comparison. The producer of a statistical product has to care that the conditions of comparability are fulfilled to the highest extent possible. In the cross-national context, international organizations like ►Eurostat are fostering the compilation of standards for concepts and definitions and of principles and standards for methods and processes in order to harmonize statistical products and improve their cross-national comparability.

For the assessment of comparability, a wide range of information is needed, as many aspects of the statistics to be compared but also of the purpose and conditions of the comparison have to be taken into account. No general rules are available that guarantee a valid assessment of comparability; only experts with profound knowledge can be expected to give a reliable assessment. For such an assessment, metadata which document all relevant characteristics are essential and have to be provided by the producer of the statistical product. For cross-national purposes, organizations like Eurostat have to care that the relevant metadata are provided by the respective producers. The user, e.g., the consumer of an economic or social analysis, has to trust that the analysts and experts made use of the involved statistics responsively.

About the Author

Dr. Peter Hackl was born 1942 in Linz, Austria. He is a Professor (since 1981) at the Department of Statistics, Vienna University of Business and Economics (Wirtschaftsuniversität); Head of the Division of Economic Statistics (since 1991). During the academic year 1988/1989 and during the summer term 1992, he was visiting professor at the University of Iowa, Iowa City. He was President of the Austrian Statistical Society (Österreichische Statistische Gesellschaft), (1995–2000). He was Vice-Dean of Studies (1995–2000) at the Wirtschaftsuniversität, member and deputy chairman (1999–2004) of the Statistikrat, the advisory board of Statistics Austria, the Austrian National Statistical Office; Chairman of the Committee for Quality Assurance. He was Director General of Statistics Austria (2005–2009). Professor Hackl is Elected member of the International Statistical Institute (since 1981). He has authored/coauthored about 100 articles in refereed journals in statistical theory and methods and applications of statistics. He was also editor of two books and has authored/coauthored 5 books. He was awarded an Honorary Doctorate, Stockholm University of Economics (1996).

Complier-Average Causal Effect (CACE) Estimation

Graham Dunn
Professor of Biomedical Statistics and Head of the Health Methodology Research Group
University of Manchester, Manchester, UK

Imagine a simple randomized controlled trial evaluating a psychotherapeutic intervention for depression. Participants are randomized to one of two treatment groups. The first (the control condition) comprises treatment and management as usual (TAU). Participants in the second group are offered a course of individual cognitive behavior therapy (CBT) *in addition* to TAU. The outcome of the trial is evaluated by assessing the severity of depression in all of the participants 6 months after ▶randomization. For simplicity, we assume there are no missing outcomes. We find a difference between the average outcomes for the two groups to be about four points on the depression rating scale, a difference that is of only borderline clinical significance. This difference of four points is the well-known intention-to-treat (ITT) effect – it is the estimated effect treatment *allocation* (i.e., offering the treatment). This we will call ITT_{ALL}.

Participants in the control (TAU) condition did not get any access to CBT but we now discover that only about half of those offered psychotherapy actually took up the offer. Only 50% of the treatment group actually received CBT. So, it might be reasonable to now ask "What was the effect of receiving CBT?" or "What was the treatment effect in those who complied with the trial protocol (i.e., treatment allocation)?" Traditionally, trialists have been tempted to carry out what is called a "Per Protocol" analysis. This involves dropping the non-compliers from the treatment arm and comparing the average outcomes in the compliers with the average outcome in all of the controls. But this is not comparing like with like. There are likely to be selection effects (confounding) – those with a better (or worse) treatment-free prognosis might be more likely to turn up for their psychotherapy. The same criticism also applies to the abandonment of randomization altogether and comparing the average outcomes in those who received treatment with those who did not (a mixture of controls and non-compliers) in a so-called "As treated" analysis.

To obtain a valid estimate of the *receipt* of treatment we need to be able to compare the average of the outcomes in those who received CBT with the average of the outcomes of the control participants who *would have received* CBT had they been allocated to the treatment group. This is the Complier-Average Causal Effect (CACE) of treatment. How do we do this? The simplest approach is based on the realization that the ITT effect is attenuated estimate of the CACE, and that the amount of attenuation is simply the proportion of compliers (or would-be compliers) in the trial. The proportion of compliers (P_C) is simply estimated by the proportion of those allocated to the treatment group who actually receive CBT. We postulate that we have two (possibly hidden) classes of participant: Compliers and Non-compliers. Non-compliers receive no CBT irrespective of their treatment allocation. The intention-to-treat effects in the Compliers and Non-compliers are ITT_C (≡ CACE) and ITT_{NC}, respectively. It should be clear to the reader that $ITT_{ALL} = P_C ITT_C$ and $(1 - P_C)ITT_{NC}$.

To make use of this simple relationship, let's now assume that treatment allocation in the Non-compliers has no impact on their outcome (i.e., does not affect the severity of their depression). This assumption is often referred to as an exclusion restriction. It follows that $ITT_{ALL} = P_C ITT_C$ and that

$$CACE = ITT_C = ITT_{ALL}/P_C$$

So with 50% compliance, and estimated overall ITT effect of 4 units on the depression scale, the CACE estimate is 8 units – a result with much more promise to our clinicians. To get a standard error estimate we might apply a simple bootstrap (see ▶Bootstrap Methods). Note that CACE estimation is not a means of conjuring up a treatment effect from nowhere – if the overall ITT effect is zero so will the CACE be. If the overall ITT effect is not statistically-significant, the CACE will not be statistically-significant.

One last point: in a conventional treatment trial aiming to demonstrate efficacy, the ITT estimate will be conservative, but in a trial designed to demonstrate equivalence (or non-inferiority) it is the CACE estimate that will be the choice of the cautious analyst (we do not wish to confuse attenuation arising from non-compliance with differences in efficacy).

Here we have illustrated the ideas with the simplest of examples. And here we have also made the derivation of the CACE estimate as simple as possible without any detailed reference to required assumptions. An analogous procedure was first used by Bloom (1984) but its

formal properties were derived and compared with instrumental variable estimators of treatment effects by Angrist et al. (1996). Non-compliance usually has an implication for missing data – those that do not comply (or would-be Non-compliers) with their allocated treatment are also those who are less likely to turn up to have their outcome assessed. The links between CACE estimation and missing data models (assuming latent ignorability) are discussed by Frangakis and Rubin (1999). Generalizations of CACE methodology to estimation of treatment effects through the use of Principal Stratification have also been introduced by Frangakis and Rubin (2002).

Components of Statistics

Clive William John Granger†
Professor Emeritus
University of California-San Diego, San Diego, CA, USA

The two obvious subdivisions of statistics are: (a) Theoretical Statistics and (b) Practical Statistics.

1. The theoretical side is largely based on a mathematical development of probability theory (*see* ►Probability Theory: An Outline) applicable to data, particularly the asymptotic properties of estimates (*see* ►Properties of Estimators) which lead to powerful theorems such as the ►Central Limit Theorem. The aim is to put many practical approaches to data analysis (*see also* ►Categorical Data Analysis; ►Multivariate Data Analysis: An Overview; ►Exploratory Data Analysis; ►Functional Data Analysis) on a sound theoretical foundation and to develop theorems about the properties of these approaches. The theories are usually based on a number of assumptions that may or may not hold in practice.
2. Practical statistics considers the analysis of data, how the data can be summarized in useful fashions, and how relationships between sets of data from different variables can be described and interpreted. The amount and the quality of the data (*see* ►Data Quality) that is available are essential features in this area. On occasions data may be badly constructed or terms may be missing which makes analysis more complicated.

Descriptive statistics include means, variances, histograms, correlations, and estimates of quantiles, for example. There are now various types of statistics depending on the area of application. General statistics arose from considerations of gambling (*see* ►Statistics and Gambling), agriculture (*see* ►Agriculture, Statistics in; ►Analysis of Multivariate Agricultural Data), and health topics (*see* ►Medical research, Statistics in; ►Medical Statistics) but eventually a number of specialized areas arose when it was realized that these areas contained special types of data which required their own methods of analysis. Examples are:

1. Biometrics (*see* ►Biostatistics), from biological data which required different forms of measurement and associated tests.
2. ►Econometrics, for which ►Variables may or may not be related with a time gap; data can be in the form of ►Time Series (particularly in economies and finance) or in large panels (*see* ►Panel Data) in various parts of economics. The techniques developed over a wide range and the ideas have spread into other parts of statistics.
3. Psychometrics, where methods are required for the analysis of results from very specific types of experiments used in the area of psychology (*see* ►Psychology, Statistics in).

Other major areas of application such as engineering, marketing, and meteorology generally use techniques derived from methods in the areas mentioned above, but all have developed some area-specific methods.

About the Author

In 2003 Professor Granger was awarded the Nobel Memorial Prize in Economic Sciences (with Professor Robert

Engle) for methods of analyzing economic time series with common trends (cointegration). Granger was knighted in 2005.

Professor Granger had sent his contributed entry on June 2 2008, excusing himself for not writing a bit longer, "Lexicon" kind of paper: "I have never written anything for a 'Lexicon' before and so have failed in my attempt to be helpful, but I do attach a page or so. I wish you good luck with your effort." We are immensely thankful for his unselfish contribution to the prosperity of this project.

Composite Indicators

Jože Rovan
Associate Professor, Faculty of Economics
University of Ljubljana, Ljubljana, Slovenia

Definition: A composite indicator is formed when individual indicators are compiled into a single index, on the basis of an underlying model of the multidimensional concept that is being measured (OECD, Glossary of Statistical Terms).

Multidimensional concepts like welfare, well-being, human development, environmental sustainability, industrial competitiveness, etc., cannot be adequately represented by individual indicators. For that reason, composite indicators are becoming increasingly acknowledged as a tool for summarizing complex and multidimensional issues.

Composite indicators primarily arise in the following areas: economy, society, globalization, environment, innovation, and technology. A comprehensive list of indicators can be found at the following address: http:// composite-indicators.jrc.ec.europa.eu/FAQ.htm#List_of_Composite_Indicators_

The *Handbook on Constructing Composite Indicators: Methodology and User Guide* (OECD 2008) recommends a ten-step process of constructing composite indicators:

- **Theoretical framework** is the starting point of the process of constructing composite indicators, defining individual indicators (e.g., variables) and their appropriate weights, reflecting the structure of the investigated multidimensional concept. This step is crucial in construction process because it has the greatest impact on the relevance of the indicator of the investigated phenomena. For that reason, the constructors team should include, besides the statisticians, who play the major role, the experts and stakeholders from the topic of the composite indicator.

Due to the fact that many new multidimensional concepts do not have a generally agreed theoretical framework, transparency is essential in constructing credible indicators.

- **Data selection** should acquire analytically sound relevant indicators, having in mind their avaliability (country coverage, time, appropriate scale of measurement, etc.). Engagement of experts and stakeholders is recommended.
- **Imputation of missing data** (see ►Imputation) provides a complete dataset (single or. multiple). Inspection of presence of ►outliers in the dataset should not be omitted.
- **Multivariate analysis** reveals the structure of the considered dataset from two aspects: (a) units and (b) available individual indicators, using appropriate multivariate methods, e.g., ►principal component analysis, factor analysis (see ►Factor Analysis and Latent Variable Modelling), Cronbach coefficient alpha, cluster analysis (see ►Cluster Analysis: An Introduction), ►correspondence analysis, etc. These methods are able to reveal internally homogenous groups of countries or groups of indicators and interpret the results.
- **Normalization procedures** are used to achieve comparability of variables of the considered dataset, taking into account theoretical framework and the properties of the data. The robustness of normalization methods against possible ►outliers must be considered.
- **Weighting and aggregation** should take into account the theoretical framework and the properties of the data. The most frequently used aggregation form is *a weighted linear aggregation rule* applied to a set of variables (OECD 2003). Weights shoud reflect the relative importance of individual indicators in a construction of the particular composite indicator.
- **Uncertainty and ►sensitivity analysis** are necessary to evaluate robustness of composite indicators and to improve transparency, having in mind selection of indicators, data quality, imputation of missing data, data normalization, weighting, aggregation methods, etc.
- **Back to the original data**, to (a) reconsider the relationships between composite indicator and the original

data set and to identify the most influential indicators and (b) compare profiled performance of the considered units to reveal what is driving the composite indicator results, and in particular whether the composite indicator is overly dominated by a small number of indicators.

- **Links to other indicators** identify the relationships between the composite indicator (or its dimensions) and other individual or composite indicators.
- **Visualization of results** should attract audience, presenting composite indicators in a clear and accurate way.

Following the above-mentioned guidelines, the constructors of composite indicators should never forget *that composite indicators should never be seen as a goal per se. They should be seen, instead, as a starting point for initiating discussion and attracting public interest and concern* (Nardo et al. 2005).

However, there is now general agreement about the usefulness of composite indicators: There is a strong belief among the constructors of composite indicators that such summary measures are meaningful and that they can capture the main characteristic of the investigated phenomena. On the other side, there is a scepticism among the critics of this approach, who believe that there is no need to go beyond an appropriate set of individual indicators. Their criticism is focused on the "arbitrary nature of the weighting process" (Sharpe 2004) in construction of the composite indicators.

Computational Statistics

Colin Rose
Director
Theoretical Research Institute, Sydney, NSW, Australia

What Is Computational Statistics?

We define *computational statistics* to be: ... 'statistical methods/results that are enabled by using computational methods'. Having set forth a definition, it should be stressed, first, that names such as *computational statistics* and *statistical computing* are essentially semantic constructs that do not have any absolute or rigourous structure within the profession; second, that there are any number of competing definitions on offer. Some are unsatisfactory because they focus purely on data or graphical methods and exclude symbolic/exact methods; others are unsatisfactory because they place undue emphasis on 'computationally-intensive methods' or brute force, almost as if to exclude well-written efficient and elegant algorithms that might be computationally quite simple. Sometimes, the difficulty is not in the execution of an algorithm, but in writing the algorithm itself.

Computational statistics can enable one:

- To work with arbitrary functional forms/distributions, rather than being restricted to traditional known textbook distributions.
- To simulate distributional properties of estimators and test statistics, even if closed-form solutions do not exist (*computational inference* rather than *asymptotic inference*).
- To compare statistical methods under different alternatives.
- To solve problems numerically, even if closed-form solutions are not possible or cannot be derived.
- To derive symbolic solutions to probability, moments, and distributional problems that may never have been solved before, and to do so essentially in real-time.

- To explore multiple different models, rather than just one model.
- To explore potentially good or bad ideas via simulation in just a few seconds.
- To choose methods that are theoretically appropriate, rather than because they are mathematically tractable.
- To check symbolic/exact solutions using numerical methods.
- To bring to life theoretical models that previously were too complicated to evaluate . . .

Journals and Societies

Important journals in the field include:

- Combinatorics, Probability & Computing
- Communications in Statistics – Simulation and Computation
- Computational Statistics
- Computational Statistics and Data Analysis
- Journal of Computational and Graphical Statistics
- Journal of the Japanese Society of Computational Statistics
- Journal of Statistical Computation and Simulation
- Journal of Statistical Software
- SIAM Journal on Scientific Computing
- Statistics and Computing

Societies include: the International Association for Statistical Computing (IASC – a subsection of the ISI), the American Statistical Association (Statistical Computing Section), the Royal Statistical Society (Statistical Computing Section), and the Japanese Society of Computational Statistics (JSCS) . . .

Computational statistics consists of three main areas, namely numerical, graphical and symbolic methods . . .

Numerical Methods

The numerical approach is discussed in texts such as Gentle (2009), Givens and Hoeting (2005), and Martinez and Martinez (2007); for Bayesian methods, see Bolstad (2009). Numerical methods include: Monte Carlo studies to explore asymptotic properties or finite sample properties, pseudo-random number generation and sampling, parametric density estimation, non-parametric density estimation, ▶bootstrap methods, statistical approaches to software errors, information retrieval, statistics of databases, high-dimensional data, temporal and spatial modeling, ▶data mining, model mining, statistical learning, computational learning theory and optimisation etc. . . . While optimisation itself is an absolutely essential tool in the field, it is very much a field in its own right.

Graphical Methods

Graphical methods are primarily concerned with either (a) viewing theoretical models and/or (b) viewing data/fitted models.

In the case of *theoretical* models, one typically seeks to provide understanding by viewing one, two or three variables, or indeed even four dimensions (using 3-dimensional plots animated over time, translucent graphics etc.).

Visualizing *data* is essential to data analysis and assessing fit; see, for instance, Chen et al. (2008). Special interest topics include smoothing techniques, kernel density estimation, multi-dimensional data visualization, clustering, exploratory data analysis, and a huge range of special statistical plot types. Modern computing power makes handling and interacting with large data sets with millions of values feasible . . . including live interactive manipulations.

Symbolic/Exact Methods

The 21st century has brought with it a conceptually entirely new methodology: symbolic/exact methods. Recent texts applying the symbolic framework include Andrews and Stafford (2000), Rose and Smith (2002), and Drew et al. (2008).

Traditional 20th century computer packages are based on numerical methods that tend to be designed much like a cookbook. That is, they consist of hundreds or even thousands of numerical recipes designed for specific cases. One function is written for one aspect of the Normal distribution, another for the LogNormal, etc. This works very well provided one stays within the constraints of the known common distributions, but unfortunately, it breaks down as soon as one moves outside the catered framework. It might work perfectly for random variable X, but not for X^2, nor $\exp(X)$, nor mixtures, nor truncations, nor reflections, nor folding, nor censoring, nor products, nor sums, nor . . .

By contrast, symbolic/exact methods are built on top of computer algebra systems . . . programs such as *Mathematica* and Maple that understand algebra and mathematics. Accordingly, symbolic algorithms can provide exact general solutions . . . not just for specific distributions/models. Symbolic computational statistical packages include mathStatica (2002–2010, based on top of *Mathematica*) and APPL (based on top of Maple).

Symbolic methods include: automated expectations for arbitrary distributions, probability, combinatorial probability, transformations of random variables, products of random variables, sums and differences of random variables, generating functions, inversion theorems, maxima/minima of random variables, symbolic and numerical maximum likelihood estimation (using exact methods),

curve fitting (using exact methods), non-parametric kernel density estimation (for arbitrary kernels), moment conversion formulae, component-mix and parameter-mix distributions, copulae, pseudo-random number generation for arbitrary distributions, decision theory, asymptotic expansions, ▶order statistics (for identical and non-identical parents), unbiased estimators (h-statistics, k-statistics, polykays), moments of moments, etc.

The Changing Notion of What is Computational Statistics

Just 10 or 20 years ago, it was quite common for people working in computational statistics to write up their own code for almost everything they did. For example, the *Handbook of Statistics 9: Computational Statistics* (see Rao 1993) starts out Chapter 1 by describing algorithms for sorting data. Today, of course, one would expect to find sorting functionality built into any software package one uses . . . indeed even into a word processor. And, of course, the 'bar' keeps on moving and evolving. Even in recent texts such as Gentle (2009), about half of the text (almost all of Part 1) is devoted to computing techniques such as fixed- and floating-point, numerical quadrature, numerical linear algebra, solving non-linear equations, optimisation etc., . . . techniques that Gentle et al. (2004, p. 5) call "*statistical computing*" but which are really just *computing*. Such methods lie firmly within the domain of computational science and/or computational mathematics . . . they are now built into any decent modern statistical/mathematical software package . . . they take years of work to develop into a decent modern product, and they require tens of thousands of lines of code to be done properly . . . all of which means that it is extremely unlikely that any individual would write their own in today's world. Today, one does not tend to build an airplane simply in order to take a flight. And yet many current texts are still firmly based in the older world of 'roll your own', devoting substantial space to routines that are (a) general mathematical tools such as numerical optimisation and (b) which are now standard functionality in modern packages used for computational statistics. While it is, of course, valuable to understand how such methods work (in particular so that one is aware of their limitations), and while such tools are absolutely imperative to carrying out the discipline of computational statistics (indeed, as a computer itself is) – these tools are now general mathematical tools and the days of building one's own are essentially long gone.

Future Directions

It is both interesting and tempting to suggest likely future directions.

(a) *Software packages*: At the present time, the computational statistics software market is catered for from two polar extremes. On the one hand, there are major general mathematical/computational languages such as *Mathematica* and Maple which provide best of breed general computational/numerical/graphical tools, and hundreds of high-level functional programming constructs to expand on same, but they are less than comprehensive in field-specific functionality. It seems likely such packages will further evolve by developing and growing tentacles into specific fields (such as statistics, combinatorics, finance, econometrics, biometrics etc.). At the other extreme, there exist narrow field-specific packages such as S-Plus, Gauss and R which provide considerable depth in field-specific functionality; in order to grow, these packages will likely need to broaden out to develop more general methods/general mathematical functions, up to the standard offered by the major packages. The software industry is nascent and evolving, and it will be interesting to see if the long-run equilibrium allows for both extremes to co-exist. Perhaps, all that is required is for a critical number of users to be reached in order for each eco-system to become self-sustaining.

(b) *Methodology*: It seems likely that the field will see a continuing shift or growth from *statistical inference* to *structural inference*, . . . from *data mining* to *model mining*, . . . from *asymptotic inference* to *computational inference*.

(c) *Parallel computing*: Multicore processors have already become mainstream, while, at the same time, the growth in CPU speeds appears to be stagnating. It seems likely then that parallel computing will become vastly more important in evolving computational statistics into the future. Future computational statistical software may also take advantage of GPUs (graphical processing units), though it should be cautioned that the latter are constrained in serious statistical work by the extremely poor numerical precision of current GPUs.

(d) *Symbolic methods*: Symbolic methods are still somewhat in their infancy and show great promise as knowledge engines i.e., algorithms that can derive exact theoretical results for arbitrary random variables.

(e) *On knowledge and proof*: Symbolic algorithms can derive solutions to problems that have never been posed before – they place enormous technological power into the hands of end-users. Of course, it is possible (though rare) that an error may occur (say in integration, or by mis-entering a model). In a sense,

this is no different to traditional reference texts and journal papers which are also not infallible, and which are often surprisingly peppered with typographical or other errors.

In this regard, the computational approach offers both greater exposure to danger, as well as the tools to avoid it. The "danger" is that it has become extremely easy to generate output in real-time. The sheer scale and volume of calculation has magnified, so that the average user is more likely to encounter an error, just as someone who drives a lot is more likely to encounter an accident. *Proving* that the computer's output is actually correct can be very tricky, or impractical, or indeed impossible for the average practitioner to do, just as the very same practitioner will tend to accept a journal result at face value, without properly checking it, even if they could do so. The philosopher, Karl Popper, argued that the aim of science should not be to prove things, but to seek to refute them. Indeed, the advantage of the computational statistical approach is that it is often possible to check one's work using two completely different methods: both numerical and symbolic. Here, numerical methods take on a new role of checking symbolic results. One can throw in some numbers in place of symbolic parameters, and one can then check if the solution obtained using symbolic methods (the exact theoretical solution) matches the solution obtained using numerical methods (typically, ►numerical integration or Monte Carlo methods, see ►Monte Carlo Methods in Statistics). If the numerical and symbolic solutions do *not* match, there is an obvious problem and we can generally immediately reject the theoretical solution (*a la* Popper). On the other hand, if the two approaches match up, we still do not have a proof of correctness . . . all we have is just one point of agreement in parameter space. We can repeat and repeat and repeat the exercise with different parameter values . . . and as we do so, we effectively build up, not an absolute proof in the traditional sense, but, appropriately for the statistics profession, an ever increasing degree of confidence . . . effectively a proof by probabilistic induction . . . that the theoretical solution is indeed correct. This is an extremely valuable (though time-consuming) skill to develop, not only when working with computers, but equally with textbooks and journal papers.

Conditional Expectation and Probability

Takis Konstantopoulos
Professor
Heriot-Watt University, Edinburgh, UK

In its most elementary form, the conditional probability $P(A|B)$ of an event A given an event B is defined by

$$P(A|B) = \frac{B(A \cap B)}{P(B)},$$

provided that $P(B) \neq 0$. This is a well-motivated definition, compatible both with the frequency interpretation of probability as well as with elementary probability on countable spaces. An immediate consequence of the definition is ▶*Bayes' theorem*: if $A_1, A_2, \ldots, A_n$ are mutually disjoint events whose union has probability one, then $P(A_1|B) = \frac{P(B|A_1)P(A_1)}{\sum_{i=1}^{n} P(B|A_i)P(A_i)}$.

Suppose now that X, Y are random variables taking values in finite sets. We define the conditional distribution of X given Y by

$$P(X = x|Y = y) = \begin{cases} \frac{P(X=x,Y=y)}{P(Y=y)}, & \text{if } P(Y = y) \neq 0 \\ 0, & \text{if } P(Y = y) = 0. \end{cases}$$

The latter choice, i.e., 0/0 interpreted as 0, is both physically motivated and mathematically desirable. The object $P(X = x|Y = y)$ is a probability in x (i.e., it sums up to 1 over x) and a function of y. If X takes values in a set of real numbers then we can define the conditional expectation of X given $Y = y$ by

$$E(X|Y = y) = \sum_x xP(X = x|Y = y), \tag{1}$$

where the summation extends over all possible values x of X. This is a function of y, say $h(y) = E(X|Y = y)$. We can then talk about the conditional expectation of X given Y as the *random variable* $h(Y)$ obtained by substituting y by the random variable Y in the argument of $h(y)$. From this definition the following important property of $E(X|Y)$ is easily derived:

$$E\big[(X - E(X|Y)) \cdot g(Y)\big] = 0, \tag{2}$$

for any random variable $g(Y)$ which is a (deterministic) function of Y.

One can easily generalise the above to countably-valued random variables. However, defining conditional probability and expectation for general random variables cannot be done in the previous naive manner. One can mimic the definitions for random variables possessing density but this has two drawbacks: first, it is not easy to rigorously reconcile with the previous definitions; second, it is not easy to generalize. Instead, we resort to an axiomatic definition of conditional expectation, stemming directly from the fundamental property (2). It can be easily verified that, in the earlier setup, there is only one function $h(y)$ satisfying (2) for all functions $g(y)$, and this $h(y)$ is defined by (1).

The last observation leads us to the following definition: Let $(\Omega, \mathcal{F}, P)$ be a probability space and X a positive random variable (i.e., a measurable function $X : \Omega \to \mathbb{R}_+$). Let $\mathcal{G} \subset \mathcal{F}$ be another sigma-algebra. We say that $E(X|\mathcal{G})$ is the conditional expectation of X given $\mathcal{G}$ if (a) $E(X|\mathcal{G})$ is $\mathcal{G}$-measurable and (b) for all bounded $\mathcal{G}$-measurable random variables G, we have

$$E[XG] = E[E(X|\mathcal{G})G]. \tag{3}$$

Such an object exists and is *almost surely* unique. The latter means that if two random variables, H_1, H_2, say, satisfy $E[XG] = E[H_iG]$, $i = 1, 2$, for all G then $P(H_1 = H_2) = 1$. (Such H_i are called *versions* of the conditional expectation.) Existence is immediate by the ▶Radon–Nikodým theorem. Consider two measures on $(\Omega, \mathcal{G})$: the first one is P; the second one is $E[X\mathbb{1}_G]$, $G \in \mathcal{G}$ (where $\mathbb{1}_G$ is defined as 1 on G and 0 on $\Omega\backslash G$). When $P(G) = 0$ we have $E[X\mathbb{1}_G] = 0$ and therefore the second measure is *absolutely continuous* with respect to the first. The Radon–Nikodým theorem ensures that the derivative (density) of the second measure with respect to the first exists and that it satisfies (3). This observation and string of arguments is due to Kolmogorov (1933), and it is through this that modern Probability Theory was established as a mathematical discipline having a natural connection with Measure Theory.

Having defined $E[X|\mathcal{G}]$ for positive X we can define it for negative X by reversing signs and for general X via the formula $E[X|\mathcal{G}] = E[\max(X, 0)|\mathcal{G}] + E[\min(X, 0)|\mathcal{G}]$, provided that wither $E[\max(X, 0)] < \infty$ or $E[\min(X, 0)] > -\infty$.

Given then two random variables X, Y (the first of which is real-valued, but the second may take values in fairly arbitrary spaces (such as a space of functions), we can define $E[X|Y]$ as $E[X|\sigma(Y)]$ where $\sigma(Y)$ is the σ-algebra generated by Y. It can be seen that this is entirely compatible with the initial definition (1).

Passing on to conditional probability, observe that if A is an event, the expectation of $\mathbb{1}_A$ is precisely $P(A)$. By analogy, we define

$$P(A|\mathcal{G}) = E[\mathbb{1}_A|\mathcal{G}].$$

For each event $A \in \mathcal{F}$, this is a random variable, i.e., a measurable function of $\omega \in \Omega$ which is defined almost surely uniquely (see explanation after formula (3)). For a real-valued random variable X we define the conditional distribution function $P(X \leq x|\mathcal{G})$ as $E[\mathbb{1}_{X \leq x}|\mathcal{G}]$. We would like this to be a right-continuous non-decreasing function of x. Since, for each x, $P(X \leq x|\mathcal{G})$ is defined only almost surely, we need to show that we can, for each x, pick a version H_x of $P(X \leq x|\mathcal{G})$ in a way that the probability of the event $\{H_x \leq H_y \text{ if } x \leq y \text{ and } \lim_{\epsilon \downarrow 0} H_{x+\epsilon} = H_x\}$ is one. This can be done and $\{H_x\}_{x \in \mathbb{R}}$ is referred to as a *regular conditional distribution function* of X given $\mathcal{G}$. Informally (and in practice) it is denoted as $P(X \leq x|\mathcal{G})$. Regular conditional

probabilities exist not only for real random variables X but also for random elements X taking values in a Borel space Kallenberg (2002).

From this general viewpoint we can now go down again and verify everything we wish to have defined in an intuitive or informal manner. For instance, if (X, Y) is a pair of real-valued random variables having joint density $f(x,y)$ then, letting $f_Y(y) := \int_{\mathbb{R}} f(x,y)dx$, define

$$h(x|y) := \begin{cases} \frac{f(x,y)}{f_Y(y)}, & \text{if } f_Y(y) \neq 0 \\ 0, & \text{if } f_Y(y) = 0 \end{cases}.$$

Then the function $\int_{-\infty}^{x} h(s|Y)ds$ serves as a the regular conditional distribution of X given Y. We can also verify that $E(\max(X,0)|Y) = \int_0^\infty P(X > x|Y)dx$ (in the sense that the right-hand side is a version of the left) and several other elementary formulae.

It is important to mention an interpretation of $E(X|Y)$ as a projection. First recall the definition of projection in Euclidean space: Let x be a point (vector) in the space $\mathbb{R}^n$ and Π a hyperplane. We define the projection $\widehat{x}$ of x onto Π as the unique element of Π which has minimal distance from x. Equivalently, the angle between $x - \widehat{x}$ and any other vector g of Π must be 90°: this can be written as $\langle x - \widehat{x}, g\rangle = 0$, i.e., the standard inner product of $x - \widehat{x}$ and g is equal to 0. Next suppose that $E[X^2] < \infty$. Then it can be seen that

$$E[(X - E(X|\mathcal{G}))^2] = \min_G E[(X - G)^2],$$

where the minimum is taken over all $\mathcal{G}$-measurable random variables G with $E[G^2] < \infty$. The defining property (3) then says that the inner product between $X - E(X|\mathcal{G})$ and any G is zero, just as in Euclidean space. Keeping the geometric meaning in mind, we can devise (prove and interpret) several properties of the conditional expectation. We mention one below.

The *tower property*: If $\mathcal{G}_2 \subset \mathcal{G}_1$ are two sigma-algebras then

$$E[E(X|\mathcal{G}_1)|\mathcal{G}_2] = E[X|\mathcal{G}_2].$$

The geometric meaning is as follows: If Π_1 is a hyperplane (e.g., a plane in three dimensions) and Π_2 a hyperplane contained in Π_1 (e.g., a line on the plane) then we can find the projection onto Π_2 by first projecting onto Π_1 and then projecting the projection. The tower property holds for general random variables as long as conditional expectation can be defined, i.e., it does not require $E[X^2] < \infty$. Another interpretation of it is as follows: if $\mathcal{G}_1, \mathcal{G}_2$ represent states of knowledge (information, say) and $\mathcal{G}_1$ is wider than $\mathcal{G}_2$ (in the sense that $\mathcal{G}_2$ can be obtained from $\mathcal{G}_1$) then, in finding the conditional expectation of X given $\mathcal{G}_2$, the additional knowledge contained in $\mathcal{G}_1$ can be ignored. A particular form of this property is in the relation

$$E[E(X|\mathcal{G})] = E[X].$$

Another important property is that $E[GX|\mathcal{G}] = GE[X|\mathcal{G}]$ if G is $\mathcal{G}$-measurable. On the other hand, if Z is independent of (X, Y) then $E[X|Y,Z] = E[X|Y]$. For further properties, see Williams (1989). In particular, if X and Y are independent then $E[X|Y] = E[X]$, i.e., it is a constant.

For *normal* random variables, the geometric picture completely characterizes what we can do with them. Recall that a random variable X is centred normal if it has finite variance σ^2 and if for all constants a, b there is a constant c such that cX has the same distribution as $aX' + bX''$ where X', X'' are independent copies of X. It follows that $a^2 + b^2 = c^2$ and that X has density proportional to $e^{-x^2/2\sigma^2}$. We say that X is normal if $X - E[X]$ is centred normal. We say that a collection of random variables $\{X_t\}_{t\in T}$, with T being an arbitrary set, is (jointly) normal if for any $t_1, \ldots, t_n$, and any constants $c_1, \ldots, c_n$, the random variable $c_1X_{t_1} + \cdots + c_nX_{t_n}$ is normal. It follows that if $\{X, Y_1, \ldots, Y_k\}$ are jointly normal then $E[X|Y_1, \ldots, Y_k] = E[X|\sigma(Y_1, \ldots, Y_k)] = a_1Y_1 + \cdots + a_kY_k + b$ where the constants can be easily computed by (3). The *Kalman filter property* says that if $\{X, Y_1, Y_2\}$ are centred jointly normal such that Y_1 and Y_2 are independent then $E[X|Y_1, Y_2] = E[X|Y_1] + E[X|Y_2]$. The geometric interpretation of this is: to project a vector onto a plane defined by two orthogonal lines, we project to each line and then add the projections. The Kalman filter is one of the important applications of Probability to the fields of Signal Processing, Control, Estimation, and Inference (Catlin 1989).

By the term *conditioning* in Probability we often mean an effective application of the tower property in order to define a probability measure or to compute the expectation of a functional. For example, if $X_1, X_2, \ldots$ are i.i.d. positive random variables and an N is a geometric random variable, say $P(N = n) = \alpha^{n-1}(1 - \alpha)$, $n = 1, 2, \ldots$, then $E[\theta^{X_1+\cdots+X_N}] = E[E(\theta^{X_1+\cdots+X_N}|N)]$. But $E[\theta^{X_1+\cdots+X_N}|N = n] = E[\theta^{X_1+\cdots+X_n}] = (E[\theta^{X_1}])^n$, by independence. Hence $E[\theta^{X_1+\cdots+X_N}|N] = (E[\theta^{X_1}])^N$ and so $E[\theta^{X_1+\cdots+X_N}] = E\big[(E[\theta^{X_1}])^N\big] = (1 - \alpha)/(1 - \alpha E[\theta^{X_1}])$. Conditional expectation and probability are used in defining various classes of ▶stochastic processes such as ▶*martingales* and ▶*Markov chains* (Williams 1989). Conditional probability is a fundamental object in ▶*Bayesian statistics* (Williams 2001). Other applications are in the field of Financial Mathematics where the operation of taking conditional expectation of a future random variable with respect to the sigma-algebra of all events prior to the

current time t plays a fundamental role. In fact, it can be said that the notion of conditioning, along with that of independence and coupling, are the cornerstones of modern probability theory and its widespread applications.

Confidence Distributions

William E. Strawderman
Professor
Rutgers University, Newark, NJ, USA

A Confidence Distribution (CD), $H(X,\theta)$, for a parameter is a function of the data, X, and the parameter in question, θ, such that: (a) for each data value X, $H(X,.)$ is a (continuous) cumulative distribution function for the parameter, and (b) for the true parameter value, θ_0, $H(.,\theta_0)$ has a uniform distribution (see ►Uniform Distribution in Statistics) on the interval (0,1). The concept of CD has its historic roots in Fisher's fiducial distribution (Fisher 1930), although, in its modern version, it is a strictly frequentist construct (Schweder and Hjort 2002, 2003; Singh et al. 2005, 2007, and see also Efron 1993). The CD carries a great deal of information pertinent to a variety of frequentist inferences and may be used for the construction of confidence intervals, tests of hypotheses and point estimation.

For instance, the αth quantile of $H(X,.)$, is the upper end of a $100(1-\alpha)$ percent one sided confidence interval for θ, and also the interval formed by the sth and tth quantiles $(s<t)$ is a $100(t-s)$ percent confidence interval. These properties indicate that a confidence distribution is, in a sense, a direct frequentist version of Fisher's fiducial distribution.

Similarly, a level α test of the one-sided hypothesis $K_0: \theta \le \theta_0$ versus $K_1: \theta > \theta_0$ is given by rejecting K_0 when $H(X,\theta_0) \le \alpha$, and an analogous result holds for testing $K_0: \theta \ge \theta_0$ versus $K_1: \theta < \theta_0$. Additionally, for testing the two sided hypothesis $K_0: \theta = \theta_0$ versus $K_1: \theta \ne \theta_0$, the rejection region $2\{\min(H(X,\theta_0), 1-H(X,\theta_0))\} \ge \alpha$ gives an α level test.

The CD may also be used in a natural ways to construct a point estimate of θ. Perhaps the most straightforward estimator is the median of $H(X,.)$, which is median unbiased, and under mild conditions, consistent. Another obvious estimator, $\tilde{\theta} = \int \theta(\partial \mathrm{H}(\mathrm{X},\theta)/\partial\theta)\mathrm{d}\theta$ is also consistent under weak conditions.

One particularly simple way to construct a CD is via a pivotal quantity, $\psi(X,\theta)$, a function of X and θ whose cumulative distribution function, $G(.)$ under the true θ does not depend on θ. Then $G(\Psi(X,\theta))$ is a CD provided $\Psi(X,\theta)$ is increasing in θ. Such quantities are easy to construct in invariant models such as location or scale models. Here is a prototypical example in a normal location model. Suppose $X_i \sim N(\theta,1)$, for $i = 1,\cdots,n$, are iid. Then $\Psi(X_1,\cdots,X_n,\theta) = (\overline{X}-\theta) \sim N(0,1/n)$ so that $H(X_1,\cdots,X_n,\theta) = \Phi^{-1}\left(\sqrt{n}(\theta-\overline{X})\right)$ is a CD.

Another common construction is based on a series of one sided α-level tests of $K_0: \theta \le \theta_0$ versus $K_1: \theta > \theta_0$. If the function $P[\theta_0, X]$ is a p-value for each value of θ_0, then typically $P[\theta_0,.]$ has a uniform distribution for each value of θ_0, and hence $H(X,\theta) = P[\theta, X]$ is a CD.

The above discussion can be extended naturally to include the notion of an asymptotic CD by replacing (b) above, with the requirement that $H(.,\theta_0)$ approaches a uniform distribution on $(0,1)$ weakly as the sample size approaches infinity, and dropping the continuity requirement in (a). Profile likelihoods (see, e.g., Efron 1993; Schweder and Hjort 2002; Singh et al. 2007), and Bootstrap Distributions (see Efron 1998; Singh et al. 2005, 2007) are asymptotic CD's under weak conditions.

It can also be extended to include nuisance parameters. For example, in the case of a sample from a normal population with unknown mean and variance, the usual t-pivot can be used to construct a CD for the mean, while the usual chi-square pivot can be used to construct a CD for the variance.

See Schweder and Hjort (2002, 2003) or Singh et al. (2005, 2007), for more detailed discussion on construction,

properties and uses of *CD*'s. In particular Singh et al. (2005) discusses the combination of information from independent sources via *CD*'s.

Confidence Interval

Michael Smithson
Professor
The Australian National University, Canberra, ACT, Australia

A $100(1-\alpha)\%$ confidence interval is an interval estimate around a population parameter θ that, under repeated random samples of size N, is expected to include θ's true value $100(1-\alpha)\%$ of the time. The confidence interval thereby indicates the precision with which a population parameter is estimated by a sample statistic, given N and α. For many statistics there are also methods of constructing *confidence regions,* which are multivariate versions of simultaneous confidence intervals.

The *confidence level,* $100(1-\alpha)\%$, is chosen a priori. A *two-sided* confidence interval uses a lower limit L and upper limit U that each contain θ's true value $100(1-\alpha/2)\%$ of the time, so that together they contain θ's true value $100(1-\alpha)\%$ of the time. This interval often is written as $[L, U]$, and sometimes writers combine a confidence level and interval by writing $\Pr(L \leq \theta \leq U) = 1-\alpha$. In some applications, a *one-sided* confidence interval is used, primarily when only one limit has a sensible meaning or when interest is limited to bounding a parameter estimate from one side only.

The confidence interval is said to be an inversion of its corresponding significance test because the $100(1-\alpha)\%$ confidence interval includes all hypothetical values of the population parameter that cannot be rejected by its associated significance test using a Type I error-rate criterion of α. In this respect, it provides more information than a significance test does. Confidence intervals become narrower with larger sample size and/or lower confidence levels. Narrower confidence intervals imply greater statistical power for the corresponding significance test, but the converse does not always hold.

The limits L and U are derived from a sample statistic (often the sample estimate of θ) and a sampling distribution specifying a probability for each value that the sample statistic can take. Thus L and U also are sample statistics and will vary from one sample to another. This fact underscores a crucial point of interpretation regarding a confidence interval, namely that we cannot claim that a particular interval has a $1-\alpha$ probability of containing the population parameter value.

A widespread practice regarding two-sided confidence intervals is to place L and U so that α is evenly split between the lower and upper tails. This is often a matter of convention, but can be dictated by criteria that statisticians have used for determining the "best" possible confidence interval. One such criterion is simply narrowness. It is readily apparent, for instance, that if a sampling distribution is symmetric and unimodal then for high confidence levels the shortest $100(1-\alpha)\%$ confidence interval constructed from that distribution is one that allocates $\alpha/2$ to the tails outside of the lower and upper limits.

Other criteria for evaluating confidence intervals are as follows. A $100(1-\alpha)\%$ confidence interval is *exact* if it can be expected to contain the relevant parameter's true value $100(1-\alpha)\%$ of the time. When approximate intervals

are used instead, if the rate of coverage is greater than $100(1-\alpha)\%$ then the interval is *conservative*; if the rate is less then the interval is *liberal*. The $100(1-\alpha)\%$ interval that has the smallest probability of containing values other than the true parameter value is said to be *uniformly most accurate*. A confidence interval whose probability of including any value other than the parameter's true value is less than or equal to $100(1-\alpha)\%$ is *unbiased*.

Example 1 Suppose that a standard IQ test has been administered to a random sample of $N = 25$ adults from a large population with a sample mean of 103 and standard deviation $s = 10$. We will construct a two-sided 95% confidence interval for the mean, μ. The limits U and L must have the property that, given a significance criterion of α, sample size of 25, mean of 103 and standard deviation of 10, we could reject the hypotheses that $\mu > 103 + U$ or $\mu < 103 - L$ but not $L \le \mu \le U$.

The sampling distribution of the t-statistic defined by $t = \dfrac{\overline{X} - \mu}{s_{err}}$ is a t-distribution with $df = N - 1 = 24$. When $df = 24$ the value $t_{\alpha/2} = 2.064$ standard-error units above the mean cuts $\alpha/2 = .025$ from the upper tail of this t-distribution, and likewise $-t_{\alpha/2} = -2.064$ standard-error units below the mean cuts $\alpha/2 = .025$ from the lower tail. The sample standard error is $s_{err} = s/\sqrt{N} = 4.128$. So a t-distribution around $U = 103 + (2.064)(4.128) = 107.13$ has .025 of its tail below 103, while a t-distribution around $L = 103 - (2.064)(4.128) = 98.87$ has 0.025 of its tail above 103. These limits fulfill the above required property, so the 95% confidence interval for μ is $[98.87, 107.13]$. Thus, we cannot reject hypothetical values of μ that lie between 98.87 and 107.13, using $\alpha = .05$.

Example 2 (transforming one interval to obtain another) Cohen's d for two independent samples is defined by $\delta = (\mu_1 - \mu_2)/\sigma_p$, where μ_1 and μ_2 are the means of two populations from which the samples have been drawn and σ_p is the population pooled standard deviation. This quantity has a noncentral t distribution with a noncentrality parameter $\Delta = \delta[N_1N_2/(N_1 + N_2)]^{1/2}$, where N_1 and N_2 are the sizes of the two samples. The sample t-statistic is the sample estimate of Δ. Suppose a two-condition between-subjects experiment with $N_1 = N_2 = 40$ yields $t(78) = 3.45$. Using an appropriate algorithm (Smithson 2003) we can find the 95% confidence interval for Δ, which is $[1.407, 5.473]$. Because δ and Δ are monotonically related by $\delta = \Delta/[N_1N_2/(N_1 + N_2)]^{1/2}$, we can obtain a 95% confidence interval for δ by applying this formula to the lower and upper limits of the interval for Δ. The sample estimate of δ is $d = t/[N_1N_2/(N_1 + N_2)]^{1/2} = 3.45/4.472 = 0.771$, and applying the same transformation to the limits of the interval for Δ gives an interval of $[0.315, 1.224]$ for δ.

Introduction

The word *confounding* has been used to refer to at least three distinct concepts. In the oldest and most widespread usage, confounding is a source of bias in estimating causal

effects. This bias is sometimes informally described as a mixing of effects of extraneous factors (called confounders) with the effect of interest, and important in causal inference (*see* ▶Causation and Causal Inference). This usage predominates in nonexperimental research, especially in epidemiology and sociology. In a second and more recent usage originating in statistics, confounding is a synonym for a change in an effect measure upon stratification or adjustment for extraneous factors (a phenomenon called *noncollapsibility* or *Simpson's paradox; see* ▶Simpson's Paradox; Collapsibility). In a third usage, originating in the experimental-design literature, confounding refers to inseparability of main effects and interactions under a particular design (*see* ▶Interaction).

The three concepts are closely related and are not always distinguished from one another. In particular, the concepts of confounding as a bias in effect estimation and as noncollapsibility are often treated as equivalent, even though they are not. Only the first usage, confounding as a bias, will be described here; for more detailed coverage and comparisons of concepts see, Greenland et al. (1999a), Pearl (2009), and Greenland et al. (2008).

Confounding as a Bias in Effect Estimation

In the first half of the nineteenth century, John Stuart Mill described the problem of confounding in causal inference; he acknowledged the seventeenth century scientist Francis Bacon as a forerunner in dealing with these issues (Mill 1843, Chap. III). Mill listed a key requirement for an experiment intended to determine causal relations:

> "...none of the circumstances [of the experiment] that we do know shall have effects susceptible of being *confounded* with those of the agents whose properties we wish to study" (emphasis added) (Mill 1843, Chap. X).

In Mill's time the word "experiment" referred to an observation in which some circumstances were under the control of the observer, as it still is used in ordinary English, rather than to the notion of a comparative trial. Nonetheless, Mill's requirement suggests that a comparison is to be made between the outcome of our "experiment" (which is, essentially, an uncontrolled trial) and what we would expect the outcome to be if the agents we wish to study had been absent. If the outcome is not as one would expect in the absence of the study agents, then Mill's requirement ensures that the unexpected outcome was not brought about by extraneous "circumstances" (factors). If, however, those circumstances do bring about the unexpected outcome, and that outcome is mistakenly attributed to effects of the study agents, then the mistake is one of confounding (or confusion) of the extraneous effects with the agent effects.

Much of the modern literature follows the same informal conceptualization given by Mill. Terminology is now more specific, with "treatment" used to refer to an agent administered by the investigator and "exposure" often used to denote an unmanipulated agent. The chief development beyond Mill is that the expectation for the outcome in the absence of the study exposure is now almost always explicitly derived from observation of a control group that is untreated or unexposed.

Confounding typically occurs when natural or social forces or personal preferences affect whether a person ends up in the treated or control group, and these forces or preferences also affect the outcome variable. While such confounding is common in observational studies, it can also occur in randomized experiments when there are systematic improprieties in treatment allocation, administration, and compliance. A further and somewhat controversial point is that confounding (as per Mill's original definition) can also occur in perfect randomized trials due to *random* differences between comparison groups (Fisher 1935; Rothman 1977); this problem will be discussed further below.

The Potential-Outcome Model of Confounding

Various models of confounding have been proposed for use in statistical analyses. Perhaps the one closest to Mill's concept is based on the *potential-outcome* or counterfactual model for causal effects (*see* ▶Causation and Causal Inference). Suppose we wish to consider how a health-status (outcome) measure of a population would change in response to an intervention (population treatment). More precisely, suppose our objective is to determine the effect that applying a treatment x_1 had or would have on an outcome measure μ relative to applying treatment x_0 to a specific target population A. For example, this population could be a cohort of breast-cancer patients, treatment x_1 could be a new hormone therapy, x_0 could be a placebo therapy, and the measure μ could be the 5-year survival probability. The treatment x_1 is sometimes called the *index* treatment; and x_0 is sometimes called the *control* or *reference* treatment (which is often a standard or placebo treatment).

The potential-outcome model posits that, in population A, μ will equal μ_{A1} if x_1 is applied, μ_{A0} if x_0 is applied; the causal effect of x_1 relative to x_0 is defined as the change from μ_{A0} to μ_{A1}, which might be measured as $\mu_{A1} - \mu_{A0}$, or if μ is strictly positive, μ_{A1}/μ_{A0}. If A is given treatment x_1,

then μ will equal μ_{A1} and μ_{A1} will be observable, but μ_{A0} will be unobserved.

Suppose now that μ_{B0} is the value of the outcome μ observed or estimated for a population B that was administered treatment x_0. If this population is used as a substitute for the unobserved experience of population A under treatment x_0, it is called the control or reference population. *Confounding* is said to be present if $\mu_{A0} \neq \mu_{B0}$, for then there must be some difference between populations A and B *other than treatment difference* that is affecting μ.

If confounding is present, a naive (crude) association measure obtained by substituting μ_{B0} for μ_{A0} in an effect measure will not equal the effect measure, and the association measure is said to be *confounded.* Consider $\mu_{A1} - \mu_{B0}$, which measures the association of treatments with outcomes *across* the populations. If $\mu_{A0} \neq \mu_{B0}$, then $\mu_{A1} - \mu_{B0}$ is said to be *confounded* for $\mu_{A1} - \mu_{A0}$, which measures the effect of treatment x_1 on population A. Thus, to say an association measure $\mu_{A1} - \mu_{B0}$ is confounded for an effect measure $\mu_{A1} - \mu_{A0}$ is to say these two measures are not equal.

Dependence of Confounding on the Outcome Measure and the Population

A noteworthy aspect of the potential-outcome model is that confounding depends on the outcome measure. For example, suppose populations A and B have a different 5-year survival probability μ under placebo treatment x_0; that is, suppose $\mu_{B0} \neq \mu_{A0}$ so that $\mu_{A1} - \mu_{B0}$ is confounded for the actual effect $\mu_{A1} - \mu_{A0}$ of treatment on 5-year survival. It is then still possible that 10-year survival, v, under the placebo would be identical in both populations; that is v_{A0} could still equal v_{B0}, so that $v_{A1} - v_{B0}$ is not confounded for the actual effect of treatment on 10-year survival. Lest one think this situation unlikely, note that we should generally expect no confounding for 200-year survival, since no known treatment is likely to raise the 200-year survival probability of human patients above zero.

Even though the presence of confounding is dependent on the chosen outcome measure, as defined above its presence does not depend on how the outcome is contrasted between treatment levels. For example, if Y is binary so that $\mu = E(Y)$ is the Bernoulli parameter or risk $\Pr(Y = 1)$, then the risk difference $\mu_{A1} - \mu_{B0}$, risk ratio μ_{A1}/μ_{B0}, and odds ratio $\{\mu_{A1}/(1-\mu_{A1})\}/\{\mu_{B0}/(1-\mu_{B0})\}$ are all confounded under exactly the same circumstances. In particular, and somewhat paradoxically, confounding may be absent even if the odds ratio changes upon covariate adjustment, i.e., even if the odds ratio is noncollapsible (Greenland and Robins 1986; Greenland et al. 1999a, 2008; *see* ►Collapsibility).

A second noteworthy point is that confounding depends on the target population. The preceding example, with A as the target, had different 5-year survivals μ_{A0} and μ_{B0} for A and B under placebo therapy, and hence $\mu_{A1} - \mu_{B0}$ was confounded for the effect $\mu_{A1} - \mu_{A0}$ of treatment on population A. A lawyer or ethicist may also be interested in what effect the hormone treatment would have had on population B. Writing μ_{B1} for the (unobserved) outcome under treatment, this effect on B may be measured by $\mu_{B1} - \mu_{B0}$. Substituting μ_{A1} for the unobserved μ_{B1} yields $\mu_{A1} - \mu_{B0}$. This measure of association is confounded for $\mu_{B1} - \mu_{B0}$ (the effect of treatment x_1 on 5-year survival in population B) if and only if $\mu_{A1} \neq \mu_{B1}$. Thus, the same measure of association, $\mu_{A1} - \mu_{B0}$, may be confounded for the effect of treatment on neither, one, or both of populations A and B, and may or may not be confounded for the effect of treatment on other targets such as the combined population $A \cup B$.

Confounders (Confounding Factors) and Covariate Imbalance

The potential-outcome model is that it invokes no explicit differences (imbalances) between populations A and B with respect to circumstances or covariates that might influence μ. (Greenland and Robins 1986, 2009). Clearly, if μ_{A0} and μ_{B0} differ, then A and B must differ with respect to factors that influence μ. This observation has led some authors to define confounding as the presence of such covariate differences between the compared populations (Stone 1993). This is incorrect, however, because confounding is only a consequence of these covariate differences. In fact, A and B may differ profoundly with respect to covariates that influence μ, and yet confounding may be absent. In other words, a covariate difference between A and B is a necessary but not sufficient condition for confounding, as can be seen when the impact of covariate differences may balance each other out, leaving no confounding.

Suppose now that populations A and B differ with respect to certain covariates, and that these differences have led to confounding of an association measure for the effect measure of interest. The responsible covariates are then termed *confounders* of the association measure. In the above example, with $\mu_{A1} - \mu_{B0}$ confounded for the effect $\mu_{A1} - \mu_{A0}$, the factors responsible for the confounding (i.e., the factors that led to $\mu_{A0} \neq \mu_{B0}$) are the confounders.

It can be deduced that a variable cannot be a confounder unless it can affect the outcome parameter μ within treatment groups and it is distributed differently among the compared populations (e.g., see Yule 1903, who uses terms such as "fictitious association" rather than confounding). These two necessary conditions are sometimes

offered together as a definition of a confounder. Nonetheless, counterexamples show that the two conditions are not sufficient for a variable with more than two levels to be a confounder (Greenland et al. 1999a). Note that the condition of affecting the outcome parameter is a causal assertion and thus relies on background knowledge for justification (Greenland and Robins 1986; Robins 2001; Pearl 2009).

Control of Confounding

Prevention of Confounding

An obvious way to avoid confounding is estimating $\mu_{A1} - \mu_{A0}$ is to obtain a reference population B for which μ_{B0} is known to equal μ_{A0}. Such a population is sometimes said to be *comparable* to or *exchangeable* with A with respect to the outcome under the reference treatment. In practice, such a population may be difficult or impossible to find. Thus, an investigator may attempt to construct such a population, or to construct exchangeable index and reference populations. These constructions may be viewed as design-based methods for the control of confounding.

Perhaps no approach is more effective for preventing confounding by a known factor than *restriction*. For example, gender imbalances cannot confound a study restricted to women. However, there are several drawbacks: restriction on enough factors can reduce the number of available subjects to unacceptably low levels, and may greatly reduce the generalizability of results as well. *Matching* the treatment populations on confounders overcomes these drawbacks, and, if successful, can be as effective as restriction. For example, gender imbalances cannot confound a study in which the compared groups have identical proportions of women. Unfortunately, differential losses to observation may undo the initial covariate balances produced by matching.

Neither restriction nor matching prevents (although it may diminish) imbalances on unrestricted, unmatched, or unmeasured covariates. In contrast, ►*randomization* offers a means of dealing with confounding by covariates not accounted for by the design. It must be emphasized, however, that this solution is only probabilistic and subject to severe constraints in practice. Randomization is not always feasible or ethical, and many practical problems (such as differential loss and noncompliance) can lead to confounding in comparisons of the groups actually receiving treatments x_1 and x_0.

One somewhat controversial solution to noncompliance problems is *intent-to-treat analysis,* which defines the comparison groups A and B by treatment assigned rather than treatment received. Confounding may, however, affect even intent-to-treat analyses, and (contrary to widespread misperceptions) the bias in those analyses can exaggerate the apparent treatment effect (Robins 1998). For example, the assignments may not always be random, as when blinding is insufficient to prevent the treatment providers from protocol violations. And, purely by bad luck, randomization may itself produce allocations with severe covariate imbalances between the groups (and consequent confounding), especially if the study size is small (Fisher 1935; Rothman 1977). *Blocked* (matched) randomization can help ensure that random imbalances on the blocking factors will not occur, but it does not guarantee balance of unblocked factors.

Adjustment for Confounding

Design-based methods are often infeasible or insufficient to prevent confounding. Thus, there has been an enormous amount of work devoted to analytic adjustments for confounding. With a few exceptions, these methods are based on observed covariate distributions in the compared populations. Such methods can successfully control confounding only to the extent that enough confounders are adequately measured. Then, too, many methods employ parametric models at some stage, and their success may thus depend on the faithfulness of the model to reality. These issues cannot be covered in depth here, but a few basic points are worth noting. The simplest and most widely trusted methods of adjustment begin with *stratification* on confounders. A covariate cannot be responsible for confounding within internally homogeneous strata of the covariate. For example, gender imbalances cannot confound observations within a stratum composed solely of women. More generally, comparisons within strata cannot be confounded by a covariate that is unassociated with treatment within strata. This is so, whether the covariate was used to define the strata or not. Thus, one need not stratify on all confounders in order to control confounding; it suffices to stratify on a balancing score (such as a propensity score) that yields strata in which the confounders are unassociated with treatment.

If one has accurate background information on relations among the confounders, one may use this information to identify sets of covariates statistically sufficient for adjustment, for example by using causal diagrams or conditional independence conditions (Pearl 1995, 2009; Greenland et al. 1999ab; Glymour and Greenland 2008). Nonetheless, if the stratification on the confounders is too coarse (e.g., because categories are too broadly defined), stratification may fail to adjust for much of the confounding by the adjustment variables.

One of the most common adjustment approaches today is to enter suspected confounders into a model for the outcome parameter μ. For example, let μ be the mean (expectation) of an outcome variable of interest Y,

let X be the treatment variable of interest, and let Z be a suspected confounder of the $X - Y$ relation. Adjustment for Z is often made by fitting a generalized-linear model (see ▶Generalized Linear Models) $g(\mu) = g(\alpha + \beta x + \gamma z)$ or some variant, where $g(\mu)$ is a strictly increasing function such as the natural log $\ln(\mu)$, as in log-linear modeling, or the logit function $\ln\{\mu/(1 - \mu)\}$, as in ▶logistic regression; the estimate of β that results is then taken as the Z-adjusted estimate of the X effect on $g(\mu)$.

An oft-cited advantage of model-based adjustment is that it allows adjustment for more variables and in finer detail than stratification. If however the form of the fitted model cannot adapt well to the true dependence of Y on X and Z, such model-based adjustments may fail to adjust for confounding by Z. For example, suppose Z is symmetrically distributed around zero within X levels, and the true dependence is $g(\mu) = g(\alpha + \beta x + \gamma z^2)$; then using the model $g(\mu) = g(\alpha + \beta x + \gamma z)$ will produce little or no adjustment for Z. Similar failures can arise in adjustments based on models for treatment probability (propensity scores). Such failures can be minimized or avoided by using reasonably flexible models, by carefully checking each fitted model against the data, and by combining treatment-probability and outcome models to produce *doubly robust* effect estimators (Hirano et al. 2003; Bang and Robins 2005).

Finally, if (as is often done) a variable used for adjustment is not a confounder, bias may be introduced by the adjustment (Greenland and Neutra 1980; Greenland et al. 1999b; Hernán et al. 2002; Pearl 2009). The form of this bias often parallels *selection bias* familiar to epidemiologists, and tends to be especially severe if the variable is affected by both the treatment and the outcome under study, as in classic *Berksonian bias* (Greenland 2003). In some but not all cases the resulting bias is a form of confounding within strata of the covariate (Greenland et al. 1999b); adjustment for covariates affected by treatment can produce such confounding, even in randomized trials (Cox 1958, Chap. 2; Greenland 2003).

Confounded Mechanisms Versus Confounded Assignments

If the mechanism by which the observational units come to have a particular treatment is independent of the potential outcomes of the units, the mechanism is sometimes described as *unconfounded* or *unbiased* for μ (Rubin 1991; Stone 1993); otherwise the mechanism is confounded or biased. Randomization is the main practical example of such a mechanism. Graphical models (*see* ▶Causal Diagrams) provide an elegant algorithm for checking whether the graphed mechanism is unconfounded within strata of covariates (Pearl 1995, 2009; Greenland et al. 1999b; Glymour and Greenland 2008). Note however that in typical epidemiologic usage the term "confounded" refers to the result of a single assignment (the study group actually observed), not the behavior of the mechanism. Thus an unconfounded mechanism can by chance produce confounded assignments.

The latter fact resolves a controversy about adjustment for baseline (pre-treatment) covariates in randomized trials. Although Fisher asserted that randomized comparisons were "unbiased," he also pointed out that particular assignments could be confounded in the single-trial sense used in epidemiology; see Fisher (1935, p. 49). Resolution comes from noting that Fisher's use of the word "unbiased" referred to the design and corresponds to an unconfounded assignment mechanism; it was not meant to guide analysis of a given trial (which has a particular assignment). Once the trial is underway and the actual treatment allocation is completed, the unadjusted treatment-effect estimate will be biased conditional on the observed allocation if the baseline covariate is associated with treatment in the allocation and the covariate affects the outcome; this bias can be removed by adjustment for the covariate (Rothman 1977; Greenland and Robins 1986, 2009; Greenland et al. 1999a).

Confounder Selection

An essential first step in the control of confounding is to identify which variables among those measured satisfied the minimal necessary conditions to be a confounder. This implies among other things that the variables cannot be affected by exposure or outcome; it thus excludes intermediate variables and effects of exposure and disease, whose control could introduce Berksonian bias. This initial screening is primarily a subject-matter decision that requires consideration of the causal ordering of the variables. Relatively safe candidate confounders will be "pre-treatment" covariates (those occurring before treatment or exposure), which have the advantage that they cannot be intermediates or effects of exposure and outcome. Exceptions occur in which control of certain pre-treatment variables introduce bias (Pearl 1995, 2009; Greenland et al. 1999b), although the bias so introduced may be much less than the confounding removed (Greenland 2003).

Variables that pass the initial causal screening are sometimes called "potential confounders." Once these are identified, the question arises as to which must be used for adjustment. A common but unjustified strategy is to select confounders to control based on a test (usually a significance test) of each confounder's association with the treatment X (a test of imbalance) or with the outcome Y, e.g.,

using stepwise regression. Suppose Z is a pre-treatment covariate (potential confounder). The strategy of testing the Z association with X arises from a confusion of two distinct inferential problems:

1. Do the treated ($X = 1$) evince larger differences from the untreated ($X = 0$) with respect to Z than one should expect from a random (or unconfounded) assignment mechanism?
2. Should we control for Z to estimate the treatment effect?

A test of the $X - Z$ association addresses question (a), but not (b). For (b), the "large-sample" answer is that control is advisable, regardless of whether the $X - Z$ association is random. This is because an imbalance produces bias conditional on the observed imbalance, even if the imbalance derived from random variation.

The mistake of significance testing for confounding lies in thinking that one can ignore an imbalance if it is from random variation. Random assignment only guarantees valid performance of statistics over all possible treatment allocations. It does not however guarantee validity conditional on the observed Z imbalance, even though any such imbalance must be random in a randomized trial. Thus the $X - Z$ test addresses a real question (one relevant to a field methodologist studying determinants of response/treatment), but is irrelevant to the second question (b) (Greenland and Neutra 1980; Robins and Morgenstern 1987; Greenland et al. 1999a).

The case of testing the Z association with Y devolves in part to whether one trusts prior (subject-matter) knowledge that Z affects Y (or is a proxy for a cause of Y) more than the results of a significance test in one's own limited data. There are many examples in which a well-known risk factor exhibits the expected association with Y in the data, but for no more than chance reasons or sample-size limitations, that association fails to reach conventional levels of "significance" (e.g., Greenland and Neutra 1980). In such cases there is a demonstrable statistical advantage to controlling Z, thus allowing subject-matter knowledge to over-ride nonsignificance (Robins and Morgenstern 1987).

Another problematic strategy is to select a potential confounder Z for control based on how much the effect estimate changes when Z is controlled. Like the testing methods described above, it also lacks formal justification and can exhibit poor performance in practice (Maldonado and Greenland 1993). The strategy can also mislead if the treatment affects a high proportion of subjects and one uses a "noncollapsible" effect measure (one that changes upon stratification even if no confounding is present), such as an odds ratio or rate ratio (Greenland and Robins 1986; Greenland 1996; Greenland et al. 1999a).

In practice, there may be too many variables to control using conventional methods, so the issue of confounder selection may seem pressing. Nonetheless, hierarchical-Bayesian or other shrinkage methods may be applied instead. These methods adjust for all the measured confounders by estimating the confounder effects using a prior distribution for those effects. See Greenland (2000, 2008) for details. Some of these methods (e.g., the Lasso; Tibshirani 1996) may drop certain variables entirely, and thus in effect result in confounder selection; unlike significance-testing based selection, however, this selection has a justification in statistical theory.

About the Author

Dr. Greenland is Professor of Epidemiology, UCLA School of Public Health, and Professor of Statistics, UCLA College of Letters and Science. He has published over 300 scientific papers, two of which have been cited over 500 times. Professor Greenland is a coeditor (with Kenneth J.h Rothman) of the highly influential text in the field of epidemiology, *Modern Epidemiology*. This book has received the highest number of citations among all texts and papers in the field, over 8,000 (M. Porta et al. 2006). *Book citations: influence of epidemiologic thought in the academich community*, Rev Saúde Púbica, 40, p. 50; Lippincott-Raven 1998. Currently, he is an Associate editor for *Statistics in Medicine*. He was Chair, Section in Epidemiology, American Statistical Association (2005–2007). He is Chartered Statistician and Fellow, Royal Statistical Society (1993), and a Fellow American Statistical Association (1998).

Contagious Distributions

Seng Huat Ong[1], Choung Min Ng
[1]Professor
University of Malaya, Kuala Lumpur, Malaysia

The term contagious distribution was apparently first used by Neyman (1939) for a discrete distribution that exhibits clustering or contagious effect. The classical Neyman Type *A* distribution is one well-known example. However, contagious distributions are used nowadays to describe a plethora of distributions, many of which possess complicated probability distribution expressed in terms of special functions (see, for instance, Johnson et al. 2005).

It is instructive to give an account of the derivation of the Neyman Type *A* distribution as developed by Neyman (1939) in his paper "On a new class of contagious distributions applicable in entomology and bacteriology." Neyman wanted to model the distribution of larvae on plots in a field. He assumed that the number of clusters of eggs per unit area, N, followed a Poisson distribution with mean θ denoted by $Poi(\theta)$, while the number of larvae developing from the egg clusters $X_i, i = 1, 2, \ldots, N$ is distributed as another Poisson distribution $Poi\ (\phi)$. Mathematically, this may be expressed as follows:

$$S_N = X_1 + X_2 + \ldots + X_N$$

where S_N is the total number of larvae per unit area. The distribution of S_N is then a Neyman Type *A*.

The above model is known as a *true contagion* model, where the occurrence of "a favourable event depends on the occurrence of the previous favorable events" (Gurland 1959). Among other terms used for the distribution arising from this model are *generalized, clustered, stopped*, or *stopped-sum* distribution (see Douglas 1980; Johnson et al. 2005). It is convenient to represent the distribution of S_N concisely by

$$S_N \sim U_1 \vee U_2,$$

which reads S_N distribution is a U_1 distribution generalized by a U_2 distribution. As an example, the Neyman Type *A* distribution for S_N, above, is

$$\text{Neyman Type } A \sim Poi\,(\theta) \vee Poi\,(\phi).$$

In addition, the probability generating function (pgf) of S_N distribution is

$$E\left[z^{S_N}\right] = g_1(g_2(z)),$$

where $g_i(z)$ is the pgf for the corresponding $U_i, i = 1, 2$ distribution.

Next, using the same example as above but instead, the number of larvae per unit area is now considered to be distributed as a Poisson distribution, $Poi\,(k\theta)$, where due to heterogeneity, the mean number of eggs that hatched into larvae is assumed to vary with k following a Poisson distribution $Poi\,(\phi)$. The distribution for the number of larvae per unit area is again a Neyman Type A.

The model that gives rise to a distribution as in the preceding formulation is known as an *apparent contagion* model. Generally, this distribution arises when a parameter of a U_1 distribution is a random variable Ω that follows a U_2 distribution of its own. This type of distribution is also known as a *mixed, mixture*, or *compound* distribution (see Ord 1971; Johnson et al. 2005). A compound (mixture) distribution can be represented by

$$U_1 \underset{\Omega}{\wedge} U_2,$$

which means that the U_1 distribution is compounded by U_2 distribution (the distribution of Ω). U_2 is known as the compounding (mixing) distribution. Thus, the Neyman Type A distribution formulated through compounding is represented by

$$\text{Neyman Type } A \sim Poi\,(k\theta) \underset{k}{\wedge} Poi\,(\phi)$$

The pgf of a compound (mixture) distribution is

$$\int_{\omega} g_1\,(z|\,\omega)\; dF_2\,(\omega)$$

where $g_1(.)$ is the pgf for the U_1 and $F_2(.)$ is the cumulative distribution function for U_2. The class of mixed Poisson distributions is a well-known class of compound distributions that has found applications in many areas of study including biology, sociology, and medicine.

Note that both given examples of contagion models lead to the Neyman Type A distribution. The relationship between the generalized and compound distributions is given by the following theorem:

Theorem 1 (Gurland 1957) Let U_1 be a random variable with pgf $[h\,(z)]^{\theta}$, where θ is a given parameter. Suppose now θ is regarded as a random variable. Then, whatever be U_2

$$U_1 \wedge U_2 \sim U_2 \vee U_1. \tag{1}$$

This relation shows that it may not be possible to distinguish between the two types of contagion directly from the data (Gurland 1959).

Contagious distributions have been studied by many researchers including Feller (1943), Skellam (1952), Beall and Rescia (1953), Gurland (1958), Hinz and Gurland (1970), Khatri (1971), and Hill (1993), creating a rich literature in this field. The readers are referred to Ord (1972, p. 126) for a list of generalized and compound Poisson distributions such as Polya-Aeppli, negative binomial, and Hermite distributions. Other references for generalized and compound distributions can be found in Douglas (1980, Chaps. 4 and 5) and Johnson et al. (2005, Chaps. 8 and 9). These references also describe statistical inference for the contagious distributions. Recent review articles on this subject are Gupta and Ong (2005) and Karlis and Xekalaki (2005).

Continuity Correction

Rabi Bhattacharya
Professor of Mathematics
The University of Arizona, Tucson, AZ, USA

According to the central limit theorem (*CLT*) (see ►Central Limit Theorems), the distribution function F_n of a normalized sum $n^{-1/2}(X_1 + \ldots + X_n)$ of n independent random variables $X_1, \ldots, X_n$, having a common distribution with mean zero and variance $\sigma^2 > 0$, converges to the distribution function Φ_σ of the normal distribution with mean zero and variance σ^2, as $n \to \infty$. We will write Φ for Φ_1 for the case $\sigma = 1$. The densities of Φ_σ and Φ are denoted by ϕ_σ and ϕ, respectively. In the case $X_j's$ are discrete, F_n has jumps and the normal approximation is not very good when n is not sufficiently large. This is a problem which most commonly occurs in statistical tests and estimation involving the normal approximation to the binomial and, in its multi-dimensional version, in Pearson's frequency ►chi-square tests, or in tests for association in categorical data. Applying the *CLT* to a binomial random variable T with distribution $B(n,p)$, with mean np and variance $npq(q = 1 - p)$, the normal approximation is given, for integers $0 \le a \le b \le n$, by

$$P(a \le T \le b) \approx \Phi\left((b - np)/\sqrt{npq}\right) - \Phi\left((a - np)/\sqrt{npq}\right). \quad (1)$$

Here $\approx$ indicates that the difference between its two sides goes to zero as $n \to \infty$. In particular, when $a = b$, the binomial probability $P(T = b) = C_b^n p^b q^{n-b}$ is approximated by zero. This error is substantial if n is not very large. One way to improve the approximation is to think graphically of each integer value b of T being uniformly spread over the interval $\left[b - \frac{1}{2}, b + \frac{1}{2}\right]$. This is the so called *histogram approximation*, and leads to the *continuity correction* given by replacing $\{a \le T \le b\}$ by $\left\{a - \frac{1}{2} \le T \le b + \frac{1}{2}\right\}$

$$P\left(a - \frac{1}{2} \le T \le b + \frac{1}{2}\right) \approx \Phi\left(\left(b + \frac{1}{2} - np\right)/\sqrt{npq}\right) - \Phi\left(\left(a - \frac{1}{2} - np\right)/\sqrt{npq}\right). \quad (2)$$

To give an idea of the improvement due to this correction, let $n = 20, p = 0.4$. Then $P(T \le 7) = 0.4159$, whereas the approximation (1) gives a probability $\Phi(-0.4564) = 0.3240$, and the continuity correction (2) yields $\Phi(-0.2282) = 0.4177$. Analogous continuity corrections apply to the Poisson distribution with a large mean.

For a precise mathematical justification of the continuity correction consider, in general, i.i.d. integer-valued random variables $X_1, \ldots, X_n$, with lattice span 1, mean μ, variance σ^2, and finite moments of order at least four. The distribution function $F_n(x)$ of $n^{-1/2}(X_1 + \ldots + X_n)$ may then be approximated by the ►*Edgeworth expansion* (See Bhattacharya and Ranga 1976, p. 239, or Gnedenko and Kolmogorov 1954, p. 213)

$$F_n(x) = \Phi_\sigma(x) - n^{-\frac{1}{2}} S_1\left(n\mu + n^{\frac{1}{2}}x\right)\phi_\sigma(x) + n^{-\frac{1}{2}}\mu_3/(6\sigma^3)(1 - x^2/\sigma^2)\phi_\sigma(x) + O(n^{-1}), \quad (3)$$

where $S_1(y)$ is the right continuous periodic function $y - \frac{1}{2}$ (mod 1) which vanishes when $y = \frac{1}{2}$. Thus, when a is an integer and $x = (a - n\mu)/\sqrt{n}$, replacing a by $a + \frac{1}{2}$ (or $a - \frac{1}{2}$) on the right side of (3) gets rid of the discontinuous term involving S_1.

Consider next the continuity correction for the *(Mann-Whitney-)Wilcoxon two sample test* (see ►Wilcoxon–Mann–Whitney Test). Here one wants to test nonparametrically if one distribution G is stochastically larger than another distribution F, with distribution functions $G(.), F(.)$. Then the null hypothesis is $H_0 : F(x) = G(x)$ for all x, and the alternative is $H_1 : G(x) \le F(x)$ for all x, with strict inequality for some x. The test is based on independent random samples $X_1, \ldots, X_m$ and $Y_1, \ldots, Y_n$ from the two unknown continuous distributions F and G, respectively. The test statistic is W_s = the sum of the ranks of the $Y_j's$ in the combined sample of $m + n$ $X_i's$ and $Y_j's$. The test rejects H_0 if $W_s \ge c$, where c is chosen such that the probability of rejection under H_0 is a given level α. It is known (see Lehmann 1975, pp. 5–18) that W_s is asymptotically normal and $E(W_s) = \frac{1}{2}n(m + n + 1)$, $Var(W_s) = mn(m + n + 1)/12$. Since W_s is integer-valued, the continuity correction yields

$$P(W_s \ge c|H_0) = P\left(W_s \ge c - \frac{1}{2}|H_0\right) \approx 1 - \Phi(z), \quad (4)$$

where $z = \left(c - \frac{1}{2} - \frac{1}{2}n(m + n + 1)\right)/\sqrt{mn(m + n + 1)/12}$.

As an example, let $m = 5$, $n = 7$, $c = 54$. Then $P(W_s \ge 54 \mid H_0) = 0.101$, and its normal approximation is $1 - \Phi(1.380) = 0.0838$. The continuity correction yields the better approximation $P(W_s \ge 54 \mid H_0) = P(W_s \ge 53.5 \mid H_0) \approx 1 - \Phi(1.299) = 0.0097$.

The continuity correction is also often used in 2×2 *contingency tables* for testing for association between two categories. It is simplest to think of this as a two-sample problem for comparing two proportions p_1, p_2 of individuals with a certain characteristic (e.g., smokers) in two populations (e.g., men and women), based on two independent random samples of sizes n_1, n_2 from the two populations, with $n = n_1 + n_2$. Let r_1, r_2 be the numbers in the samples possessing the characteristic. Suppose first that we

wish to test $H_0 : p_1 = p_2$, against $H_1 : p_1 < p_2$. Consider the test which rejects H_0, in favor of H_1, if $r_2 \geq c(r)$, where $r = r_1 + r_2$, and $c(r)$ is chosen so that the conditional probability (under H_0) of $r_2 \geq c(r)$, given $r_1 + r_2 = r$, is α. This is the uniformly most powerful unbiased (*UMPU*) test of its size (See Lehmann 1959, pp. 140–146, or Kendall and Stuart 1973, pp. 570–576). The conditional distribution of r_2, given $r_1 + r_2 = r$, is multinomial, and the test using it is called *Fisher's exact test*. On the other hand, if $n_i p_i \geq 5$ and $n_i(1 - p_i) \geq 5$ $(i = 1, 2)$, the normal approximation is generally used to reject H_0. Note that the (conditional) expectation and variance of r_2 are $n_2 r/n$ and $n_1 n_2 r(n-r)/[n^2(n-1)]$, respectively (See Lehmann 1975, p. 216). The normalized statistic t is then

$$t = [r_2 - n_2 r/n]/\sqrt{n_1 n_2 r(n-r)/[n^2(n-1)]}, \quad (5)$$

and H_0 is rejected when t exceeds $z_{1-\alpha}$, the $(1 - \alpha)th$ quantile of Φ. For the continuity correction, one subtracts $\frac{1}{2}$ from the numerator in (5), and rejects H_0 if this adjusted t exceeds $z_{1-\alpha}$. Against the two-sided alternative $H_1 : p_1 \neq p_2$, Fisher's *UMPU* test rejects H_0 if r_2 is either too large or too small. The corresponding continuity corrected t rejects H_0 if either the adjusted t, obtained by subtracting $\frac{1}{2}$ from the numerator in (5), exceeds $z_{1-\alpha/2}$, or if the t adjusted by adding $\frac{1}{2}$ to the numerator in (5) is smaller than $-z_{1-\alpha/2}$. This may be compactly expressed as

$$\text{Reject } H_0 \text{ if } V \equiv (n-1)\left[\,|\, r_1 n_2 - r_2 n_1 \,|\, - \frac{1}{2}n\right]^2 \Big/ (n_1 n_2 r(n-r)) > \chi^2_{1-\alpha}(1), \quad (6)$$

where $\chi^2_{1-\alpha}(1)$ is the $(1 - \alpha)$th quantile of the ▶chi-square distribution with one degree of freedom. This two-sided continuity correction was originally proposed by F. Yates in 1934, and it is known as *Yates' correction*. For numerical improvements due to the continuity corrections above, we refer to Kendall and Stuart (1973, pp. 575–576) and Lehmann (1975, pp. 215–217). For a critique, see Connover (1974). If the sampling of n units is done at random from a population with two categories (men and women), then the *UMPU* test is still the same as Fisher's test above, conditioned on fixed marginals n_1,(and, therefore, n_2) and r.

Finally, extensive numerical computations in Bhattacharya and Chan (1996) show that the chisquare approximation to the distribution of *Pearson's frequency chi-square* statistic is reasonably good for degrees of freedom 2 and 3, even in cases of small sample sizes, extreme asymmetry, and values of expected cell frequencies much smaller than 5. One theoretical justification for this may be found in the classic work of Esseen (1945), which shows that the error of chisquare approximation is $O(n^{-d/(d+1)})$ for degrees of freedom d.

Control Charts

Alberto Luceño
Professor
University of Cantabria, Santander, Spain

Introduction

A control chart is a graphical statistical device used to monitor the performance of a repetitive process. Control charts were introduced by Shewhart in the 1920s while working for Western Electric and Bell Labs and, since then, they have been routinely used in Statistical Process Control (SPC). According to Shewhart, control charts are useful to define the standard to be attained for a process, to help

attaining that standard, and to judge whether that standard has been reached.

Variability and Its Causes

Any manufacturing or business process shows some degree of variability. This is obviously true when little effort has been made to try to keep the process stable around a target, but it continues to be true even when a lot of effort has already been dedicated to stabilize the process. In other words, the amount of variability can be reduced (as measured, for example, by the output standard deviation), but cannot be eliminated completely. Therefore, some knowledge about the types of variability that can be encountered in practice and the causes of this variability is necessary.

Concerning the types of variability, one must recognize at least the difference between stationary and non-stationary behavior, the former being desirable, the latter undesirable. A stationary process has fixed mean, variance and probability distribution, so that it is difficult (if not impossible) to perfectly attain this desirable state in practice. A non-stationary process does not have fixed mean, variance or probability distribution, so that its future behavior is unpredictable. Moreover, any natural process, when left to itself, tends to be non-stationary, sometimes in the long run, but most often in the short run. Consequently, some control effort is almost always necessary to, at least, induce stationarity in the process. Control charts are useful for this purpose.

Concerning the causes of variability, the most obvious facts are that there are a lot of causes, that many of them are unknown, and, consequently, that they are difficult to classify. Nevertheless, Shewhart suggested that it is conceptually useful to classify the causes of variability in two groups: common causes and special causes. Common causes are those that are still present when the process has been brought to a satisfactory stationary state of control; they can be described as chance variation, because the observed variation is the sum of many small effects having different causes. Special causes are those that have larger effects and, hence, have the potential to send the process out of control; hopefully, they can eventually be discovered (assigned) and permanently removed from the system.

Control charts are useful tools to detect the presence of special causes of variation worthy of removal. They do so by modelling the likely performance of a process under the influence of the common causes of variation, so that the unexpected behavior (and possible non-stationarity) of the process caused by the emergence of a special cause at any time can be detected efficiently.

Shewhart Charts

When Shewhart presented his control charts, he did not claim any mathematical or statistical optimality for such charts, but he did demonstrate that the cost of controlling a process could often be reduced by using control charts. Consequently, Shewhart control charts are much more justifiable for their practical benefits than for their theoretical properties.

A Basic Chart

Bearing this in mind, a Shewhart control chart for a measurable quality characteristic is constructed in the following way. (1) Select the frequency of sampling and the sample size; e.g., take $n = 4$ observations every 2 h. (2) Calculate the sample average $\bar{X}_t$ for every time interval t (e.g., every 2 h) and plot $\bar{X}_t$ versus t for all the values of t at hand. By doing so, one obtains a run chart. (3) Add a center line (CL) to the run chart. The ordinate of this horizontal line can be a target value for the quality characteristic, a historical mean of past observations, or simply the mean of the observations at hand. (4) Add an upper control limit (UCL) and a lower control limit (LCL). These horizontal lines are usually situated symmetrically around the CL and at a distance of three times the standard deviation of the statistics plotted in the run chart (e.g., three times the standard deviation of $\bar{X}_t$).

This chart is used at every time interval t to take the decision of whether the process should be considered to be in a state of economic control or not. The usual decision rule is: (1) Decide that the process stays in control at time t if the plotted statistics ($\bar{X}_t$) lies between the UCL and the LCL, and continue plotting. (2) Declare an out of control situation otherwise; in this case, a search for an assignable cause should be started, which hopefully will eventually lead to the identification of this cause and its permanent removal from the system. This type of control procedure is sometimes called process monitoring, or process surveillance, and is a part of SPC. Figure 1 shows a Shewhart chart for a random sample of values of $\bar{X}_t$ having mean $\mu = 50$ and standard deviation $\sigma = 2$. The chart does not show any alarm.

Some Modifications of the Basic Chart

Under certain theoretical assumptions, the basic chart can claim some type of optimality. However, it may not be completely satisfactory in practice. Consequently, the form of the basic chart and how it is used can be modified in many different ways. For example, the control limits could not be symmetrically placed around the CL or could not necessarily lie at three standard deviations from the CL.

Warning limits situated at two standard deviations from the CL could also be plotted. Lines at one standard deviation from the CL could be added. The decision rule could correspondingly be modified using, for example, the so called Western Electric rules, etc.

The usefulness of these modifications of the basic chart should be judged, in each particular application, on the bases of the economical or practical advantages they provide. In doing so, the costs of declaring that the process is in control when in fact is not, and vice versa, usually play a role. The elapsed time since the process starts to be out of control until this state is detected can also play a role (true alarm), as well as the time between consecutive declarations of out of control situations when the process stays in control (false alarm rate). These elapsed random times are usually called run lengths (RLs) and their means are called average run lengths (ARLs). Clearly, the frequency distribution (or probability distribution) of the RL will depend on whether the process is in control (RL for false alarms) or out of control (RL for true alarms), and the ARL for false alarms should be much larger than the ARL for true alarms.

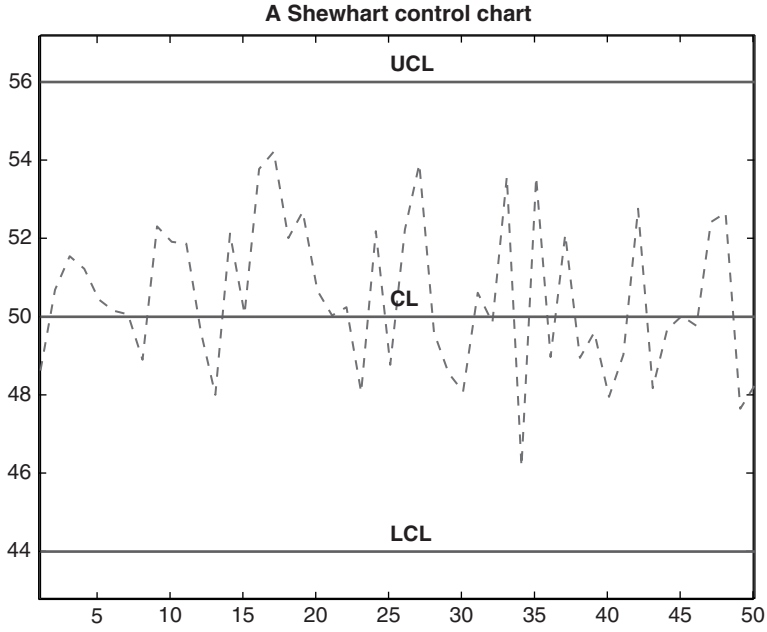
Some More Basic Charts

Control of the mean of a measurable quality characteristic is important, but a process can also be out of control because of excessive variation around its mean. Therefore, in addition to the basic $\bar{X}$ chart, previously described, it is customary to simultaneously run a chart to control the range (R-chart) or the standard deviation (S-chart) of the observations taken every time interval t.

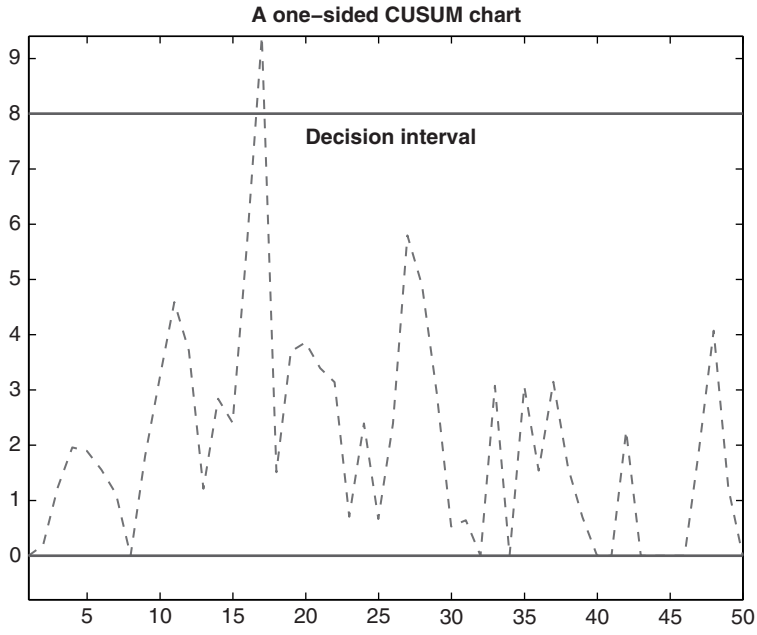
Similarly, when the quality characteristic is not measurable, one can use a p-chart or an np-chart to control the fraction nonconforming for each time interval t, or a c-chart or a u-chart to control the total numbers (counts) of nonconforming items for each period t.

Some Other Types of Control Charts

Basic Shewhart charts are useful to detect relatively large and sporadic deviations from the state of control. However, the control of a process may be jeopardized also by small but persistent deviations from the state of control. The Western Electric rules may be considered as one of many attempts to tackle this problem. However, a more formal approach was suggested by Page (1954, 1957) by introducing the cumulative sum (CUSUM) charts. Moreover, the introduction of the exponentially weighted moving average (EWMA) charts provided an alternative procedure. More recently, cumulative score (CUSCORE) charts, specialized in detecting particular types of deviation from the state of control, have also been suggested (e.g., by Box and Ramírez 1992; Box and Luceño 1997; Box et al. 2009).



Control Charts. Fig. 1 An example of a Shewhart chart



Control Charts. Fig. 2 An example of a one-sided CUSUM chart for the same data as in Fig. 1

CUSUM Charts

To be able to efficiently detect small persistent deviations from target occurring before and at period t, some use of recent observations is necessary. CUSUM charts do so by using the following statistics:

$$S_t^+ = \max\left[S_{t-1}^+ + (\bar{X}_t - k^+); 0\right];$$
$$S_t^- = \max\left[S_{t-1}^- + (-\bar{X}_t - k^-); 0\right]; \quad (1)$$

where k^+ and k^- are called reference values. The process is considered to be in control until the period t at which one of the inequalities $S_t^+ > h^+$ or $S_t^- > h^-$ becomes true, where h^+ and h^- are called decision intervals. At this time, an alarm is declared, and the search for a special cause (or assignable cause, in Deming's words) should begin.

The reference values and decision intervals of the chart are often chosen in the light of the theoretical ARLs that they produce when the process is on target and when the process is out of target by an amount of D times the standard deviation of X_t (or, equivalently, $D\sqrt{n}$ times the standard deviation of $\bar{X}_t$).

If only one of the statistics in (1) is used, the CUSUM chart is called one-sided; if both are used, the CUSUM is called two-sided. The theoretical evaluation of the run length distributions for two-sided CUSUM charts is considerably more difficult than for their one-sided counterparts. Figure 2 shows a one-sided CUSUM chart based on S_t^+, with reference value $\mu + 0.25\sigma$ and decision interval at 4σ, for the sample used in Fig. 1. This chart produces an alarm at $t = 17$.

EWMA Charts

EWMA charts use recent data in a different way than CUSUM charts. The EWMA statistic is

$$\tilde{X}_t = (1-\lambda)\tilde{X}_{t-1} + \lambda\bar{X}_t, \quad (2)$$

where $0 < \lambda < 1$, but most often $0.1 \le \lambda \le 0.4$. The EWMA statistic at time t is an average of all observations taken at time t and before, in which each observation receives a weight that decreases exponentially with its age. In other words, Eq. (2) can be written as

$$\tilde{X}_t = \lambda[\bar{X}_t + (1-\lambda)\bar{X}_{t-1} + (1-\lambda)^2\bar{X}_{t-2} + \cdots]. \quad (3)$$

The smaller the value of λ, the smoother the chart.

The process is usually considered to be in control until the period t at which $|\tilde{X}_t|$ reaches three times the standard deviation of the EWMA statistic $\tilde{X}_t$. It can be shown that the variance of $\tilde{X}_t$ is the product of the variance of $\bar{X}_t$ by a factor $\lambda[1-(1-\lambda)^{2t}]/(2-\lambda)$, where $t = 0$ is the origin of the chart. When an alarm is triggered, the search for a special cause should start.

Information about the above mentioned charts and many possible variants can be found in the bibliography that follows.

About the Author

Professor Luceño was awarded 1998 Brumbaugh Award of the American Society for Quality jointly with Professor George E.P. Box. He is a co-author (with G.E.P. Box) of the well known text *Statistical Control By Monitoring and Feedback Adjustment* (John Wiley & Sons, 1997), and (with G.E.P. Box and M.A. Paniagua-Quiñones) ñ (John Wiley & Sons, 2009). Convergence of Random Variables

Pedro J. Rodríguez Esquerdo
Professor, Head
University of Puerto Rico, San Juan, Puerto Rico

C

Introduction

The convergence of a sequence of random variables (RVs) is of central importance in probability theory and in statistics. In probability, it is often desired to understand the long term behavior of, for example, the relative frequency of an event, does it converge to a number? In what sense does it converge? In statistics, a given estimator often has the property that for large samples the values it takes are distributed around and are close to the value of the desired parameter. In many situations the distribution of this estimator can be approximated by a well known distribution, which can simplify the analysis. Thus it is necessary to understand the types of convergence of such sequences, and conditions under which they occur.

Four modes of convergence are presented here.

1. *Weak convergence*, also called *convergence in distribution* or *convergence in law*, refers to the conditions under which a sequence of distribution functions converges to a cumulative distribution function (cdf).
2. A second mode is *convergence in probability*, which studies the limiting behavior of the sequence of probabilities that for each n, a RV deviates by more than a given quantity from a limiting RV.
3. *Convergence with probability one*, or almost sure convergence, studies the conditions under which the probability of a set of points in the sample space for which a sequence of RVs converges to another RV is equal to one.
4. *Convergence in the rth mean* refers to the convergence of a sequence of expected values. As it is to be expected, there are some relations between the different modes of converge.

The results here are explained, for their formal proof, the reader is referred to the included references. In general, the RVs $\{X_n\}$ cannot be assumed to be independent or identically distributed. For each value of the subscript n, the distribution of X_n may change (Casella and Berger 2002). In many cases, however, the sequence of *dfs* converge to another df.

A large amount of literature exists on the convergence of random variables. An excellent reference for understanding the definitions and relations is Rohatgi (1976). For

a discussion of some of these modes of convergence and as they apply to statistics, see Casella and Berger (2002). Chow and Teicher (1997), Loeve (1976) and Dudley (1989) present a more formal and general approach to the concept of convergence of random variables. In this paper, the notation $\{X_n\}$ is used to represent the sequence $X_1, X_2, X_3, \ldots$

Convergence in Distribution

Let $\{X_n\}$ be a sequence of RVs defined on a sample space (Ω, F, P), and let $\{F_n\}$ be the corresponding sequence of cdfs. Let X be a RV with cdf F. The sequence $\{X_n\}$ is said to *converge in distribution* to X if $\lim_{n\to\infty} F_n(x) = F(x)$ at every point where $F(x)$ is continuous. This type of convergence is sometimes also called *convergence in law* and denoted $X_n \xrightarrow{\mathcal{L}} X$. A sequence of distribution functions does not have to converge, and when it does:

1. *The limiting function does not have to be a cdf itself.* Consider the sequence given by $F_n(x) = 0$ if $x < n$ and $F_n(x) = 1$ if $x \geq n$; $n = 1, 2, \ldots$ Then, at each real value x, $F_n(x) \to 0$, which is not a cdf.
2. *Convergence in distribution does not imply that the sequence of moments converges.* For $n = 1, 2, \ldots$, consider a sequence of cdfs $\{F_n\}$ defined by $F_n(x) = 0$, if $x < 0$; $F_n(x) = 1 - 1/n$, for $0 \leq x < n$; and $F_n(x) = 1$ for $x \geq n$. The sequence of cdfs converges to the cdf $F(x) = 1$ for $x \geq 0$, and $F(x) = 0$ otherwise. For each n, the cdf F_n corresponds to a discrete RV X_n that has probability function (pf) given by $P\{X_n = 0\} = 1 - 1/n$ and $P\{X_n = n\} = 1/n$. The limiting cdf F, corresponds to a RV X with pf $P(X = 0) = 1$. For $k \geq 1$, the kth moment of X_n is $E\left(X_n^k\right) = 0(1 - 1/n) + n^k(1/n) = n^{k-1}$. Finally, $E(X^k) = 0$, so that $E\left(X_n^k\right)$ does not converge to $E(X^k)$.
3. *Convergence in distribution does not imply convergence of their pfs or probability density functions* (pdfs). Let a and b be fixed real numbers, and $\{X_n\}$ a sequence of RVs with pfs given by $P\{X_n = x\} = 1$ for $x = b + a/n$ and $P\{X_n = x\} = 0$ otherwise. None of the pfs assigns any probability to the point $x = b$. Then $P\{X_n = x\} \to 0$, which is not a pf, but the sequence of cdfs $\{F_n\}$ of the RVs X_n converges to a cdf, $F(x) = 1$ for $x \geq b$ and $F(x) = 0$ otherwise.
4. *For integer valued RVs, its sequence of pfs converges to another pf if and only if the corresponding sequence of RVs converges in distribution.*
5. *If a sequence of RVs $\{X_n\}$ converges in distribution to X and c is a real constant, then $\{X_n + c\}$, and $\{cX_n\}$ converge in distribution to $\{X + c\}$, and $\{cX\}$, respectively.*

Convergence in Probability

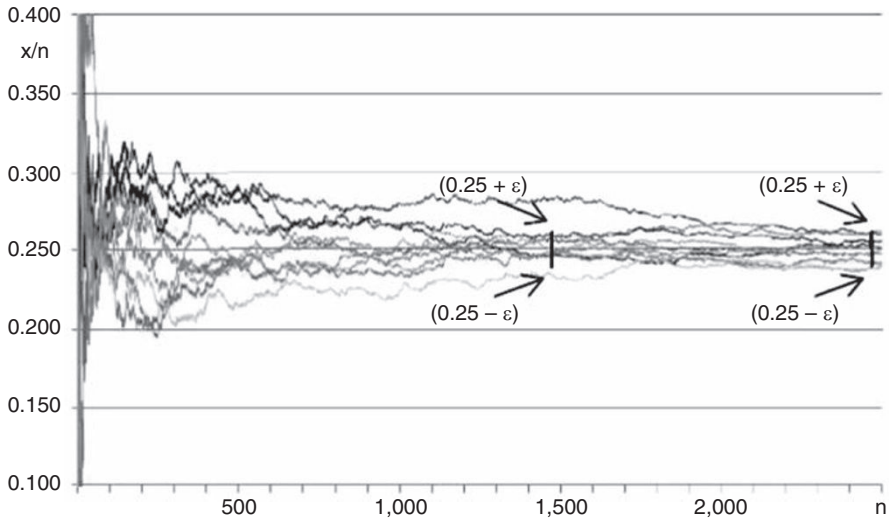
Let $\{X_n\}$ be a sequence of RVs defined on a sample space (Ω, F, P). The sequence $\{X_n\}$ is said to *converge in probability* to a RV X, denoted by $X_n \xrightarrow{p} X$, if for every real number $\varepsilon > 0$,

$$\lim_{n\to\infty} P\{|X_n - X| > \varepsilon\} = 0.$$

Convergence in probability of $\{X_n\}$ to the RV X refers to the convergence of a sequence of probabilities, real numbers to 0. It means that the probability that the distance between X_n and X is larger than $\varepsilon > 0$ tends to 0 as the n increases to infinity. It does not mean that given $\varepsilon > 0$, we can find N such that $|X_n - X| < \varepsilon$ for all $n \geq N$.

Convergence in probability, behaves in many respects as one would expect with respect to common arithmetic operations and under continuous transformations. The following results hold (Rohatgi 1976):

1. $X_n \xrightarrow{p} X$ if and only if $X_n - X \xrightarrow{p} 0$.
2. If $X_n \xrightarrow{p} X$ and $X_n \xrightarrow{p} Y$, then $P\{X = Y\} = 1$.
3. If $X_n \xrightarrow{p} X$, then $X_n - X_m \xrightarrow{p} 0$, as $n, m \to \infty$.
4. If $X_n \xrightarrow{p} X$ and $Y_n \xrightarrow{p} Y$, then $X_n + Y_n \xrightarrow{p} X + Y$, and $X_n - Y_n \xrightarrow{p} X - Y$.
5. If $X_n \xrightarrow{p} X$ and k is a real constant then $kX_n \xrightarrow{p} kX$.
6. If $X_n \xrightarrow{p} k$ then $X_n^2 \xrightarrow{p} k^2$.
7. If $X_n \xrightarrow{p} a$ and $Y_n \xrightarrow{p} b$; a, b real constants, then $X_n Y_n \xrightarrow{p} ab$.
8. If $X_n \xrightarrow{p} 1$ then $1/X_n \xrightarrow{p} 1$.
9. If $X_n \xrightarrow{p} a$ and $Y_n \xrightarrow{p} b$; a, b real constants, $b \neq 0$, then $X_n/Y_n \xrightarrow{p} a/b$.
10. If $X_n \xrightarrow{p} X$ and Y is a RV then $X_n Y \xrightarrow{p} XY$.
11. If $X_n \xrightarrow{p} X$ and $Y_n \xrightarrow{p} Y$, then $X_n Y_n \xrightarrow{p} XY$.
12. Convergence in probability is stronger than convergence in distribution; that is, if $X_n \xrightarrow{p} X$ then $X_n \xrightarrow{\mathcal{L}} X$.
13. Let k be a real number, then convergence in distribution to k implies convergence in probability to k, that is, if $X_n \xrightarrow{\mathcal{L}} k$ then $X_n \xrightarrow{p} k$.
14. In general, convergence in distribution does not imply convergence in probability. For an example, consider the identically distributed RVs $X, X_1, X_2, \ldots$ with sample space $\{0, 2\}$, such that for every n, $P(X_n = 0, X = 0) = P(X_n = 2, X = 2) = 0$ and $P(X_n = 2, X = 0) = P(X_n = 0, X = 2) = {}^1/_2$. Because X, X_n, are identically distributed RVs, $X_n \xrightarrow{\mathcal{L}} X$, but $P\{|X_n - X| > {}^1/_2\} \geq P\{|X_n - X| = 2\} = 1 \neq 0$. (Rohatgi 1976).



Ten series of 2,500 trials each, of a Binomial (4, 0.25) RV X were simulated. The ratio of the running total of successes x, to the number of trials n is plotted for each series. For X/n to converge in probability to 0.25 implies for this experiment, that as n increases, for fixed ε, the probability of observing a series outside the interval $(0.25 - \varepsilon, 0.25 + \varepsilon)$, will decrease to zero. It does not mean there is a value N such that all the series that we can possibly simulate n will be found inside the interval for all $n > N$.

Convergence of Random Variables. Fig. 1 Illustration of convergence in probability

15. Convergence in probability does not imply that the kth moments converge, that is, $X_n \xrightarrow{p} X$ does not imply that $E\left(X_n^k\right) \to E(X^k)$ for any integer $k > 0$. This is illustrated by the example in (14) above.

Figure 1 illustrates the concept of convergence in probability for series of sample means of RVs from a Binomial(4, .025) distribution. The following results further relate convergence in distribution and convergence in probability. Let $\{X_n, Y_n\}, n = 1, 2, \ldots$ be a sequence of pairs of random variables, and let c be a real number.

16. If $|X_n - Y_n| \xrightarrow{p} 0$ and $Y_n \xrightarrow{\mathcal{L}} Y$, then $X_n \xrightarrow{\mathcal{L}} Y$.
17. If $X_n \xrightarrow{\mathcal{L}} X$ and $Y_n \xrightarrow{p} c$, then $X_n + Y_n \xrightarrow{\mathcal{L}} X + c$. This is also true for the difference $X_n - Y_n$.
18. If $X_n \xrightarrow{\mathcal{L}} X$ and $Y_n \xrightarrow{p} c$ then $X_n Y_n \xrightarrow{\mathcal{L}} cX$ (for $c \neq 0$) and $X_n Y_n \xrightarrow{p} 0$ (for $c = 0$).
19. If $X_n \xrightarrow{\mathcal{L}} X$ and $Y_n \xrightarrow{p} c$ then $X_n/Y_n \xrightarrow{\mathcal{L}} X/c$ (for $c \neq 0$).

Almost Sure Convergence

Let $\{X_n\}$ be a sequence of RVs defined on a sample space (Ω, F, P). The sequence $\{X_n\}$ is said to *converge to X with probability one* or almost surely, denoted $X_n \xrightarrow{as} X$ if

$$P\left(\lim_{n\to\infty} X_n = X\right) = 1.$$

Almost sure convergence of a sequence of RVs $\{X_n\}$ to an RV X, means that the probability of the event $\left\{\omega;\ \lim_{n\to\infty} X_n(\omega) = X(\omega)\right\}$ is one (see also ▶Almost Sure Convergence of Random Variables). That is, the set of all points ω in the sample space Ω, where $X_n(\omega)$ converges to $X(\omega)$, has probability one. It is not required that the sequence of functions $\{X_x(\omega)\}$ converge to the function $X(\omega)$ pointwise, for all ω in the sample space, only that the set of such ω has probability one.

1. Convergence almost surely implies convergence in probability. If the sequence of random variables $\{X_n\}$ converges almost surely to X then it converges in probability to X.

2. Skorokhod's representation theorem shows that if a sequence of RVs $\{X_n\}$ converges in distribution to an RV X, then there exists a sequence of random variables $\{Y_n\}$, identically distributed as $\{X_n\}$ such that $\{Y_n\}$ converges almost surely to a RV Y, which itself is identically distributed as X (Dudley 1989).
3. Continuity preserves convergence in distribution, in probability, and almost sure convergence. If X_n converges in any of these modes to X, and f is a continuous function defined on the real numbers, then $f(X_n)$ converges in the same mode to $f(X)$.
4. If $\{X_n\}$ is a strictly decreasing sequence of positive random variables, such that X_n converges in probability to 0, then X_n converges almost surely to 0.
5. Convergence in probability does not imply convergence almost surely. Consider (Casella and Berger 2002) the sample space given by the interval $[0, 1]$, and the uniform probability distribution. Consider the RV $X(\omega) = \omega$ and let $\{X_n\}$ be defined by

$$X_1(\omega) = \omega + I_{[0,1]}(\omega), \quad X_2(\omega) = \omega + I_{[0,1/2]}(\omega),$$
$$X_3(\omega) = \omega + I_{[1/2,1]}(\omega), \quad X_4(\omega) = \omega + I_{[0,1/3]}(\omega),$$
$$X_5(\omega) = \omega + I_{[1/3,2/3]}(\omega), \quad X_6(\omega) = \omega + I_{[2/3,1]}(\omega),$$

and so on. Here $I_A(\omega)$ is the indicator function of the set A. Then $\{X_n\}$ converges in probability to X, but does not converge almost surely since the value $X_n(\omega)$ alternates between ω and $\omega + 1$ infinitely often.

Convergence in the *r*th Mean

Definition Let $\{X_n\}$ be a sequence of RVs defined on a sample space (Ω, F, P) The sequence $\{X_n\}$ is said to *converge to X in the rth mean*, $r \geq 1$, if $E(|Xn|^r) < \infty$, $E(|X|^r) < \infty$ and $\lim_{n\to\infty} E\left(|X_n - X|^r\right) = 0$.

1. When $r = 1$ we say that $\{X_n\}$ converges in the mean, while for $r = 2$, we say that $\{X_n\}$ converges in the mean square.
2. If a sequence $\{X_n\}$ converges in the rth mean, and $s < r$, then $\{X_n\}$ converges in the sth mean. For example, convergence in the mean square implies convergence in the mean. This means that if the variances of a sequence converge, so do the means.
3. Convergence in the rth mean implies convergence in probability, if $\{X_n\}$ converges in the rth mean to X, then $\{X_n\}$ converges in probability to X. However, the converse is not true. For an example, consider the sequence $\{X_n\}$ with probability function defined by $P(X_n = 0) = 1 - \frac{1}{n^3}$ and $P(X_n = n) = \frac{1}{n^3}$ for $r > 0$. (Rohatgi 1976).

About the Author

Dr. Pedro J. Rodríguez Esquerdo is Professor at the Department of Mathematics, College of Natural Sciences and is currently Professor and Head, Institute of Statistics and Computer Information Science, College of Business Administration, both at the University of Puerto Rico, Rio Piedras. He is past Associate Dean for Academic Affairs at the University of Puerto Rico (1988–1993). Professor Rodríguez Esquerdo has served on several advisory boards, including the Advisory Board of Gauss Research Laboratory (2000–) in San Juan, Puerto Rico. He has been a consultant on education, technology, statistics, mathematics, and intellectual property law. He designed and maintains his statistics education web site www.eduesta.org since 1997. Prof. Rodríguez Esquerdo coauthored a book with professors Ana Helvia Quintero and Gloria Vega, *Estadística Descriptiva* (Publicaciones Puertorriqueñas, 1997), and is currently participating in a distance learning project in applied mathematics.

Cook's Distance

R. Dennis Cook
Professor
University of Minnesota, Minneapolis, MN, USA

Introduction

Prior to 1975 there was little awareness within statistics or the applied sciences generally that a single observation can influence a statistical analysis to a point where inferences drawn with the observation included can be diametrically opposed to those drawn without the observation. The recognition that such *influential observations* do occur with notable frequency began with the 1977 publication of *Cook's Distance*, which is a means to assess the influence of individual observations on the estimated coefficients in a linear regression analysis (Cook 1977). Today the detection of influential observations is widely acknowledged as an important part of any statistical analysis and Cook's distance is a mainstay in linear regression analysis. Generalizations of Cook's distance and of the underlying ideas have been developed for application in diverse statistical contexts. Extensions of Cook's distance for linear regression along with a discussion of surrounding methodology were presented by Cook and Weisberg (1982).

Cook's distance and its direct extensions are based on the idea of contrasting the results of an analysis with and without an observation. Implementation of this idea beyond linear and ▶generalized linear models can be problematic. For these applications the related concept of *local influence* (Cook 1986) is used to study the touchiness of an analysis to local perturbations in the model or the data. Local influence analysis continues to be an area of active investigation (see, for example, Zhu et al. 2007).

Cook's Distance

Consider the linear regression of a response variable Y on p predictors $X_1, \ldots, X_p$ represented by the model

$$Y_i = \beta_0 + \beta_1 X_{i1} + \cdots + \beta_p X_{ip} + \boldsymbol{\varepsilon}_i,$$

where $i = 1, \ldots, n$ indexes observations, the β's are the regression coefficients and ε is an error that is independent of the predictors and has mean 0 and constant variance σ^2. This classic model can be represented conveniently in matrix terms as $\mathbf{Y} = \mathbf{X}\boldsymbol{\beta} + \boldsymbol{\varepsilon}$. Here, $\mathbf{Y} = (Y_i)$ is the $n \times 1$ vector of responses, $\mathbf{X} = (X_{ij})$ is the $n \times (p+1)$ matrix of predictor values X_{ij}, including a constant column to account for the intercept β_0, and $\boldsymbol{\varepsilon} = (\varepsilon_i)$ is the $n \times 1$ vector of errors. For clarity, the ith response Y_i in combination with its associated values of the predictors $X_{i1}, \ldots, X_{ip}$ is called the ith *case*. Let $\widehat{\boldsymbol{\beta}}$ denote the ordinary least squares (OLS) estimator of the coefficient vector $\boldsymbol{\beta}$ based on the full data and let $\widehat{\boldsymbol{\beta}}_{(i)}$ denote the OLS estimator based on the data after removing the ith case. Let s^2 denote estimator of σ^2 based on the OLS fit of the full dataset – s^2 the residual sum of squares divided by $(n-p-1)$.

Cook (1977) proposed to assess the influence of the ith case on $\widehat{\boldsymbol{\beta}}$ by using a statistic D_i, which subsequently became known as Cook's distance, that can be expressed in three equivalent ways:

$$D_i = \frac{(\widehat{\boldsymbol{\beta}} - \widehat{\boldsymbol{\beta}}_{(i)})^T \mathbf{X}^T \mathbf{X} (\widehat{\boldsymbol{\beta}} - \widehat{\boldsymbol{\beta}}_{(i)})}{(p+1)s^2} \tag{1}$$

$$= \frac{(\widehat{\mathbf{Y}} - \widehat{\mathbf{Y}}_{(i)})^T (\widehat{\mathbf{Y}} - \widehat{\mathbf{Y}}_{(i)})}{(p+1)s^2} \tag{2}$$

$$= \frac{r_i^2}{p+1} \times \frac{h_i}{1-h_i}. \tag{3}$$

The first form (1) shows that Cook's distance measures the difference between $\widehat{\boldsymbol{\beta}}$ and $\widehat{\boldsymbol{\beta}}_{(i)}$ using the inverse of the contours of the estimated covariance matrix $s^2(\mathbf{X}^T\mathbf{X})^{-1}$ of $\widehat{\boldsymbol{\beta}}$ and scaling by the number of terms $(p+1)$ in the model. The second form shows that Cook's distance can be viewed also as the squared length of the difference between the $n \times 1$ vector of fitted values $\widehat{\mathbf{Y}} = \mathbf{X}\widehat{\boldsymbol{\beta}}$ based on the full data and the $n \times 1$ vector of fitted values $\widehat{\mathbf{Y}}_{(i)} = \mathbf{X}\widehat{\boldsymbol{\beta}}_{(i)}$ when $\boldsymbol{\beta}$ is estimated without the ith case.

The final form (3) shows the general characteristics of cases with relatively large values of D_i. The ith *leverage* h_i, $0 \le h_i \le 1$, is the ith diagonal of the projection matrix $\mathbf{H} = \mathbf{X}(\mathbf{X}^T\mathbf{X})^{-1}\mathbf{X}$ that puts the "hat" on $\mathbf{Y}$, $\widehat{\mathbf{Y}} = \mathbf{H}\mathbf{Y}$. It measures how far the predictor values $\mathbf{X}_i = (X_{i1}, \ldots, X_{ip})^T$ for the ith case are from the average predictor value $\overline{\mathbf{X}}$. If $\mathbf{X}_i$ is far from $\overline{\mathbf{X}}$ then the ith case will have substantial pull on the fit, h_i will be near its upper bound of 1, and the second factor of (3) will be very large. Consequently, D_i will be large unless the first factor in (3) is small enough to compensate. The second factor tells us about the leverage or pull that $\mathbf{X}_i$ has on the fitted model, but it does not depend on the response and thus says nothing about the actual fit of the ith case. That goodness of fit information is provided by r_i^2 in first factor of (3): r_i is the *Studentized residual* for the ith case – the ordinary residual for the ith case divided by $s\sqrt{1-h_i}$. The squared Studentized residual r_i^2 will be large when Y_i does not fit the model and thus can be regarded as an *outlier*, but it says nothing about leverage. In short, the

first factor gives information on the goodness of the fit of Y_i, but it says nothing about leverage, while the second factor gives the leverage information but says nothing about goodness of fit. When multiplied, these factors combine to give a measure of the influence of the ith case.

The Studentized residual r_i is a common statistic for testing the hypothesis that Y_i is not an outlier. That test is most powerful when h_i is small, so $\mathbf{X}_i$ is near $\overline{\mathbf{X}}$, and least powerful when h_i is relatively large. However, leverage or pull is weakest when h_i is small and strongest when h_i is large. In other words, the ability to detect ►outliers is strongest where the outliers tend to be the least influential and weakest where the outliers tend to be the most influential. This gives another reason why influence assessment can be crucial in an analysis.

Cook's distance is not a test statistic and should not by itself be used to accept cases or reject cases. It may indicate an anomalous case that is extramural to the experimental protocol or it may indicate the most important case in the analysis, one that points to a relevant phenomenon not reflected by the other data. Cook's distance does not distinguish these possibilities.

Illustration

The data that provided the original motivation for the development of Cook's distance came from an experiment on the absorption of a drug by rat livers. Nineteen rats were given various doses of the drug and, after a fixed waiting time, the rats were sacrificed and the percentage Y of the dose absorbed by the liver was measured. The predictors were dose, body weight and liver weight. The largest absolute Studentized residual is $\max|r_i| = 2.1$, which is unremarkable when adjusting for multiple testing. The case with the largest leverage 0.85 has a modest Studentized residual of 0.80, but a relatively large Cook's distance of 0.93 – the second largest Cook's distance is 0.27. Body weight and dose have significant effects in the analysis of the full data, but there are no significant effects after the influential case is removed. It is always prudent to study the impact of cases with relatively large values of D_i and all case for which $D_i > 0.5$. The most influential case in this analysis fits both of these criteria. The rat data are discussed in Cook and Weisberg (1999) and available from the accompanying software.

Copulas

Carlo Sempi
Professor, Dean of the Faculty of Mathematical, Physical and Natural Sciences
Università del Salento, Lecce, Italy

Copulas were introduced by Sklar in 1959 (Sklar 1959). In a statistical model they capture the dependence structure of the random variables involved, whatever the distribution

functions of the single random variables. They also allow the construction of families of bivariate or multivariate distributions.

The definition of the notion of copula relies on those of d-box (Definition 1) and of H-volume (Definition 2). Here, and in the following, we put $\mathbb{I} := [0,1]$.

Definition 1 *Let* $\boldsymbol{a} = (a_1, a_2, \ldots, a_d)$ *and* $\mathrm{b} = (b_1, b_2, \ldots, b_d)$ *be two points in* $\overline{\mathbb{R}}^d$, *with* $0 \le a_j \le b_j \le 1$ $(j \in \{1, 2, \ldots, d\})$; *the* d-box $[\mathbf{a}, \mathbf{b}]$ *is the cartesian product*

$$[\mathbf{a}, \mathbf{b}] = \prod_{j=1}^{d} [a_j, b_j],$$

Definition 2 *For a function* $H : \overline{\mathbb{R}}^d \to \overline{\mathbb{R}}$, *the* H-volume V_H *of the* d-box $[\mathbf{a}, \mathbf{b}]$ *is defined by*

$$V_H([\mathbf{a}, \mathbf{b}]) := \sum_{\mathbf{v}} sign(\mathbf{v})\, H(\mathbf{v}),$$

where the sum is taken over the 2^d *vertices* $\mathbf{v}$ *of the box* $[\mathbf{a}, \mathbf{b}]$; *here*

$$sign(\mathbf{v}) = \begin{cases} 1, & \text{if } v_j = a_j \text{ for an even number of indices,} \\ -1, & \text{if } v_j = a_j \text{ for an odd number of indices.} \end{cases}$$

Definition 3 *A function* $C_d : \mathbb{I}^d \to \mathbb{I}$ *is a* d-copula *if*

(a) $C_d(x_1, x_2, \ldots, x_d) = 0$, *if* $x_j = 0$ *for at least one index* $j \in \{1, 2, \ldots, d\}$;

(b) *when all the arguments of* C_d *are equal to* 1, *but for the* j*-th one, then*

$$C_d(1, \ldots, 1, x_j, 1, \ldots, 1) = x_j;$$

(c) *the* V_{C_d}*-volume of every* d-box $[\mathbf{a}, \mathbf{b}]$ *is positive,* $V_{C_d}([\mathbf{a}, \mathbf{b}]) \ge 0$.

The set of d*-copulas* $(d \ge 2)$ *is denoted by* C_d; *in particular, the set of (bivariate) copulas is denoted by* C_2.

Property (c) is usually referred to as the "d-increasing property of a d-copula". Thus every copula is the restriction to the unit cube $\mathbb{I}^d$ of a distribution function that concentrates all the probability mass on $\mathbb{I}^d$ and which has uniform margins (and this may also serve as an equivalent definition).

It is possible to show that C_d is a compact set in the set of all continuous functions from $\mathbb{I}^d$ into $\mathbb{I}$ equipped with the product topology, which corresponds to the topology of pointwise convergence. Moreover, in C_d pointwise and uniform convergence are equivalent.

Every d-copula satisfies the Fréchet–Hoeffding bounds: for all $x_1, \ldots, x_d$ in $\mathbb{I}$, one has

$$W_d(x_1, \ldots, x_d) \le C(x_1, \ldots, x_d) \le M_d(x_1, \ldots, x_d), \quad (1)$$

where

$$W_d(x_1, \ldots, x_d) := \max\{0, x_1 + \cdots + x_d - d + 1\}$$
$$M_d(x_1, \ldots, x_d) := \min\{x_1, \ldots, x_d\}.$$

Also relevant is the "independence copula"

$$\Pi_d(x_1, \ldots, x_d) := \prod_{j=1}^{d} x_j.$$

While Π_d and M_d are copulas for every $d \ge 2$, W_d is a copula only for $d = 2$, although the lower bound provided by (1) is the best possible.

- Π_d is the distribution function of the random vector $\mathbf{U} = (U_1, U_2, \ldots, U_d)$ whose components are independent and uniformly distributed on $\mathbb{I}$.
- M_d is the distribution function of the vector $\mathbf{U} = (U_1, U_2, \ldots, U_d)$ whose components are uniformly distributed on $\mathbb{I}$ and such that $U_1 = U_2 = \cdots = U_d$ almost surely.
- W_2 is the distribution function of the vector $\mathbf{U} = (U_1, U_2)$ whose components are uniformly distributed on $\mathbb{I}$ and such that $U_1 = 1 - U_2$ almost surely.

The importance of copulas for the applications in statistics stems from Sklar's theorem.

Theorem 1 (Sklar 1959) *Let* H *be a* d*-dimensional distribution function with margins* $F_1, F_2, \ldots, F_d$, *and let* A_j *denote the range of* F_j, $A_j := F_j(\overline{\mathbb{R}})$ $(j = 1, 2, \ldots, d)$. *Then there exists a* d*-copula* C, *uniquely defined on* $A_1 \times A_2 \times \cdots \times A_d$, *such that, for all* $(x_1, x_2, \ldots, x_d) \in \overline{\mathbb{R}}^d$,

$$H(x_1, x_2, \ldots, x_d) = C(F_1(t_1), F_2(t_2), \ldots, F_d(t_d)). \quad (2)$$

Conversely, if $F_1, F_2, \ldots, F_d$ *are distribution functions, and if* C *is any* d*-copula, then the function* $H : \overline{\mathbb{R}}^d \to \mathbb{I}$ *defined by* (2) *is a* d*-dimensional distribution function with margins* $F_1, F_2, \ldots, F_d$.

For a compact and elegant proof of this result see (Rüschendorf 2009).

The second ("converse") part of Sklar's theorem is especially important in the construction of statistical models, since it allows to proceed in two separate steps:

- Choose the one-dimensional distribution functions F_1, $F_2, \ldots, F_d$ that describe the behavior of the individual statistical quantities (random variables) $X_1, X_2, \ldots, X_d$ that appear in the model.
- Fit these in (2) by means of a copula C that captures the dependence relations among $X_1, X_2, \ldots, X_d$.

These two steps are independent in the sense that, once a copula C has been chosen, any choice of the distribution functions $F_1, F_2, \ldots, F_d$ is possible.

It should be stressed that the copula whose existence is established in Sklar's theorem is uniquely defined only when the distribution functions have no discrete component; otherwise, there are, in general, several copulas that coincide on $A_1 \times A_2 \times \cdots \times A_d$ and which satisfy (2). This lack of uniqueness may have important consequences when dealing with the copula of random variables (see, e.g., (Marshall 1996)).

The introduction of copulas in the statistical literature has allowed an easier way to construct models by proceeding in two separate steps: (i) the specification of the marginal laws of the random variables involved and (ii) the introduction of a copula that describes the dependence structure among these variables. In many applications (mainly in Engineering) this has allowed to avoid the mathematically elegant and easy-to-deal, but usually unjustified, assumption of independence.

In view of possible applications, it is important to have at one's disposal a stock of copulas. Many families of bivariate copulas can be found in the books by Nelsen (2006), by Balakrishnan and Lai (2009) and Jaworski et al. (2010). Here we quote only the gaussian, the meta-elliptical (Fang et al. 2002) and the extreme-value copulas (Ghoudi et al. 1998). A popular family of copulas is provided by the *Archimedean* copulas, which, in the two-dimensional case, are represented in the form

$$C_\varphi(s,t) = \varphi^{[-1]}\left(\varphi(s) + \varphi(t)\right),$$

where the *generator* $\varphi : [0,1] \to [0,+\infty]$ is continuous, strictly decreasing, convex and $\varphi(1) = 0$, and $\varphi^{[-1]}$ is the *pseudo-inverse* of φ, defined by $\varphi^{[-1]}(t) := \varphi^{-1}(t)$, for $t \in [0, \varphi(0)]$, and by 0, for $t \in [\varphi(0), +\infty]$. These copulas depend on a function of a single variable, the generator φ; as a consequence, the statistical properties of a pair of random variables having C_φ as their copula are easily computed in terms of φ (Genest and MacKay 1986; Nelsen 2006). For the multivariate case the reader is referred to the paper by McNeil and Nešlehová (2009), where the generators of a such a copula are completely characterized.

Notice, however, that the choice of a symmetric copula, in particular of an Archimedean one, means that the random variables involved are exchangeable, if they have the same distribution. The effort to avoid this limitation motivates the recent great interest in the construction of nonsymmetric copulas (see, e.g., Liebscher (2008)).

It must also be mentioned that many methods of construction for copulas have been introduced; here we mention

- Ordinal sums (Mesiar and Sempi 2010);
- Shuffles of Min (Mikusiński et al. 1992) and its generalization to an arbitrary copula (Durante et al. 2009);
- The $*$-product (Darsow et al. 1992) and its generalization (Durante et al. 2007a);
- Transformations of copulas, $C_h(u,v) := h^{[-1]}\left(C(h(u),h(v))\right)$, where the function $h : \mathbb{I} \to \mathbb{I}$ is concave (Durante and Sempi 2005);
- Splicing of symmetric copulas (Durante et al. 2007b; Nelsen et al. 2008);
- Patchwork copulas (De Boets and De Meyer 2007; Durante et al. 2009);
- Gluing of copulas (Siburg and Stoimenov 2008).

A strong motivation for the development of much of copula theory in recent years has come from their applications in Mathematical Finance (see, e.g., (Embrechts et al. 2003), in Actuarial Science (Free and Valdez 1998), and in Hydrology (see, e.g., (Genest and Favre 2007; Salvadori et al. 2007)).

About the Author

Carlo Sempi received his Ph.D. in Applied Mathematics in 1974, University of Waterloo, Canada (his advisor was Professor Bruno Forte). He was Chairman of the Department of Mathematics, Università del Salento (2002–2008). Currently, he is Faculty of Mathematical, Physical and Natural Sciences, University of Salento. Professor Sempi has (co-)authored about 75 refereed papers; many of these papers are on Copulas (some written with the leading authorities on this subject (including Abe Sklar and Roger Nelsen). He was the organizer of the conference "Meeting Copulæ: the 50th anniversary," Lecce, June 2009.

Introduction

Correlation trading denotes the trading activity aimed at exploiting changes in correlation or more generally in the dependence structure of assets or risk factors. Likewise, correlation risk is defined as the exposure to losses triggered by changes in correlation. The copula function technique, which enables analyzing the dependence structure of a joint distribution independently from the marginal distributions, is the ideal tool to assess the impact of changes in market comovements on the prices of assets and the amount of risk in a financial position. As far as the prices of assets are concerned, copula functions enable pricing multivariate products consistently with the prices of univariate products. As for risk management, copula functions enable assessing the degree of diversification in a financial portfolio as well as the sensitivity of risk measures to changes in the dependence structure of risk factors. The concept of consistency between univariate and multivariate prices and risk factors is very similar, and actually parallel, to the problem of compatibility between multivariate probability distributions and distribution of lower dimensions. In finance, this concept is endowed with a very practical content, since it enables designing strategies involving univariate and multivariate products with the aim of exploiting changes in correlation.

Copulas and Spatial Dependence in Finance

Most of the applications of copula functions in finance are limited to multivariate problems in a cross-sectional sense (as econometricians are used to saying), or in a spatial sense (as statisticians prefer). In other words, almost all the applications have to do with the dependence structure of different variables (prices or losses in the case of finance) at the same date. The literature on applications like these is too large to be quoted here in detail, and we refer the reader to the bibliography below and to those in Bouyé et al. (2000) and Cherubini et al. (2004) for more details.

Pricing Applications

Standard asset pricing theory is based on the requirement that the prices of financial products must be such that no arbitrage opportunities can be exploited, meaning that no financial strategy can be built yielding positive return

with no risk. The price consistent with absence of arbitrage opportunities is also known as the "*fair value*" of the product. The fundamental theorem of finance states that this amounts to assert that there must exist a probability measure, called *risk-neutral* measure, under which the expected future returns on each and every asset must be zero, or, which is the same, that the prices of financial assets must be endowed with the martingale property, when measured with that probability measure. Then, the price of each asset promising some payoff in the future must be the expected value with respect to the same probability measure. This implies that if the payoff is a function of one risk factor only, the price is the expected value with respect to a univariate probability measure. If the payoff is instead a function of more than one variable, then it must be computed by taking expectations with respect to the joint distribution of the risk factors. Notice that this implies that there must be a relationship of price consistency between the prices of univariate and multivariate products, and more generally there must be *compatibility* relationships (in the proper meaning of the term in statistics) among prices. This is particularly true for derivative products promising some payments contingent on a multivariate function of several assets. These are the so-called basket derivative products, which are mainly designed on common equity stock (*equity derivatives*), or insurance policies against default of a set of counterparties (*credit derivatives*). The same structure may be used for products linked to commodities or actuarial risks. There are also products called "*hybrids*" that include different risk factors (such as market risk, i.e., the risk of market movements and default of some obligors) in the same product. For the sake of illustration, we provide here two standard examples of basket equity and credit derivatives:

Example 1 (*Altiplano Note*) These are so-called *digital* products, that is, paying a fixed sum if some event takes place at a given future date T. Typically, the event is defined as a set of stocks or market indexes, and the product pays the fixed sum if all of them are above some given level, typically specified as a percentage of the initial level. The price of this product is of course the joint *risk-neutral* probability that all the assets be above a specified level at time T : $Q(S_1(T) > K_1, S_2(T) > K_2, \ldots, S_m(T) > K_m)$, where K_i are the levels (so-called *strike* prices). Consider now that we can actually estimate the marginal distributions from the option markets, so that we can price each $Q_i(S_i(T) > K_i)$. As a result, the only reason why one wants to invest in the multivariate digital product above instead of on a set of univariate ones is to exploit changes in correlation among the assets. To put it in other terms, the value of a multivariate product can increase even if the prices of all the univariate products remain unchanged, and this may occur if the correlation increases. Copula functions are ideal tools to single out this effect.

Example 2 (Collateralized Debt Obligation (*CDO*)) Today it is possible to invest in portfolios of credit derivatives. In nontechnical terms, we can buy and sell insurance ("*protection*" is the term in market jargon) on the first x% losses on defaults of a set of obligors (called "names"). This product is called $0-x$% *equity tranche* of a portfolio of credit losses. For the sake of simplicity assume 100 names and a 0–1% equity tranche, and assume that in case of default, each loss is equal to 1. So, this tranche pays insurance the first time a default occurs (it is also called a *first-to-default* protection). Again, we can easily recover the univariate probabilities of default from other products, namely the so-called credit default swap (*CDS*) market. So, we can price the protection for every single name in the basket. The price of the *first-to-default* must then be compatible with such prices. In fact, with respect to such prices, the multivariate product is different only because it allows to invest in correlation. Again, the equity tranche can increase in value even though the values of single-insurance *CDS* for all the names remain constant, provided that the correlation of defaults increase. Even in this case, copula functions provide the ideal tool to evaluate and trade the degree of dependence of the events of default.

Risk Management

The risk manager faces the problem of measuring the exposure of the position to different risk factors. In the standard practice, he transforms the financial positions in the different assets and markets into a set of *exposures* (*buckets*, in jargon) to a set of risk factors (*mapping* process). The problem is then to estimate the joint distribution of losses $L_1, L_2, L_3, \ldots, L_k$, on these exposures and define a risk measure on this distribution. Typical measures are *Value-at-Risk* (*VaR*) and *Expected Shortfall* (*ES*) defined as

$$VaR(L_i) \equiv \inf(x : H_i(L_i) > 1-\alpha) \qquad ES \equiv E(L_i | L_i \geq VaR)$$

where $H_i(.)$ is the marginal probability distribution of loss L_i. The risk measure of the overall portfolio will analogously be

$$VaR\left(\sum_{i=1}^{k} L_i\right) \equiv \inf\left(x : H\left(\sum_{i=1}^{k} L_i\right) > 1-\alpha\right)$$
$$ES \equiv E\left(\sum_{i=1}^{k} L_i | L_i \geq VaR\right)$$

where $H(.)$ is now the probability distribution of the sum of losses. It is clear that the relationship between

univariate and multivariate risk measures is determined by the dependence structure linking the losses themselves. Again, copula functions are used to merge these risk measures together. Actually, if the max(.,.) instead of the sum were used as the aggregation operator, the risk measure would use the copula function itself as the aggregated distribution of losses.

Copula Pricing and Arbitrage Relationships

Using copula functions is very easy to recover arbitrage relationships (i.e., consistency, or compatibility relationships) among prices of multivariate assets. These relationships directly stem from links between copula functions representing the joint distribution of a set of events and those representing the joint distribution of the complement sets. A *survival copula* is defined as

$$Q(S_1 > K_1, S_2 > K_2, \ldots, S_m > K_m) = \overline{C}(1-u_1, 1-u_2, \ldots, 1-u_m)$$

The relevance of this relationship in finance is clear because it enforces the so-called put-call parity relationships. These relationships establish a consistency link between the price of products paying out if all the events in a set take place and products paying out if none of them take place. Going back to the Altiplano note above, we may provide a straightforward check of this principle.

Example 3 (Put-Call Parity of Altiplano Notes) Assume an Altiplano Note like that in Example 1, with the only difference that the fixed sum is paid if all the assets S_i are below (instead of above) the same predefined thresholds K_i. Clearly, the value of the product will be $Q(S_1(T) \leq K_1, S_2(T) \leq K_2, \ldots, S_m(T) \leq K_m)$. Given the marginal distributions, the dependence structure of this product, which could be called *put*, or *bearish*, Altiplano should be represented by a copula, while the price of the *call* or *bullish* Altiplano in Example 1 should be computed using the survival copula. It can be proved that if this is not the case, one could exploit arbitrage profits (see Cherubini and Luciano 2002; Cherubini and Romagnoli 2009).

Copulas and Temporal Dependence in Finance

So far, we have described correlation in a spatial setting. The flaw of this approach, and of copula applications to finance in general, is that no consistency link is specified, among prices with the same underlying risk factors, but payoffs at different times. We provide three examples here, two of which extend the equity and credit products cases presented above, while the third one refers to a problem arising in risk management applications. Research on this topic, as far as applications to finance are concerned, is at an early stage, and is somewhat covered in the reference bibliography below.

Example 4 (Barrier Altiplano Note) Assume an Altiplano Note with a single asset, but paying a fixed sum at the final date if the price of that asset S remains above a given threshold K on a set of different dates $\{t_1, t_2, t_3, \ldots, t_n\}$. This product can be considered multivariate just like that in Example 1, by simply substituting the concept of *temporal dependence* for that of *spatial dependence*. Again, copula functions can be used to single out the impact of changes in temporal dependence on the price of the product. For some of these products, it is not uncommon to find the so-called memory feature, according to which the payoff is paid for all the dates in the set at the first time that the asset is above the threshold.

Example 5 (Standard Collateralized Debt Obligations) (CDX, iTraxx) In the market there exist *CDO* contracts, like those described in Example 2 above, whose terms are standardized, so that they may be of interest for a large set of investors. These products include 125 "names" representative of a whole market (*CDX* for the US and *iTraxx* for Europe), and on these markets people may trade tranches buying and selling protection on 0–3%, 3–6%, and so on, according to a schedule, which is also standardized. So, for example, you may buy protection against default of the first 3% of the same 125 names, but for a time horizon of 5 or 10 years (the standard maturities are 5, 7, and 10 years). For sure you will pay more for the 10 years insurance than for the 5 years insurance on the same risk. How much more will depend on the relationship between the losses which you may incur in the first 5 years and those that you may face in the remaining 5 years. Clearly, temporal dependence cannot be avoided in this case and it is crucial in order to determine a consistency relationship between the price of insurance against losses on a term of 5 years and those on a term of 10 years. This consistency relationship is known as the *term structure* of *CDX* (or *iTraxx*) premia.

Example 6 (Temporal aggregation of risk measures) We may also think of a very straightforward problem of temporal dependence in risk management, which arises whenever we want to compute the distribution of losses over different time horizons. An instance in which this problem emerges is when one wants to apply risk measures to compare the performance of managed funds over different investment horizons. The same problem arises whenever we have to establish a dependence structure between risk factors that are measured with different time frequencies.

To take the typical example, assume you want to study the dependence structure between market risk and credit risk in a portfolio. The risk measures of market risk are typically computed on losses referred to a period of 1 or 10 days, while credit risk losses are measured in periods of months. Before linking the measures, one has to modify the time horizon of one of the two in order to match that of the other one. The typical "*square root rule*" used in the market obviously rests on the assumption of independent losses with Gaussian distribution, but this is clearly a coarse approximation of reality.

Financial Prices Dynamics and Copulas

The need to extend copulas to provide a representation of both spatial and temporal dynamics of financial prices and risk factors has led to the rediscovery of the relationship between ►copulas and the Markov process (see ►Markov Processes) that was first investigated by Darsow et al. (1992). Actually, even though the Markov assumption may seem restrictive for general applications, it turns out to be consistent with the standard *Efficient Market Hypothesis* paradigm. This hypothesis postulates that all available information must be embedded in the prices of assets, so that price innovations must be unpredictable. This leads to models of asset prices driven by independent increments, which are Markovian by construction. For these reasons, this approach was rediscovered both for pricing and financial econometrics applications (Cherubini et al. 2008, 2009; Cherubini and Romagnoli 2010; Ibragimov 2009; Chen 2009).

We illustrate here the basic result going back to Darsow et al. (1992) with application to asset prices. We assume a set of $\{S_1, S_2, \ldots, S_m\}$ assets and a set of $\{t_0, t_1, t_2, \ldots, t_n\}$ dates, and a filtered probability space generated by the prices and satisfying the usual conditions. Denote S_i^j the price of asset i at time j. First, define the product of two copulas as

$$A * B(u,v) \equiv \int_0^1 \frac{\partial A(u,t)}{\partial t}\frac{\partial B(t,v)}{\partial t}dt$$

and the extended concept of "star-product" as

$$A * B(u_1, u_2, \ldots, u_{m+n-1}) \equiv \int_0^{u_m} \frac{\partial A(u_1, u_2, \ldots, u_{m-1}, t)}{\partial t} \times \frac{\partial B(t, u_{m+1}, u_{m+2}, \ldots, u_{m+n-1})}{\partial t} dt$$

Now, Darsow et al. proved that a stochastic process S_i is a first order ►Markov chain if and only if there exists a set of bivariate copula functions $T_i^{j,j+1}, j = 1, 2, \ldots, n$, such that the dependence among $\{S_i^1, S_i^2, \ldots, S_i^n\}$ can be written as

$$G_i^j\left(u_i^1, u_i^2, \ldots, u_i^j\right) = T_i^{1,2}\left(u_i^1, u_i^2\right) * T_i^{2,3}\left(u_i^1, u_i^2\right) \ldots * T_i^{j-1,j}\left(u_i^1, u_i^2\right)$$

The result was extended to general Markov processes of order k by Ibragimov (2009). Within this framework, Cherubini et al. (2009) provided a characterization of processes with independent increments. The idea is to represent the price S^j (or its logarithm) as $S^{j-1} + Y^j$. Assume that the dependence structure between S^{j-1} and Y^j is represented by copula $C(u,v)$. Then, the dependence between S^{j-1} and S^j may be written as

$$T^{j-1,j}(u,v) = \int_0^u D_1 C\left(w, F_Y\left(F_{S,j}^{-1}(v) - F_{S,j-1}^{-1}(w)\right)\right)\mathrm{d}w$$

where D_1 represents partial derivative with respect to the first variable, $F_Y(.)$ denotes the probability distribution of the increment, and the distribution $F_{S,k}(.)$ the probability distribution of S^k. The probability distribution of S^k is obtained by taking the marginal

$$F(S^j \le s) = T^{j-1,j}(1,v) = \int_0^1 D_1 C\left(w, F_Y\left(s - F_{S,j-1}^{-1}(w)\right)\right)\mathrm{d}w$$

This is a sort of extension of the concept of convolution to the case in which the variables in the sum are not independent. Of course, the case of independent increments is readily obtained by setting $C(u,v) = uv$. The copula linking S^{j-1} and S^j becomes in this case

$$T^{j-1,j}(u,v) = \int_0^u F_Y\left(F_{S,j}^{-1}(v) - F_{S,j-1}^{-1}(w)\right)\mathrm{d}w$$

A well-known special case is

$$T^{j-1,j}(u,v) = \int_0^u \Phi\left(\Phi^{-1}(v) - \Phi^{-1}(w)\right)\mathrm{d}w$$

with $\Phi(x)$ the standard normal distribution, which yields the dependence structure of a Brownian motion (see ►Brownian Motion and Diffusions) upon appropriate standardization. As for pricing applications, Cherubini et al. (2008) applied the framework to temporal dependence of losses and the term structure of *CDX* premia, and Cherubini and Romagnoli (2010) exploited the model to price barrier Altiplanos. This stream of literature, which applies copulas to modeling stochastic processes in discrete time, casts a bridge to a parallel approach, that directly applies copulas to model dependence among

stochastic processes in continuous time: this is the so-called Lévy copula approach (Kallsen and Tankov 2006). Both these approaches aim at overcoming the major flaw of copula functions as a static tool and unification of them represents the paramount frontier issue in this important and promising field of research.

Copulas: Distribution Functions and Simulation

Pranesh Kumar
Professor
University of Northern British Columbia, Prince George, BC, Canada

Introduction

In multivariate data modelling for an understanding of stochastic dependence the notion of correlation has been central. Although correlation is one of the omnipresent concepts in statistical theory, it is also one of the most misunderstood concepts. The confusion may arise from the literary meaning of the word to cover any notion of dependence. From mathematics point of view, correlation is only one particular measure of stochastic dependence. It is the canonical measure in the world of ►multivariate normal distributions and in general for spherical and elliptical distributions. However empirical research in many applications indicates that the distributions of the real world seldom belong to this class. We collect and present ideas of copula functions with applications in statistical probability distributions and simulation.

Dependence

We denote by (X, Y) a pair of real-valued nondegenerate random variables with finite variances σ_x^2 and σ_y^2 respectively. The correlation coefficient between X and Y is the standardized covariance σ_{xy}, i.e., $\rho = \frac{\sigma_{xy}}{\sigma_x \sigma_y}$, $\rho \in [-1, 1]$. The correlation coefficient is a measure of linear depen-hh dence only. In case of independent random variables, correlation is zero. Embrechts, McNeil and Straumann (1999) have discussed that in case of imperfect linear dependence, i.e., $-1 < \rho < 1$, misinterpretations of correlation are possible. Correlation is not ideal for a dependence measure and

causes problems when there are heavy-tailed distributions. Independence of two random variables implies they are uncorrelated but zero correlation does not in general imply independence. Correlation is not invariant under strictly increasing linear transformations. Invariance property is desirable for the statistical estimation and significance testing purposes. Further correlation is sensitive to ▶outliers in the data set. The popularity of linear correlation and correlation based models is primarily because it is often straightforward to calculate and manipulate them under algebraic operations. For many ▶bivariate distributions it is simple to calculate variances and covariances and hence the correlation coefficient. Another reason for the popularity of correlation is that it is a natural measure of dependence in multivariate normal distributions and more generally in multivariate spherical and elliptical distributions. Some examples of densities in the spherical class are those of the multivariate t-distribution and the ▶logistic distribution.

Another class of dependence measures is rank correlations. They are defined to study relationships between different rankings on the same set of items. Rank correlation measures the correspondence between two rankings and assess their significance. Two commonly used measures of concordance are Spearman's rank correlation (ρ_s) and Kendall's rank correlation (τ). Assuming random variables X and Y have distribution functions F_1 and F_2 and joint distribution function F, Spearman's rank correlation $\rho_s = \rho(F_1(X), F_2(Y))$ where ρ is the linear correlation coefficient. If (X_1, Y_1) and (X_2, Y_2) are two independent pairs of random variables from the distribution function F, then the Kendall's rank correlation is $\tau = \Pr[(X_1 - X_2)(Y_1 - Y_2) > 0] - \Pr[(X_1 - X_2)(Y_1 - Y_2) < 0]$. The main advantage of rank correlations over ordinary linear correlation is that they are invariant under monotonic transformations. However rank correlations do not lend themselves to the same elegant variance–covariance manipulations as linear correlation does since they are not moment-based.

A measure of dependence like linear correlation summarizes the dependence structure of two random variables in a single number. Scarsini (1984) has detailed properties of copula based concordance measures. Another excellent discussion of dependence measures is by Embrecht et al. (1999). Let $D(X, Y)$ be a measure of dependence which assigns a real number to any real-valued pair of random variables (X, Y). Then dependence measure $D(X, Y)$ is desired to have properties: (i) Symmetry: $D(X, Y) = D(Y, X)$; (ii) Normalization: $-1 \leq D(X, Y) \leq +1$; (iii) Comonotonic or Countermonotonic: The notion of comonotonicity in probability theory is that a random vector is comonotonic if and only if all marginals are non-decreasing functions (or non-increasing functions) of the same random variable. A measure $D(X, Y)$ is comonotonic if $D(X, Y) = 1 \iff X, Y$ or countermonotonic if $D(X, Y) = -1 \iff X, Y$; (iv) For a transformation T strictly monotonic on the range of X, $D(T(X), Y) = D(X, Y)$, $T(X)$ increasing or $D(T(X), Y) = -D(X, Y)$, $T(X)$ decreasing.

Linear correlation ρ satisfies properties (i) and (ii) only. Rank correlations fulfill properties (i)–(iv) for continuous random variables X and Y. Another desirable property is: (v) $D(X, Y) = 0 \iff X, Y$ (Independent). However it contradicts property (iv). There is no dependence measure satisfying properties (iv) and (v). If we desire property (v), we should consider dependence measure $0 \leq D^*(X, Y) \leq +1$. The disadvantage of all such dependence measures $D^*(X, Y)$ is that they can not differentiate between positive and negative dependence (Kimeldorf and Sampson 1978; Tjøstheim 1996).

Copulas

▶Copulas have recently emerged as a means of describing joint distributions with uniform margins and a tool for simulating data. They express joint structure among random variables with any marginal distributions. With a copula we can separate the joint distribution into marginal distributions of each variable. Another advantage is that the conditional distributions can be readily expressed using the copula. An excellent introduction of copulas is presented in Joe (1997) and Nelsen (2006). Sklar's theorem (1959) states that any multivariate distribution can be expressed as the k-copula function $C(u_1, \ldots, u_i, \ldots, u_k)$ evaluated at each of the marginal distributions. Copula is not unique unless the marginal distributions are continuous. Using probability integral transform, each continuous marginal $U_i = F_i(x_i)$ has a uniform distribution (see ▶Uniform Distribution in Statistics) on $I \in [0, 1]$ where $F_i(x_i)$ is the cumulative integral of $f_i(x_i)$ for the random variable $X_i \in (-\infty, \infty)$. The k-dimensional probability distribution function F has a unique copula representation $F(x_1, x_2, \ldots, x_k) = C(F_1(x_1), F_2(x_2), \ldots, F_k(x_k)) = C(u_1, u_2, \ldots, u_k)$. The joint probability density function is written as $f(x_1, x_2, \ldots, x_k) = \Pi_{i=1}^{k} f_i(x_i) \times c(F_1(x_1), F_2(x_2), \ldots, F_k(x_k))$ where $f_i(x_i)$ is each marginal density and coupling is provided by copula density $c(u_1, u_2, \ldots, u_k) = \partial^k C(u_1, u_2, \ldots, u_k)/\partial u_1 \partial u_2 \ldots \partial u_k$ if it exists. In case of independent random variables, copula density $c(u_1, u_2, \ldots, u_k)$ is identically equal to one. The importance of the above equation $f(x_1, x_2, \ldots, x_k)$

is that the independent portion expressed as the product of the marginals can be separated from the function $c(u_1, u_2, \ldots, u_k)$ describing the dependence structure or shape. The dependence structure summarized by a copula is invariant under increasing and continuous transformations of the marginals. This means that suppose we have a probability model for dependent insurance losses of various kinds. If our interest now lies in modelling the logarithm of these losses, the copula will not change, only the marginal distributions will change.

The simplest copula is independent copula $\Pi := C(u_1, u_2, \ldots, u_k) = u_1 u_2 \ldots u_k$ with uniform density functions for independent random variables. Another copula example is the Farlie–Gumbel–Morgenstern (FGM) bivariate copula. The general system of FGM bivariate distributions is given by $F(x_1, x_2) = F_1(x_1) \times F_2(x_2) [1 + \rho (1 - F_1(x_1)) (1 - F_2(x_2))]$ and copula associated with this distribution is a FGM bivariate copula $C(u, v) = uv[1 + \rho (1 - u) (1 - v)]$. A widely used class of copulas is Archimedean copulas which has a simple form and models a variety of dependence structures. Most of the Archimedean copulas have closed-form solutions. To define an Archimedean copula, let ϕ be a continuous strictly decreasing convex function from $[0,1]$ to $[0, \infty]$ such that $\phi(1) = 0$ and $\phi(0) = \infty$. Let ϕ^{-1} be the pseudo inverse of ϕ. Then a k-dimensional Archimedean copula is $C(u_1, u_2, \ldots, u_k) = \phi^{-1} [\phi(u_1) + \ldots + \phi(u_k)]$. The function ϕ is known as a generator function. Thus any generator function satisfying $\phi(1) = 0$; $\lim_{x \to 0} \phi(x) = \infty$; $\phi'(x) < 0$; $\phi''(x) > 0$ will result in an Archimedean copula. For an example, generator function $\phi(t) = \left(t^{-\theta} - 1\right)/\theta$, $\theta \in [-1, \infty) \backslash \{0\}$ results in the bivariate Clayton copula $C(u_1, u_2) = \max\left[\left(u_1^{-\theta} + u_2^{-\theta} - 1\right)^{-1/\theta}, 0\right]$. The copula parameter θ controls the amount of dependence between X_1 and X_2.

The Frécht–Hoeffding bounds for copulas: The lower bound for k-variate copula is $W(u_1, u_2, \ldots, u_k) := \max\{1 - n + \sum_{i=1}^{k} u_i, 0\} \leq C(u_1, u_2, \ldots, u_k)$. The upper bound for k-variate copula is $C(u_1, u_2, \ldots, u_k) \leq \min_{i \in \{1,2,\ldots,k\}} u_i =: M(u_1, u_2, \ldots, u_k)$. For all copulas, the inequality $W(u_1, \ldots, u_k) \leq C(u_1, \ldots, u_k) \leq M(u_1, \ldots, u_k)$ is satisfied. This inequality is well known as the Frécht-Hoeffding bounds for copulas. Further, W and M are copulas themselves. It may be noted that the Frécht-Hoeffding lower bound is not a copula in dimension $k > 2$. Copulas M, W and Π have important statistical interpretations (Nelson, 2006). Given a pair of continuous random variables (X_1, X_2), (i) copula of (X_1, X_2) is $M(u_1, u_2)$ if and only if each of X_1 and X_2 is almost surely increasing function of the other; (ii) copula of (X_1, X_2) is $W(u_1, u_2)$ if and only if each of X_1 and X_2 is almost surely decreasing function of the other and (iii) copula of (X_1, X_2) is $\Pi(u_1, u_2) = u_1 u_2$ if and only if X_1 and X_2 are independent.

Three famous measures of concordance Kendall's τ, Spearman's ρ_s and Gini's index γ could be expressed in terms of copulas (Schweizer and Wolff 1981) $\tau = 4 \int \int_{I^2} C(u_1, u_2)\, dC(u_1, u_2) - 1$, $\rho_s = 12 \int \int_{I^2} u_1 u_2\, dC(u_1, u_2) - 3$ and $\gamma = 2 \int \int_{I^2} (|u_1 + u_2 - 1| - |u_1 - u_2|)\, dC(u_1, u_2)$. It may however be noted that the linear correlation coefficient ρ cannot be expressed in terms of copula.

The tail dependence indexes of a multivariate distribution describe the amount of dependence in the upper right tail or lower left tail of the distribution and can be used to analyze the dependence among extremal random events. Tail dependence describes the limiting proportion that one margin exceeds a certain threshold given that the other margin has already exceeded that threshold. Joe (1997) defines tail dependence: If a bivariate copula $C(u_1, u_2)$ is such that $\lambda_U := \lim_{u \to 1} \frac{[1 - 2u + C(u,u)]}{(1-u)}$ exists, then $C(u_1, u_2)$ has upper tail dependence for $\lambda_U \in (0,1]$ and no upper tail dependence for $\lambda_U = 0$. Similarly lower tail dependence in terms of copula is defined $\lambda_L := \lim_{u \to 0} \frac{C(u,u)}{u}$. Copula has lower tail dependence for $\lambda_L \in (0,1]$ and no lower tail dependence for $\lambda_L = 0$. This measure is extensively used in extreme value theory. It is the probability that one variable is extreme given that other is extreme. Tail measures are copula-based and copula is related to the full distribution via quantile transformations, i.e., $C(u_1, u_2) = F\left(F_1^{-1}(u_1), F_2^{-1}(u_2)\right)$ for all $u_1, u_2 \in (0,1)$ in the bivariate case.

Simulation

Simulation in statistics has a pivotal role in replicating and analysing data. Copulas can be applied in simulation and Monte Carlo studies. Johnson (1987) discusses methods to generate a sample from a given joint distribution. One such method is a recursive simulation using the univariate conditional distributions. The conditional distribution of U_i given first $i - 1$ components is $C_i(u_i | u_1, \ldots, u_{i-1}) = \frac{\partial^{i-1} C_i(u_1, \ldots, u_i)}{\partial u_1 \ldots \partial u_{i-1}} \Big/ \frac{\partial^{i-1} C_{i-1}(u_1, \ldots, u_{i-1})}{\partial u_1 \ldots \partial u_{i-1}}$. For $k \geq 2$, procedure is as follows: (i) Simulate a random number $u_1$from Uniform (0,1); (ii) Simulate value u_2 from the conditional distribution $C_2(u_2|u_1)$;(iii) Continue in this way; (iv) Simulate a value u_k from $C_k(u_k|u_1, \ldots, u_{k-1})$.

We list some important contributions in the area of copulas under the reference section.

Cornish–Fisher Expansions

Vladimir V. Ulyanov
Professor
Lomonosov Moscow State University, Moscow, Russia

Introduction

In statistical inference it is of fundamental importance to obtain the sampling distribution of statistics. However, we often encounter situations where the exact distribution cannot be obtained in closed form, or even if it is obtained, it might be of little use because of its complexity. One practical way of getting around the problem is to provide reasonable approximations of the distribution function and its quantiles, along with extra information on their possible errors. This can be accomplished with the help of Edgeworth and Cornish–Fisher expansions. Recently, interest in Cornish–Fisher expansions has increased

because of intensive study of VaR (Value at Risk) models in financial mathematics and financial risk management (see Jaschke (2002)).

Expansion Formulas

Let X be a univariate random variable with a continuous distribution function F. For $\alpha : 0 < \alpha < 1$, there exists x such that $F(x) = \alpha$, which is called the (lower) $100\alpha\%$ *point* of F. If F is strictly increasing, the inverse function $F^{-1}(\cdot)$ is well defined and the $100\alpha\%$ point is uniquely determined. We also speak of "quantiles" without reference to particular values of α meaning the values given by $F^{-1}(\cdot)$.

Even in the general case, when $F(x)$ is not necessarily continuous nor is it strictly increasing, we can define its inverse function by the formula

$$F^{-1}(u) = \inf\{x; F(x) > u\}.$$

This is a right-continuous nondecreasing function defined on the interval (0,1) and $F(x_0) \geq u_0$ if $x_0 = F^{-1}(u_0)$.

Let $F_n(x)$ be a sequence of distribution functions and let each F_n admit the ▶Edgeworth expansion (EE) in the powers of $\epsilon = n^{-1/2}$ or n^{-1}:

$$\begin{aligned} F_n(x) &= G_{k,n}(x) + O(\epsilon^k) \quad \text{with} \\ G_{k,n}(x) &= G(x) + \{\epsilon a_1(x) + \cdot + \epsilon^{k-1} a_{k-1}(x)\} g(x), \end{aligned} \tag{1}$$

where $g(x)$ is the density function of the limiting distribution function $G(x)$. An important approach to the problem of approximating the quantiles of F_n is to use their asymptotic relation to those of G's. Let x and u be the corresponding quantiles of F_n and G, respectively. Then we have

$$F_n(x) = G(u). \tag{2}$$

Write $x(u)$ and $u(x)$ to denote the solutions of (2) for x in terms of u and u in terms of x, respectively [i.e. $u(x) = G^{-1}(F_n(x))$ and $x(u) = F_n^{-1}(G(u))$]. Then we can use the EE (1) to obtain formal solutions $x(u)$ and $u(x)$ in the form

$$x(u) = u + \epsilon b_1(u) + \epsilon^2 b_2(u) + \cdots \tag{3}$$

and

$$u(x) = x + \epsilon c_1(x) + \epsilon^2 c_2(x) + \cdots. \tag{4}$$

Cornish and Fisher (1937) and Fisher and Cornish (1946) obtained the first few terms of these expansions when G is the standard normal distribution function (i.e., $G = \Phi$). We call both (3) and (4) the *Cornish–Fisher expansions*, (CFE). Concerning CFE for random variables obeying limit laws from the family of Pearson distributions see Bol'shev (1963). Hill and Davis (1968) gave a general algorithm for obtaining each term of CFE when G is an analytic function:

Theorem 1 *Assume that the distribution function G is analytic. Then the following relation for x and u satisfying $F_n(x) = G(u)$ holds:*

$$x = u - \sum_{r=1}^{\infty} \frac{1}{r!} \{-[g(u)]^{-1} d_u\}^{r-1} \left[\{z_n(u)\}^r / g(u)\right], \tag{5}$$

where $d_u = d/du$ and $z_n(u) = F_n(u) - G(u)$.

A similar relation can be written for u as a function of x.

In many statistical applications, $F_n(x)$ is known to have an asymptotic expansion of the form

$$F_n(x) = G(x) + g(x)\left[n^{-a} p_1(x) + n^{-2a} p_2(x) + \cdots\right],$$

where $p_r(x)$ may be polynomials in x and $a = 1/2$ or 1. Then the formulas (5) can be written as

$$x = u - \sum_{r=1}^{\infty} \frac{1}{r!} d_{(r)} \{g_n(u)\}^r, \tag{6}$$

where $q_n(u) = n^{-a} p_1(u) + n^{-2a} p_2(u) + \cdots$,
$m(x) = -g'(x)/g(x)$,

$d_{(1)}$ = the identity operator,
$d_{(r)} = \{m(u) - d_u\}\{2m(u) - d_u\}\cdots\{(r-1)m(u) - d_u\}$,
$r = 2, 3, \ldots$

The rth term in (6) is of order $O(n^{-ra})$.

It is a tedious process to rewrite (6) in the form of (3) and to express the adjustment terms $b_k(u)$ directly in terms of the cumulants (see Hill and Davis (1968)). Lee and Lin developed a recurrence formula for $b_k(u)$, which is implemented in the algorithm AS269 (see Lee and Lin (1992, 1993)).

Usually the CFE are applied in the following form with $k = 1, 2$, or 3:

$$x_k(u) = u + \sum_{j=1}^{k-1} \epsilon^j b_j(u) + O(\epsilon^k), \tag{7}$$

In order to find the explicit expressions for $b_1(u)$ and $b_2(u)$ we substitute (7) with $k = 2$ to (1) and using (2) we have

$$\begin{aligned} F_n(x) &= F_n(u + \epsilon b_1 + \epsilon^2 b_2 + \cdots) \\ &= G(u + \epsilon b_1 + \epsilon^2 b_2) + g(u + \epsilon b_1 + \epsilon^2 b_2) \\ &\quad \times \{\epsilon a_1(u + \epsilon b_1) + \epsilon^2 a_2(u)\} + O(\epsilon^2). \end{aligned}$$

By Taylor's expansions for G, g, and a_1, we obtain

$$\begin{aligned} F_n(x) =& G(u) + \epsilon g(u)\{b_1 + a_1(u)\} \\ &+ \epsilon^2 \left[g(u) b_2 + \frac{1}{2} g'(u) b_1^2 + g(u) a_1'(u) b_1 \right. \\ &\left. + g(u) a_2(u) + g'(u) b_1 a_1(u)\right] + O(\epsilon^3), \end{aligned}$$

which should be $G(u)$. Therefore,

$$b_1 = -a_1(u),$$
$$b_2 = \frac{1}{2}\{g'(u)/g(u)\}a_1^2(u) - a_2(u) + a_1'(u)a_1(u).$$

An application of general formulas (6) in the case of normal limit distribution see the entry ►Edgeworth Expansion.

Suppose that

$$F_n(x) = G_f(x) + \frac{f\gamma}{4n}[G_f(x) + 2G_{f+2}(x) + G_{f+4}(x)] + \frac{f}{960n^2}\sum_{j=0}^{4}(-1)^j c_j G_{f+2j}(x) + o(n^{-2}),$$

where $G_f(x) = \Pr\{\chi_f^2 \le x\}$; that is, the distribution function of the ►chi-square distribution with f degrees of freedom, γ is a constant, and c_j are constants such that $\sum_{j=0}^{4}(-1)^j c_j = 0$. Then $G(u) = G_f(u)$,

$$g(u) = g_f(u) = \left[\Gamma(f/2)2^{f/2}\right]^{-1} u^{f/2-1}\exp(-u/2),$$
$$m(u) = -g_f'(u)/g_f(u) = \frac{1}{2} - \frac{1}{u}\left(\frac{f}{2} - 1\right).$$

Thus, we can write

$$q_n(u) = -\frac{u(u-f-2)}{2n(f+2)} - \frac{u}{48n^2(f+2)(f+4)(f+6)}[c_4u^3 + (c_4 - c_3)(f+6)u^2 + (c_1 - c_0)(f+4)(f+6)u - c_0(f+2)(f+4)(f+6)] + o(n^{-2}).$$

Therefore, we obtain

$$x = u - q_n(u) - [\gamma^2 u(u-f-2)/\{16n^2(f+2)^2\}] \times \{u^2 - 2(f+4)u + (f+2)^2\} + o(n^{-2}).$$

The upper and lower bounds for the quantiles $x = x(u)$ and $u = u(x)$, satisfying the equation (2), i.e.

$$\underline{x}_n(u) \ge x(u) \ge \bar{x}_n(u), \quad \underline{u}_n(x) \ge u(x) \ge \bar{u}_n(x)$$

were obtained for some special distributions by Wallace (1959).

Validity of Cornish–Fisher Expansions

In applications, the CFE are usually used in the form (7). It is necessary to remember that the approximations for α-quantiles provided by the CFE

(i) become less and less reliable for $\alpha \to 0$ and $\alpha \to 1$;
(ii) do not necessarily improve (converge) for a fixed F_n and increasing order of approximation k.

Let x_α and x_α^* be the upper $100\alpha\%$ points of F_n and $G_{k,n}$ from (1), respectively; that is, they satisfy

$$F_n(x_\alpha) = G_{k,n}\left(x_\alpha^*\right) = 1 - \alpha.$$

The approximate quantile x_α^* based on the Edgeworth expansion is available in numerical form but cannot be expressed in explicit form. Suppose that the remainder term, $R_{k,n}(x) = F_n(x) - G_{k,n}(x)$, is such that

$$|R_{k,n}| \le \epsilon^n C_k.$$

Then

$$\left|F_n\left(x_\alpha^*\right) - (1-\alpha)\right| = \left|F_n\left(x_\alpha^*\right) - G_{k,n}\left(x_\alpha^*\right)\right| \le \epsilon^n C_k.$$

This gives an error bound for the absolute differences between the probabilities based on the true quantiles and their approximations.

The other validity of the CFE was obtained by considering the distribution function $\tilde{F}_{k,n}$ of

$$\tilde{X} = U + \sum_{j=1}^{k-1}\epsilon^j b_j(U),$$

where U is the standard normal variable. Takeuchi and Takemura (1988) showed that if $|F_n(x) - G_{k,n}(x)| = o(\epsilon^{k-1})$, then $|F_n(x) - \tilde{F}_{k,n}| = o(\epsilon^{k-1})$.

Function of Sample Mean

Usually the conditions that are sufficient for validity of EE are sufficient as well for validity of CFE. Under the conditions of section "►Function of Sample Means" in the entry ►Edgeworth Expansion and in its notation we have (see Hall (1992)):

$$\sup_{\epsilon<\alpha<1-\epsilon}\left|x_\alpha - u_\alpha - \sum_{j=1}^{k-2}\frac{b_j(u_\alpha)}{n^{j/2}}\right| = o\left(\frac{1}{n^{(k-2)/2}}\right),$$

where $x_\alpha = \inf\{x; \Pr(\sqrt{n}H(\bar{\mathbf{Y}})/\sigma \le x) > \alpha\}$, $u_\alpha = \Phi^{-1}(\alpha)$, ϵ is any constant in (0,1/2) and b_j's are polynomials depending on Q_j's.

Error Bounds

It is possible to get error bounds for approximation given by the CFE provided we have error bounds for EE. For simplicity, we give error bounds for the first-order CFE (see Chap. 5 in Fujikoshi et al. (2010)):

Theorem 2 *Suppose that for the distribution function of U we have*

$$F(x) \equiv Pr\{U \le x\} = G(x) + R_1(x),$$

where for remainder term $R_1(x)$ there exists a constant c_1 such that

$$|R_1(x)| \le d_1 \equiv c_1\epsilon.$$

Let x_α and u_α be the upper $100\alpha\%$ points of F and G, respectively; that is,

$$Pf\{U \le x_\alpha\} = G(u_\alpha) = 1 - \alpha.$$

Then, for any α such that $1 > \alpha > d_1$ and $1 > \alpha + d_1$:

1. $u_{\alpha+d_1} \le x_\alpha \le u_{\alpha-d_1}$.
2. $|x_\alpha - u_\alpha| \le d_1 / g(u_{(1)})$, *where*

$$g(u_1) = \min_{u \in [u_{\alpha+d_1}, u_{\alpha-d_1}]} g(u).$$

About the Author

DSc Vladimir V. Ulyanov is Professor, Department of Mathematical Statistics, Faculty of Computational Mathematics and Cybernetics at Lomonosov Moscow State University. He has received the State Prize of the USSR for Young Scientists (1987), Alexander von Humboldt Research Fellowship, Germany (1991–1993), JSPS Research Fellowship, Japan (1999, 2004). He was visiting Professor/Researcher at Bielefeld University, Germany, University of Leiden, Université de Paris V, University of Hong Kong, Institute of Statistical Mathematics in Tokyo, National University of Singapore, the University of Melbourne etc. He is a member of the Bernoulli Society. Professor Ulyanov is the author of more than 50 journal articles and a book *Multivariate Statistics: High-Dimensional and Large-Sample Approximations* (with Y. Fujikoshi and R. Shimizu, John Wiley and Sons, 2010).

Correlation Coefficient

Nitis Mukhopadhyay
Professor
University of Connecticut-Storrs, Storrs, CT, USA

Introduction

A covariance term loosely aims at capturing some essence of *joint dependence* between two random variables. A correlation coefficient is nothing more than an appropriately scaled version of the covariance.

Section "Population Correlation Coefficient" introduces the concepts of a covariance and the population correlation coefficient. Section "Correlation Coefficient and Independence" highlights some connections between the correlation coefficient, independence, and dependence.

Section "A Sample Correlation Coefficient" summarizes the notion of a sample correlation coefficient and its distribution, both exact and large-sample approximation, due to Fisher (1915; 1925). Section "Partial Correlations" gives a brief summary of the concept of partial correlation coefficients.

Population Correlation Coefficient

A covariance term tries to capture a sense of *joint dependence* between two real valued random variables. A correlation coefficient, however, is an appropriately scaled version of a covariance.

Definition 1 *The covariance between two random variables X_1 and X_2, denoted by $Cov(X_1, X_2)$, is defined as*

$$Cov(X_1, X_2) = E\left[(X_1 - \mu_1)(X_2 - \mu_2)\right]$$

$$\text{or equivalently } E\left[X_1 X_2\right] - \mu_1 \mu_2,$$

where $\mu_i = E(X_i)$, $i = 1, 2$ and $E\left[X_1 X_2\right]$, μ_1, μ_2 are assumed finite.

Definition 2 *The correlation coefficient between two random variables X_1 and X_2, denoted by ρ_{X_1,X_2}, is defined as*

$$\rho_{X_1,X_2} = \frac{Cov(X_1, X_2)}{\sigma_1 \sigma_2},$$

whenever one has $0 < \sigma_1^2 = V(X_1) < \infty$ *and* $0 < \sigma_2^2 = V(X_2) < \infty$.

One may note that we do not explicitly assume $-\infty < Cov(X_1, X_2) < \infty$. In view of the assumption $0 < \sigma_1^2, \sigma_2^2 < \infty$, one can indeed claim the finiteness of $Cov(X_1, X_2)$ by appealing to Cauchy–Schwartz inequality. It should also be clear that

$$Cov(X_1, X_2) = Cov(X_2, X_1) \text{ and } Cov(X_1, X_1) = V(X_1),$$

as long as those terms are finite.

Two random variables X_1, X_2 are respectively called negatively correlated, uncorrelated, or positively correlated if and only if ρ_{X_1,X_2} *is neg*ative, zero or positive.

Theorem 1 *Consider random variables* X_1 *and* X_2 *and assume that* $0 < V(X_1), V(X_2) < \infty$. *Then, we have the following results:*

1. *Let* $Y_i = c_i + d_i X_i$ *w.p.*1 *where* $-\infty < c_i < \infty$ *and* $0 < d_i < \infty$ *are fixed numbers,* $i = 1, 2$. *Then,* $\rho_{Y_1,Y_2} = \rho_{X_1,X_2}$.
2. $|\rho_{X_1,X_2}| \le 1$, *the equality holds if and only if* $X_1 = a + bX_2$ *w.p.*1 *for some real numbers* a *and* b.

More details can be found from Mukhopadhyay (2000, Sect. 3.4).

Correlation Coefficient and Independence

If ρ_{X_1,X_2} is finite and X_1, X_2 are independent, then $\rho_{X_1,X_2} = 0$. Its converse is not necessarily true. In general, $\rho_{X_1,X_2} = 0$ may not imply independence between X_1, X_2. An example follows.

Example 1 Let X_1 be $N(0,1)$ and $X_2 = X_1^2$. Then, $Cov(X_1, X_2) = 0$, and surely $0 < V(X_1), V(X_2) < \infty$, so that $\rho_{X_1,X_2} = 0$. But, X_1 and X_2 are dependent variables. More details can be found from Mukhopadhyay (2000, Sect. 3.7). The recent article of Mukhopadhyay (2010) is relevant here.

Now, we state an important result which clarifies the role of zero correlation in a bivariate normal distribution.

Theorem 2 *Suppose that* (X_1, X_2) *has the* $N_2\left(\mu_1, \mu_2, \sigma_1^2, \sigma_2^2, \rho\right)$ *distribution where* $-\infty < \mu_1, \mu_2 < \infty$, $0 < \sigma_1, \sigma_2 < \infty$ *and* $-1 < \rho (= \rho_{X_1,X_2}) < 1$. *Then,* X_1 *and* X_2 *are independent if and only if* $\rho = 0$.

Example 2 A zero correlation coefficient implies *independence* not merely in the case of a bivariate normal distribution. Consider random variables X_1 and X_2 whose joint probability distribution puts mass only at four points $(0,0)$, $(0,1)$, $(1,0)$, and $(1,1)$. Now, if $Cov(X_1, X_2) = 0$, then X_1 and X_2 must be independent.

A Sample Correlation Coefficient

We focus on a bivariate normal distribution. Let $(X_1, Y_1), \ldots, (X_n, Y_n)$ be iid $N_2\left(\mu_1, \mu_2, \sigma_1^2, \sigma_2^2, \rho\right)$ where $-\infty < \mu_1, \mu_2 < \infty, 0 < \sigma_1^2, \sigma_2^2 < \infty$ and $-1 < \rho < 1, n \ge 2$. Let us denote

$$\overline{X} = n^{-1}\Sigma_{i=1}^n X_i \quad \overline{Y} = n^{-1}\Sigma_{i=1}^n Y_i$$

$$S_1^2 = (n-1)^{-1}\Sigma_{i=1}^n (X_i - \overline{X})^2 \quad S_2^2 = (n-1)^{-1}\Sigma_{i=1}^n (Y_i - \overline{Y})^2$$

$$S_{12} = (n-1)^{-1}\Sigma_{i=1}^n (X_i - \overline{X})(Y_i - \overline{Y}) \quad r = S_{12}/(S_1 S_2).$$

Here, r is called the *Pearson* (or *sample*) *correlation coefficient*. This r is customarily used to estimate ρ.

The probability distribution of r is complicated, particularly when $\rho \ne 0$. But, even without explicitly writing the pdf of r, it is simple enough to see that the distribution of r can not involve μ_1, μ_2, σ_1^2 and σ_2^2.

Francis Galton introduced a numerical measure, r, which he termed "reversion" in a lecture at the Royal Statistical Society on February 9, 1877 and later called "regression." The term "cor-relation" or "correlation" probably appeared first in Galton's paper to the Royal Statistical Society on December 5, 1888. At that time, "correlation" was defined in terms of deviations from the median instead of the mean. Karl Pearson gave the definition and calculation of correlation r in 1897. In 1898, Pearson and his collaborators discovered that the standard deviation of r happened to be $(1-\rho^2)/\sqrt{n}$ when n was large. "Student" derived the "probable error of a correlation coefficient" in 1908. Soper (1913) gave large-sample approximations for the mean and variance of r which performed better than those proposed earlier by Pearson. Refer to DasGupta (1980) for more historical details.

The unsolved problem of finding the exact pdf of r for normal variates came to R. A. Fisher's attention via Soper's 1913 paper. The pdf of r was published in the year 1915 by Fisher for all values of $\rho \in (-1,1)$. Fisher, at the age of 25, brilliantly exploited the n-dimensional geometry to come up with the solution, reputedly within one week. Fisher's genius immediately came into limelight. Following the publication of Fisher's results, however, Karl Pearson set up a major cooperative study of the correlation. One will notice that in the team formed for this cooperative project (Soper et al. 1917) studying the distribution of the sample correlation coefficient, the young Fisher was not included. This happened in spite of the fact that Fisher was right there and he already earned quite some fame. Fisher felt hurt as he was left out of this project. One thing led to another. RA. Fisher and Karl Pearson continued criticizing each other even more as each held on to his own philosophical stand.

We will merely state the pdf of r when $\rho = 0$. This pdf is given by

$$f(r) = c\,(1-r^2)^{\frac{1}{2}(n-4)} \text{ for } -1 < r < 1,$$

where $c = \Gamma\left(\frac{1}{2}(n-1)\right)\left\{\sqrt{\pi}\,\Gamma\left(\frac{1}{2}(n-2)\right)\right\}^{-1}$ for $n \geq 3$. Using a simple transformation technique, one can easily derive the following result:

$r(n-2)^{1/2}(1-r^2)^{-1/2}$ has the Student's t distribution with $(n-2)$ degrees of freedom when $\rho = 0$.

Fisher's geometric approach (1915) also included the exact pdf of r in the form of an infinite power series for all values of $\rho \neq 0$. One may also look at Rao (1973, pp. 206–209) for a non-geometric approach.

Large-Sample Distribution

But, now suppose that one wishes to construct an *approximate* $100(1-\alpha)\%$ confidence interval for ρ, $0 < \alpha < 1$. In this case, one needs to work with the *non-null* distribution of r. We mentioned earlier that the *exact* distribution of r, when $\rho \neq 0$, was found with an ingenious geometric technique by Fisher (1915). That exact distribution being very complicated, Fisher (1915) proceeded to derive the following asymptotic distribution when $\rho \neq 0$:

$$\sqrt{n}(r-\rho) \xrightarrow{\mathcal{L}} N\left(0, (1-\rho^2)^2\right) \text{ as } n \to \infty.$$

For a proof, one may look at Sen and Singer (1993, pp. 134–136) among other sources.

One should realize that a variance stabilizing transformation may be useful here. We may invoke Mann-Wald Theorem (see Mukhopadhyay 2000, pp. 261–262) by requiring a suitable function $g(.)$ such that the asymptotic variance of $\sqrt{n}\,[g(r) - g(\rho)]$ becomes free from ρ. That is, we want to have:

$$g'(\rho)(1-\rho^2) = k, \text{ a constant.}$$

So, $g(\rho) = k\int \frac{1}{(1-\rho^2)}d\rho$. Hence, we rewrite

$$g(\rho) = \tfrac{1}{2}k\int\left\{\tfrac{1}{1-\rho} + \tfrac{1}{1+\rho}\right\}d\rho = \tfrac{1}{2}k\log\left\{\tfrac{1+\rho}{1-\rho}\right\} + \text{constant.}$$

It is clear that we should look at the transformations:

$$U = \frac{1}{2}\log\left\{\frac{1+r}{1-r}\right\} \text{ and } \xi = \frac{1}{2}\log\left\{\frac{1+\rho}{1-\rho}\right\},$$

and consider the asymptotic distribution of $\sqrt{n}[U-\xi]$. Now, we can claim that

$$\sqrt{n}[U-\xi] \xrightarrow{\mathcal{L}} N(0,1) \text{ as } n \to \infty,$$

since with $g(\rho) = \frac{1}{2}\log\left\{\frac{1+\rho}{1-\rho}\right\}$, one has $g'(\rho) = \frac{1}{1-\rho^2}$. That is, for large n, we should consider the following pivot:

$\sqrt{n}[U-\xi]$, which is approximately $N(0,1)$ for large n.

These transformations can be *equivalently* stated as

$$U = \tanh^{-1}(r) \text{ and } \xi = \tanh^{-1}(\rho),$$

which are referred to as Fisher's Z transformations introduced in 1925.

Fisher obtained the first four moments of $\tanh^{-1}(r)$ which were later updated by Gayen (1951). It turns out that the variance of $\tanh^{-1}(r)$ is approximated better by $\frac{1}{n-3}$ rather than $\frac{1}{n}$ when n is moderately large. Hence, in many applications, one uses an alternate pivot (for $n > 3$):

$$\sqrt{n-3}\left[\tanh^{-1}(r) - \tanh^{-1}(\rho)\right], \text{ which is approximately } N(0,1),$$

for large n whatever be ρ, $-1 < \rho < 1$.

For large n, one customarily uses Fisher's Z transformations to come up with an *approximate* $100(1-\alpha)\%$ confidence interval for ρ. Also, to test a null hypothesis $H_0 : \rho = \rho_0$, for large n, one uses the test statistic

$$Z_{calc} = \sqrt{n-3}\left[\tanh^{-1}(r) - \tanh^{-1}(\rho_0)\right]$$

and comes up with an *approximate* level α test against an appropriate alternative hypothesis. These are customarily used in all areas of statistical science whether the parent population is bivariate normal or not.

Partial Correlations

Suppose that in general $\mathbf{X} = (X_1, \ldots, X_p)$ has a p-dimensional probability distribution with all pairwise correlations finite. Now, ρ_{X_i,X_j} will simply denote the correlation coefficient between X_i, X_j based on their joint bivariate distribution derived from the distribution of $\mathbf{X}$, for any $i \neq j = 1, \ldots, p$.

Next, $\rho_{X_i,X_j.X_k}$ is simply the correlation coefficient between X_i, X_j based on their joint bivariate conditional distribution given X_k that is derived from the distribution of $\mathbf{X}$, for any $i \neq j \neq k = 1, \ldots, p$.

Similarly, $\rho_{X_i,X_j.X_k,X_l}$ is simply the correlation coefficient between the pair of random variables X_i, X_j based on their joint bivariate conditional distribution given X_k, X_l derived from the distribution of $\mathbf{X}$, for any $i \neq j \neq k \neq l = 1, \ldots, p$. Clearly, one may continue further like this.

Such correlation coefficients $\rho_{X_i,X_j.X_k}$, $\rho_{X_i,X_j.X_k,X_l}$ are referred to as partial correlation coefficients. Partial correlation coefficients have important implications in multiple linear regression analysis. One may refer to Ravishanker and Dey (2002, pp. 160–164) among other sources.

Correspondence Analysis

Jörg Blasius
Professor
University of Bonn, Bonn, Germany

Correspondence analysis (CA) has been developed in the 1960s in France by Jean-Paul Benzécri and his collaborators; it is the central part of the French "Analyse des Données," or in English, geometric data analysis (cf. Benzécri et al. 1973; Greenacre 1984, 2007; Lebart et al. 1984; Le Roux and Rouanet 2004). The method can be applied to any data table with nonnegative entries. The main objective of CA is to display rows and columns of data tables in two-dimensional spaces, called "maps." This kind of data description via visualization reflects a way of thinking that is typical for the social sciences in France, especially associated with the name of Pierre Bourdieu, and of many statisticians in the 1970s and 1980s in France, who at that time published almost only in French. The philosophy behind their work can be expressed by the famous quotation of Jean-Paul Benzécri who pointed out that "The model must follow the data, and not the other way around." Instead of limiting the data to restrictive and subjectively formulated statistical models, they show the importance of the data and of the features in the data themselves. The discussion outside of France started with the textbooks by Greenacre (1984) and Lebart et al. (1984).

CA translates deviations from the independence model in a contingency table into distances as the following brief introduction shows. In the simple case, there is a two-way table $\mathbf{N}$ with I rows and J columns. In cases where the data are from survey research, the cells n_{ij} of $\mathbf{N}$ contain the frequencies of a bivariate cross-tabulation of two variables, with $\sum_{ij} n_{ij} = n$. Dividing n_{ij} by the sample size n provides the percentages of the total p_{ij}, or, for the entire table, with the $(I \times J)$ correspondence matrix $\mathbf{P}$. Thereby, $\mathbf{r} = \mathbf{P1}$ is the vector of the "row masses," or the "average column profile" with elements $r_i = n_{i+}/n$, and $\mathbf{c} = \mathbf{P}^T\mathbf{1}$ is the vector of "column masses" or the "average row profile" with elements $c_j = n_{+j}/n$; $\mathbf{D}_r$ and $\mathbf{D}_c$ are the diagonal matrices of the row and column masses, respectively.

The matrix of row profiles can be defined as the rows of the correspondence matrix $\mathbf{P}$ divided by their respective row masses, $D_r^{-1}P$; for the matrix of columns profiles yields PD_c^{-1}. As a measure of similarity between two row profiles (or between two column profiles, respectively), a weighted Euclidian or chi-square distance in the metric D_r^{-1} (or, D_c^{-1}, respectively) is used. For chi-square calculations, the weighted deviations from independence over all cells of the contingency table are used. For each cell, the unweighted deviation of the observed from the expected value can be calculated by $(n_{ij} - \hat{n}_{ij})$, with $\hat{n}_{ij} = (n_{i+} \times n_{+j})/n$. Dividing $(n_{ij} - \hat{n}_{ij})$ by n provides with $(p_{ij} - r_i c_j)$, or, in matrix notation, $(\mathbf{P} - \mathbf{rc}^T)$, with the unweighted deviations from the independence model for the entire table.

To fulfill the chi-square statistic, this matrix is weighted by the product of the square root of the row and column masses to give the standardized residuals $s_{ij} = (p_{ij} - r_i c_j)/\sqrt{r_i c_j}$, or in matrix notation, the $(I \times J)$ matrix of

standardized residuals $S = D_r^{-1/2}(P - rc^T)D_c^{-1/2}$. The similarity to chi-square analysis and total inertia as a measure for the variation in the data table, which is defined as $\sum_{ij} s_{ij}^2 = \frac{\chi^2}{n} = \sum_{i=1}^{I}\sum_{j=1}^{J}\frac{(p_{ij} - r_i c_j)^2}{r_i c_j}$, becomes apparent. Applying singular value decomposition to $\mathbf{S}$ results in $SVD(\mathbf{S}) = U\mathbf{\Gamma}V^T$, where $\mathbf{\Gamma}$ is a diagonal matrix with singular values in descending order $\gamma_1 \geq \gamma_2 \geq \ldots \geq \gamma_S > 0$, with S = rank of $\mathbf{S}$. The columns from $\mathbf{U}$ are the left singular vectors, the columns from $\mathbf{V}$ are the right singular vectors, with $\mathbf{U}^T\mathbf{U} = \mathbf{V}^T\mathbf{V} = \mathbf{I}$.

The connection between SVD as used in CA and the well-known canonical decomposition is shown by $S^TS = V\mathbf{\Gamma}\mathbf{U}^TU\mathbf{\Gamma}\mathbf{V}^T = V\mathbf{\Gamma}^2\mathbf{V}^T = V\mathbf{\Lambda}V^T$, with $SS^T = U\mathbf{\Gamma}\mathbf{V}^TV\mathbf{\Gamma}\mathbf{U}^T = U\mathbf{\Gamma}^2\mathbf{U}^T = U\mathbf{\Lambda}U^T$, and $\lambda_1 \geq \lambda_2 \geq \ldots \geq \lambda_S > 0$; $\chi^2/n = \sum_s \lambda_s$ = total inertia, since trace $(\mathbf{SS}^T)$ = trace $(\mathbf{S}^T\mathbf{S})$ = trace $(\mathbf{\Gamma}^2)$ = trace $(\mathbf{\Lambda})$.

As in ▶principal component analysis (PCA), the first axis is chosen to explain the maximum variation in the data; the second axis captures the maximum of the remaining variation, and so on. Again, analogous to PCA, it is possible to interpret the variable categories in relation to the axes, which can be considered the latent variables. And furthermore, as in PCA and other data reduction methods, only the s major components are used for interpretation. The number of interpretable dimensions depends on criteria such as the eigenvalue criteria, theory (how many latent variables can be substantively interpreted), or the scree test (for more details, see Blasius 1994).

For the graphical representation, we use $F = D_r^{-1/2}U\mathbf{\Gamma}$ providing the principal coordinates of the rows, and $G = D_c^{-1/2}V\mathbf{\Gamma}$ providing the principal coordinates of the columns (for further details see Greenacre 1984, 2007). The maps drawn on the basis of principal coordinates are called "symmetric maps." In the full space, the distances between the rows and the distances between the columns can be interpreted as Euclidian distances, whereas the distances between the rows and the columns are not defined.

As in PCA, the input data can be factorized. Understanding correspondence analysis as a model (see, e.g., van der Heijden et al. 1989, 1994), the row and column coordinates can be used for recomputing the input data. Adding the latent variables successively models the deviations from independency. This is similar to the loglinear model and other modeling approaches such as the latent class model or the log-multiplicative model (see, e.g., van der Heijden et al. 1989, 1994; Goodman 1991). In loglinear analysis, for example, these deviations are modeled by using higher-order interaction effects; in correspondence analysis latent variables are used. For any cell yields $n_{ij} = nr_ic_j\left(1 + \sum_{s=1}^{S} f_{is}g_{js}/\gamma_s\right)$, or $p_{ij} = r_ic_j\left(1 + \sum_{s=1}^{S} f_{is}g_{js}/\gamma_s\right)$, and in matrix notation $P = rc^T + D_rF\mathbf{\Gamma}^{-1}G^TD_c$. The left part of the equation reflects the independence model and the right part, the modeling from independency by including the S factors in successive order. Including all factors in the model fully reconstructs the original data table $\mathbf{N}$.

The interpretation of CA is similar to the one of PCA, both methods provide eigenvalues and their explained variances, factor loadings, and factor values. While PCA is restricted to metric data, CA can be applied to any kind of data table with nonnegative entries, among others, to indicator and Burt matrices – in these two cases the method is called multiple correspondence analysis (MCA).

Whereas simple correspondence analysis is applied to a single contingency table or to a stacked table, MCA uses the same algorithm to an indicator or a Burt matrix. In the case of survey research, input data to simple CA is usually a matrix of raw frequencies of one or more contingency tables. In this context, there is usually one variable to be described, for example, preference for a political party, and one or more describing variables, for example, educational level and other sociodemographic indicators such as age groups, gender, and income groups. The number of variables can be quite high, apart from theoretical considerations there is no real limitation by the method. In the given case, each of the describing variables is cross-tabulated with the variable to be described in order to investigate the importance of this association. Concatenating, or stacking the tables before applying CA allows to visualize and interpret several relationships of "preferred political party" with the sociodemographic indicators in the same map.

Applying CA to the indicator matrix $\mathbf{Z}$ (=MCA), the table of input data has as many rows as there are respondents, and as many columns as there are response alternatives in all variables included in the analysis. A "1" in a given row indicates the respondent who chose that specific response category; otherwise there is a "0" for "specific response category not chosen." Considering all categories of all variables provides row sums that are constant and equal to the number of variables, the column sums reflect the marginals. An alternative to the indicator matrix as input to MCA is the Burt matrix $\mathbf{B}$. This matrix can either be generated by cross-tabulating all variables by all variables, including the cross-tabulations of the variables by themselves, and stacking them row- and column-wise. Further, $\mathbf{B}$ can be computed by multiplying the transposed indicator matrix by itself, that is $\mathbf{B} = \mathbf{Z}^T\mathbf{Z}$. The solutions from $\mathbf{Z}$ can be directly converted to those of $\mathbf{B}$ by rescaling the solution; for example, the squared eigenvalues of $\mathbf{Z}$

are equal to those of **B**. As it is true for PCA, MCA contains all first-order interaction effects, the method can be understood as a generalization of PCA to categorical data.

Taking a two-way contingency table with $I = 7$ rows, $J = 5$ columns, and $n = 500$ cases as an example, input data of the simple CA would be the frequencies of the (7×5) cross-table. Turning to MCA, input data is an indicator matrix with 500 rows (the number of cases) and 12 columns (the number of variable categories). MCA is also known under the names "homogeneity analysis" (see Gifi 1990; Heiser and Meulman 1994), "dual scaling" (Nishisato 1980, 2007), and "quantification of qualitative data III" (Hayashi 1954); CA procedures are available in all major statistic packages as well as in *R* (Greenacre and Nenadić 2006). For details regarding the history of CA and related methods, we refer to Nishisato (2007, Chap. 3).

CA employs the concept of inertia: the farther the categories are from the centroid along a given axis (squared distances) and the higher their masses (their marginals), the more the categories determine the geometric orientation of that axis. In the graphical solution, the locations of all variable categories can be compared to each other (except in simple CA and using symmetric maps, in this case the distances between rows and columns are not defined), short distances imply high similarities and long distances imply high dissimilarities. For all dimensions, CA supplies principal inertias that can be interpreted as canonical correlation coefficients (they are the singular values of the solution, i.e., the square roots of the eigenvalues), correlation coefficients between the item categories and the latent variables as well as scores for all item categories and all respondents.

There are several extensions of simple CA and MCA. With respect to the Burt matrix **B**, it is apparent that most of the variation in this super matrix is caused by the main diagonal blocks. These sub-matrices contain the cross-tabulations of the variables by themselves; the main diagonal elements of them contain the marginals of the variables while their off-diagonal elements are equal to zero. Excluding this variation in an iterative procedure and visualizing the variation of the off-diagonal blocks of **B** only is the objective of joint correspondence analysis. The aim of subset correspondence analysis is to concentrate on some response categories only, while excluding others from the solution. For example, applying subset MCA to a set of variables, the structure of non-substantive responses ("don't know," "no answer") can be analyzed separately, or these responses can be excluded from the solution while concentrating on the substantive responses. Variables can also be included in the model as supplementary or passive ones; in this case they do not have any impact on the geometric orientation of the axes but they can be interpreted together with the active variables. CA can not only be applied to single and stacked contingency tables or to indicator matrix, it can also be used to analyze rank and metric data, multiple responses, or squared tables. The statistical background and examples of these kinds of data can be found in the textbook of Greenacre (2007) as well as in the readers of Greenacre and Blasius (1994, 2006), and Blasius and Greenacre (1998).

About the Author

Jörg Blasius is the President of RC33 (Research Committee of Logic and Methodology in Sociology) at ISA (International Sociological Association) (2006–2010). Together with Michael Greenacre (Barcelona) he founded CARME (Correspondence Analysis and Related Methods Network) and edited three books on Correspondence Analysis, in June 2009 they had a special issue on this topic in *Computational Statistics and Data Analysis* (further coeditors: Patrick Groenen and Michel van de Velden).

C_p Statistic

Colin Mallows
Basking Ridge, Avayalabs, NJ, USA

The C_p statistic was invented by C. Mallows in 1963. It facilitates the comparison of many subset-regression models, by giving for each model an unbiased estimate of the (scaled) total mean-square-error for that model. There is an associated graphical technique called the "C_p plot" in which values of C_p (one for each subset of regressors) are plotted against p.

The problem in choosing a subset-regression model for predicting a response is that including too many unnecessary terms will add to the variance of the predictions, while including too few will result in biased predictions.

In more detail, if we have n observations, and k regressors are available (possibly including a constant term), let P denote some subset of these. (Usually if a constant term is to be considered, this will appear in each subset). Let p be the number of regressors in the subset P. Then C_p (for the P-subset model) is defined to be

$$C_p = \frac{RSS_P}{s^2} - n + 2p$$

where RSS_P is the residual sum of squares for this P-model, and s^2 is an estimate of the residual variance when all relevant terms are included in the model. Usually this is taken to be RSS_K where K is the set of all available regressors.

Under the usual assumptions, that the vector of observations y equals $v + z$ where v is the vector of true means, and the z's are independent with mean zero and constant variance σ^2, $s^2 C_p$ is an unbiased estimate of $\sigma^2 E(J_P)$ where J_P is $|\hat{v}_P - v|^2$, and where $\hat{v}_P$ is the estimate of v that is obtained by fitting the P model. Thus J_P is a measure of the adequacy for prediction of the P model. This result holds even when the true model v is not expressible in terms of the available regressors. However in this case we cannot use the residual sum of squares from the full (K) model as an estimate of σ^2.

The C_p statistic is often used to guide selection of a subset-model, but this cannot be recommended; while for each P separately, C_p gives an unbiased estimate of the scaled mean-square error for that subset, this is not true if the subset is chosen to minimise C_p. In fact this approach can lead to worse results than are obtained by simply fitting all available regressors. In a 1995 paper, Mallows has attempted to quantify this effect.

The C_p statistic is similar to ►Akaike's Information criterion.

About the Author

Colin L. Mallows spent 40 years at AT&T Bell Labs and one of its descendants, AT&T Labs. Since retiring he has been a consultant at another descendant, Avaya Labs. He is a Fellow of the American Statistical Association, the Institute of Mathematical Statistics, and the Royal Statistical Society. He has served on several committees of the IMS and ASA. He was an Associate editor of JASA (1966–1972). He has been COPSS Fisher Lecturer and ASA Deming Lecturer, and has received the ASA Wilks Medal. He has written over 150 papers, and has edited two books.

Cramér–Rao Inequality

Maarten Jansen[1], Gerda Claeskens[2]
[1]Université libre de Bruxelles, Brussels, Belgium
[2]K. U. Leuven, Leuven, Belgium

The Cramér–Rao Lower Bound

The Cramér–Rao inequality gives a lower bound for the variance of an unbiased estimator of a parameter. It is named after work by Cramér (1946) and Rao (1945). The inequality and the corresponding lower bound in the inequality are stated for various situations. We will start with the case of a scalar parameter and independent and identically distributed random variables $X_1, \ldots, X_n$, with the same distribution as X.

Denote $\boldsymbol{X} = (X_1, \ldots, X_n)$ and denote the common probability mass function or probability density function of X at a value x by $f(x;\theta)$ where $\theta \in \Theta$, which is a subset of the real line $\mathbb{R}$ and $x \in \mathbb{R}$. Denote the support of X by R, that is, $R = \{x : f(x;\theta) > 0\}$.

Assumptions

1. The partial derivative $\frac{\partial}{\partial\theta} \log f(x;\theta)$ exists for all $\theta \in \Theta$ and all $x \in R$ and it is finite. This is equivalent to stating that the Fisher information value $I_X(\theta) = E\left[\left(\frac{\partial}{\partial\theta} \log f(X;\theta)\right)^2\right]$ is well defined, for all $\theta \in \Theta$.
2. The order of integration and differentiation is interchangeable in $\int \frac{\partial}{\partial\theta} \log f(x;\theta) dx$. If the support of X, that is, the set R, is finite, then the interchangeability is equivalent with the condition that the support does not depend on θ. A counter-example on uniformly distributed random variables is elaborated below.

The Cramér–Rao inequality

Under assumptions (i) and (ii), if $\hat{\theta} = g(\boldsymbol{X})$ is an unbiased estimator of θ, this means that $E[\hat{\theta}] = \theta$, then

$$\mathrm{var}(\hat{\theta}) \geq 1/\left[n \cdot I_X(\theta)\right].$$

The lower bound in this inequality is called the Cramér–Rao lower bound.

The proof starts by realizing that the correlation of the score $V = \frac{\partial}{\partial\theta} \sum_{i=1}^{n} \log f_X(X_i;\theta)$ and the unbiased estimator $\hat{\theta}$ is bounded above by 1. This implies that $\left(\mathrm{var}(V) \cdot \mathrm{var}(\hat{\theta})\right)^{1/2} \geq \mathrm{cov}(V, \hat{\theta})$. The assumptions are needed to prove that the expected score $E(V)$ is zero. This implies that the covariance $\mathrm{cov}(V, \hat{\theta}) = 1$, from which the stated inequality readily follows.

A second version of the Cramér–Rao inequality holds if we estimate a functional $\kappa = H(\theta)$. Under assumptions (i) and (ii), if $\boldsymbol{X}$ is a sample vector of independent observations from random variable X with density function $f(x;\theta)$ and $\hat{\kappa} = h(\boldsymbol{X})$ is an unbiased estimator of $H(\theta)$, such that the first derivative $\frac{dH(\theta)}{d\theta}$ exists and is finite for all θ, then

$$\mathrm{var}(\hat{\kappa}) \geq \left[\frac{dH(\theta)}{d\theta}\right]^2 / \left[n \cdot I_X(\theta)\right].$$

Similar versions of the inequality can be phrased for observations that are independent but not identically distributed.

In the case of a vector parameter $\boldsymbol{\theta}$, the variance of the single parameter estimator $\mathrm{var}(\hat{\theta})$ is replaced by the covariance matrix of the estimator vector $\Sigma_{\hat{\boldsymbol{\theta}}}$. This matrix is bounded by a matrix expression containing the inverse of the Fisher information matrix, where bounded means that the difference between the covariance matrix and its "upper bound" is a negative semidefinite matrix.

The Cramér–Rao inequality is important because it states what the best attainable variance is for unbiased estimators. Estimators that actually attain this lower bound are called efficient. It can be shown that maximum likelihood estimators asymptotically reach this lower bound, hence are asymptotically efficient.

Cramér–Rao and UMVUE

If $\boldsymbol{X}$ is a sample vector of independent observations from the random variable X with density function $f_X(x;\theta)$ and $\hat{\theta} = g(\boldsymbol{X})$ is an unbiased estimator of θ, then $\mathrm{var}(\hat{\theta}) = 1/\left[n \cdot I_X(\theta)\right] \Leftrightarrow \hat{\theta} = aV + b$ with probability one, where V is the score and a and b are some constants. This follows from the proof of the Cramér–Rao inequality: the lower bounded is reached if the correlation between the score and the estimator is one. This implies that $\mathrm{var}\left(\frac{V}{\sigma_V} + \frac{\hat{\theta}}{\sigma_{\hat{\theta}}}\right) = 0 \Rightarrow \frac{V}{\sigma_V} + \frac{\hat{\theta}}{\sigma_{\hat{\theta}}} = c$ almost surely for some constant c. We here used the notation σ_X to denote the standard deviation of a random variable X.

The coefficients a and b may depend on θ, but $\hat{\theta}$ should be observable without knowing θ.

If a and b exist such that $\hat{\theta}$ is unbiased and observable, then $\hat{\theta}$ has the smallest possible variance among all unbiased estimators: it is then certainly the uniformly minimum variance unbiased estimator (UMVUE).

It may, however, be well possible that no a and b can be found. In that case, the UMVUE, if it exists, does not reach the Cramér-Rao lower bound. In that case, the notion of *sufficiency* can be used to find such UMVUE.

Counter example: estimators for the upperbound of uniform data

Let $X \sim \text{unif}[0,a]$, so $f_X(x) = \frac{1}{a} I(0 \le x \le a)$, where $I(c \le x \le d)$ is the *indicator* function of the interval $[c,d]$. We want to estimate a. The maximum likelihood estimator (MLE) is $\hat{a}_{\text{MLE}} = \max_{i=1,\ldots,n} X_i$, which is biased. Define $\hat{a}_u = \frac{n}{n-1}\hat{a}_{\text{MLE}}$, which is unbiased. The method of moments leads to an estimator $\hat{a}_{\text{MME}} = 2\overline{X}$, which is also unbiased. The score is $V_i = \frac{\partial}{\partial a} \log f_X(X_i;a) = -\frac{1}{a}$. This is a constant (so, not a random variable), whose expected value is of course *not zero*. This is because the partial derivative and expectation cannot be interchanged, as the boundary of the support of X depends on a. As a consequence, the Cramér–Rao lower bound is *not* valid here. We can verify that $\text{var}(\hat{a}_{\text{MLE}}) = \frac{n}{(n+2)(n+1)^2} a^2$ and $\text{var}(\hat{a}_u) = \frac{1}{n(n+2)} a^2$. This is (for $n \to \infty$) one order of magnitude smaller than $\text{var}(\hat{a}_{\text{MME}}) = \frac{1}{3n} a^2$ and also one order of magnitude smaller than what you would expect for an unbiased estimator if the Cramér–Rao inequality would hold.

A Bayesian Cramér–Rao Bound

It should be noted that biased estimators can have variances below the Cramér–Rao lower bound. Even the MSE (mean squared error), which equals the sum of the variance and the squared bias can be lower than the Cramér–Rao lower bound (and hence lower than any unbiased estimator could attain). A notable example in this respect is Stein's phenomenon on shrinkage rules (Efron and Morris 1977).

In practice, large classes of estimators, for example most nonparametric estimators, are biased. An inequality that is valid for biased or unbiased estimators is due to van Trees (1968, p. 72), see also Gill and Levit (1995) who developed multivariate versions of the inequality.

We assume that the parameter space Θ is a closed interval on the real line and denote by g some probability distribution on Θ with density $\lambda(\theta)$ with respect to the Lebesgue measure. This is where the Bayesian flavor enters. The θ is now treated as a random variable with density λ. We assume that λ and $f(x;\cdot)$ are absolutely continuous and that λ converges to zero at the endpoints of the interval Θ. Moreover we assume that $E[\frac{\partial}{\partial\theta} \log f(X;\theta)] = 0$. We denote $I(\lambda) = E[\{\log \lambda(\theta)\}^2]$ and have that $E[I_X(\theta)] = \int I_X(\theta) g(\theta) d\theta$. Then, for an estimator $\hat{\theta} = \hat{\theta}(X)$, it holds that

$$E[\{\hat{\theta} - \theta\}^2] \ge \frac{1}{E[I_X(\theta)] + I(\lambda)}.$$

A second form of this inequality is obtained for functionals $\kappa = H(\theta)$. Under the above assumptions, for an estimator $\hat{\kappa} = h(\boldsymbol{X})$ of $H(\theta)$, such that the first derivative $\frac{dH(\theta)}{d\theta}$ exists and is finite for all θ,

$$E[\{\hat{\kappa} - H(\theta)\}^2] \ge \frac{\{E[\frac{d}{d\theta} H(\theta)]\}^2}{E[I_X(\theta)] + I(\lambda)}.$$

Cramér–Von Mises Statistics for Discrete Distributions

Michael A. Stephens
Professor Emeritus
Simon Fraser University, Burnaby, B.C., Canada

Introduction

Cramér–von Mises statistics are well established for testing fit to continuous distributions; see Anderson (2010) and Stephens (2010), both articles in this encyclopedia. In this paper, the corresponding statistics for testing discrete distributions will be described.

Consider a discrete distribution with k cells labeled $1, 2, \ldots, k$, and with probability p_i of falling into cell i. Suppose n independent observations are given; let o_i be the observed number of observations and $e_i = np_i$ be the expected number in cell i. Let $S_j = \sum_{i=1}^{j} o_i$ and $T_j = \sum_{i=1}^{j} e_i$.

Then S_j/n and $H_j = T_j/n$ are the cumulated histograms of observed and expected values and correspond to the empirical distribution function $F_n(z)$ and the cumulative distribution function $F(.)$ for continuous distributions. Suppose $Z_j = S_j - T_j, j = 1, 2, \ldots, k$; the weighted mean of the Z_i is $\bar{Z} = \sum_{j=1}^{k} Z_j t_j$, where $t_j = (p_j + p_{j+1})/2$, with $p_{k+1} = p_1$. The modified Cramér–von Mises statistics are then defined as follows:

$$W_d^2 = n^{-1} \sum_{j=1}^{k} Z_j^2 t_j; \tag{1}$$

$$U_d^2 = n^{-1} \sum_{j=1}^{k} (Z_j - \bar{Z})^2 t_j; \tag{2}$$

$$A_d^2 = n^{-1} \sum_{j=1}^{k} Z_j^2 t_j / \{H_j(1 - H_j)\}. \tag{3}$$

note that $Z_k = 0$ in these summations, so that the last term in W_d^2 is zero. The last term in A_d^2 is of the form 0/0, and is set equal to zero.

The well-known Pearson χ^2 statistic is

$$\chi^2 = \sum_{i=1}^{k} (o_i - e_i)^2 / e_i.$$

Statistics corresponding to the Kolmogorov–Smirnov statistics (see ▶Kolmogorov-Smirnov Test) for continuous observations are

$$D_d^+ = \max_j (Z_j)/\sqrt{n}, D_d^- = \max_j (-Z_j)/\sqrt{n},$$

$$D_d = \max_j |Z_j|/\sqrt{n}.$$

Comments on the Definitions

1. Several authors have examined distributions of the Kolmogorov–Smirnov family, see Pettitt and Stephens (1977) and Stephens (1986) for tables and references. In general, for continuous data, the Kolmogorov–Smirnov statistic is less powerful as an omnibus test statistic than the Cramér–von Mises family; limited Monte Carlo studies suggest that this holds also for D_d.
2. The Cramér–von Mises and Kolmogorov–Smirnov statistics take into account the order of the cells, in contrast to the Pearson χ^2 statistic.
3. Use of t_j in these definitions ensures that the value of the statistic does not change if the cells are labelled in reverse order.

   For instance, in testing the ▶binomial distribution, one statistician might record the histogram of successes, and another the histogram of failures; or in a test involving categorical data such as the tones of a photograph, the histogram of cells with light to dark observations might be recorded, or *vice versa*.
4. The statistic U_d^2 is intended for use with a discrete distribution around a circle, since its value does not change with different choices of origin; this is why p_{k+1} is set equal to p_1.

Matrix Formulation

To obtain asymptotic distributions it is convenient to put the above definitions into matrix notation. Let a prime, e.g., Z', denote the transpose of a vector or matrix. Let $\mathbf{I}$ be the $k \times k$ identity matrix, and let p' be the $1 \times k$ vector $(p_1, p_2, \ldots, p_k)$. Suppose $\mathbf{D}$ is the $k \times k$ diagonal matrix whose j-th diagonal entry is $p_j, j = 1, \ldots, k$ and let $\mathbf{E}$ be the diagonal matrix with diagonal entries t_j, and $\mathbf{K}$ be the diagonal matrix whose (j,j)-th element is $K_{jj} = 1/\{H_j(1 - H_j)\}, j = 1, \ldots, k-1$ and $K_{kk} = 0$. Let o_i and e_i be arranged into column vectors $\mathbf{o}$, $\mathbf{e}$ (so that, for example, the j-th component of $\mathbf{o}$ is $o_j, j = 1, \ldots, k$). Then $Z = Ad$, where $d = o - e$ and A is the $k \times k$ partial- sum matrix

$$A = \begin{pmatrix} 1 & 0 & 0 & \ldots & 0 \\ 1 & 1 & 0 & \ldots & 0 \\ 1 & 1 & 1 & \ldots & 0 \\ \vdots & \vdots & \vdots & \ddots & \vdots \\ 1 & 1 & 1 & \ldots & 1 \end{pmatrix}.$$

The definitions become

$$W_d^2 = Z'EZ/n, \tag{4}$$

$$U_d^2 = Z'(I - E11')E(I - 11'E)Z/n, \tag{5}$$

$$A_d^2 = Z'EKZ/n, \tag{6}$$

$$X^2 = (d'D^{-1}d)/n = Z'A^{-1'}D^{-1}A^{-1}Z/n. \tag{7}$$

Asymptotic Theory

All Parameters Known

All four statistics above are of the general form $S = Y'MY$, where $Y = Z/\sqrt{n}$ and $\mathbf{M}$ is symmetric. For W_d^2, $M = E$, for U_d^2, $M = (I - E11')E(I - 11'E)$, and for A_d^2, $M = EK$. Also Y has mean 0. Suppose its covariance matrix is $\mathbf{\Sigma}_y$, to be found below; then S may be written

$$S = Y'MY = \sum_{i=1}^{k-1} \lambda_i (w_i' Y)^2, \tag{8}$$

where λ_i are the $k-1$ non-zero eigenvalues of $M\boldsymbol{\Sigma}_y$ and w_i are the corresponding eigenvectors, normalized so that $w_i'\boldsymbol{\Sigma}_y w_j = \delta_{ij}$ where δ_{ij} is 1 if $i=j$ and 0 otherwise.

As $n \to \infty$, the s_i tend to standard normal, and they are independent; the limiting distribution of S is that of S_∞ where

$$sinf S_\infty = \sum_{i=1}^{k-1} \lambda_i s_i^2 \tag{9}$$

which is a sum of independent weighted χ_1^2 variables.

Recall that $Y = Z/\sqrt{n} = Ad/\sqrt{n}$; its covariance $\boldsymbol{\Sigma}_y$ is found as follows. Calculate the $k \times k$ matrix

$$\boldsymbol{\Sigma}_0 = D - pp'; \tag{10}$$

this is the covariance matrix of $(o-e)/\sqrt{n}$. Then $\boldsymbol{\Sigma}_y = A\boldsymbol{\Sigma}_0 A'$, with entries $\boldsymbol{\Sigma}_{y,ij} = \min(H_i, H_j) - H_i H_j$.

For the appropriate M for the statistic required, the eigenvalues λ_i, $i = 1, \cdots, k$ of $M\boldsymbol{\Sigma}_y$ are used in (9) to obtain the limiting distribution of the statistic. The limiting distributions have been examined in detail in Choulakian et al. (1994).

Parameters Unknown

Cramér–von Mises statistics when the tested distribution contains unknown parameters θ_i have been investigated by Lockhart et al. (2007). The θ_i must be estimated efficiently, for example by maximum likelihood (ML). Suppose $\boldsymbol{\theta} = (\theta_1, \theta_2, \ldots, \theta_m)'$ is the vector of m parameters.

The log-likelihood is (omitting irrelevant constants)

$$L^* = \sum_{i=1}^{k} o_i \log p_i,$$

and p_i contains the unknown parameters. The ML estimation consists of solving the m equations

$$\frac{\partial L^*}{\partial \theta_j} = \sum_{i=1}^{k} \frac{o_i}{p_i} \frac{\partial p_i}{\partial \theta_j} = 0,$$

for $j = 1, \ldots, m$.

Let $\hat{\boldsymbol{\theta}}$ be the ML estimate of $\boldsymbol{\theta}$, let $\hat{p}$ be the estimate of p, evaluated using $\hat{\boldsymbol{\theta}}$, and let $\hat{e}$ be the estimated vector of expected values in the cells, with components $\hat{e}_j = n\hat{p}_j$. Then let $\hat{d} = (o - \hat{e})$ and $\hat{Z} = A\hat{d}$.

Define a k by m matrix B with entries

$$B_{i,j} = \partial p_i / \partial \theta_j$$

for $i = 1, \ldots, k$ and $j = 1, \ldots, m$. The matrix $B'D^{-1}B$ is the Fisher Information matrix for the parameter estimates. Define $V = (B'D^{-1}B)^{-1}$. The asymptotic covariance of $\hat{\boldsymbol{\theta}}$ is then V/n, the covariance of $\hat{d}/\sqrt{n}$ is $\boldsymbol{\Sigma}_d = \boldsymbol{\Sigma}_0 - BVB'$, where $\boldsymbol{\Sigma}_0$ is defined in (10), and the covariance of $\hat{Z}/\sqrt{n} = A\hat{d}/\sqrt{n} = \hat{Y}$ is

$$\boldsymbol{\Sigma}_u = A\boldsymbol{\Sigma}_d A'.$$

Then, as in the previous section, where parameters were known, the weights λ_i in the asymptotic distribution (9) are the k eigenvalues of $M\boldsymbol{\Sigma}_u$ for the appropriate M for the statistic required.

In practice, in order to calculate the statistics, using (4–7), the various vectors and matrices must be replaced by their estimates where necessary. For example, let matrix $\hat{D}$ be D with p replaced by $\hat{p}$ and similarly obtain $\hat{B}, \hat{E}, \hat{V}, \hat{K}$ and $\hat{\boldsymbol{\Sigma}}_0$ using estimates in an obvious way. The eigenvalues will also be found using the estimated matrices $\hat{\boldsymbol{\Sigma}}_u$ and $\hat{M}$. Consistent estimates of the λ_i will be obtained and (9) used to find the estimated asymptotic distribution.

Thus the steps are :

1. Calculate $\hat{V} = (\hat{B}'\hat{D}^{-1}\hat{B})^{-1}$.
2. Calculate $\hat{\boldsymbol{\Sigma}}_d = \hat{\boldsymbol{\Sigma}}_0 - \hat{B}\hat{V}\hat{B}'$ and $\hat{\boldsymbol{\Sigma}}_u = A\hat{\boldsymbol{\Sigma}}_d A'$.
3. For the statistic required, let $\hat{M}$ be the estimate of the appropriate M. Find the $k-1$ eigenvalues of $\hat{M}\hat{\boldsymbol{\Sigma}}_u$, or (equivalently) those of the symmetric matrix $\hat{M}^{1/2}\hat{\boldsymbol{\Sigma}}_u\hat{M}^{1/2}$ and use them in (9) to obtain the asymptotic distribution.

For practical purposes, percentage points of S_∞ using exact or estimated λs, can be used for the distributions of the statistics for finite n; this has been verified by many Monte Carlo studies. One therefore needs good approximate points in the upper tail of S_∞; these can be found from the percentage points of $S1$, where $S1$ has the distribution $a + b\chi_p^2$, and the a, b, p are chosen so that the first three cumulants of $S1$ match those of S_∞ in (9). These cumulants are $\kappa_j = 2^{j-1}(j-1)! \sum_{i=1}^{k-1} \lambda_i^j$. In particular, the mean κ_1 is $\sum_{i=1}^{k-1} \lambda_i$, the variance κ_2 is $\sum_{i=1}^{k-1} 2\lambda_i^2$ and κ_3 is $8\sum_{i=1}^{k-1} \lambda_i^3$. Then for the $S1$ approximation, $b = \kappa_3/(4\kappa_2)$, $p = 8\kappa_2^3/\kappa_3^2$, and $a = \kappa_1 - bp$. This approximation is generally accurate in the upper tail, at levels $\alpha < 0.15$. More accurate points can be obtained by the method of Imhof (1961).

About the Author

Michael A. Stephens is Professor Emeritus of Mathematics and Statistics at Simon Fraser University in Burnaby, British Columbia, Canada. Prior to that he taught at several universities including McGill, Nottingham, McMaster, and Toronto, and was a visiting professor at Stanford, Wisconsin-Madison, and Grenoble. He has (co-)authored over 100 papers on the analysis of directional data, continuous proportions, curve-fitting, and tests of fit. Professor Stephens was President of the Statistical Society of Canada in 1983. He is a Fellow of the Royal Statistical Society, and

his honors include membership in the International Statistical Institute, and fellowships of the American Statistical Association and the Institute of Mathematical Statistics. Dr. Stephens received the B.Sc. degree (1948) from Bristol University and A.M. degree (1949) in physics from Harvard University, where he was the first Frank Knox Fellow, and Ph.D. degree (1962) from the University of Toronto. In 1989 he was awarded the Gold Medal, Statistical Society of Canada for two main areas of research: analysis of directional data, and statistical theory and methods associated with goodness of fit.

Cross Classified and Multiple Membership Multilevel Models

Harvey Goldstein
Professor of Social Statistics
University of Bristol, Bristol, UK

Hierarchically Structured Data

Interesting real life data rarely conform to classical text book assumptions about data structures. Traditionally these assumptions are about observations that can be modelled with independently, and typically identically, distributed "error" terms. More often than not, however, the populations that generate data samples have complex structures where measurements on data units are not mutually independent, but depend on each other through complex structural relationships. For example, a household survey of voting preferences will typically show variation among households and voting constituencies (constituencies and households differ on average in their political preferences). This implies that the replies from individual respondents within a household or constituency will be more alike than replies from individuals in the population at large. Another example of such "hierarchically structured data" would be measurements on students in different schools, where, for example, schools differ in terms of the average attainments of their students. In epidemiology we would expect to find differences in such things as fertility and disease rates across geographical and administrative areas.

Techniques for modelling such data have come to be known as "multilevel" or "hierarchical data" models and basic descriptions of these are dealt with in other articles (*see* ►Multilevel Analysis). In the present article we shall consider two particular extensions to the basic multilevel model that allow us to fit structures that have considerable complexity and are quite commonly found, especially in the social and medical sciences.

The Basic Multilevel Model

A simple multilevel model for hierarchical data structures with normally distributed responses can be written as:

$$y_{ij} = \beta_0 + \beta_1 x_{1ij} + u_j + e_{ij},\ u_j \overset{iid}{\sim} N(0, \sigma_u^2),\ e_{ij} \overset{iid}{\sim} N(0, \sigma_e^2). \quad (1)$$

This might be applied to a sample, say, of school students where i indexes students (level 1), who are grouped within schools (level 2). The response y might be an attainment measure and x a predictor such as a prior test score. Often referred to as a "variance components" model this may be extended in a number of ways to better fit a data set. For example, we may introduce further covariates and we may allow the coefficients of such covariates to vary at level 2, so that, say, β_1, may vary from school to school. Another possibility is to allow the level 1 variance to depend on a set of explanatory variables, so that, for example, we can allow the variance between male students to be different from that for female students. We can have several responses that are correlated leading to a multivariate model, and we can consider non-normal responses, such as binary ones, in order to fit generalised linear multilevel models. We can also have several further levels; for example schools may be

grouped within school boards or authorities, so yielding a three level structure. Goldstein (2010) provides further details and discusses estimation methods.

Cross Classified Structures

The above only describes purely hierarchical models. In practice, however, data structures are often more complicated. Consider an educational example where students move through both their primary and secondary education with the response being attainment at the end of secondary school. For any given primary school, students will generally move to different secondary schools, and any given secondary school will draw students from a number of primary schools. We therefore have a *cross classification* of primary by secondary schools where each cell of the classification will be populated by students (some may be empty). When we model such a structure we have a contribution to the response that is the sum of an effect from the primary and an effect from the secondary school attended by a student. A basic, variance components, cross classified model may be written as

$$\begin{aligned} y_i^{(1)} &= \beta_0 + \beta_1 x_{1i} + u^{(2)}_{\text{primary school}(i)} + u^{(3)}_{\text{secondary school}(i)} \\ &\quad + u^{(1)}_{\text{student}(i)} \\ u^{(2)}_{\text{primary school}(i)} &\overset{iid}{\sim} N(0, \sigma^2_{u(2)}), \\ u^{(3)}_{\text{secondary school}(i)} &\overset{iid}{\sim} N(0, \sigma^2_{u(3)}) \\ u^{(1)}_{\text{student}(i)} &\overset{iid}{\sim} N(0, \sigma^2_{u(1)}),\ i = 1, \ldots, N. \end{aligned} \tag{2}$$

We have changed the notation to make it more general and flexible. The superscript refers to the set of units, or classification; 1 being students, 2 primary school and 3 secondary school. Model (2) thus assumes that there are separate, additive, contributions from the primary and the secondary school attended. As with the simple hierarchical model we can extend (2) in several ways by introducing random coefficients, complex variance structures and further cross classifications and levels. There are many examples where cross classified structures are important. Thus, for example, students will generally be grouped by the neighborhood where they live and this will constitute a further classification. In a repeated measures study where there is a sample of subjects and a set of raters or measurers, if the subjects are rated by different people at each occasion we would have a cross classification of subjects by raters.

Multiple Membership Structures

In many circumstances units can be members of more than one higher level unit at the same time. An example is friendship patterns where at any time individuals can be members of more than one friendship group. In an educational system students may attend more than one school over time. In all such cases we shall assume that for each higher level unit to which a lower level unit belongs there is a known weight (summing to 1.0 for each lower level unit), which represents, for example, the amount of time spent in the higher level unit. The choice of weights may be important but is beyond the scope of this article. For more details about choosing weights see Goldstein et al. (2007).

Using the general notation we used for cross classifications we can write a basic variance components multiple membership model as

$$\begin{aligned} y_i^{(1)} &= \beta_0 + \beta_1 x_i + \sum_{j \in school(i)} w^{(2)}_{i,j} u^{(2)}_{(j)} + u^{(1)}_i \\ u^{(2)}_{(j)} &\sim N(0, \sigma^2_{u(2)}),\ u^{(1)}_{(i)} \sim N(0, \sigma^2_{u(1)}) \\ \sum_{j \in school(i)} w^{(2)}_{i,j} &= 1. \end{aligned} \tag{3}$$

This assumes that the total contribution from the level 2 units (schools) is a weighted sum over all the units of which the level 1 unit has been a member. Thus, for example, if every student spends half their time in one school and half their time in another (randomly selected) then the variance at level 2 will be

$$\text{var}(0.5u^{(2)}_{j_1} + 0.5u^{(2)}_{j_2}) = \sigma^2_{u(2)}/2. \tag{2}$$

Thus, a failure to account for the multiple membership of higher level units in this case will lead us to treat the estimate of the level 2 variance, $\sigma^2_{u(2)}/2$ as if it were a consistent estimate of the true level 2 variance $\sigma^2_{u(2)}$. More generally, ignoring a multiple membership structure will lead to an underestimation of the higher level variance.

Finally, we can combine cross classified and multiple membership structures within a single model and this allows us to handle very complex structures. An example where the response is a binary variable is given in Goldstein (2010, Chap. 13). It is possible to use maximum likelihood estimation for these models, but apart from small scale datasets, MCMC estimation is more efficient and flexible. The MLwiN software package (Rasbash et al. 2009; Browne 2009. http://www.cmm.bristol.ac.uk) is able to fit these models.

About the Author

Professor Goldstein is a chartered statistician, has been editor of the *Royal Statistical Society's Journal, Series A*, a member of the Society's Council and was awarded the Society's Guy medal in silver in 1998. He was elected a member of the International Statistical Institute in 1987, and a Fellow of the British Academy in 1996. He was awarded an honorary doctorate by the Open University in 2002.

His most important research interest is in the methodology of multilevel modelling. He has had research funding for this since 1986 and has been involved in the production (with Jon Rasbash and William Browne) of a widely used software package (MLwiN) and made a number of theoretical developments. These include multiple membership models, multilevel structural equation models and more recently the use of multilevel multivariate latent normal models and especially their application to missing data problems. The major text on multilevel modelling is his book *Multilevel Statistical Models* (New York, Wiley, Fourth Edition, 2010). He has also written extensively on the use of statistical modelling techniques in the construction and analysis of educational tests. The implications of adopting such models have been explored in a series of papers since 1977.

Cross-Covariance Operators

Charles R. Baker
Professor Emeritus
University of North Carolina, Chapel Hill, NC, USA

This article will initially treat joint probability measures and their associated cross-covariance operators. Subsequently, attention will be shifted to three examples of problems on capacity of information channels.

Cross-covariance operators were introduced in Baker (1970) as a tool in solving a basic problem in information theory, and treated more extensively in Baker (1973). Related results are in Gualtierotti (1979) and Fortet (1995). The empahsis in Baker (1973) was in two directions: showing the added power of analysis obtained by introducing the cross-covariance operator of a joint measure, and providing new results for actually computing likelihood ratios for joint measures. Applications to date have included results on absolute continuity of probability measures, mutual information for pairs of ►stochastic processes, and analysis of information capacity for communication channels. More recently, there has been interest in this topic by researchers in machine learning, who have applied theory from Baker (1973) in a number of interesting publications (e.g., Fukumizu et al. 2004, 2009; Gretton et al. 2005).

The joint measures to be discussed are probability measures on the product of two real separable Hilbert spaces, H_1 and H_2, with Borel sigma fields θ_1. and θ_2. Denote the inner products by $<,>_1$ on H_1 and $<,>_2$ on H_2. H_1 x H_2 is then a real separable Hilbert space under the inner product defined by $<(x,u),(v,y)>_{12} = <x,v>_1 + <u,y>_2$. Next, introduce a joint measure π_{12} on the measurable space (H_1 x H_2, θ_1 x θ_2). Only strong second-order probability measures will be considered: those joint measures ∂_{12} such that $E_{\partial_{1,2}}|||(x,y)||||^2_{12} = \int_{H_1xH_2}(||x||^2_1 + ||y||^2_2)d\partial_{12}(x,y)$ is finite. All Gaussian measures on H_1xH_2 are strong second order, as are their projections on H_1 and H_2. From the measure π_{12} one has projections π_i on (H_i, θ_i), $i = 1,2$. Let m_1 and m_2 denote the mean elements and R_1 and R_2 the covariance operators of π_1 and π_2.

The first result of note is the definition and properties of the cross-covariance operator for the joint measure π_{12}. Denoting that operator by C_{12}, it is defined for all (u,v) in H_1xH_2 by

$$<C_{12}v,u>_1 = \int_{H_1xH_2} <x - m_1,u>_1 <y - m_2,v>_2 \, d\pi_{12}(x,y).$$

Theorem 1 *C_{12} has representation $C_{12} = R_1^{1/2}VR_2^{1/2}$, V: $H_2 \to H_1$ a unique linear operator having $||V|| \le 1$ and $P_1VP_2 = V$, P_i the projection of H_i onto the closure of range(R_i).* ⊡

Next, we turn to the definition and properties of the covariance operator $\mathbf{R}_{12}$ of π_{12}. By direct computation (Baker 1973), one can show that this operator is defined on every element (u,v) in H_1xH_2 by

$$\begin{aligned}\mathbf{R}_{12}(u,v) &= (R_1u + C_{12}v, R_2v + C_{12}^*u)\\ &= (R_1 \otimes R_2)(u,v) + (C_{12}^* \otimes C_{12})(u,v).\end{aligned}$$

We now give a result that illustrates both similarity and difference between a joint measure and the usual measure.as defined on one of the spaces H_1 or H_2. We define a self-adjoint operator $\mathbf{V}$ in H_1xH_2 by $\mathbf{V}(u,v) = (Vv, V^*u) = (V^* \otimes V)(u,v)$ and denote by $\mathbf{I}$ the identity operator in H_1xH_2; it is shown in Baker (1973) that $||\mathbf{V}|| \le 1$ and that the non-zero eigenvalues of VV^* are squares of the non-zero eigenvalues of $\mathbf{V}$.

Theorem 2 *The covariance operator* $\boldsymbol{R}_{12}$ *of the measure* π_{12} *on* $H_1 x H_2$ *has representation* $\boldsymbol{R}_{12} = \boldsymbol{R}_{1\otimes 2}^{1/2}(\boldsymbol{I}+\boldsymbol{V})\boldsymbol{R}_{1\otimes 2}^{1/2}$, *where* $\boldsymbol{R}_{1\otimes 2}$ *is the covariance operator of the product measure* $\pi_1 \otimes \pi_2$. *If* π_{12} *is Gaussian, then* π_{12} *and* $\pi_1 \otimes \pi_2$ *are mutually absolutely continuous if and only if* $\boldsymbol{V}$ *is Hilbert-Schmidt with* $||\boldsymbol{V}|| < 1$, *and otherwise orthogonal.*⊡

The preceding results give some of the basic properties of the covariance operator of a joint measure, and it is seen that the cross-covariance operator is an essential component in the definition and properties of the covariance operator. In Baker (1973), considerable attention is given to Gaussian joint measures. However, it should be noted that the definition of the cross-covariance operator and its relation to the covariance operator hold for any strong-second order joint probability measure When the joint measure at hand is not Gaussian, one still has the cross-covariance operator available as well as the mean and the covariance operator. These functions can frequently be estimated from data and used to develop suboptimum but effective operations using (for example) second moment criteria.

We now turn to a brief introduction to three problems on the capacity of a Gaussian channel without feedback (Baker 1978, 1987; Baker and Chao 1996a, b). The cited papers provide examples of the use of results from Baker (1973) in applications to information theory. The definition of the channel capacity is as follows. We have a joint measure $\pi_{S,AS+N}$ where S is the actual signal, AS is the transmitted coded signal (from a measurable space (Ω, Θ)) and AS+N is the received waveform of signal+noise from a measurable space (Ψ, Γ). The (average) mutual information will be finite if $\pi_{S,AS+N}$ is absolutely continuous with respect to its product measure $\pi_{S\otimes AS+N}$, and its value is then given by

$$\int_{\Omega x \Psi} \log[(d\pi_{S,AS+N}/d\pi_{S\otimes AS+N})(x,y)]d\pi_{S,AS+N}(x,y).$$

The transmitted signal AS and the received AS+N can vary with choices by the coder (and the jammer in the third example below), and the channel capacity is the supremum of the mutual information over all admissible S and AS+N.pairs.

In each case, the transmitted signal has a constraint given in terms of the ambient noise process. When the constraint on the transmitted signal is given in terms of the channel noise covariance, one says that the channel is "matched" (coder constraint is matched to the channel noise covariance) (Baker 1978). The second type of channel is "mismatched" (the signal constraint is not given in terms of the channel noise covariance) (Baker 1987). The third class is the jamming channel without feedback, wherein the noise in the channel consists of a known Gaussian ambient noise (nature's contribution) plus an independent noise that is under the control of a hostile jammer (Baker and Chao 1996a, b). In this channel, there is a constraint on the jammer's noise as well as one on the coder's.transmitted signal.

In the jamming channel, the jammer has no constraints on the choice of the probability distributions of the noise at his command. However, it is known (Ihara 1978) that if the channel noise due to nature is Gaussian, then the information capacity is minimized by the jammer choosing (among all processes satisfying the constraints) a Gaussian process. Thus, the original problem becomes a problem involving an ambient Gaussian noise (which is used to calculate the coder's constraint) and an independent Gaussian process (jamming) giving the covariance constraint that the jammer uses.

Data Analysis

Alfredo Rizzi
Professor
Sapienza Università di Rome, Rome, Italy

The Development of Data Analysis

Data analysis began to be developed for use in statistical methodology in the early 1960s. Today, it includes a number of techniques which allow an acceptable synthesis of information collected from n statistical units or objects which are each characterized by p qualitative or quantitative variables.

The basics of certain data analysis techniques were established in the last century, principal components at the beginning of the 1900s, factor analysis in the 1930s, and automated classification methods in the 1940s.

During the same period, statistical methodology also saw development in statistical inference (classic and Bayesian) and in studies of interpretative models of complex phenomena (linear, loglinear, generalized linear, analysis of time series such as ARMA, ARIMA, autoregressive, etc.). Data analysis has made use and at times stimulated the development of two important "tools": the language of matrices and appropriate computer software requiring hardware with large memory capacity and very fast access to information.

The development of data analysis has been stimulated by the operational needs of its application in various sectors, in particular, business and the social sciences. For example, automatic classification methods are interesting applications used for classifying clients and market segments and for establishing homogeneity between company units and territorial administrative divisions. These methods are also applied in medicine for pattern recognition (see ►Pattern Recognition, Aspects of and ►Statistical Pattern Recognition Principles), for the automatic assessment of words used by speakers in different situations, as well as in many other sectors. Cluster analysis (see ►Cluster Analysis: An Introduction), when used in sample surveys of a population with known structural characteristics, allows one to reduce the variability within an equal sample size, thereby increasing precision. Multiway matrix analysis is especially interesting when seeking trends in a single location at different times or in different locations at the same time.

Methods such as ►multidimensional scaling allow us to represent a set of n objects belonging to a space with $p > 3$ dimensions in spaces of two or three dimensions, so that the distortion of the matrix of the distance between points is minimal. ►Principal component analysis has also been the subject of in-depth studies which have opened the way for its use in a wide variety of fields. ►Correspondence analysis, introduced by Benzécri at the end of the 1960s, is considered to be the acme of data analysis. The French school has, in some way, introduced this new sector of statistics to scholars and has carried out research in social sciences, economics, ►demography, and business using methodologies which have proved to be very useful in many research situations.

Data analysis uses not only the matrix language and advanced software mentioned above but also methods of mathematical optimization, the theory of eigenvalues (see ►Eigenvalue, Eigenvector and Eigenspace) which are of great importance in many analyses, certain results from vector analysis, the theory of graphs and operations research along with some theorems of mathematical analysis, and the theory of linear spaces and fuzzy sets. Important and interesting contributions to classification have been made by scientists studying mathematical optimization methods, who have introduced rigorous algorithms to establish the partitions of a set of n objects characterized by p variables, which constitute the statistical population or group of reference.

The studies carried out by Minkowski and Fréchet and other mathematicians on metrics are applicable to the realm of data analysis. Euclidean metrics is one of many but is often preferred by certain software for reasons of tradition. The *L1* norm, for example, and the geometry based on it is, in many research situations, better suited than other metrics to represent complex phenomena in various fields. But metrics in the traditional mathematical sense have proved completely inadequate for the applications.

Miodrag Lovric (ed.), *International Encyclopedia of Statistical Science*, DOI 10.1007/978-3-642-04898-2,

Therefore, these interesting studies of distance and similarity indices and, most importantly, of ultra-metrics have become an important part of data analysis.

It is also of great importance in data analysis to be very careful about conclusions drawn from surveys which have been carried out using methodologies which are not justified by the hypotheses on which the research is based. The great progress and widespread availability of hardware and software has made it possible for those who are not students or specialists in the field to carry out research. This may lead to data processing done without in-depth knowledge of the methodology, techniques, or parametrization used; so, the default settings are chosen by the software without an understanding of the meaning of many statistical parameters which allow an a posteriori evaluation of the goodness of the data model adopted.

The data coding step is of fundamental importance for the evaluation of any outcome although it is often given less attention than needed by those preferring to concentrate on the mathematical aspects of the analysis.

Inferential problems also arise in data analysis. Data analysis has, in the first stage, been viewed only as a methodology for synthesizing information with any probabilistic or inferential approach excluded. Attempts to apply classical inferential methodologies requiring strong distribution hypotheses, especially in the multidimensional field, have not led to any worthwhile outcome. In some techniques – such as principal components and factor analysis – inferential aspects were considered to be of primary importance and were the subject of wide studies during the first half of the last century.

As is often the case in scientific research, techniques used in statistical induction have proved to be unsuited to solving inferential problems in data analysis. Furthermore, in this field, induction has a wider meaning that is merely passing from "the sample to the population," both in terms of an estimate of the parameters and of a verification of the hypotheses. The themes of fundamental importance here are those concerning the stability of results in terms of knowing to what extent the relations found between individuals and/or between variables can be considered valid. The relations between variables – linear and nonlinear – are often very strong.

The verification of the hypotheses and the estimation of the parameters are not specific interests. One is nearly always concerned with data gathered from populations of a finite number of individuals, which makes the stability of the results extremely important. In sampling, on the other hand, it is important to carefully consider what the expected outcome is and what the meaning of the extension is. We are unaware of any studies of the sampling plans capable of guaranteeing an acceptable level of representation of the samples extracted. This is also a completely new field of research regarding the methodological instruments usable in this important field.

The Techniques of Data Analysis

The expression "data analysis" (*analyse des données in French*) or multidimensional data analysis (MDA) originated from the methodological approach first used in France in the late 1960s (Benzécri 1973; Bertier and Bouroche 1975; Caillez and Pages 1976, etc.). It includes two groups of multivariate statistical methods: classification methods or automatic clustering and linear data analysis and specifically principal component analysis, canonic correlation analysis, both simple and multiple correspondence analysis, and multidimensional scaling.

During the 1980s, MDA spreaded to other countries of Europe and was established as an autonomous branch of statistics. This created the conditions for new developments in both methodology and in applications, which characterize recent developments in multidimensional data analysis. There were important contributions in this area from Italian statisticians.

In addition to those mentioned above, there are other methods available for multivariate statistical analysis: regression, ►analysis of variance, discriminant analysis (see ►Discriminant Analysis: An Overview and ►Discriminant Analysis: Issues and Problems), common factor analysis, etc., in which probabilities and inferential aspects are treated. These may be called validation analyses for assumptions formulated about the multidimensional data set.

Inferential and validation aspects come into play in MDA and can also be introduced, with some conditions, into the methods. In general, the various methods of ►multivariate statistical analysis have different ways, depending on the purpose, to analyze, describe, and synthesize the relations between statistical characteristics and statistical units or cases.

It is useful to this purpose to divide the different methods of multivariate statistical analysis according to the role of the variables that come into play in the analysis. In the original MDA approach, the methods used for multivariate statistical analysis could be divided into:

Symmetric Analyses: with variables of the same role (interdependence). The principals are:

- Cluster analysis
- Principal component analysis
- Canonic correlation analysis
- Factor analysis of correspondences
- Common factor analysis
- Symmetric multidimensional scaling

Asymmetric Analyses: where some variables are explicative, independent attributes of other variables, dependent and endowed with attributes or where pairs of variables or units are ranked as in:

- Regression
- Analysis of variance
- Discriminant analysis
- Nonsymmetrical multidimensional scaling
- Path analysis

In the context of recent developments in MDA, such a split is no longer sharp because asymmetric variants have been introduced in all the main methods of data analysis. For example, in principal component analysis, the supplemental or passive variables can be treated as variables in a reference subspace instead of being handled as supplemental elements in the plots of the principal axes without having been used in the actual computations. Asymmetric variants have also been introduced in simple and multiple correspondence analysis.

Multiway data analysis concerning particular extensions of the methods of data analysis is linked to asymmetric data analysis because of the different role it assigns to variables. Instead of the traditional data classification according the two criteria (statistical units *x* variables), these methods are applied, with different approaches, to data classified according to three or more criteria or statistical ways (statistical units *x* variables *x* occurrences).

The combination of multivariate statistical methods and the automatic data processing necessary for this type of analysis is what brought about MDA. MDA is an important tool of ▶data mining. One can consider data mining to be a procedure that starts from elementary data in a Data Warehouse to arrive at a decision. One can consider data mining to be the heir of artificial intelligence and expert systems. In each case, MDA is the basis for discovering data structure.

Three-Way Data Analysis

Since the last 2 decades of the twentieth century, there has been growing attention paid to the analysis of phenomena characterized by a set **X** of *nkr* variables, observed on a set of *n* units on *r* occasions (different times, places, etc.). These phenomena must be distinguished from the classical multivariate and are referred to as multivariate-multioccasion. The set X is called a three-way data set because its elements can be classified according to modes: units, variables, and occasions. The data structure associated with this data set is a *three-indices* or *three-way array*.

The most widely collected three-way data set occurs when modes are units and variables and occasions are different times. Here, we will especially refer to this data type. The repetition in time of the observation of the units allows us to evaluate the dynamics of the phenomenon differently from the classical case of a multivariate or cross-sectional (two-way) data set. There are several major advantages over a conventional cross-sectional or time series data set in using these, so-called three-way longitudinal data. The researcher has a larger number of data which increases the degree of freedom and reduces collinearity among explanatory variables and the possibility of making inferences about the dynamics of change from cross-sectional evidence.

The three-way longitudinal data set may be given by:

- *Repeated recurring surveys with no overlapping units*. That is, a survey organization repeats a survey on a defined topic, generally at regular time intervals. No overlaps of the sample units are required at different times. Examples of these surveys are given by the repeated analyses made by Central Bureau of Statistics in most countries.
- *Repeated surveys with partially overlapping units*. These surveys are also repeated at regular intervals. The survey design includes rotating units to allow variance reduction, i.e., the units are included in the analysis a number of times, then rotated out of the survey.
- *Longitudinal surveys with no rotation of units*. A set of units is followed over time with a survey designed with this aim. In the economic field, these collected data are called ▶*panel data*. An example of this type is the Survey of Income.
- *Longitudinal surveys with rotation*. A group of units is followed for a period of time, so that new units are introduced and followed over time. These are repeated surveys with a partially overlapping units. An example of this type is the Monthly Retail Trade Survey.

In longitudinal surveys, it is generally the same variable which is observed on the units to allow comparison over time.

Examples of the applications of the analyses of three-way data sets are found in many different fields, including chemometrics*, biology, economics.

Different objectives can be pursued in analyzing three-way data sets:

1. To synthesize a three-way data set
2. To study the multiway variability of a three-way data set
3. To study the interrelationships between sets of elements of **X**:
   (a) Between sets of variates

(b) Between sets of units
(c) Between sets of occasions

4. To define virtual modes or derivational modes for the three sets of modes of **X**:
   (a) Virtual units
   (b) Factors or latent variables
   (c) Virtual occasions
5. To analyze individual differences in the judgments of different sets dissimilarities:
   (a) Three-way scaling of a replicated set of dissimilarities (replicated multidimensional scaling): metric and nonmetric Euclidean models
   (b) Weighted multidimensional scaling: metric and nonmetric weighted Euclidean models
6. To simultaneously classify different sets of the elements of **X**:
   (a) Clustering of units
   (b) Clustering of variables
   (c) Clustering of occasions
7. To give a linear or nonlinear model of **X**

Data Depth

Reza Modarres
Chair and Professor of Statistics
The George Washington University, Washington, D.C., USA

Data depth provides a systematic approach to order multivariate observations in R^d. A data depth function is any function $D(\mathbf{t}; F)$ that measures the closeness or centrality of a point $\mathbf{t} \in R^d$ with respect to a distribution function F. Thus, a depth function assigns to each $x \in R^d$ a nonnegative score as its center-outward depth with respect to F. Observations close to the center of F receive high ranks whereas peripheral observations receive low ranks. Hotelling (1929) characterized the univariate median as the point which minimizes the maximum number of observations on one of its sides. That is, $D(\mathbf{t}; F) = \min(F(t), 1 - F(t))$. This notion was generalized by Tukey (1975), giving rise to the definition of half-space or Tukey's multivariate depth (Donoho 1982). The seminal work of Oja (1983) and Liu (1990) has renewed interest in data depth functions. Over the past two decades, various new notions of data depth have emerged as powerful explanatory and inferential tools for nonparametric multivariate analysis. Zuo and Serfling (2000) proposed a formal framework for statistical depth functions based on the following four properties.

Let F be the class of distributions on the Borel set on R^d and $F_{\mathbf{X}}$ be the distribution function of a given random

vector $\mathbf{X}$. Let $D : R^d \times \mathrm{F} \longmapsto R$ be bounded, nonnegative, and satisfy the following four conditions:

- *Affine invariance:* $D(A\mathbf{t} + \mathbf{b}; F_{A\mathbf{X}+\mathbf{b}}) = D(\mathbf{t}; F_{\mathbf{X}})$ holds for any random vector $\mathbf{X}$, any $d \times d$ nonsingular matrix A, and any vectors $\mathbf{t}$ and $\mathbf{b}$ in R^d;
- *Maximality at center:* $D(\theta; F) = sup_{t \in R^d} D(\mathbf{t}; F)$ holds for any $F \in \mathrm{F}$ with center θ_F (a point of symmetry);
- *Monotonicity relative to deepest point:* For any $F \in \mathrm{F}$ with center θ, $D(\mathbf{t}; F) \leq D(\theta + \alpha(\mathbf{t} - \theta); F)$ holds for $\alpha \in [0, 1]$; and
- *Vanishing at infinity:* $D(\mathbf{t}; F) \to 0$ as $\| \mathbf{t} \| \to \infty$, for each $F \in \mathrm{F}$.

A sample version of $D(\cdot; F)$ is denoted by $D(\cdot; F_m)$, where F_m is the sample or empirical distribution function. Several novel depth functions have appeared in the literature, including Mahalanobis (*MD*) (Mahalanobis 1936), half-space (*HSD*) or Tukey's depth (Tukey 1975), convex hull peeling (*CHPD*) (Mosler 2002), simplicial volume (*SVD*) or Oja's depth (Oja 1983), majority (*MJD*) (Singh 1991), simplicial (*SD*) (Liu 1990), spatial (*SPD*) (Vardi and Zhang 2000), projection (*PD*) (Stahel 1981; Donoho, 1982), zonoid (*ZD*) (Koshevoy and Mosler 1997; Mosler, 2002); spherical (*SPHD*) (Elmore et al. 2006); and triangle (Liu and Modarres 2008) depth functions. Some of the above data depth functions are described below.

Let F be a multivariate distribution function in $R^d, d \geq 1$ and $\mathbf{X} = \{\mathbf{x}_1, \ldots, \mathbf{x}_m\}$ be a random sample from F. The Mahalanobis depth $MD(\mathbf{t}; F)$ is defined as

$$MD(\mathbf{t}; F) = \left[1 + (\mathbf{t} - \mu_F)\Sigma_F^{-1}(\mathbf{t} - \mu_F)\right]^{-1},$$

where μ_F and Σ_F are the mean vector and dispersion matrix of F, respectively. The sample version of $MD(\mathbf{t}; F)$ is obtained by replacing μ_F and Σ_F with their sample estimates. The half-space depth $HSD(\mathbf{t}; F)$ is defined as

$$\begin{aligned} HSD(\mathbf{t}; F) &= \inf_H \{P(H) : H \text{ is a closed half-space in } R^d \\ &\qquad \text{and } \mathbf{t} \in H\} \\ &= \inf_{\mathbf{u} \in R^d} P_F(\{\mathbf{X} : \mathbf{u}^T\mathbf{X} \geq \mathbf{u}^T\mathbf{t}\}) = \inf_{\|\mathbf{u}\|=1} \\ &\qquad P_F(\{\mathbf{X} : \mathbf{u}^T\mathbf{X} \geq \mathbf{u}^T\mathbf{t}\}). \end{aligned}$$

The sample version of $HSD(\mathbf{t}; F)$ is $HSD(\mathbf{t}; F_m) = \frac{1}{m} \min_{\|\mathbf{u}\|=1} \#\{i : \mathbf{u}^T\mathbf{x}_i \geq \mathbf{u}^T\mathbf{t}\}$.

The simplicial depth $SD(\mathbf{t}; F)$ is defined as $SD(\mathbf{t}; F) = P_F\{\mathbf{t} \in S[\mathbf{X}_1, \ldots, \mathbf{X}_{d+1}]\}$ where $S[\mathbf{X}_1, \ldots, \mathbf{X}_{d+1}]$ is a closed simplex formed by $(d + 1)$ random observations from F. The sample version of $SD(\mathbf{t}; F)$ is obtained by replacing F by F_m, or alternatively, by computing the fraction of the sample random simplices containing the point t. The projection depth $PD(\mathbf{t}; F)$ (Zuo 2003) is defined as $PD(\mathbf{t}; F) = (1 + O(\mathbf{t}; F))^{-1}$ where $O(\mathbf{t}; F)$ is a measure of outlyingness of a point $\mathbf{t}$ w.r.t. F. For example, the outlyingness of a point $\mathbf{t}$ can be defined as the maximum outlyingness of $\mathbf{t}$ with respect to the univariate median in any one dimensional projection, that is,

$$O(\mathbf{t}; F) = \sup_{\|\mathbf{u}\|=1} \frac{|\mathbf{u}^T\mathbf{t} - Med(\mathbf{u}^T\mathbf{X})|}{MAD((\mathbf{u}^T\mathbf{X}))}$$

where $Med(\cdot)$ denotes the univariate median, $MAD(\cdot)$ denotes the univariate median absolute deviation; i.e., $MAD(Y) = Med(|Y - Med(Y)|)$, and $\|\cdot\|$ is the Euclidean norm.

The spatial depth $SPD(\mathbf{t}; F)$ or L_1 depth is defined as

$$SPD(\mathbf{t}; F) = 1 - \left\| E_F\left(\frac{\mathbf{t} - \mathbf{X}}{\|\mathbf{t} - \mathbf{X}\|}\right)\right\|.$$

The spherical depth $SPHD(\mathbf{t}; F)$ is defined as the probability that $\mathbf{t}$ is contained in the unique, closed random hypersphere, $S(\mathbf{X}_1, \mathbf{X}_2)$, formed by two random points $\mathbf{X}_1$ and $\mathbf{X}_2$, which are i.i.d with c.d.f. F . That is, $SPHD(\mathbf{t}; F) = P(\mathbf{t} \in S(\mathbf{X}_1, \mathbf{X}_2))$. The sample version of the spherical depth at a point $\mathbf{t}$ is $SPHD(\mathbf{t}; F_m) = \frac{1}{\binom{m}{2}} \sum_{i<j}^{m} I[\mathbf{t} \in S(\mathbf{x}_i, \mathbf{x}_j)]$.

The empirical convex hull peeling depth $CHPD(\mathbf{t}; F_m)$ at $\mathbf{t}$ w.r.t. the sample $\mathbf{X} = \{\mathbf{x}_1, \ldots, \mathbf{x}_m\}$ is defined as $CHPD(\mathbf{t}, F_m) = \min\{k : \mathbf{t} \in E_k\}$, if such a k exists; and zero, otherwise, where E_k denotes the level k convex layer to which $\mathbf{t}$ belongs.

To obtain a convex layer at level k, one initially construct the smallest convex hull which enclose all samples points $\{\mathbf{x}_1, \ldots, \mathbf{x}_m\}$ and $\mathbf{t}$. The points on the perimeter are designated the first convex layer and removed. The convex hull for the remaining points is now constructed; the points on the perimeter constitute the second layer. This process is repeated, and a sequence of nested convex layers is formed.

The empirical zonoid depth $ZD(\mathbf{t}; F_m)$ at $\mathbf{t}$ w.r.t. the sample $\mathbf{X} = \{\mathbf{x}_1, \ldots, \mathbf{x}_m\}$ is defined as $ZD(\mathbf{t}, F_m) = \sup\{\alpha : \mathbf{t} \in D_\alpha(\mathbf{x}_1, \ldots, \mathbf{x}_m)\}$ where $D_\alpha(\mathbf{x}_1, \ldots, \mathbf{x}_m) = \left\{\sum_{i=1}^m \lambda_i \mathbf{x}_i : \sum_{i=1}^m \lambda_i = 1, \quad 0 \leq \lambda_i, \alpha\lambda_i \leq \frac{1}{n}, \quad \text{for all} \quad i\right\}$.

For a continuous distribution F on R^d, let $L(\mathbf{X}_1, \mathbf{X}_2)$ denote the hyper-lens defined by the intersection of two identical closed hyper-spheres centered at $\mathbf{X}_1$ and $\mathbf{X}_2$, respectively, with radius $\|\mathbf{X}_1 - \mathbf{X}_2\|$. The hyper-lens of any two i.i.d. random vectors $\mathbf{X}_1$ and $\mathbf{X}_2$ in R^d is defined as $L(\mathbf{X}_1, \mathbf{X}_2) = B(\mathbf{X}_1, \|\mathbf{X}_1 - \mathbf{X}_2\|) \cap B(\mathbf{X}_2, \|\mathbf{X}_1 - \mathbf{X}_2\|)$ where $B(c, r)$ is the closed ball of radius r centered at c. The triangle depth function $TD(\mathbf{t}; F)$ for a vector $\mathbf{t} \in R^d$, with

respect to a distribution F on R^d, is the probability that $\mathbf{t}$ is contained in the random hyper-lens $L(\mathbf{X}_1, \mathbf{X}_2)$. That is, $TD(\mathbf{t}; F) = P(\mathbf{t} \in L(\mathbf{X}_1, \mathbf{X}_2))$ where $\mathbf{X}_1$ and $\mathbf{X}_2$ are i.i.d with c.d.f. F. Let $\mathbf{X}_1, \ldots, \mathbf{X}_m$ be an i.i.d. random sample with c.d.f. F. The sample (empirical) version of $TD(\mathbf{t}; F)$ is the proportion of $L(\mathbf{X}_i, \mathbf{X}_j), 1 \le i < j \le m$, that contain $\mathbf{t}$. That is, $TD(\mathbf{t}; F_m) = \frac{1}{\binom{m}{2}} \sum_{i<j}^{m} I[\mathbf{t} \in L(\mathbf{x}_i, \mathbf{x}_j)]$.

Data Mining

Bruno Scarpa
University of Padua, Padua, Italy

In recent decades technological innovation has made the availability of large and sometimes huge amounts of information on a phenomenon of interest simple and cheap. This is due to two main reasons: on one side the development of automatic methods of data acquisition, and on the other side the progress of storage technology producing the fall of related costs. This new environment involves all areas of human endeavor.

- Every month a supermarket chain releases millions of receipts, one for each shopping trolley checking out. The content of each trolley summarizes the needs, the propensities and the economic behavior of the customer that selected it. The collection of all these shopping lists forms an important information base for the supermarket in order to decide the sales and purchases politics. Such an analysis becomes even more interesting when each shopping list is connected with the customers loyalty cards, allowing to follow the single client behavior by recording the purchases sequences; a similar problem arises in analyzing the usage of credit cards.
- Telecommunication companies generate every day data on millions of phone calls and of other services. Companies are interested in analyzing the customers behavior in order to measure chances of up sell and cross sell, and to identify potential *churners* (customers with high propensity to move to others operators).
- The growth of the World Wide Web in the last years, and its success and usage in research, business and daily life, makes it the largest publicly accessible data source in the world. Analysts often need to extract knowledge from this huge source of available data. Search engines need to identify the small part of the documents that are related to each single query; this operation is complicated by a number of elements: (a) the total size of the set of documents is amazing, (b) data are not collected in a structured form, such as a well organized data base, (c) inside each single document the elements related with the specific query are not in a pre-specified position either with respect to the entire document or among themselves.
- In scientific research huge amount of data are also available, for example in microbiology for the study of DNA structure. The analysis of sequences of portions of DNA produces very large tables, called "DNA microarray", where each column represents a sequence of some thousands of numerical values associated to DNA of an individual and each row represents different individuals. The goal is, for example, to connect the configuration of these sequences with the occurrence of some disease.
- The set of physical, chemical or other measurements finalized to examining the Earth's climate is becoming massive. Even the simple structured organization of

such data is problematic as much as the analysis to summarize all these pieces of information.

- Digital images of the sky will create massive data sets of observational data regarding many different features of hundreds of millions of sky objects. Astronomers are often interested in finding some algorithm that can perform as well as human experts in classifying stars and galaxies.

These are only few examples, but from all of these (and from many other that could be provided), it is clear that nowadays the analysis of huge amount of data is often required in order to solve real world problems. Specific statistical tools are required in order to extract important and useful knowledge from such an abundant amount of information. In fact, from one side the large number of cases are difficult to visualize effectively and, on the other side, as dimensionality increases, it becomes more difficult to describe data. Also, as we have seen in some of the examples above, data may not assume the simple structure of a database and sometimes they are even collected from streaming (e.g., for recording electricity usage).

The exploration and analysis of huge amount of data is often called "data mining" recalling the extraction (of relevant knowledge) from a mine of data:

> Data mining *is the activity of graphical and numerical analysis of large observational data sets or streaming data in order to find useful knowledge for the data owner.*

"Useful knowledge" in this context is quite generic, since very often it is not a priori specified what is the object of interest, which is in general acquired by "mining" the data. From such a definition, it is clear that data mining is an interdisciplinary exercise where statistics, database technology, machine learning, pattern recognition (see ►Pattern Recognition, Aspects of and ►Statistical Pattern Recognition Principles), artificial intelligence and visualization play a role (Hand et al. 2001). Therefore, data mining requires an understanding of both statistical and computational issues.

Looking at it as a statistician, (e.g., Azzalini and Scarpa 2010) it is worthwhile outlining some statistical specificities of data mining:

- The size of the data is huge. When many variables are available, the problem of the curse of dimensionality appears: the number of unit cells in a space as the number of variables increases linearly has an exponential growth rate, so that, in high dimensional spaces, "nearest" points may be very far away. Also, when the number of cases is of the order of millions, computational issues need to be considered. "Every time the amount of data increases by a factor of ten, we should totally rethink how we analyze it" (Friedman 1997).
- The observational context: data are often not collected from an experiment, but purely observational. They just "exists." Often they have been collected by convenience or opportunity, rather than randomly.
- Data used for the analysis have often been collected for some other purpose (e.g., they may have been collected in order to maintain an up-to-date record of all the transactions in a bank).
- Data may be dirty, corrupted, contaminated, missing and need to be preprocessed in order to be used.
- Sampling and population issues: the huge amount of data can be tackled by sampling, if the aim is modeling, but not necessarily so if the aim is pattern detection. When data sets are entire populations (e.g., the entire customer base of a company), the standard statistical notion of inference has no relevance.
- "If you torture data long enough, Nature will always confess" (Coase 1982), with so large data sets it would be easy to find a model that will fit the data well, but often this model will not really describe the phenomenon of interest. In this context the trade off between bias and variance needs to be managed.

In summary, while data mining does overlap considerably with the standard exploratory data analysis techniques of statistics, it also runs into new problems, many of which are consequences of size and the non-traditional nature of the data sets involved.

Using a machine learning classification, data mining tasks may be divided into two groups, the *supervised learning* problems, "supervised" because of the presence of an outcome variable to guide the learning process, and the *unsupervised learning* problems, (also said in a more statistical language *internal analysis* problems) where we observe only the features and have no measurements of the outcome.

Often the aim of supervised learning is to build a model that will permit the prediction of the value of one variable from known values of other variables. If the variables being predicted (called dependent variables or outputs or responses) are categorical, the problem is termed *classification*, while if they are quantitative the problem is called *regression*. A large number of methods have been developed in statistics and machine learning to tackle these problems, from simple parametric models such as ►generalized linear models (McCullagh and Nelder 1989) to nonparametric structures such as generalized additive models (Hastie and Tibshirani 1990), ►neural networks (e.g., Ripley 1996), support vector machines (Vapnik 1996), classification and regression trees (Breiman et al. 1984)

and their resampling versions such as bagging (Breiman 1996), boosting (Freund and Schapire 1996) or random forests (Breiman 2001a) and many others that have been developed in recent years.

Unsupervised learning is a class of problems in which one seeks to determine how the data are organized, directly inferring the properties of the density of a multivariate variable without the help of a "teacher" providing correct answers. Classical statistics and machine learning literature (e.g., Kaufman and Rousseeuw 1990; Ripley 1996) provide many clustering algorithms with the aim of grouping or segmenting a collection of objects into subsets or "clusters," such that those within each cluster are more closely related to one another than objects assigned to different clusters. Another family of algorithmic techniques based on *association rules* (e.g., Hastie, Tibshirani and Friedman 2008) is related to the task of finding combinations of items that occur frequently in transaction databases. Other goals of interest, in this context, are on detecting patterns among data, like spotting fraudulent behavior among customers of a company, or detecting unusual stars or galaxies in astronomical work in order to identify previously unknown phenomena. A particular case of this pattern detection is when a pattern of interest is already known by the user and he is interested in finding similar patterns in the data set. This task is very common in text and image data sets, where the pattern can be a set of keywords, and the user may wish to find relevant documents within a large set of possibly important documents, or the user may have a sample image, and wish to find similar images from a large set of images.

Most of the methods included in data mining are often considered as automatic tools that do not require any human intervention. In particular many algorithms generated in the machine learning context, dealing with really huge amount of data with, sometimes, very complicated computational structure, and seems to present an objective advantage by working without any human intervention. However, from empirical experience, it seems that an analysis driven by a thinking brain is much more powerful. In fact the necessity to "understand the problem" characterizes the style of statistical data mining, in all the phases of the analysis from the data preparation to the interpretation of the results. Even when black box algorithms are used, one can never hope to solve every problem by using software on a powerful computer just by "pushing a button". A deep knowledge of the nature of the tools used and of how the used methods work is crucial for, at least, three broad reasons (Azzalini and Scarpa 2010):

1. Understanding the characteristics of the tools is crucial in choosing the right method.
2. The same mastery is required in order to correctly interpret the results of the algorithms.
3. Some ability in the computational and algorithmic aspects is very useful in order to better evaluate the computer output, considering also its reliability.

The paper by Breiman (2001b), with the discussion that it generated, describes quite well the specificities of the type of statisticians needed to tackle these problems.

About the Author

Dr. Bruno Scarpa joined the Department of Statistical Sciences, University of Padova, in 2007, after four years being at the Department of Applied Statistics at the University of Pavia. Previously, he used to work as a manager for some telecommunication companies where he was in charged of activities of customer profiling, churn analysis, CRM and data mining services for marketing. He is author of several scientific papers and jointly with Adelchi Azzalini is author of the book *Data Mining and Data Analysis* (published in 2004 by Springer in Italian and soon will be published in English).

Data Mining Time Series Data

Eamonn J. Keogh
Professor, University Scholar
University of California-Riverside, Riverside, CA, USA

Time series data is ubiquitous; large volumes of time series data are routinely created in medical and biological domains, examples include gene expression data (Aach and Church 2001), electrocardiograms, electroencephalograms, gait analysis, growth development charts etc. Although statisticians have worked with time series for more than a century, many of their techniques hold little utility for researchers working with massive time series databases (for reasons discussed below).

Below are the major task considered by the time series data mining community:

- **Indexing** (Query by Content): Given a query time series Q, and some similarity/dissimilarity measure D(Q,C), find the most similar time series in database *DB* (Chakrabarti et al. 2002; Faloutsos et al. 1994; Kahveci and Singh 2001; Popivanov and Miller 2002).
- **Clustering**: Find natural groupings of the time series in database *DB* under some similarity/dissimilarity measure D(Q,C) (Aach and Church 2001; Debregeas and Hebrail 1998; Kalpakis et al. 2001; Keogh and Pazzani 1998).
- **Classification**: Given an unlabeled time series Q, assign it to one of two or more predefined classes (Geurts 2001; Keogh and Pazzani 1998).
- **Prediction** (Forecasting): Given a time series Q containing n datapoints, predict the value at time $n+1$.
- **Association Detection**: Given two or more time series, find relationships between them. Such relationships may or may not be casual and may or may not exist for the entire duration of the time series.
- **Summarization**: Given a time series Q containing n datapoints where n is an extremely large number, create a (possibly graphic) approximation of Q which retains its essential features but fits on a single page, computer screen etc. (Indyk et al. 2000; van Wijk and van Selow 1999).
- **Anomaly Detection** (Interestingness Detection): Given a time series Q, assumed to be normal, and an unannotated time series R. Find all sections of R which contain anomalies or "surprising/interesting/unexpected" occurrences (Guralnik and Srivastava 1999; Keogh et al. 2002; Shahabi et al. 2000).
- **Segmentation**: Given a time series Q containing n datapoints, construct a model $\overline{Q}$, from K piecewise segments ($K << n$) such that $\overline{Q}$ closely approximates Q (Keogh and Pazzani 1998).

Note that indexing and clustering make *explicit* use of a distance measure, and many approaches to classification, prediction, association detection, summarization and anomaly detection make *implicit* use of a distance measure. For this reason, there has been significant research on finding the "best" distance measure for time series (Keogh and Kasetty 2002). Recent work, however, suggests that the simple Euclidean distance is surprisingly competitive (Ding et al. 2008).

It is interesting to note that with the exception of indexing, research into the tasks enumerated above predate not only the decade old interest in ▶data mining, but computing itself. What then, are the essential differences between the classic, and the data mining versions of these problems? The key difference is simply one of size and scalability; time series data miners routinely encounter datasets that are gigabytes in size. As a simple motivating example, consider hierarchal clustering. The technique has a long history, and well-documented utility. If however, we wish to hierarchically cluster a mere million items, we would need to construct a matrix with 10^{12} cells, well beyond the abilities of the average computer for many years to come. A data mining approach to clustering time series, in contrast, must explicitly consider the scalability of the algorithm (Kalpakis et al. 2001).

In addition to the large volume of data, it is often the case that each individual time series has a very high dimensionality (Chakrabarti et al. 2002). Whereas classic algorithms assume a relatively low dimensionality (e.g., a few measurements such as "height, weight, blood sugar etc."), time series data mining algorithms must be able to deal with dimensionalities in the hundreds and thousands. The problems created by high dimensional data are more than mere computation time considerations, the very meanings of normally intuitive terms such as "similar to" and "cluster forming" become unclear in high dimensional space. The reason is that as dimensionality increases, all objects

become essentially equidistant to each other, and thus classification and clustering lose their meaning. This surprising result is known as the "curse of dimensionality" and has been the subject of extensive research (Aggarwal et al. 2001). The key insight that allows meaningful time series data mining is that although the actual dimensionality may be high, the *intrinsic* dimensionality is typically much lower. For this reason, virtually all time series data mining algorithms avoid operating on the original "raw" data, instead they consider some higher-level representation or abstraction of the data.

Time Series Representations

As noted above, time series datasets are typically very large, for example, just 8 h of electroencephalogram data can require in excess of a gigabyte of storage. This is a problem because for almost all data mining tasks, most of the execution time spent by algorithm is used simply to move data from disk into main memory. This is acknowledged as the major bottleneck in data mining, because many naïve algorithms require multiple accesses of the data. As a simple example, imagine we are attempting to do k-means clustering of a dataset that does not fit into main memory. In this case, every iteration of the algorithm will require that data in main memory to be swapped. This will result in an algorithm that is thousands of times slower than the main memory case.

With this in mind, a generic framework for time series data mining has emerged. The basic idea is summarized in (Table 1).

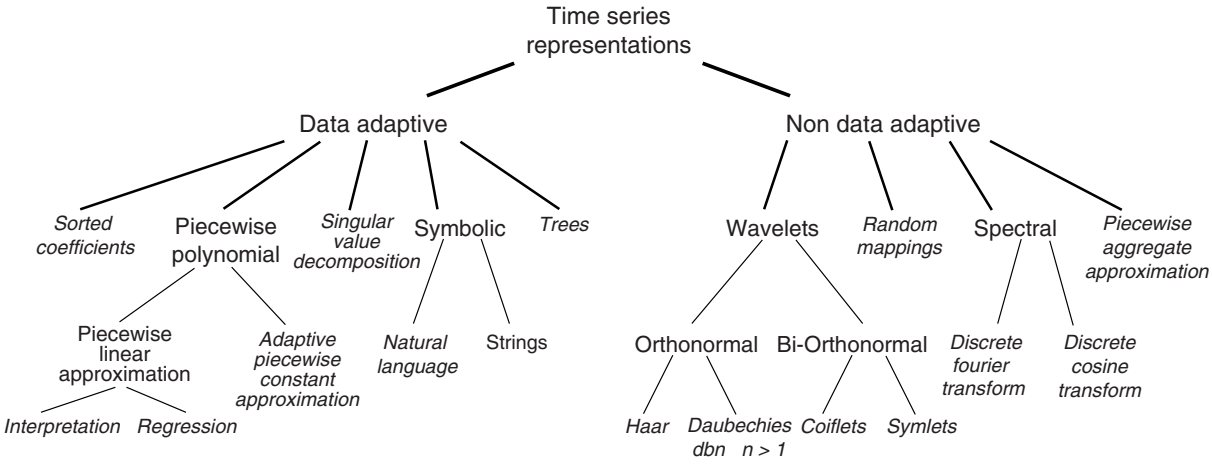
It should be clear that the utility of this framework depends heavily on the quality of the approximation created in Step 1. If the approximation is very faithful to the original data, then the solution obtained in main memory is likely to be the same, or very close to, the solution we would have obtained on the original data. The handful of disk accesses made in Step 2 to confirm or slightly modify the solution will be inconsequential compared to the number of disks accesses required if we had worked on the original data. With this in mind, there has been a huge interest in approximate representation of time series. Figure 1 illustrates a hierarchy of every major representation proposed in the literature.

Data Mining Time Series Data. Table 1 A generic time series data mining approach

1. Create an approximation of the data, which will fit in main memory, yet retains the essential features of interest
2. Approximately solve the problem at hand in main memory
3. Make (hopefully very few) accesses to the original data on disk to confirm the solution obtained in Step 2, or to modify the solution so it agrees with the solution we would have obtained on the original data

Given the plethora of different representations, it is natural to ask which is best. Recall that the more faithful the approximation, the less clarification disks accesses we will need to make in Step 3 of Table 1. There have been many attempts to answer the question of which is the best representation, with proponents advocating their favorite technique (Chakrabarti et al. 2002; Faloutsos et al. 1994; Popivanov and Miller 2002; Rafiei and Mendelzon 1998). The literature abounds with mutually contradictory statements such as "*Several wavelets outperform the . . . DFT*" (Popivanov and Miller 2002), "*DFT-based and DWT-based techniques yield comparable results*" (Wu et al. 2000), and "*Haar wavelets perform. . . better that DFT*" (Kahveci and Singh 2001). However an extensive empirical comparison on 50 diverse datasets suggests that while some datasets favor a particular approach, overall there is little difference between the various approaches in terms of their ability to approximate the data (Ding et al. 2008; Keogh and Kasetty 2002). There are however, other important differences in the usability of each approach (Chakrabarti et al. 2002). We will consider some representative examples of strengths and weaknesses below.

The wavelet transform is often touted as an ideal representation for time series data mining, because the first few wavelet coefficients contain information about the overall shape of the sequence while the higher order coefficients contain information about localized trends (Popivanov and Miller 2002; Shahabi et al. 2000). This multiresolution property can be exploited by some algorithms, and contrasts with the Fourier representation in which every coefficient represents a contribution to the global trend (Faloutsos et al. 1994; Rafiei and Mendelzon 1998). However wavelets do have several drawbacks as a data mining representation. They are only defined for data whose length is an integer power of two. In contrast, the Piecewise Constant Approximation suggested by (Yi and Faloutsos 2000), has exactly the fidelity of resolution of as the Haar wavelet, but is defined for arbitrary length time series. In addition, it has several other useful properties such as the ability to support several different distance measures (Yi and Faloutsos 2000), and the ability to be calculated in an incremental fashion as the data arrives (Chakrabarti et al. 2002). Choosing the right representation for the task



Data Mining Time Series Data. Fig. 1 A hierarchy of time series representations

at hand is the key step in any time series data-mining endeavor. The points above only serve as a sample of the issues that must be addressed.

Readings

The field of time series data mining is relatively new, and ever changing. Because of the length of journal publication delays, the most interesting and useful work tends to appear in top-tier conference proceedings. Interested readers are urged to consult the latest proceedings of the major conferences in the field. These include the ACM Knowledge Discovery in Data and Data Mining, IEEE International Conference on Data Mining and the IEEE International Conference on Data Engineering.

About the Author

Eamonn J. Keogh received his Ph.D. in Computer Science in 2001, UC Irvine. His research areas include data mining, machine learning and information retrieval, specializing in techniques for solving similarity and indexing problems in time-series datasets. Dr. Keogh is a prolific author in data mining/database conferences. He has (co-)authored more than 120 papers. His papers on time series data mining have been referenced well over 5,000 times (his H-index is 34). He received the IEEE ICDM 2007 best paper award, SIGMOD 2001 best paper award, and runner up best paper award in KDD 1997. He has made some important contributions in data mining time series data, including: Symbolic Aggregate approXimation (SEX) (with Jessica Lin, 21002), the first symbolic representation for time series that allows for dimensionality reduction and indexing with a lower-bounding distance measure, and LB_Keogh, a tool for lower bounding various time series distance measure, that makes retrieval of time-warped time series feasible even for large data sets.

Data Privacy and Confidentiality

Introduction

Data privacy is an overarching concern in modern society, as government and non-government agencies alike collect, archive, and release increasing amounts of potentially sensitive personal data. Data owners or stewards, in the case of statistical agencies, often critically evaluate both the type of data that they make publicly available and the format of the data product releases. The statistical challenge is to discover how to release important characteristics of existing databases without compromising the privacy of those whose data they contain.

Modern databases, however, pose new privacy problems due to the types of information they hold and their size. In addition to traditional types of information contained in censuses (see ▶Census), surveys, and medical and public health studies, contemporary information repositories store social network data (e.g., cell phone and Facebook data), product preferences (e.g., from commercial vendors), web search data, and other statistical information that was hitherto unavailable in digital format. The information in modern databases is also more commercially exploitable than pure census data (e.g., credit cards, purchase histories, medical history, mobile device locations). As the amount of data in the public realm accumulates and record-linkage methodologies improve, the threat to confidentiality and privacy magnifies. Repeated database breaches demonstrate that removing obviously identifying attributes such as names is insufficient to protect privacy (e.g., Narayanan and Shmatikov 2006; Backstrom et al. 2007). Even supposed anonymization techniques can leak sensitive information when the intruder has modest partial knowledge about the data from external sources (e.g., Coull et al. 2008; Ganta et al. 2008).

Two rich traditions of investigating data confidentiality have developed within the scientific community, one in statistics, e.g., see Federal Committee on Statistical Methodology (2005), and the other more recently in computer science. Both tackle the fundamental trade-off between utility and privacy, but in essentially different ways. In statistics the focus has been on the trade-off

between disclosure risk and data utility while in computer science the focus has been on algorithmic aspects of the problem and more recently on rigorous definitions of privacy that may also allow for utility. A special 2009 issue of the *Journal of Privacy and Confidentiality* features survey articles describing the current approaches and open research problems (http://repository.emu.edu/jpe/).

Statistical Disclosure Limitation

Statistical disclosure limitation (SDL) applies and develops statistical tools for limiting releases of sensitive information from statistical databases while allowing for valid statistical inference. Emanating from official statistics involving censuses and large-scale national surveys, modern SDL emphasizes statistical inference as the main yardstick of utility; e.g., given a statistical model, how well can one "anonymize" the data and still carry out valid model estimation and assessment? The goal of disclosure limitation is to examine and manage a trade-off between data utility and disclosure risk (e.g., Doyle et al. 2001; Trottini and Fienberg 2002; Duncan and Stokes 2009). Data utility is a measure of usefulness of a dataset for an intended analyst. Disclosure risk measures the degree to which a dataset and its released statistics reveal sensitive information. This notion is probabilistic; as released data accumulate in the public domain, the probability of uniquely identifying members of the population increases.

Starting with Dalenius (1977) and continuing to modern work with connections to algebraic geometry, multivariate analysis, optimization, and the generation of synthetic data, SDL has a vast literature with primary applications to social sciences and health data. In general, SDL methods introduce bias and variance to data in order to minimize identity and attribute disclosure while trying to retain sufficient information needed for proper statistical inference. Data masking involves transforming an $n \times p$ (cases by variables) original data matrix Z through pre- and post-multiplication and the possible addition of noise. That is, $Z = AZB + C$, where A is a matrix that operates on the n cases, B is a matrix that operates on the p variables, and C is a matrix that adds noise. Matrix masking can be applied to either microdata or table of counts, and includes a variety of standard approaches to disclosure limitation (*see* ►Statistical Approaches to protecting confidentiality in public use data): (a) recodings such as (e.g., rounding and thresholding), (b) cell suppression, (c) data swapping, and (d) perturbation. More recent methods include *sampling* which involves releasing subsets of data or variables – deleting rows that is columns of Z, and *simulations* such as adding rows to Z (e.g., see Reiter 2005 for generation of synthetic Microdata, Slavkovic and Lee 2010 for creation of synthetic tables, and Dobra et al. 2008 for partial information release, including optimization bounds on contingency tables).

Computer Science Approaches

Closely related to SDL techniques are privacy-preserving data mining (PPDM) methods that aim to construct efficient data mining algorithms (see ►Data Mining) while maintaining privacy with the emphasis on automation and scalability of the anonymization process. Currently proposed methods can be roughly grouped in (a) randomization methods (e.g., multiplicative perturbations, data swapping), (b) group based anonymization, (c) distributed PPDM, and (d) privacy-preservation of application rules (e.g., see Fienberg and Slavković 2005 for association rule hiding). For an overview of the PPDM models and algorithms, and related issues see Aggarwal and Yu (2008).

Research emerging from cryptography has emphasized that privacy and security are properties of the anonymization algorithm, rather than of a particular output. This perspective allows for rigorous definitions and proofs of privacy. In particular, a concept called *differential privacy* (e.g., Dwork et al. 2006) provides rigorous guarantees no matter what external information is available to an intruder. The algorithmic perspective also leads to utility being defined in terms of functional approximation: given a database x and a function f, how well does the released information allow one to approximate $f(x)$.

Some recent developments aim to establish connections between differential privacy and traditional statistical inference; e.g., see Smith (2008) for private parametric estimation and Wasserman and Zhou (2008) for approximation of smooth densities. In some cases, the theory has sufficiently advanced for the development of concrete methodological guidelines; e.g., related to the additive perturbation techniques of Dwork et al. (2006), Vu and Slavković (2009) have begun to develop rules for sample size calculations and statistical ►power analysis. Machanavajjhala et al. (2008) describe the first application of privacy tools to large-scale public-use databases by creating differentially private synthetic data based on Bayesian posterior predictive distributions.

Another more recent promising approach uses cryptographic protocols for distributing privacy-preserving algorithms for valid statistical analysis among a group of servers (or data owners) so as to avoid pooling data in any single location. Using ideas from secure multiparty computation (Lindell and Pinkas 2009), statisticians have been working on variations of secure protocols for generalized linear models analysis (e.g., Ghosh et al. 2007).

Future Directions

Protecting privacy in statistical databases is an increasingly challenging problem. Any useful statistics extracted from a database must reveal some information about the individuals whose data are included. Despite an increasing focus on large and often sparse data sets, the evaluation of disclosure risk and utility of statistical results often involves human-guided tuning of parameters and context-specific notions of privacy. New policies and data privacy research calls for methodology that achieves maximum utility, minimal risk and transparency. Current trends aim at integration of the computationally focused, rigorous definitions of privacy and cryptographic protocols emanating from computer science with notions of utility from statistics.

About the Authors

Stephen E. Fienberg is Maurice Falk University Professor of Statistics and Social Science at Carnegie Mellon University, with appointments in the Department of Statistics, the Machine Learning Department, Cylab, and i-Lab. Professor Fienberg is Past President of the Institute of Mathematical Statistics (1998–1999), and Past President of the International Society for Bayesian Analysis (1996–1997) and he has been Vice President of the American Statistical Association. He is an Elected member of the U.S. National Academy of Sciences (1999) and co-chair of its Report Review Committee (2008–2012). He is a fellow of the American Academy of Arts and Sciences (2007), the American Academy of Political and Social Science (2004), and the Royal Society of Canada (2004). Professor Fienberg is an Editor of the *Annals of Applied Statistics* (2006–), and former editor of the *Journal of the American Statistical Association*. He was Co-Founder of the *Journal of Privacy and Confidentiality* and *Chance*. He has received the Wilks Award (2000) and the Founders Award (2009) from the American Statistical Association, and the Lise Manchester Award from the Statistical Society of Canada (2008).

Aleksandra Slavkovic received her Ph.D. from Carnegie Mellon University in 2004. She is currently an Associate Professor of Statistics, with appointments at the Department of Statistics and the Institute for CyberScience at Penn State University, University Park, and at the Department of Public Health Sciences, Pennsylvania State College of Medicine, Hershey. She is currently serving as an Associate Editor of the Annals of Applied Statistics, Journal of Privacy and Confidentiality and Journal of Statistical Computation and Simulation. Dr. Slavkovic has served as a consultant to the National Academy of Sciences/National Research Council Committee to Review the Scientific Evidence of Polygraph in 2001 and part of 2002. In 2003, she received and honorable mention for the best student paper from the Committee on Statisticians in Defense and National Security of the American Statistical Association.

Introduction and Summary

In recent years a powerful combination of database technologies, data mining techniques (see ▶Data Mining) and analytics software have created vast new opportunities for data analysts and statisticians. For example, corporations have duly stored the results of their customer transactions in corporate databases for over a generation. There are, quite literally millions of records. Massively parallel engines can examine these data in heretofore unimagined ways. The potentials to understand customer profitability, develop better understandings of customers' past needs and predict future ones, and to use those insights to develop new product niches are enormous.

Yet all is not well in the world of data analytics. Unlocking the mysteries data have to offer is difficult at best. And putting the discoveries to work can be even harder. One major reason is poor quality data. Bad data camouflage the hidden nuggets in data or, worse, send an analysis in the wrong direction altogether. Some years ago George Box observed that "...all models are wrong, but some are useful". Compare Box (1976) and see Box and Draper (1987). Many decision makers seem to intuitively grasp the "all models are wrong" portion and so are skeptical of data mining. Poor data quality exacerbates the problem. Indeed most decision makers are well aware that poor data cause problems in operations. How can things be any better when bad data are combined with incorrect models?!

What is a poor data analyst to do? Our advice: "Think and act like an experimenter!" Since time immemorial, experimenters have understood the importance of high-quality data – data that are relevant to the subject area, are clearly defined, have minimal or no bias and high precision. And they invest considerable time and energy to achieve this goal. The following summarizes some of these investments and how they apply to analytics.

Experimenters plan and design their experiments carefully: Perhaps because their data are so dear, experimenters take time to understand what is already known and to carefully define their objectives, the populations and sub-populations of interest, and the hypotheses of primary interest. In contrast, it is too easy to turn an analytics tool loose, in hope that the computer can make interesting discoveries on its own. Much is lost, especially the abilities to interpret results and identify spurious correlations. So data analysts are well-advised to narrow their foci and develop working knowledge of their subject areas. Then they should aim their analytic tools rather more like a high-powered rifle than a shotgun.

Some may object that doing so limits opportunities for serendipity. In our experience just the opposite is true. Serendipitous discoveries are more likely when the current level of understanding does not explain the data and piques the experimenter's curiosity. That cannot happen without adequate background.

Similarly, experimenters *design* their experiments, seeking exactly the right data. Data analysts should be just as persistent in creating or searching for the data that best meets their needs, not the data that are easy to find. They should confirm interesting results based on large-scale analyzes with small, designed studies.

Experimenters get very close to their data: First, they develop deep understanding of their data collection

devices. Analysts can do the same thing by working backwards, identifying and understanding the business processes that created their data. Business people are often more casual than experimenters about data definition, so it is critical that data analysts understand the nuance in their data.

Second, experimenters build controls into their data collection processes. The simplest example is calibrating their equipment. Data analysts do not own these processes, but they must understand existing controls and recommend others where needed to prevent poor data, whenever possible.

Third, experimenters search for and eliminate ►outliers. When one of us (Redman) worked at Bell Labs in the 80s and 90s, we used the expression "rinse, wash, scrub" for increasing efforts to identify and eliminate suspect data. It was intense, manual effort, certainly not feasible for enormous databases. But data analysts can certainly rinse, wash, and scrub a small sample. Doing so provides a basis for evaluating the quality of the entire database. And if the results of a large analysis are confirmed on the scrubbed validating subset, one can proceed with greater confidence.

Experimenters are transparent in discussing strengths and weaknesses in their data collection processes: Data analysts must do so as well. It is the only way to understand the limitations on what they've learned.

Experimenters recognize they are part of an ongoing process: For an experimenter, there is no "ultimate experiment." A good experiment increases the body of knowledge (even if by saying "there's nothing of interest here") and leads to another experiment. Most business data analysts are not engaged in formal science, *per se*. But they may well be part of an end-to-end innovation process. Such data analysts should develop an understanding of where they fit and how they can make product developers, marketers, and others more effective. (Note: if your organization doesn't have such a process, data analysts are well-advised to behave as though it did.)

Final Remarks: Taken together, relatively simple actions, quite natural to experimenters, can assist data analysts to better understand their data, know how good their data really are, and improve their overall effectiveness. For learning more about the area of data quality, we recommend these books, among many out there, English (1999), Huang et al. (1999), and Redman (2008, 2001).

Decision Theory: An Introduction

Martin Peterson
Associate Professor
Eindhoven University of Technology, Eindhoven, Netherlands

Decision theory (see also ►Decision Theory: An Overview) is the theory of rational decision making. This is an interdisciplinary field to which philosophers, economists, psychologists, computer scientists and statisticians contribute their expertise. It is common to distinguish between *normative* and *descriptive* decision theory. Normative decision theory seeks to yield prescriptions about what decision makers are *rationally required* – or *ought* – to do. Descriptive decision theories seek to explain and predict how people *actually* make decisions. Descriptive decision theory is thus an empirical discipline, which has its roots in experimental psychology. Descriptive and normative decision theory are, thus, two separate fields of inquiry, which may or may not be studied independently of each other.

In decision theory, a *decision problem* is situation in which a *decision maker*, (a person, a company, or a society) chooses what to do from a set of *alternative acts*, where the *outcome* of the decision depends on which *state of the world* turns out to be the actual one. Decision problem are classified as decisions under *risk* or *ignorance* (or *uncertainty)* depending on the information available to the agent at the time at which he makes his choice. In decisions under risk the decision maker knows the probability of the possible outcomes, whereas in decisions under ignorance the probabilities are either unknown or non-existent. The term uncertainty is either used as a synonym for ignorance, or as a broader term referring to both risk and ignorance.

Let us consider an example. Suppose that you are thinking about taking out insurance against theft of your

new sports car. Perhaps it costs $300 to take out insurance on a car worth $90,000, and you ask: Is it worth it? In case you know that the probability that the car is stolen is, say, 1 in 1,000, then you are clearly facing a decision under risk. However, in case you are not able to assess the probability of theft then you are on the contrary facing a decision under uncertainty or ignorance.

The most widely applied decision rule for making decisions under risk is to apply the principle of maximizing expected value (or utility). According to this decision rule, the total value of an act equals the sum of the values of its possible outcomes weighted by the probability for each outcome. Hence, the expected values of not taking out fire insurance is 1/1,000 times the value of losing $200,000, whereas the expected value of taking out insurance equals the value of losing $200 (since the insurance guarantees that you will suffer no financial loss in case of a fire).

Modern decision theory is dominated by attempts to axiomatise the principles of rational decision making, and in particular the principle of maximizing expected utility. (The term "utility" refers to a technically precise notion of value.) The first axiomatisation was presented by Ramsey in his paper *Truth and Probability*, written in 1926 but published posthumously in 1931. Ramsey was a philosopher working at Cambridge together with Russell, Moore, and Wittgenstein. In his paper, Ramsey proposed a set of eight axioms for how rational decision makers ought to choose among uncertain prospects. He pointed out that every decision maker behaving in accordance with these axioms will act in a way that is *compatible* with the principle of maximizing expected value, by implicitly assigning numerical probabilities and values to outcomes. However, it does not follow that the decision maker's choices were *actually trigged* by these implicit probabilities and utilities. This way of thinking about rational decision making is very influential in the modern literature, and similar ideas were put forward by Savage in *The Foundations of Statistics* about two decades later.

Another important point of departure in modern decision theory is von Neumann and Morgenstern's book *Theory of Games and Economic Behavior*. Von Neumann and Morgenstern showed how a linear measure of value for outcomes (i.e., a utility function) can be generated from a set of axioms dealing with how rational decision makers ought to choose among lotteries. For von Neumann and Morgenstern a lottery is a probabilistic mixture of outcomes; for example, "a fifty-fifty chance of winning either $100 or a trip to London" is a lottery. They showed that every decision maker behaving in accordance with their axioms implicitly behaves in accordance with the principle of maximizing expected utility, and implicitly assigns numerical utilities to outcomes. The main difference compared to Ramsey's axiomatisation is that von Neumann and Morgenstern presented no novel theory of probability.

The use of the principle of maximizing expected utility has been criticized by some decision theorists. The most famous counter argument was proposed by Allais in the 1950s. Consider the following lotteries in which exactly one winning ticket will be drawn at random.

	Ticket no. 1	Ticket no. 2–11	Ticket no. 12–100
Gamble 1	$1 Million	$1 Million	$1 Million
Gamble 2	$0	$5 Million	$1 Million
Gamble 3	$1 Million	$1 Million	$0
Gamble 4	$0	$5 Million	$0

In a choice between Gamble 1 and Gamble 2 it seems reasonable to choose Gamble 1 since it gives the decision maker $1 Million for sure, whereas in a choice between Gamble 3 and Gamble 4 many people would feel that it makes sense to trade a ten-in-hundred chance of getting $5 Million, against a one-in-hundred risk of getting nothing, and consequently choose Gamble 4. Several empirical studies have confirmed that most people reason in this way. However, no matter what utility one assigns to money, the principle of maximizing expected utility recommends that the decision maker prefers Gamble 1 to Gamble 2 if and only if Gamble 3 is preferred to Gamble 4. There is simply no utility function such that the principle of maximizing utility is consistent with a preference for Gamble 1 to Gamble 2 and a preference for Gamble 4 to Gamble 3. To see why this is so, we calculate the *difference* in expected utility between the two pairs of gambles. Note that the probability that ticket 1 will be drawn is 0.01, and the probability that one of tickets numbered 2–11 will be drawn is 0.1; hence, the probability that one of tickets numbered 12–100 will be drawn is 0.89. This gives the following equations:

$$\begin{aligned} u(\mathrm{G1}) - u(\mathrm{G2}) &= u(1\mathrm{M}) - [0.01u(0\mathrm{M}) \\ &\quad + 0.1u(5\mathrm{M}) + 0.89u(1\mathrm{M})] \\ &= 0.11u(1\mathrm{M}) - [0.01u(0) \\ &\quad + 0.1u(5\mathrm{M})] \end{aligned} \tag{1}$$

$$\begin{aligned} u(\mathrm{G3}) - u(\mathrm{G4}) &= [0.11u(1\mathrm{M}) + 0.89u(0)] \\ &\quad - [0.9u(0\mathrm{M}) + 0.1u(5\mathrm{M})] \\ &= 0.11u(1\mathrm{M}) - [0.01u(0) + 0.1u(5\mathrm{M})] \end{aligned} \tag{2}$$

Equations 1 and 2 show that the difference in expected utility between G1 and G2 is precisely the same as the difference between G3 and G4. Hence, no matter what the decision maker's utility for money is, it is impossible to simultaneously prefer G1 to G2 and to prefer G4 to G3 without violating the expected utility principle. However, since many people who have thought very hard about this example still feel it would be rational to stick to the problematic preference pattern described above, there seems to be something wrong with the expected utility principle.

Let us now move on to the other type of decision problems mentioned above, viz., decisions under ignorance (or uncertainty). There is no single decision rule for decision making under ignorance that is currently widely accepted by decision theorists. However, the *maximin* rule and the *principle of insufficient reason* are two of the most influential rules, which have been widely discussed in the literature. The maximin rule, famously adopted by Rawls, focuses on the worst possible outcome of each alternative. According to this principle, one should *maximize* the *minimal* value obtainable with each act. If the worst possible outcome of one alternative is better than that of another, then the former should be chosen. According to the principle of insufficient reason, adopted by e.g., Bernoulli and Laplace, it holds that if one has *no* reason to think that one state of the world is more probable than another, then all states should be assigned *equal* probability. A well-known objection to the principle of insufficient reason is that that it seems completely arbitrary to infer that all states are equally probable. If one has *no* reason to think that one state is more probable than another, it seems strange to conclude anything at all about probabilities. Or, alternatively put, if one has *no* reason to think that some state is *twice* as probable as another, why not then reason as if that state is twice as probable as the other? Every possible distribution of probabilities seems to be equally justified.

However, not every decision problem can be classified as being either a decision under risk or a decision under ignorance. A major sub-field of modern decision theory is so-called multi-attribute approaches to decision theory. The difference between single- and multi-attribute approaches is that in a single-attribute approach, all outcomes are compared on a single utility scale. For example, in a decision between saving a group of fishermen from a sinking ship at a cost of one million dollars or letting the fishermen die and save the money, the value of a human life will be directly compared with monetary outcomes on a single scale. However, many authors think that such direct comparisons between the value of a human life and money makes no sense – i.e., that human life and money are incommensurable.

The multi-attribute approach seeks to avoid the criticism that money and human welfare are incommensurable by giving up the assumption that all outcomes have to be compared on a common scale. In a multi-attribute approach, each type of attribute is measured in the unit deemed to be most suitable for that attribute. Perhaps money is the right unit to use for measuring financial costs, whereas the number of lives saved is the right unit to use for measuring human welfare. The total value of an alternative is thereafter be determined by aggregating the attributes, e.g., money and lives, into an overall ranking of the available alternatives.

Here is an example. Mary has somehow divided the relevant objectives of her decision problem into a list of attributes. For illustrative purposes, we assume that the attributes are (a) the number of lives saved, (b) the financial aspects of the decision, (c) the political implications of the decision, and (d) the legal aspects of the decision. Now, to make a decision, Mary has to gather information about the degree to which each attribute can be realized by each alternative. Consider the following table, in which we list four attributes and three alternatives.

	Attribute 1	Attribute 2	Attribute 3	Attribute 4
Alt. a_1	1	3	1	2
Alt. a_2	3	1	3	1
Alt. a_3	2	2	2	2

The numbers represent the degree to which each attribute is fulfilled by the corresponding alternative. For example, in the leftmost column the numbers show that the second alternative fulfills the first attribute to a higher degree than the first alternative, and so on. So far the ranking is ordinal, so nothing follows about the "distance" in value between the numbers. However, in many applications of the multi-attribute approach it is of course natural to assume that the numbers represent more than an ordinal ranking. The number of people saved from a sinking ship can, for instance, be measured on a ratio scale. This also holds true of the amount of money saved by not rescuing the fishermen. In this case, nothing prevents the advocate of the multi-attribute approach to use a ratio or interval scale if one so wishes.

Several criteria have been proposed for choosing among alternatives with multiple attributes. It is common to distinguish between additive and non-additive criteria. Additive criteria assign weights to each attribute, and rank

alternatives according to the weighted sum calculated by multiplying the weight of each attribute with its value. The weights are real numbers between zero and one, which together sum up to one. Obviously, this type of criterion makes sense only if the degree to which each alternative satisfies any given attribute can be represented at least on an interval scale, i.e., if it makes sense to measure value in quantitative terms. Let us, for the sake of the argument, suppose that this is the case for the numbers in table above, and suppose that all attributes are assigned equal weights, i.e., 1/4. This implies that the value of alternative a_1 is $1/4 \cdot 1 + 1/4 \cdot 3 + 1/4 \cdot 1 + 1/4 \cdot 2 = 7/4$. Analogous calculations show that the value of a_2 is 2, while that of a_3 is also 2. Since we defined the ranking by stipulating that a higher number is better than a lower, it follows that a_2 and a_3 are better than a_1.

Another major sub-field of contemporary decision theory is *social choice theory*. Social choice theory seeks to analyze collective decision problems: How should a group aggregate the preferences of its individual members into a joint preference ordering? In this context, a group could be any constellation of individuals, such as a married couple, a number of friends, the members of a club, the citizens of a state, or even all conscious beings in universe. A *social choice problem* is any decision problem faced by a group, in which each individual is willing to state at least ordinal preferences over outcomes. Once all individuals have stated such ordinal preferences we have a set of *individual preference orderings*. The challenge faced by the social decision theorist is to somehow combine the individual preference ordering into a *social preference ordering*, that is, a preference ordering that reflects the preferences of the group. A *social state* is the state of the world that includes everything that individuals care about, and the term *social welfare function* (SWF) refers to any decision rule that aggregates a set of individual preference orderings over social states into a social preference ordering over those states. The majority rule used in democratic elections is an example of a SWF.

The most famous technical result in social choice theory is Arrow's impossibility theorem, according to which there is no SWF that meets a set of relatively weak normative conditions. A natural interpretation is that social decisions can never be rationally justified, simply because every possible mechanism for generating a social preference ordering – including the majority rule – is certain to violate at least one of Arrow's conditions. This result received massive attention in academic circles, and in the 1960s and 70s, many people took the theorem to prove that "democracy is impossible". However, the present view is that the situation is not that bad. By giving up or modifying some of Arrow's conditions one can formulate coherent SWFs that are not vulnerable to his impossibility result. Today, the theorem is interesting mainly because it opened up an entirely new field of inquiry.

Decision Theory: An Overview

Sven Ove Hansson
Professor and Head
Royal Institute of Technology, Stockholm, Sweden

Decision theory (see also ►Decision Theory: An Introduction) is the systematic study of *goal-directed behavior under conditions when different courses of action (options) can be chosen*. The focus in decision theory is usually on the outcome of decisions as judged by pre-determined criteria or, in other words, on means-ends rationality. Decision theory has developed since the middle of the twentieth century through contributions from several academic disciplines. In this overview over fundamental decision theory, the

focus will be on how decisions are represented and on decision rules intended to provide guidance for decision-making. Finally two paradoxes will be presented in order to exemplify the types of issues that are discussed in modern decision theory.

The Representation of Decisions

The standard representation of a decision problem requires that we specify the alternatives available to the decision-maker, the possible outcomes of the decision, the values of these outcomes, and the factors that have an influence on the outcome.

Alternatives

To decide means to choose among different alternatives (options). In some decision problems, the set of alternatives is *open* in the sense that new alternatives can be invented or discovered by the decision-maker. A typical example is your decision how to spend tomorrow evening. In other decision problems, the set of alternatives is *closed* so that no new alternatives can be added. Your decision how to vote in the upcoming elections will probably be an example of this. There will be a limited number of alternatives (candidates or parties) between which you can choose.

In real life, many if not most decisions come with an open set of alternatives. In decision theory, however, alternative sets are commonly assumed to be closed. The reason for this is that closed decision problems are much more accessible to theoretical treatment. If the alternative set is open, a definitive solution to a decision problem is not in general available.

In informal deliberations about decisions, we often refer to alternatives that can be combined with each other. Hence, when deciding how to spend tomorrow evening you may begin by choosing between eating out and going to the cinema, but end up deciding to do both. In decision theory, the alternatives are assumed to be *mutually exclusive*, i.e., no two of them can both be realized. However, this difference is not very important since you can always convert a set of compatible alternatives to a set of mutually exclusive ones. This is done by listing all the possible combinations (in this example: eating out and not going to the cinema, eating out and going to the cinema, etc.).

States of Nature

The effects of a decision depend not only on what choice the decision-maker makes, but also on various factors beyond the decision-maker's control. Some of these extraneous factors constitute *background information* that the decision-maker has access to. Others are unknown. They may depend, for instance, on the actions of other persons and various natural events.

In decision theory, it is common to summarize the various unknown extraneous factors into a number of cases, called *states of nature*. The states of nature include decisions by other persons. This is a major difference between decision theory and game theory. In game theory, decisions by several persons that may compete or cooperate are treated on a par with each other in the formal representation. In decision theory, the focus is on one decision-maker, and the actions and choices of others are treated differently, namely in the same way as natural events.

As an example, consider a young boy, Peter, who makes up his mind whether or not to go to the local soccer ground to see if there is any soccer going on that he can join. The effect of that decision depends on whether there are any soccer players present. In decision theory, this situation is described in terms of two states of nature, "players present" and "no players present."

Outcomes

The possible *outcomes* of a decision are determined by the combined effects of a chosen alternative and the state of nature that materializes. Hence, if Peter goes to the soccer ground and there are no players present, then the outcome can be summarized as "walk and no soccer," if he goes and there are players present then the outcome is "walk and soccer," and if he does not go then the outcome is "no walk and no soccer."

Decision Matrices

The alternatives, the states of nature, and the resulting outcomes in a decision can be represented in a *decision matrix*. A decision matrix is a table in which the alternatives are represented by rows and the states of nature by columns. For each alternative and each state of nature, the decision matrix assigns an outcome (such as "walk, no soccer" in our example). The decision matrix for Peter's decision is as follows:

	No soccer players	Soccer players
Go to soccer ground	Walk, no soccer	Walk, soccer
Stay home	No walk, no soccer	No walk, no soccer

Such a matrix provides a clear presentation of the decision, but it does not contain all the information that the decision-maker needs to make the decision. The most important missing information concerns how the outcomes are valued.

Value Representation

When we make decisions, or choose among options, we try to obtain as good an outcome as possible, according to some standard of what is good or bad. The choice of a value-standard for decision-making is usually not considered to fall within the subject matter of decision theory. Instead, decision theory assumes that such a standard is available from other sources, perhaps from moral philosophy.

There are two major ways to express our evaluations of outcomes. One of these is *relational representation*. It is expressed in terms of the three comparative value notions, namely "better than" (*strong preference*, >), "equal in value to" (*indifference*, ≡), and "at least as good as" (*weak preference*, ≥). These three notions are interconnected according to the following two rules:

1. A is better than B if and only if A is at least as good as B but B is not at least as good as A. (A > B if and only if A ≥ B and not B ≥ A.)
2. A is equally good as B if and only if A is at least as good as B and B is at least as good as A. (A ≡ B if and only if A ≥ B and B ≥ A.)

The other major method to express our evaluations of outcomes is *numerical representation*. It consists in assigning numbers to the possible outcomes; such that an outcome has a higher number than another if and only if it is preferred to it. In an economic context, willingness to pay is often used as a measure of value. If a person is prepared to pay, say $500 for a certain used car and $250 for another, then these sums can be used to express her (economic) valuation of the two vehicles.

However, not all values are monetary. According to some moral theorists, all values can instead be reduced to one unit of measurement, *utility*. This entity may or may not be identified with units of human happiness. According to utilitarian moral theory, decision-makers should, at least in principle, always (try to) maximize total utility.

Decision theorists often use numerical values as abstract tools in the analysis of decisions. These values may be taken to represent utilities, but only in a rather abstract sense since they are not based on any method to measure utilities.

Once we have a numerical representation of value, we can replace the verbal descriptions of outcomes in a decision matrix by these values. In our example, suppose that Peter likes to play soccer but does not like walking to the soccer ground and back home. Then his utilities may be representable as follows:

	No soccer players	Soccer players
Go to soccer ground	0	10
Stay home	3	3

Mainstream decision theory is almost exclusively devoted to problems that can be expressed in matrices of this type, *utility matrices* (payoff matrices).

Probability or Uncertainty

Decisions are often categorized according to how much the decision-maker knows beforehand about what state of nature will in fact take place. In an extreme case, the decision-maker knows for sure which state of nature will obtain. If, in the above example, Peter knows with certainty that there are players at the soccer ground, then this makes his decision very simple. The same applies if he knows that there are no players. Cases like these, when only one state of nature needs to be taken into account, are called *decision-making under certainty*.

Non-certainty is usually divided into two categories, called *risk* and *uncertainty*. A decision is made under risk if it is based on exact probabilities that have been assigned to the relevant states of nature; otherwise it is made under uncertainty. Decisions at the roulette table are good examples of decisions under risk since the probabilities are known (although some players do not pay much attention to them). A decision whether to marry is a good example of a decision under uncertainty. There is no way to determine the probability that a marriage will be successful, and presumably few prospective brides or grooms would wish to base their decision on precise probability estimates of marital success or failure.

In some cases, we do not even have a full list of the relevant states of affairs. Hence, decisions on the introduction of a new technology have to be made without full knowledge of the possible future social states in which the new technology will be used. Such cases are referred to as decision-making under *great uncertainty*, or *ignorance*. This adds up to the following scale of knowledge situations in decision problems:

Certainty	It is known what states of nature will occur
Risk	The states of nature and their probabilities are known
Uncertainty	The states of nature are known but not their probabilities
Great uncertainty, ignorance	Not even the states of nature are known

The probabilities referred to in decision theory may be either objective or subjective. In some applications, reliable estimates of probabilities can be based on empirically known frequencies. As one example, death rates at high exposures to asbestos are known from epidemiological studies. In most cases, however, the basis for probability estimates is much less secure. This applies for instance to failures of a new, as yet untried technological device. In such cases we have to resort to subjective estimates of the objective probabilities. Some decision theorists deny the existence of true objective probabilities and regard all probabilities as expressions of degrees of belief, which are of course strictly subjective.

In cases when exact probabilities are not known, uncertainty can be expressed with various, more complex measures.

Binary measures: The probability values are divided into two groups, possible and impossible values (or attention-worthy and negligible values). Usually, the former form a single interval. Then the uncertainty can be expressed in terms of an interval, for instance: "The probability of a nuclear war in the next thirty years is between 10 and 25 per cent."

Multivalued measures: A numerical measure is used to distribute plausibility over the possible probability values. This measure may (but need not) be a (second-order) probability measure. Then, instead of just saying that the probability is between 10% and 25%, we can say that there is a 5% probability that the probability is between 17% and 18%, a 4% probability that it is between 18% and 19%, etc.

Robustness measures: The more certain we are about a probability, the less willing we are to change our estimate of it. Therefore, willingness to change one's estimate of a probability when new information arrives can be used as a measure of uncertainty.

Decision Rules

Decision theorists have developed a series of decision rules, intended to ensure that decisions are made in a systematic and rational way.

The Maximin Rule

Among the decision rules that are applicable without numerical information, the *maximin* rule is probably the most important one. For each alternative, we define its *security level* as the worst possible outcome with that alternative. The maximin rule urges us to choose the alternative that has the highest security level. In other words, we *maxi*mize the *mini*mal outcome.

The maximin rule has often, and quite accurately, been described as a cautious rule. It has also been described as pessimistic, but that is an unfortunate terminology, since caution and pessimism are quite independent of each other.

As an example of the maximin rule, consider the following variant of the soccer example from above:

	No soccer players	Soccer players
Go to soccer ground	Walk, no soccer	Walk, soccer
Stay home	No walk, no soccer	No walk, no soccer

The preferences are:

Walk, soccer
is better than
No walk, no soccer
is better than
Walk, no soccer

The security level of Stay home is "no walk, no soccer" whereas that of Go to soccer ground is "walk, no soccer". Since the former is better than the latter, in order to maximize the security level, Peter would have to stay at home. Consequently, this is what the maximin rule recommends him to do.

Even though the maximin rule can be applied to relational value information as above, it is easier to apply if the value information is presented in numerical form. Again, consider the following utility matrix:

	No soccer players	Soccer players
Go to soccer ground	0	10
Stay home	3	3

Here, the security level of Stay home is 3 whereas that of Go to soccer ground is 0. Since 3 is larger than 0, the maximin rule recommends Peter to stay at home, just as in the relational presentation of the same example.

The Maximax Rule

The best level that we can at all obtain if we choose a certain alternative is called its *hope level*. According to the *maxi-max* rule, we should choose the alternative whose hope level (best possible outcome) is best. Just like the maxi-min rule, the maxi-max rule can be applied even if we only have relational (non-numerical) value information. Consider again the soccer example. The hope level of

Stay home is "no walk, no soccer," and that of Go to soccer ground is "walk, soccer" that Peter values higher. Hence, the maximax rule urges Peter to go to the soccer ground. Similarly, in the numerical representation, Stay home has the hope level 3 and Go to soccer ground has 10; hence again Peter is advised to go to the soccer ground.

The maximax rule has seldom been promoted. Contrary to the maximin rule, it is often conceived as irrational or as an expression of wishful thinking. It is indeed hardly commendable as a general rule for decision-making. However, in certain subareas of life, taking chances may be beneficial, and in such areas behavior corresponding to the maximax rule may not be irrational. Life would probably be much duller unless at least some of us were maximaxers on at least some occasions.

The Cautiousness Index

There is an obvious need for a decision criterion that does not force us into the extreme cautiousness of the maximin rule or the extreme incautiousness of the maximax rule. A middle road is available, but only if we have access to numerical information. We can then calculate a weighted average between the security level and the hope level, and use this weighted average to rank the alternatives. Let us again consider the numerical presentation of the soccer example:

	No soccer players	Soccer players
Go to soccer ground	0	10
Stay home	3	3

For each alternative A, let *min*(A) be its security level and *max*(A) its hope level.

In our example, *min*(Go to soccer ground) = 0 and *max*(Go to soccer ground) = 10. If we choose to assign equal weight to the security level and the hope level, then the weighted value of Go to soccer ground is $0.5 \times 0 + 0.5 \times 10 = 5$. Since *min*(Stay home) = *max*(Stay home) = 3, the weighted average value of Stay home is 3. Hence, with these relative weights, Peter is recommended to go to the soccer ground. More generally speaking, each alternative A is assigned a value according to the following formula:

$$\alpha \times min\,(\mathrm{A}) + (1 - \alpha) \times max\,(\mathrm{A})$$

If $\alpha = 1$, then this rule reduces to the maximin criterion and if $\alpha = 0$, then it reduces to the maximax criterion. The index α is often called the *Hurwicz α index*, after economist Leonid Hurwicz who proposed it in 1950. It is also often called the *optimism-pessimism index*, but the latter terminology should be avoided since the index represents the degree of (un)cautiousness rather than that of optimism. It can more appropriately be called the *cautiousness index*.

Minimax Regret

Utility information also allows for another decision criterion that puts focus on how an outcome differs from other outcomes that might have been obtained under the same state of affairs, if the decision-maker had chosen another alternative. In our example, if Peter stays home and there are players at the soccer ground, then he has made a loss that may give rise to considerable regret. If he goes to the soccer ground and there is no one there to play with him, then he has also made a loss, but a smaller one. The decision rule based on these considerations is usually called the *minimax regret* criterion. It also has other names, such as *minimax risk*, *minimax loss*, and *minimax*.

In this decision rule the degree of regret is measured as the difference between the utility obtained and the highest utility level that could have been obtained (in the same state of the world) if another alternative had been chosen. A *regret matrix* can quite easily be derived from a utility matrix: Replace each entry by the number obtained by subtracting it from the highest utility in its column. In our example, the regret matrix will be as follows:

	No soccer players	Soccer players
Go to soccer ground	3	0
Stay home	0	7

The minimax regret criterion advices the decision-maker to choose the option with the lowest maximal regret (to *mini*mize *maxi*mal *regret*). In this case it recommends Peter to go to the soccer ground.

Just like the maximin rule, the minimax regret rule can be described as cautious, but they apply cautiousness to different aspects of the decision (the value of the actual outcome respectively its regrettableness). As this example shows, they do not always yield the same recommendation.

Expected Utility

None of the above decision rules requires or makes use of probabilistic information. When probabilities are available, the dominating approach is to maximize expected utility (EU). Then to each alternative is assigned a weighted average of its utility values under the different states of nature, with the probabilities of these states used as weights.

In the above example, suppose that based on previous experience Peter believes the probability to be 0.4 that there are players at the soccer ground. We can enter the probabilistic information into the column headings of the utility matrix as follows:

	No soccer players Probability 0.6	Soccer players Probability 0.4
Go to soccer ground	0	10
Stay home	3	3

The expected (probability-weighted) utility of going to the soccer ground is $0.6 \times 0 + 0.4 \times 10 = 4$, and that of staying at home is $0.6 \times 3 + 0.4 \times 3 = 3$. If Peter wants to maximize expected utility then he should, in this case, go to the soccer ground. Obviously, the recommendation would be different with other probabilities.

For a general formula representing expected utility, let there be n outcomes, to each of which is associated a utility and a probability. The outcomes are numbered, so that the first outcome has utility u_1 and probability p_1, the second has utility u_2 and probability p_2, etc. Then the expected utility is defined as follows:

$$p_1 \times u_1 + p_2 \times u_2 + \ldots + p_n \times u_n$$

Expected utility maximization based on subjective probabilities is commonly called *Bayesian decision theory*, or Bayesianism. (The name derives from Thomas Bayes, 1702–1761, who provided much of the mathematical foundations for probability theory). According to Bayesianism, a rational decision-maker should have a complete set of probabilistic beliefs (or at least behave as if she had one) and all her decisions should take the form of choosing the option with the highest expected utility.

Two Paradoxes of Decision Theory

Much of the modern discussion on decision theory has been driven by the presentation of paradoxes, i.e., situations in which decision-making criteria that seem to epitomize rationality nevertheless give rise to decisions that are contrary to most people's intuitions. The following two decision paradoxes serve to exemplify the kinds of philosophical problems that are discussed in the decision-theoretical research literature.

Ellsberg's Paradox

Daniel Ellsberg has presented the following decision problem: We have an urn that contains 30 red ball and 60 balls that are either black or yellow. The distribution between the latter two colors is unknown. A ball is going to be drawn at random from the urn. Before that is done you are offered bets by two persons.

Anne offers you to bet either on red or on black. If you bet on red, then you will receive € 100 if the drawn ball is red and nothing if it is either black or yellow. Similarly, if you bet on black, then you will get € 100 if the ball is black, and nothing if it is red or yellow.

Betty offers you to bet either on red-or-yellow or on black-or-yellow. If you bet on red-or-yellow, then you will get € 100 if the drawn ball is either red or yellow, but nothing if it is black. If you bet on black-or-yellow, then you will get € 100 if the drawn ball is either black or yellow, but nothing if it is red.

Most people, it turns out, prefer betting red to betting black, but they prefer betting black-or-yellow to betting red-or-yellow. It is fairly easy to show that this pattern is at variance with expected utility maximization, i.e., there is no way to assign utilities that would make this pattern compatible with the maximization of expected utility. Ellsberg's own conclusion was that decision-making must take into account factors not covered by probabilities and utilities, in particular the degree of uncertainty of the various probability estimates.

Another problem with this pattern is that it violates the *sure-thing principle* that is a much acclaimed rationality criterion for decisions. To introduce the principle, let A and B be two alternatives, and let S be a state of nature such that the outcome of A in S is the same as that of B. In other words, the outcome in case of S is a "sure thing," not influenced by the choice between A and B. The sure-thing principle says that if the "sure thing" (i.e., the common outcome in case of S) is changed, but nothing else is changed, then the choice between A and B is not affected.

As an example, suppose that a whimsical host wants to choose a dessert by tossing a coin. You are invited to choose between alternatives A and B. In alternative A, you will have fruit in case of heads and nothing in case of tails. In alternative B you will have pie in case of heads and nothing in case of tails. The decision matrix is as follows:

	Heads	Tails
A	Fruit	Nothing
B	Pie	Nothing

When you have made up your mind and announced which of the two alternatives you prefer, the whimsical host suddenly remembers that he has some ice cream, and

changes the options so that the decision matrix is now as follows:

	Heads	Tails
A	Fruit	Ice cream
B	Pie	Ice cream

Since only a "sure thing" (an outcome that is common to the two alternatives) has changed between the two decision problems, the sure-thing principle demands that you do not change your choice between *A* and *B* when the decision problem is revised in this fashion. If, for instance, you chose alternative *A* in the first decision problem, then you are bound to do so in the second problem as well.

In this example, the sure-thing principle appears rational enough, and it would seem natural to endorse it as a general principle for decision-making. Ellsberg's paradox shows that is not quite as self-evident as it may seem to be at first sight.

Newcomb's Paradox

The following paradox was proposed by the physicist William Newcomb: In front of you are two boxes. One of them is transparent, and you can see that it contains $1,000. The other is covered, so that you cannot see its contents. It contains either $1,000,000 or nothing. You have two options to choose between. One is to take both boxes, and the other is to take only the covered box. A predictor who has infallible (or almost infallible) knowledge about your psyche has put the million in the covered box if he predicted that you will only take that box. Otherwise, it is empty.

Let us apply maximized expected utility to the problem. If you decide to take both boxes, then the predictor has almost certainly foreseen this and put nothing in the covered box. Your gain is $1,000. If, on the other hand, you decide to take only one box, then the predictor has foreseen this and put the million in the box, so that your gain is $1,000,000. In other words, maximization of expected utility urges you to take only the covered box.

There is, however, another plausible approach to the problem that leads to a different conclusion. If the predictor has put nothing in the covered box, then it is better to take both boxes than to take only one, since you will gain $1,000 instead of nothing. If he has put the million in the box, then too it is better to take both boxes, since you will gain $1,001,000 instead of $1,000,000. Thus, taking both boxes is better in all states of nature. (It is a *dominating* option.) It seems to follow that you should take both boxes, contrary to the rule of maximizing expected utilities.

The two-box strategy in Newcomb's problem maximizes the "real gain" of having chosen an option, whereas the one-box strategy maximizes the "news value" of having chosen an option. The very fact that a certain decision has been made in a certain way changes the probabilities that have to be taken into account in that decision.

In *causal decision theory*, expected utility calculations are modified so that they refer to real value rather than news value. This is done by replacing standard probabilities by some formal means for evaluating the causal implications of the different options. Since there are several competing philosophical views of causality, there are also several formulations of causal decision theory.

About the Author

Sven Ove Hansson is professor in philosophy and Head of the division of Philosophy, Royal Institute of Technology, Stockholm. He is Editor-in-Chief of *Theoria*. His research areas include value theory, decision theory, epistemology, belief dynamics and the philosophy of probability. He is the author of well over 200 articles in refereed journals. His books include *A Textbook of Belief Dynamics. Theory Change and Database Updating* (Kluwer 1999) and *The Structures of Values and Norms* (CUP 2001). He is a member of the Royal Swedish Academy of Engineering Sciences (IVA).

Decision Trees for the Teaching of Statistical Estimation

Carlos Eduardo Valdivieso Taborga
Professor of Statistics
Universidad Privada Boliviana, Cochabamba, Bolivia

Introduction

In many experiments or research, researchers want to know whether the difference in means, proportions, or variances between two populations is significant, or sometimes if the average, proportion, or variance are near to a standard value. They also will be interested in an interval which is expected to contain the value of the difference in means, proportions, and variances of the two populations, or the average, proportion, or variance of a population. In all these cases, researchers have to rely on statistical estimation and choose the most appropriate procedure.

Since many different confidence intervals have been proposed in the literature, the choice can sometimes be difficult and confusing, especially for students. In this chapter we will show how decision trees can help in finding the most appropriate ▶confidence interval.

Types of Estimations

An estimator is a statistic of a sample that is used to estimate a population parameter such as mean, proportion, or variance. An estimate is a specific value of the observed statistics. In real life the parameter values of the populations studied are unknown. To obtain the best achievable information for the parameters we rely on the sample data and apply a procedure that is called statistical estimation. For this purpose we can use one of the following:

- *Point estimator* as is a single value that estimates the value of the parameter. Two estimators are, for example, the sample mean: $\bar{x} = \frac{\sum_{i=1}^{n} x_i}{n}$ (as estimator for the population mean), and sample variance: $s^2 = \frac{\sum_{i=1}^{n} x_i^2 - n\bar{x}^2}{n-1}$ (as estimator for the population variance).
- *Interval estimation*, which provides a numerical range in which it is intended to find the value of the parameter under study.

One disadvantage of point estimators is that they do not provide information on how close they are to the true value of the parameter. To incorporate some measure of the accuracy of an estimate, we determine a range (confidence interval). This range includes the value of the parameter with a certain predetermined probability $1 - \alpha$, which is called the confidence level, or sometimes confidence coefficient (and is typically taken to be 0.95 or 0.99).

Decision Trees for Choosing the Proper Confidence Interval

Because in statistics there are many different confidence interval expressions we'll attempt to show here how one can choose the appropriate one, in other words, the one that is best suited for the data at hand. Choice of the interval depends on several conditions:

- Which population parameter has to be estimated?
- How many populations are under investigation?
- With one population, does the sample come from a normal population or not, do we know the population variance or not, and also is the sample size small (less than 30) or large?
- In the case of two populations, are the samples independent or dependent and are population variances equal or not?

To facilitate making the proper decision regarding an adequate confidence interval a researcher may use the decision trees, discussed in the next section. Their use is simple; however, we will explain the procedure and give an example to provide more clarity.

Example

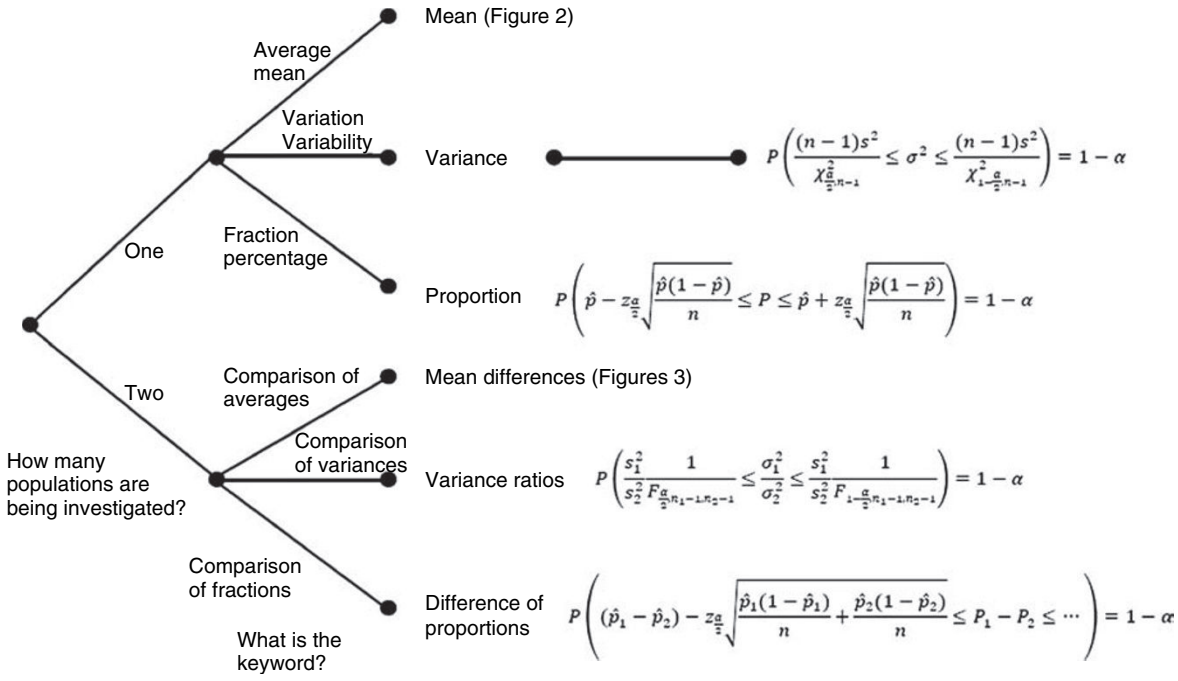
A new filtering device is installed at a chemical plant. Random samples yield the following information of percentage of impurity before and after installation:

Sample/Statistics	Mean	Variance	Sample size
Before	12.5	101.17	8
After	10.2	94.73	9

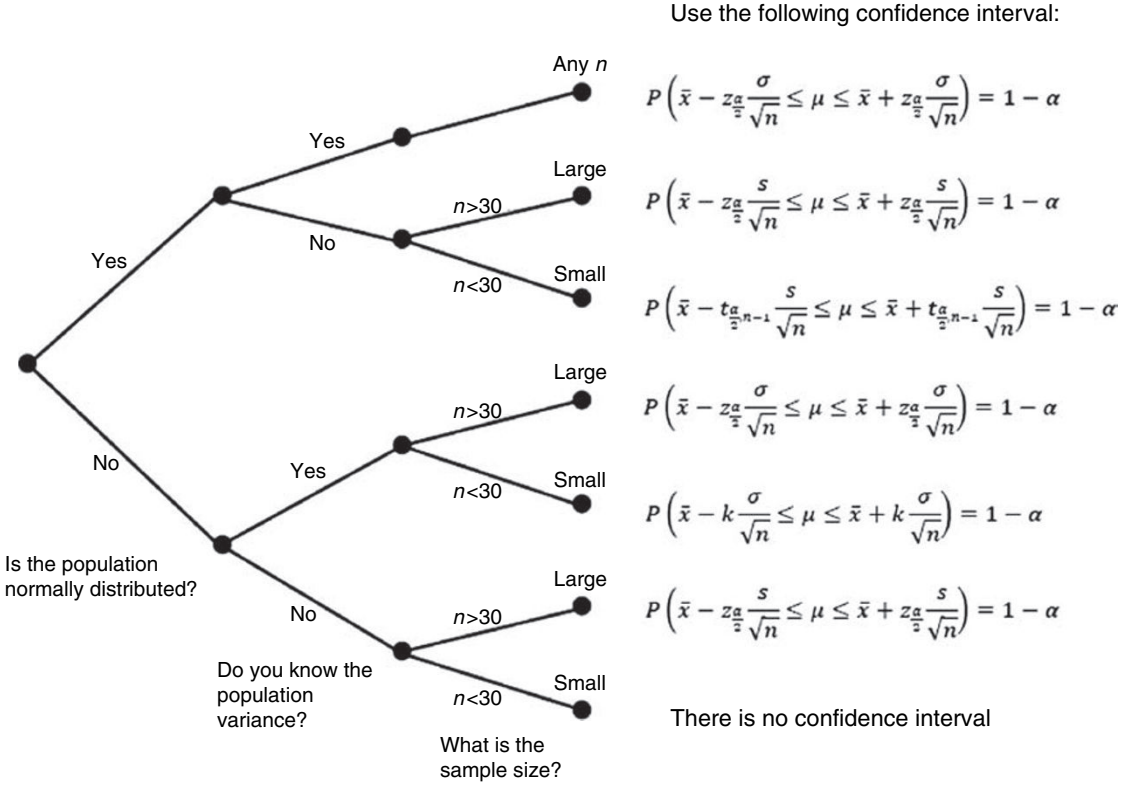
(a) Establish a way to estimate if the impurity has the same variability before and after installing the new filter device. Use $\alpha = 0.05$.
(b) Does the filtering device have reduced the average impurity significantly? Use $\alpha = 0.05$.
(c) If the average percentage of impurities allowed in the chemical plant is 5%, is the goal reached?

(a) From Fig. 1, we get the following information:

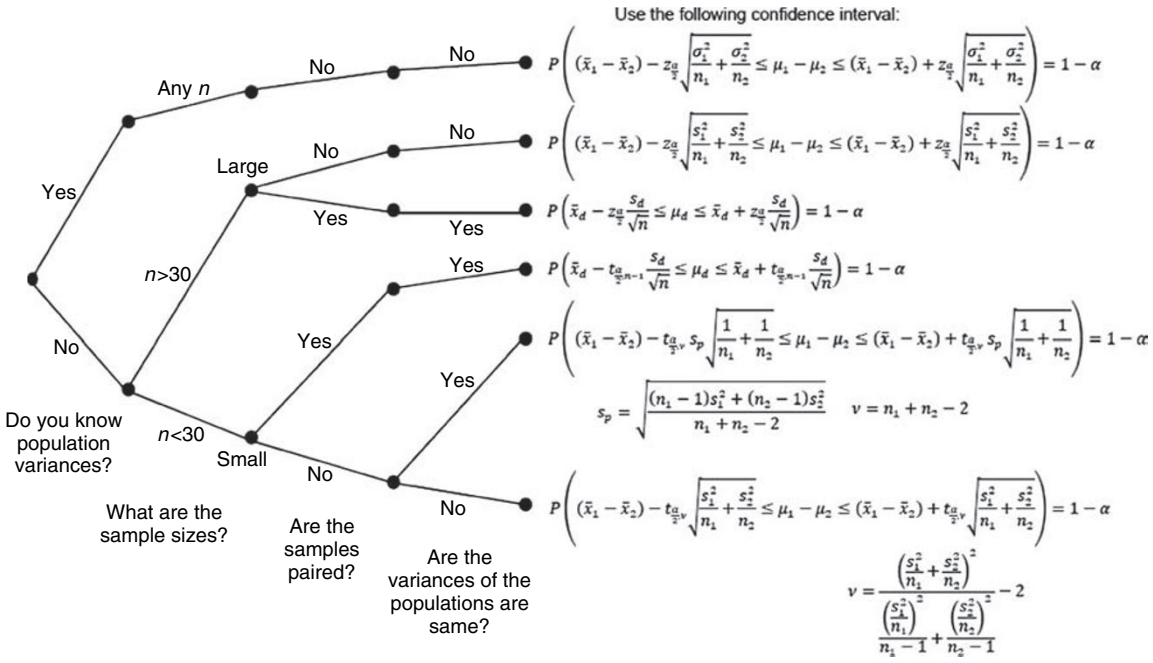
- How many populations are being investigated? *Since we have a before-and-after case, obviously there are two populations.*
- What is the keyword? *Comparison of variances.*



Decision Trees for the Teaching of Statistical Estimation. Fig. 1 Decision tree for choosing the proper confidence interval



Decision Trees for the Teaching of Statistical Estimation. Fig. 2 Decision tree for choosing the proper confidence interval for the mean of the population



Decision Trees for the Teaching of Statistical Estimation. Fig. 3 Decision tree for choosing the proper confidence interval for the difference of means of normal populations

- Therefore, we choose the interval for the variance ratio

$$P\left(\frac{s_1^2}{s_2^2}\frac{1}{F_{\alpha/2,n_1-1,n_2-1}}\le\frac{{\sigma_1}^2}{{\sigma_2}^2}\le\frac{s_1^2}{s_2^2}\frac{1}{F_{1-\alpha/2,n_1-1,n_2-1}}\right)=1-\alpha.$$

Replacing the sample information and critical points of the F distribution we obtain:

$$P\left(\frac{101.17}{94.73}\frac{1}{4.53}\le\frac{{\sigma_1}^2}{{\sigma_2}^2}\le\frac{101.17}{94.73}\frac{1}{0.20}\right)$$
$$=95\%\;P\left(0.24\le\frac{{\sigma_1}^2}{{\sigma_2}^2}\le5.23\right)=95\%.$$

We conclude that there is no significant difference between the impurity variability before and after installing the new filter device (since the interval contains 1).

(b) From Fig. 1, we acquire answers to the following questions:

- How many populations are being investigated? *Two populations, with the same argument as above.*
- What is the keyword? *Comparison of averages.* We will make use of Fig. 3.
- Do we know population variances? *No.*
- What are the sample sizes? *Less than 30.*
- Are the variances of the populations the same? *Yes* (Result of part a).

Therefore, the appropriate confidence interval is for mean difference:

$$P\left((\bar{x}_1-\bar{x}_2)-t_{\alpha/2,v}s_p\sqrt{\frac{1}{n_1}+\frac{1}{n_2}}\le\mu_1-\mu_2\le(\bar{x}_1-\bar{x}_2)\right.$$
$$\left.+t_{\alpha/2,v}s_p\sqrt{\frac{1}{n_1}+\frac{1}{n_2}}\right)=1-\alpha$$

with

$$s_p=\sqrt{\frac{(n_1-1)\,{s_1}^2+(n_2-1){s_2}^2}{n_1+n_2-2}}$$

By including the sample information and critical points of the t distribution we obtain

$$s_p=\sqrt{\frac{(8-1)101.17+(9-1)94.73}{8+9-2}}=9.89.$$

$$P\left((12.5-10.2)-(2.13)9.89\sqrt{\frac{1}{8}+\frac{1}{9}}\le\mu_1-\mu_2\le\right.$$
$$\left.(12.5-10.2)+(2.13)9.89\sqrt{\frac{1}{8}+\frac{1}{9}}\right)=0.95$$
$$P(-7.94\le\mu_1-\mu_2\le12.54)=0.95$$

The filtering device has not been effective because the average impurity before and after is the same (since the confidence interval encompasses 0).

(c) From Fig. 1, we get the following information:

- How many populations are being investigated? *Since only want to see if the new device has helped to achieve the goal: one.*
- What is the keyword? *Mean*. We will use Fig. 2.
- Is the population normally distributed? *Let us assume that the sample came from a normal population.*
- Do we know the population variance? *No*.
- What is the sample size? *Small (less than 30)*.

Thus, the appropriate confidence interval for the mean is:

$$P\left(\bar{x} - t_{\alpha/2,n-1}\frac{s}{\sqrt{n}} \le \mu \le \bar{x} + t_{\alpha/2,n-1}\frac{s}{\sqrt{n}}\right) = 1 - \alpha$$

Replacing the sample information and critical points of the t distribution:

$$P\left(10.2 - 2.31\frac{9.73}{\sqrt{9}} \le \mu \le 10.2 + 2.31\frac{9.73}{\sqrt{9}}\right) = 95\% \quad P(2.71 \le \mu \le 17.69) = 95\%$$

The impurity is within the limit allowed by the plant.

Degradation Models in Reliability and Survival Analysis

Mikhail Nikulin
Professor
Université Victor Segalen, Bordeaux, France

Introduction

Traditionally the failure time data are usually used for product reliability estimation. Failures of highly reliable units are rare and other information should be used in addition to censored failure time data. One way of obtaining complementary reliability information is to use higher levels of experimental factors or covariates to increase the number of failures and, hence, to obtain reliability information quickly. The *accelerated life testing* (ALT, see ►Accelerated Lifetime Testing) of technical, biological or biotechnical systems is an important practical method of estimation of the reliability of new systems without having to wait through the operating life of them. It is evident that the *extrapolating reliability* from ALT always carries the risk that the accelerating stresses do not properly excite the failure mechanism which dominates at operating (*usual, normal, standard*) stresses. Another way of obtaining this complementary reliability information is to measure some parameters (covariates) that characterize the aging and the degradation of the product in time. In analysis of *longevity* of highly reliable complex industrial or biological systems, the degradation processes provide additional information about the *aging, degradation, fatigue, internal wear* and *deterioration* of systems, and from this point of view the degradation data are really a very rich source of additional information and often offer many advantages over failure time data. Degradation is the natural response for some tests, and it is also natural that with degradation data it is possible to make useful reliability and statistical inference, even with no failures. It is evident that it may be difficult or costly to collect degradation measures from some components or materials. Sometimes it is possible to apply the expert's estimation of the level of degradation or fatigue, etc. Sometimes it is possible to construct degradation models in which degradation is measured *without errors*, but there are also situations when the degradation data are obtained with measurement errors.

Dynamic Regression Models

Statistical inference from ALT is possible if failure time regression models relating failure time distribution with explanatory variables (covariates, stresses), influencing the reliability are well chosen. Statistical inference from failure time-degradation data with covariates needs even more complicated models relating failure time distribution not only with external but also with internal explanatory variables (degradation, wear) which explain the state of units before the failures. In the last case models for degradation process distribution are needed, too. Here we discuss only several most used failure time-degradation regression models.

Denote by T the random time-to-failure of a unit (or system). We say also that T is the time of *hard* or *traumatic*

failure. Let S be the survival function and λ be the hazard rate of T:

$$S(t) = P\{T > t\}, \quad \lambda(t) = \lim_{h \to 0} \frac{1}{h} P\{t < T \le t + h | T > t\}, \tag{1}$$

from where it follows that $S(\cdot)$ can be written as

$$S(t) = e^{-\Lambda(t)}, \quad \text{where} \quad \Lambda(t) = \int_0^t \lambda(s) ds$$

is the cumulative hazard function of T. Denote $F(\cdot) = 1 - S(\cdot)$ the cumulative distribution function of T. In Survival Analysis and Reliability the models are often formulated in terms of cumulative hazard and hazard rate functions. The most common shapes of hazard rates are monotone, $\cup$- shaped or $\cap$- shaped, see, for example, Meeker and Escobar (1998), Lawless (2003), Zacks (2004).

Let suppose that any explanatory variable is a deterministic time function

$$x = x(\cdot) = (x_1(\cdot), \ldots, x_m(\cdot))^T : [0, \infty[\to B \in R^m,$$

which is a vector of covariates itself or a realization of a stochastic process $X(\cdot)$, which is called also the *covariate process*, $X(\cdot) = (X_1(\cdot), \ldots, X_m(\cdot))^T$. We denote by E the set of all possible (admissible) covariates. We do not discuss here the questions of choice of X_i and m, but they are very important for the organization (design) of the experiments and for statistical inference. The covariates can be interpreted as the control, so we may consider models of aging in terms of the optimal control theory. We may say also that we consider statistical modeling with dynamic design or in dynamic environments.

In accordance with (1) the survival, the hazard rate, the cumulative hazard and the distribution functions given covariate x are:

$$\begin{aligned} S(t|x) &= P(T > t | x(s); 0 \le s \le t), \\ \lambda(t|x) &= -\frac{S'(t|x)}{S(t|x)}, \\ \Lambda(t|x) &= -\ln[S(t|x)], \\ F(t|x) &= P(T \le t | x(s); 0 \le s \le t) \\ &= 1 - S(t|x), \quad x \in E, \end{aligned} \tag{2}$$

from where one can see their dependence on the life-history up to time t. On any family E of admissible stresses, we may consider a class $\{S(\cdot|x), x \in E\}$ of survival functions which could be very rich. Failure is affected by time-dependent covariates (loads, stress, usage rate) which describe heterogeneous and dynamic operating conditions.

We say that the time $f(t|x)$ under the stress x_0 is *equivalent* to the time t under the stress x if the probability that a unit used under the stress x would survive till the moment t is *equal* to the probability that a unit used under the stress x_0 would survive till the moment $f(t|x)$:

$$\begin{aligned} S(t|x) = P\{T > t | x(s); 0 \le s \le t\} = P\{T > f(t|x) | x_0(s); \\ 0 \le s \le f(t|x)\} = S(f(t|x)|x_0). \end{aligned}$$

It implies that

$$f(t|x) = S^{-1}[S(t|x)|x_0], \quad x \in E. \tag{3}$$

Let x and y be two admissible stresses: $x, y \in E$. We say that a stress y is *accelerated* with respect to x, if $S(t|x) \ge S(t|y), \quad \forall\, t \ge 0$.

The accelerated failure time (AFT) model is more adapted for failure time regression analysis, see Meeker and Escobar (1998), Bagdonavičius and Nikulin (2002), Lawless (2003), Nelson (2004).

We say that AFT model holds on E if there exists a positive continuous function $r : E \to R^1$ such that for any $x \in E$ the survival and the cumulative hazard functions under a covariate realization x are given by formulas:

$$\begin{aligned} S(t|x) &= G\left(\int_0^t r[x(s)] ds\right) \quad \text{and} \\ \Lambda(t|x) &= \Lambda_0\left(\int_0^t r[x(s)] ds\right), \quad x \in E, \end{aligned} \tag{4}$$

respectively, where $G(t) = S(t|x_0)$, $\Lambda_0(t) = -\ln G(t)$, x_0 is a given (usual) stress, $x_0 \in E$. The function r changes locally the time scale. From the definition of $f(t|x)$ (cf. (3)) it follows that for the AFT model on E

$$f(t|x) = \int_0^t r[x(s)] ds, \quad \text{hence} \quad \frac{\partial f(t|x)}{\partial t} = r(x(t))$$
$$\text{at the continuity points of } r[x(\cdot)]. \tag{5}$$

Note that the model can be considered as parametric (r and G belong to parametric families) semiparametric (one of these functions is unknown, other belongs to a parametric family) or nonparametric (both are unknown).

Modeling of Degradation Process

In reliability there is considerable interest in modeling covariate processes $Z(t), t \ge 0$, with some properties, depending on the phenomena in consideration, which describe the *real* process of wear or the usage history up to time t, indicate the level of fatigue, degradation, and deterioration of a system, and may influence the rate of degradation, risk of failure, and reliability of the system. Statistical modeling of *observed degradation* processes can help to understand different real physical, chemical, medical, biological, physiological, or social degradation processes of aging. Information about *real degradation* processes help us to construct degradation models, which permit us to

predict the cumulative damage, and so on. According to the principal idea of degradation models, a *soft failure* is observed if the degradation process reaches a *critical threshold* z_0. A soft failure caused by degradation occurs when $Z(t), t \geq 0$, reaches the value z_0. The *moment* T^0 of soft failure is defined by relation

$$T^0 = \sup\{t : Z(t) < z_0\} = \inf\{t : Z(t) \geq z_0\}. \quad (6)$$

So it is reasonable to construct the so-called degradation models, based on some suppositions about the mathematical properties of the degradation process $Z(t), t \geq 0$, in accordance with observed *longitudinal* data in the experiment. Both considered methods may be combined to construct the so-called joint degradation models. For this, it is enough to define a failure of the system when its degradation (*internal wear*) reaches a critical value or a traumatic event occurs. The joint degradation models form the class of models with *competing risk*, since for any item we consider two competing causes of failure: degradation, reaching a *threshold* (soft failure), and occurrence of a *hard* or *traumatic failure*. Let T be the moment of traumatic failure of a unit. In the considered class of models, the *failure time* τ is the *minimum* of the moments of traumatic and soft failures,

$$\tau = min(T^0, T) = T^0 \wedge T.$$

These models are also called *degradation-threshold-shock models*. For such models the degradation process $Z(t)$ can be considered as an additional time-depending covariable, which describes the process of wear or the usage history up to time t. The degradation models with covariates are used to estimate reliability when the environment is dynamic (see Singpurwalla 1995; Bagdonavičius and Nikulin 2002). The covariates cannot be controlled by an experimenter in such a case. For example, the tire wear rate depends on the quality of roads, the temperature, and other factors.

In Meeker and Escobar (1998) the use of so-called path models is proposed for construction the degradation process. The authors describe many different applications and models for *accelerated degradation* and Arrhenius analysis for data involving a destructive testing. Meeker and Escobar (1998) used *convex and concave degradation models* to study the growth of fatigue cracks, the degradation of components in electronic circuits.

The most applied ▶stochastic processes describing degradation are general path models and time scaled stochastic processes with stationary and independent increments such as the gamma process, shock processes and Wiener process with a drift.

Example 1 *General degradation path model:* The *general degradation path model* was considered by Meeker and Escobar (1998), according to which

$$Z(t) = g(t, A, \theta) \quad (7)$$

where $A = (A_1, \ldots, A_r)$ is a finite dimensional random vector with positive components and the distribution function π of A, θ is a finite dimensional non-random parameter, and g is a specified continuously differentiable in t function, which increases from 0 to $+\infty$ when t increases from 0 to $+\infty$. The form of the function g is suggested by the form of individual degradation curves, obtained from the experiments. For example, $g(t, a) = t/a$ (linear degradation, $r = 1$) or $g(t, a) = (t/a_1)^{a_2}$ (convex or concave degradation, $r = 2$). It is also supposed that, for each $t > 0$, the degradation path $(g(s, a) \mid 0 < s \leq t)$ determines in the unique way the value a of the random vector A. Degradation in these models is modeled by the process $Z(t, A)$, where t is time and A is some possibly multidimensional random variable. The *linear degradation models* are used often to study the increase in a resistance measurement over time, and the *convex degradation models* and *concave degradation models* are used to study the growth of fatigue cracks.

In many different applications and models for *accelerated degradation* for data involving a destructive testing are described. Influence of covariates on degradation is also modeled in Bagdonavičius and Nikulin (2002), Doksum and Normand (1995), Padgett and Tomlinson (2005), etc., to estimate reliability when the environment is dynamic. The semiparametric analysis of several new degradation and failure time regression models without and with covariables is described in Bagdonavičius and Nikulin (2001, 2004), Yashin (2004), Bagdonavičius et al. (2007), and Zacks (2004). The degradation under the covariate x is modeled by

$$Z(t|x) = g(f(t, x, \beta), A), \quad m(t|x) = Eg(f(t, x, \beta), A).$$

About the methods of estimation one can see also in Meeker and Escobar (1998).

Example 2 *Time scaled gamma process:* $Z(t) = \sigma^2 \gamma(t)$, where $\gamma(t)$ is a process with independent increments such that for any fixed $t > 0$

$$\gamma(t) \sim G\big(1, \nu(t)\big), \quad \nu(t) = \frac{m(t)}{\sigma^2},$$

i.e., $\gamma(t)$ has the ▶gamma distribution with the density

$$p_{\gamma(t)}(x) = \frac{x^{\nu(t)-1}}{\Gamma\big(\nu(t)\big)} e^{-x}, \quad x \geq 0,$$

where $m(t)$ is an increasing function. Then

$$Z(t|x) = \sigma^2\, \gamma(f(t,x,\beta)).$$

The mean degradation and the covariances under the covariate x are

$$m(t|x) = E(Z(t|x)) = m\left(f(t,x,\beta)\right),$$
$$Cov(Z(s|x), Z(t|x)) = \sigma^2 m(f(s \wedge t, x, \beta)).$$

Bagdonavičius and Nikulin (2001) considered estimation from failure time-degradation data, Lawless (2003), considered estimation from degradation data.

Example 3 *Time scaled Wiener process with a drift:* $Z(t) = m(t) + \sigma W(m(t))$, where W denotes the standard Wiener motion, i.e., a process with independent increments such that $W(t) \sim N(0,t)$. Then

$$Z(t|x) = m(f(t,x,\beta)) + \sigma W(m(f(t,x,\beta))).$$

The mean degradation and the covariances under the covariate x are

$$m(t|x) = m\left(f(t,x,\beta)\right), \quad Cov(Z(s|x), Z(t|x)) = \sigma^2 m(f(s \wedge t, x, \beta)).$$

Doksum and Normand (1995), Lehmann (2001, 2004, 2005) Whitmore and Schenkelberg (1997) considered estimation from degradation data.

Example 4 *Shock processes:* Assume that degradation results from shocks, each of them leading to an increment of degradation. Let T_n, $(n \geq 1)$ be the time of the nth shock and X_n the nth increment of the degradation level. Denote by $N(t)$ the number of shocks in the interval $[0,t]$. Set $X_0 = 0$. The degradation process is given by

$$Z(t) = \sum_{n=1}^{\infty} 1\{T_n \leq t\} X_n = \sum_{n=0}^{N(t)} X_n.$$

Kahle and Wendt (2006) model T_n as the moments of transition of the doubly stochastic Poisson process, i.e., they suppose that the distribution of the number of shocks up to time t is given by

$$P\{N(t) = k\} = E\left\{\frac{(Y\eta(t))^k}{k!} \exp\{-Y\eta(t)\}\right\},$$

where $\eta(t)$ is a deterministic function and Y is a non-negative random variable with finite expectation. If Y is non-random, N is non-homogenous Poisson process, in particular, when $\eta(t) = \lambda t$, N is homogenous Poisson process. If $\eta(t) = t$, then N is a mixed Poisson process. Other models for η may be used, for example, $\eta(t) = t^{\alpha}$, $\alpha > 0$. The random variable Y is taken from some parametric class of distributions. Wendt and Kahle (2004), Kahle and Wendt (2006) considered parametric estimation from degradation data. Lehmann (2005, 2006) considered estimation from failure time-degradation data.

Example 5 *Degradation model with noise:* suppose that the lifetime of a unit is determined by the degradation process $Z(t)$ and the moment of its potential traumatic failure is T. Denote by T^0 the moment at which the degradation attains some critical value z_0. Then the moment of the unit's failure is $\tau = T^0 \wedge T$. To model the degradation-failure time process, we suppose that the real degradation process is modeled by the *general path model*:

$$Z_r(t) = g(t, A) \tag{8}$$

where $A = (A_1, \ldots, A_r)$ is a random positive vector, and g is continuously differentiable increasing in t function. As remarked earlier, the real degradation process $Z_r(t)$ is often not observed, and we have to measure (to estimate) it. In this case, the *observed degradation process* $Z(t)$ is different from the real degradation process $Z_r(t)$. We supposed that we have the *degradation model with noise* according to which the *observed degradation process* is

$$Z(t) = Z_r(t)U(t), \quad t > 0 \tag{9}$$

where $\ln U(t) = V(t) = \sigma W(c(t))$, W is the standard *Wiener process* independent of A, and c is a specified continuous increasing function, with $c(0) = 0$. For any $t > 0$ the *median* of $U(t)$ is 1.

Using this model it is easy to construct a *degradation model with noise*. An important class of models based on degradation processes was developed recently by Bagdonavičius et al. (2007). Wulfsohn and Tsiatis (1997) proposed considered the so-called *joint model* for survival and longitudinal data measured with error, given by

$$\lambda_T(t|A) = \lambda_0(t) e^{\beta(A_1 + A_2 t)} \tag{10}$$

where $A = (A_1, A_2)$ follows bivariate normal distribution. On the other hand Bagdonavičius and Nikulin (2004) proposed the model in terms of a conditional survival function of T given the real degradation process:

$$S_T(t|A) = P\{T > t | g(s,A), 0 \leq s \leq t\} = \exp\left\{-\int_0^t \lambda_0(s,\theta)\lambda(g(s,A))ds\right\} \tag{11}$$

where λ is the unknown intensity function, $\lambda_0(s,\theta)$ is from a parametric family of hazard functions. The distribution of A is not specified. This model states that the conditional hazard rate $\lambda_T(t|A)$ at the moment t given the degradation

$g(s, A), 0 \le s \le t$, has the multiplicative form as in the famous Cox model:

$$\lambda_T(t|A) = \lambda_0(s, \theta)\lambda(g(s, A)) \quad (12)$$

If for example, $\lambda_0(s, \theta) = (1 + t)^{\theta}$ or $\lambda_0(s, \theta) = e^{t\theta}$, then $\theta = 0$ corresponds to the case when the hazard rate at any moment t is a function of the degradation level at this moment. One can note that in the second model the function λ, characterizing the influence of degradation on the hazard rate, is nonparametric.

Degrees of Freedom

Chong Ho Yu
Arizona State University, Tempe, AZ, USA

Many elementary statistics textbooks introduce the concept of degrees of freedom (df) in terms of the number scores that are "free to vary." However, this explanation cannot clearly show the purpose of df. There are many other approaches to present the concept of degrees of freedom. Two of the most meaningful ways are to illustrate df

in terms of sample size and dimensionality. Both represent the number of pieces of *useful information.*

DF in Terms of Sample Size

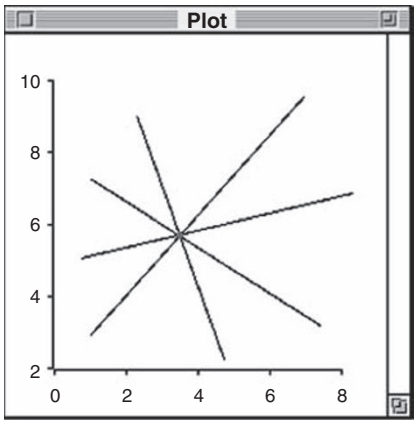
Toothaker (1986) explained *df* as the number of independent components minus the number of parameters estimated. This approach is based upon the definition provided by Walker (1940): the number of observations minus the number of necessary relations, which is obtainable from the observations ($df = n - r$). Although Good (1973) criticized that Walker's approach is not obvious in the meaning of necessary relations, the number of necessary relationships is indeed intuitive when there are just a few variables. "Necessary relationship" can be defined as the relationship between a dependent variable (Y) and each independent variable (X) in the research. Please note that this illustration is simplified for conceptual clarity. Although Walker regards the preceding equation as a universal rule, $df = n - r$ might not be applicable to all situations.

No Degree of Freedom and Effective Sample

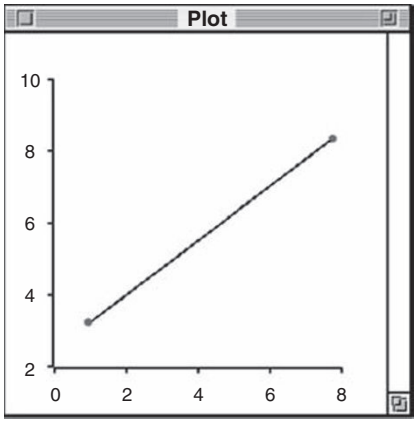
Figure 1 shows that there is one relationship under investigation ($r = 1$) when there are two variables. In the scatterplot there is only one datum point. The analyst cannot do any estimation of the regression line because the line can go in any direction, as shown in Fig. 1. In other words, there isn't any useful information. When the degree of freedom is zero ($df = n - r = 1 - 1 = 0$), it is impossible to affirm or reject the model. In this sense, the data have no "freedom" to vary. Bluntly stated, one subject is basically useless, and obviously, *df* defines the *effective* sample size (Eisenhauer 2008). The effective sample size is smaller than the actual sample size when *df* is taken into account.

Perfect Fitting and Overfitting

In order to plot a regression line, one must have at least two data points as indicated in Fig. 2. In this case, there is one degree of freedom for estimation ($n - 1 = 1$, where $n = 2$). When there are two data points only, one can always join them to be a straight regression line and get a perfect correlation ($r = 1.00$). This "perfect-fit" results from the lack of useful information. Since the data do not have much "freedom" to vary, no alternate models could be explored. In addition, when there are too many variables in a regression model, i.e., the number of parameters to be estimated is larger than the number of observations, this model is said to lacking degrees of freedom and thus is over-fit.



Degrees of Freedom. Fig. 1 No degree of freedom with one datum point



Degrees of Freedom. Fig. 2 Perfect fit with two data points

DF in Terms of Dimensions and Parameters

In this section, degrees of freedom are illustrated in terms of dimensionality and parameters. According to Good (1973), degrees of freedom can be expressed as

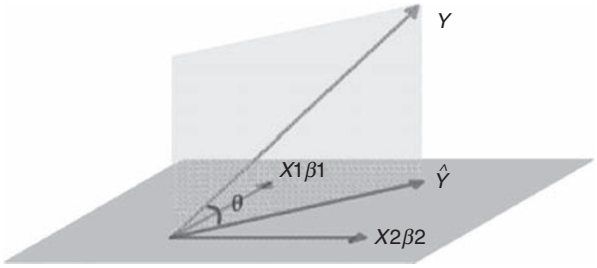
$$D(K) - D(H),$$

whereas

$D(K)$ = the dimensionality of a broader hypothesis, such as a full model in regression

$D(H)$ = the dimensionality of the null hypothesis, such as a restricted or null model.

In Fig. 3 vectors (variables) in hyperspace (Saville and Wood 1991; Wickens 1995) are used for illustrating a regression model. It is important to point out that the illustration is only a metaphor to make comprehension easier. Vectors do not behave literally as shown. In hyperspace, Vector Y represents the dimension of the outcome variable



Degrees of Freedom. Fig. 3 Vectors in hyperspace

whereas Vector $X1\beta1$ and $X2\beta2$ denote the dimensions of the predictors with two estimated parameters (βs). Vector $\hat{Y}$ is the dimension of Y expected and $\cos(\theta)$ equals R (relationship among $X1, X2$, and Y). In this example the intercept is ignored.

What is (are) the degree(s) of freedom when there is one variable (vector) in a regression model? First, we need to find out the number of parameter(s) in a one-predictor model. Since only one predictor is present, there is only one beta weight to be estimated. The answer is straightforward: There is one parameter to be estimated. How about a null model? In a null model, the number of parameters is set to zero. The expected Y score is equal to the mean of Y and there is no beta weight to be estimated. Based upon $df = D(K) - D(H)$, when there is only one predictor, the degree of freedom is just one $(1-0 = 1)$. It means that there is only one piece of useful information for estimation. In this case, the model is not well-supported. As you notice, a 2-predictor model $(df = 2 - 0 = 2)$ is better-supported than the 1-predictor model $(df = 1 - 0 = 1)$. When the number of *orthogonal* vectors increases, we have more pieces of independent information to predict Y and the model tends to be more stable. In short, the degree of freedom can be defined in the context of *dimensionality*, which conveys the amount of *useful information*. However, it is important to note that some regression methods, such as ridge regression (see ►Ridge and Surrogate Ridge Regressions), linear smoothers and ►smoothing splines are not based on ►least squares, and so *df* defined in terms of dimensionality is not applicable to these modeling.

Putting Both Together

The above illustrations (Walker's *df* and Good's *df*) compartmentalize *df* in terms of sample size and *df* in terms of dimensionality (variables). However, observations (n) and parameters (k), in the context of *df*, must be taken into consideration together. For instance, in regression, the *working definition* of degrees of freedom involves the information of both observations and dimensionality: $df = n - k - 1$ whereas n = sample size and k = the number of variables. Take the 3-observation and 2-variable case as an example. In this case, $df = 3 - 2 - 1 = 0$. Readers who are interested in *df* are referred to the online tutorial posted on http://www.creative-wisdom.com/pub/df/default.htm

Degrees of Freedom in Statistical Inference

Joseph G. Eisenhauer
Professor and Dean
University of Detroit Mercy, Detroit, MI, USA

The term *degrees of freedom* refers to the number of items that can be freely varied in calculating a statistic without violating any constraints. Such items typically include observations, categories of data, frequencies, or independent variables. Because the estimation of parameters imposes constraints on a data set, a degree of freedom is generally sacrificed for each parameter that must be estimated from sample data before the desired statistic can be calculated.

Consider first a simple case. A sample of size n initially has n degrees of freedom, in the sense that any or all of the observations could be freely discarded and replaced by others drawn from the population. However, once their sum has been calculated, only $n - 1$ observations are free to vary, the final one being determined by default. Equivalently, once the sample mean $\bar{x}$ has been calculated, n deviations from the mean can be found but they must sum to zero, so only $n - 1$ deviations are free to vary. In letters to W.S. Gosset around 1912, Sir Ronald Fisher first

showed that if the deviations are squared and averaged over $n-1$ rather than n, the resulting sample variance s^2 is an unbiased estimator of the population variance σ^2.

This basic notion recurs throughout inferential statistics. With a normal distribution, testing a hypothesis regarding σ^2 proceeds by way of a chi-square statistic, $\chi^2 = (n-1)s^2/\sigma^2$. Notice that $E(s^2) = \sigma^2$ implies $E(\chi^2) = n-1$. As this suggests, there exists an entire family of chi-square distributions, the mean of any one of which is its degrees of freedom. Moreover, because χ^2 takes only nonnegative values, the distribution is positively skewed when its mean is near zero, and it becomes increasingly symmetric as the degrees of freedom rise. Consequently, the probability that χ^2 exceeds a given value increases with the degrees of freedom. Put differently, the critical value for a chi-square test at a given level of significance increases with its degrees of freedom. Student's t statistic for testing a normal population mean likewise has the $n-1$ degrees of freedom from the sample variance. As the degrees of freedom rise, the shape of the t distribution approaches that of the standard normal; its variance decreases, and thus, the probability that t exceeds a given value diminishes. To compare the means from two normal populations with $\sigma_1^2 = \sigma_2^2$, the sample variances are pooled and the resulting t statistic then has $(n_1-1)+(n_2-1)$ degrees of freedom. For normal populations with $\sigma_1^2 \neq \sigma_2^2$, Satterthwaite (1946) proposed the approximation $t = (\bar{x}_1 - \bar{x}_2)/\sqrt{a_1 + a_2}$ with $(a_1+a_2)^2/\left[\left(a_1^2/\nu_1\right) + \left(a_2^2/\nu_2\right)\right]$ degrees of freedom, where $a_i = s_i^2/n_i$ and $\nu_i = n_i - 1$; in this case, the degrees of freedom will generally not be an integer. To test for equal variances, the F ratio (so named for Fisher), $F = s_1^2/s_2^2$, is used with $n_1 - 1$ numerator degrees and $n_2 - 1$ denominator degrees of freedom. If F is significantly larger or smaller than unity, the null hypothesis of equal variances can be rejected. Of course, because the designation of populations 1 and 2 is arbitrary, we could just as well invert the F ratio and reverse its degrees of freedom. Therefore, commonly available tables of the F distribution report only the right-hand critical value for an F test or confidence interval; to obtain the left-hand critical value, the numerator and denominator degrees of freedom are reversed, and the resulting table value is inverted.

The decomposition of a sample variance into explained and unexplained components via ▶analysis of variance (ANOVA) also relies on degrees of freedom. The sum of squared deviations from the sample mean, or sum of squares total (SST), has $n-1$ degrees of freedom as explained above. Similarly, with k treatment categories, the sum of squares due to treatment ($SSTR$) has $k-1$ degrees, and the residual, the sum of squares due to error (SSE), has $(n-1)-(k-1) = (n-k)$ degrees of freedom. Dividing the sums of squares by their respective degrees of freedom, the mean square due to treatment is $MSTR = SSTR/(k-1)$ and the mean square due to error is $MSE = SSE/(n-k)$. Because each of these is a type of variance, we compare them using the test statistic $F = MSTR/MSE$ with $k-1$ numerator degrees and $n-k$ denominator degrees of freedom. A related application involves measuring the strength, or explanatory power, of a multiple linear regression, where k is reinterpreted as the number of regression coefficients (including the intercept) and $SSTR$ denotes the sum of squares due to regression. Increasing the number of independent variables $(k-1)$ tends to alter the composition of SST by raising $SSTR$ and reducing SSE, though the increase in explained variation may be somewhat spurious; the coefficient of determination, $R^2 = 1 - (SSE/SST)$, can thereby become inflated. The customary correction is to divide SSE and SST by their respective degrees of freedom, yielding the adjusted coefficient of determination $\bar{R}^2 = 1 - \{[SSE/(n-k)]/[SST/(n-1)]\}$ as the measure of explanatory power.

Algebraically, a system of j simultaneous equations in k unknowns has $k-j$ degrees of freedom. Consider, for example, a goodness-of-fit test to determine whether the variable x, which takes the values $0, 1, 2 \ldots (k-1)$, follows a truncated Poisson distribution with a given mean. There are k expected frequencies, but since they must sum to the sample size n, one can be determined from the others. Thus, only $k-1$ are free to vary, i.e., there are $k-1$ degrees of freedom. Moreover, if it is necessary to first estimate the population mean from the sample data in order to obtain the Poisson distribution, an extra constraint is imposed, leaving $k-2$ degrees of freedom; see Eisenhauer (2008) for a numerical illustration. By the same reasoning, a goodness-of-fit test for a normal distribution segmented into k intervals has $k-1$ degrees of freedom if the mean and standard deviation of the population are known; but if both parameters need to be estimated, two more degrees are sacrificed and $k-3$ degrees of freedom remain.

Fisher (1922) originally coined the phrase *degrees of freedom* in correcting Karl Pearson's test of independence. A contingency table consisting of r rows and c columns into which frequencies are entered has rc cells, but given row and column totals, the entries for the final row and final column – totaling $r+c-1$ cells – can be determined from the others. Thus, there are only $rc-(r+c-1) = (r-1)(c-1)$ degrees of freedom for the chi-square test statistic.

About the Author

Demographic Analysis: A Stochastic Approach

Krishnan Namboodiri
Professor Emeritus
Ohio State University, Columbus, OH, USA

Introduction

Demographers study population dynamics: changes in population size and structure resulting from fertility (childbearing performance), mortality (deaths), and spatial and social mobility. The focus may be the world population or a part of it, such as the residents of a country or the patients of a hospital. Giving birth, dying, shifting usual place of residence, and trait changes (e.g., getting married) are called events. Each event involves transition from one "state" to another (e.g., from never-married state to married state). A person is said to be "at risk" or "exposed to the risk" of experiencing an event, if for that person the probability of that experience is greater than zero. The traits influencing the probability of experiencing an event are called the risk factors of that event (e.g., high blood pressure, in the case of ischemic heart disease).

Demographic data are based on censuses (see ►Census), sample surveys, and information reported to offices set up for continuously recording demographic events. Some observational studies can be viewed as random experiments. For an individual selected at random from a population at time t, the value of the variable $y_{t+\theta}$, denoting whether that individual will be alive as of a subsequent moment $t + \theta$ is unpredictable. This unpredictability of the value of $y_{t+\theta}$ qualifies the observational study involving observations at times t and $t + \theta$ to be considered as a random experiment and $y_{t+\theta}$ as a random variable, defined by a set of possible values it may take (e.g., 1 if alive at time $t + \theta$, and 0, otherwise) and an associated probability function (Kendall and Buckland 1971). The interval between a fixed date and a subsequent event is a random variable, in the above-mentioned sense.

The term rate is used in ►demography for the number of events (e.g., deaths) expressed per unit of some other quantity, such as person-years at risk (often expressed per 1,000). For example, the *crude death rate* (annual number of deaths expressed per 1,000 mid-year population) in Japan in 2007 was 9. The mid-year population in such calculations is an approximation to the sum of the person-years lived by the members of the population involved during the specified year. Death rates calculated for subpopulations, homogeneous, to some degree, with respect to one or more relevant risk factors are called specific death rates. Examples are age-specific and age-sex specific death rates.

A *life-table* (see ►Life Table) shows the life-and-death history of a group of persons, called a *cohort*, born at the same time (e.g., a year), as the cohort members survive to successive ages or die in the intervals, subject to the mortality conditions portrayed in a schedule of age-specific death rates. An account of the origin, nature, and uses of life tables is available in P. R. Cox (1975). Life tables have become powerful tools for the analysis of non-renewable (non-repeatable) processes. If a repeatable process, such as giving births, can be split into its non-renewable components (e.g., births by birth order) then each component can be studied, using the life-table method. The term: *survival analysis* is applied to the study of non-renewable processes, in general. Associated with the survival rate is the hazard rate, representing the instantaneous rate of failure (to survive). Hazard rate corresponds to the instantaneous death rate or force of mortality, as used in connection with life tables.

Macro-Level Focus

A great deal of demographic research is linked directly or indirectly to model construction and validation, viewing observations as outcomes of random experiments. Birth-and-death process (see Kendall 1948; Bhat 1984), is a continuous time, integer valued, counting process, in which

population size at time t, remains constant, increases by one unit (a birth), or decreases by 1 unit (a death), over the period: t to $t+\Delta t$. Time-trend in population size is studied using branching processes, in a simple version of which, each member of each generation produces offspring, in accordance with a fixed probability law common to all members (see, e.g., Grimmett and Stirzaker 1992 for a discussion of simple as well as complex models of branching processes). The logistic process for population growth of the "birth-and-death" type views the instantaneous rates of birth and death for each individual alive at a given moment as linear functions of population size (see Brillinger 1981; Goel and Dyn 1979; Mollison 1995). For compositional analysis, one may apply an appropriate log-ratio transformation to the composition of interest, and treat the resulting values as a random vector from a multivariate normal distribution (see Aitchison 1986; Namboodiri 1991).

Using the component model (see Keyfitz 1971) of population projection, one obtains internally consistent estimates of the size and age-sex composition of populations as of future years by combining hypothesized patterns of change in fertility, mortality, and migration. On the basis of such projections, issues such as the following can be examined: (1) Reduction in population growth rate resulting from the elimination of deaths due to a specific cause, e.g., heart disease; (2) Relative impact on the age-composition, in the long-run, of different combinations of population-change components (e.g., fertility and mortality); and (3) tendency of populations to "forget" the past features (e.g., age composition) if the components of population dynamics were to continue to operate without change over a sufficiently long time.

To estimate and communicate the uncertainty of population projections, the practitioners have been combining "high," "medium," and "low" scenarios for the components of population change in various ways (e.g., "high" fertility combined with "low" mortality to produce "high" population projection) to show different possibilities regarding future population size and composition. Since such demonstrations of uncertainties have no probabilistic interpretations, Lee and Tuljapurkar, among others, have pioneered efforts to develop and popularize the use of stochastic population projections (see Lee 2004). Lee and Tuljapurkar (1994) demonstrated, for example, how to forecast births and deaths, from time-series analyses of fertility and mortality data for the United States, and then combine the results with deterministically estimated migration to forecast population size and composition. They used in the demonstration, products of stochastic matrices.

Comparison of the simple non-stochastic trend model: $y_t = \beta_0 + \beta_1(t) + e_t$, with the stochastic (random-walk with a drift) model: $y_t = \alpha_0 + y_{t-1} + e_t$, where e_t's are $NID(0, \sigma_e)$ for all t, shows that even when the error terms have equal variance $\left(\sigma_e^2\right)$ in the two models, the prediction intervals for the latter are wider than those of the former: For a forecast horizon H, the variance of the forecast error (the departure of the forecast from the actual) in the case of $y_t = \beta_0 + \beta_1(t) + e_t$ is σ_e^2, while the corresponding quantity is $H\sigma_e^2$, in the case of $y_t = \alpha_0 + y_{t-1} + e_t$.

Micro-Level Processes

At the micro level, one focuses on events (such as giving birth to the first child, dying, recovering from illness, and so on) experienced by individuals. In event histories, points of time at which transitions occur (e.g., from not in labor force to employed) are represented by a sequence of non-negative random variables: $(T_1, T_2, \ldots)$, and the differences: $V_k = T_k - T_{k-1}, k = 2, 3, \ldots$, are commonly referred to as waiting times. Comprehensive discussions of waiting times are available, for example, in: Cleves et al. (2004); Collett (2003); Elandt-Johnson and Johnson (1980/1999); and Lawless (1982/2003).

D. R. Cox (1972) introduced, what has come to be known as, the proportional hazards model: $\lambda(t) = \lambda_0(t)\psi(z_1, z_2, \ldots, z_k)$, where "$t$" represents time, and the multiplier, $\psi(z_1, z_2, \ldots, z_k)$, is positive and time-independent. A special form of the model is: $\lambda(t) = \lambda_0(t)\exp(\Sigma\beta_j z_j)$, in which $\{\beta_j\}$ are unknown regression coefficients.

An important feature of waiting time is heterogeneity (variation among individuals) in the hazard rate (see Sheps and Menken 1973; Vaupel et al. 1979; Heckman and Singer 1982). Heterogeneity is incorporated often as a multiplier in the Cox proportional hazards model. For example, the hazard function for the ith individual may be specified as: $\lambda_0(t)v_i\exp(\Sigma_j\beta_j Z_{ij})$, representing an individual-specific, unobserved heterogeneity factor by v_i. Vaupel et al. (1979) called such models: "frailty" models (see ▶Frailty Model).

Heckman and Singer (1982) suggested the specification of the unobserved heterogeneity factor in $\lambda(t) = \lambda_0(t)v_i\exp(\Sigma_j\beta_j Z_{ij})$, as a K-category discrete random variable. Thus the ith individual is presumed to belong to one of K groups. The value of K is determined empirically so as to maximize the likelihood of the sample on hand, under a specified (e.g., the exponential or Weibull) form for $\lambda_0(t)$. In the presence of heterogeneity, inference becomes sensitive to the form assumed for the hazard function (see, e.g., Trussell and Richards 1985).

As Sheps and Perin (1963) and Menken (1975), among others, have pointed out, simplified models, unrealistic though they may be, have proved useful in gaining insights such as that a highly effective contraceptive used by a rather small proportion of a population reduces birth rates more

than does a less effective contraceptive used by a large proportion of the population.

Some fertility researchers have been modeling parts rather than the whole of the reproductive process. The components of birth intervals have been examined, with emphasis on the physiological and behavioral determinants of fertility (see Leridon 1977). Another focus has been abortions, induced and spontaneous (see Abramson 1973; Potter et al. 1975; Michels and Willett 1996). Fecundability investigations have been yet another focus (see Menken 1975; Wood et al. 1994). Menken (1975) alerts researchers to the impossibility of reliably estimating fecundability from survey data. The North Carolina Fertility Study referred to in Dunson and Zhou (2000) is of interest in this connection: In that study couples were followed up from the time they discontinued birth control in order to attempt pregnancy. The enrolled couples provided base-line data and then information regarding ovulation in each menstrual cycle, day-by-day reports on intercourse, first morning urine samples, and the like. Dunson and Zhou present a Bayesian Model and Wood et al. (1996) present a multistate model for the analysis of fecundability and sterility.

To deal with problems too complex to be addressed using analytic models, researchers have frequently been adopting the simulation strategy, involving computer-based sampling and analysis at the disaggregated (e.g., individual) level. See, for example, the study of (1) kinship-resources for the elderly by Murphy (2004); and Wachter (1997); (2) female family-headship by Moffit and Rendall (1995); (3) AIDs and the elderly by Wachter et al. (2002); and (4) the impact of heterogeneity on the dynamics of mortality by Vaupel and Yashin (1985); and Vaupel et al. (1979). Questions such as the following arise: Is it possible to reproduce by simulation the world-population dynamics, detailing the changes in the demographic-economic-spatial-social DESS) complex, over the period, say: 1900–2000? Obviously, in order to accomplish such a feat, one has to have a detailed causal model of the observed changes to be simulated. As of now no satisfactory model of that kind is available. Thinking along such lines demographers might begin to view micro-simulation as a challenge and an opportunity to delve into the details of population dynamics.

About the Author

Dr. Krishnan Namboodiri was Robert Lazarus Professor of Population Studies at the Ohio State University, Columbus, Ohio, USA, (1984–2000) and has been Professor Emeritus at the same institution since 2000. Before joining the Ohio State University, he was Assistant Professor, Associate Professor, Professor, and Chairman, Department of Sociology, University of North Carolina at Chapel Hill, USA, (1966–1984); Reader in Demography, University of Kerala, India, (1963–1966). Dr. Namboodiri was Editor of Demography (1976–1979), and Associate Editor of of a number of professional journals such as Mathematical Population Studies (1985–1989). He has authored or co-authored over 80 publications including 12 books. He is a Fellow of the American Statistical Association, and is a recipient of honors such as Lifetime Achievement Award from Kerala University, and has been consultant from time to time to Ford Foundation, World Bank, United Nations, and other organizations.

The Character of the Field of Demography

The Topics of Investigation

Demography is the statistical study of human populations, including their size, composition, and geographical distribution, and of the processes of change in these elements. Demographers focus on childbearing (fertility), death (mortality), and geographical moves (migration), but they also cover other processes, like the formation and dissolution of (marital and nonmarital) unions, the transition out of the parental home, and other transitions relevant to population structure and population trends. As a field of inquiry, Demography has roots going back to John Graunt's famous study of the bills of mortality (1662) and to T. R. Malthus's essay on the principle of population (1798). For an account of how the endeavors of demographers have developed into a discipline, see Hodgson (2001), Szreter (2001), and Caldwell, 2003). For more extensive accounts about the field of demography, see Rosenzweig and Stark (1997) and Demeny and McNicoll (2003).

The Discipline

Like all academic disciplines, demographers have formed national, regional, and international societies, such as the Population Association of America, the European Association for Population Studies, the International Union for the Scientific Study of Population, and many others. Its oldest professional journals are publishing their 65th volumes or so in 2009 (*Population Studies, Population, Genus*), and there are a large number of younger journals (*Demography*, the *Population and Development Review*, the *European Journal of Population*, *Demographic Research, Journal of Population Research, Mathematical Population Studies, Journal of Population Economics* and so on), some of which are recent start-ups (like the *Romanian Journal of Population Studies*).

Demography courses are given by some universities, often as a part of studies in other disciplines, such as geography, sociology, or statistics. More extensive teaching is organized through demographic research centers like INED (Institut National des Études Démographiques in Paris), NIDI (the Netherlands Interdisciplinary Demographic Institute in The Hague), and MPIDR (the Max Planck Institute for Demographic Research in Rostock), sometimes as a joint venture of demographic centers and university departments across Europe (like the European Doctoral School in Demography). Teaching, research, and instrumental advice are also offered by demographic centers established by the United Nations and others (e.g., the Population Council). North America has its own demographic centers. Ideally, teaching programs reflect the multidisciplinarity of demography (Caselli 2002).

Demographic Data

Since the beginning of public data collection, demographers have made use of several sources of official statistics. For instance, status data are collected in decennial

censuses, typically to provide information about population composition and about the size of local populations or other groups at census time. Vital statistics (i.e., data on births, deaths, migration, marriages, etc.) are published annually and normally provide aggregate data for an entire population or for large population units. Individual-level (micro) data are mostly collected in special sample surveys organized at the national (or sub-national) level or designed to provide internationally comparable individual-level data (the Fertility and Family Surveys, the Generations and Gender Surveys, the Demographic and Health Surveys, and so on). In the Nordic countries and in a few other countries, individual-level demographic data are organized in a continuous-register system and made available for research. Several other countries or organizations have started to make registers of specific events available for research (such as a birth register, pension registers, migration registers). Recently international databases have been established for scientific use, such as the Human Mortality Database and the Human Fertility Database, both at MPIDR, or the IPUMS-data (International Public Use Microdata Series at the Minnesota Population Center). For further insights about demographic data regimes, see Haines (2001).

Population Forecasts

Producing population forecasts is a practical activity that many demographers are engaged in. Colleagues in other disciplines often resort to population forecasts produced by demographers.

Demography at the Crossroad of many Disciplines

As a field of endeavor, demography is highly interdisciplinary. Today we would characterize as demography much of the early activity of academic statisticians, and there is a residue of common interest down to the present time. Historically, demography has also been allied particularly closely with actuarial mathematics, epidemiology, sociology, economics, geography, and history. More recently it has developed links with biology, political science, and anthropology. The overlap between scientific fields is often so great that individual scientists may find it difficult to pledge their allegiance solely to demography or to a neighboring discipline; they often see themselves as members of both. Even what initially looks like a purely demographic theory may really need an underpinning in other disciplines. One case in point is an understanding of the role that a reduction of mortality at young ages has in initiating a decline in fertility. To explain why fertility declines, why there is a link between mortality decline and fertility decline, and why the pattern of the latter differs between societies, it is natural to resort to economics, health science, and perhaps anthropology.

The following examples provide selected glimpses of some overlaps between disciplines: There is constantly a mutual enrichment between demographic studies of family dynamics and sociological theory about the family. A deep investigation of policy effects in fertility trends is unthinkable without the insight and knowledge of political scientists, and conversely the latter can benefit from demographic statisticians' understanding of measurement issues (Frejka et al. 2008, Overview Chapter 8). Studies of mortality differentials gain from a sociological understanding of class differences. Demographic items are central to some recent theories about violent conflicts internal to populations. Demographers use elements from spatial theory in their studies of childbearing patterns among immigrants. Patterns of union formation contain important signals about the integration of minority groups, including immigrants (Basu and Aaby 1998), signals that should be useful to anthropologists. On the other hand, the latter are not always happy about the lack of attention paid to anthropological insight in classical demographic explanations of fertility trends in developing countries (Greenhalgh 1996).

Demographic Methodology

Stocks and Flows; Timing and Quantum

Demography has a distinctive emphasis on stocks and flows. Conceptually, a population is subdivided into a number of subgroups between which individuals move. The subgroups may represent life statuses, like "married," "divorced," "childless," "at parity 1" (= mothers/fathers with one child), and individuals are seen as constantly exposed to the risk of transition from one subgroup (or status) into another. Deaths are counted among the flows, and a ▶life table can be seen as a tabular representation of attrition from the stock of the living at the various ages. The underlying risks determine the timing of the flows, and the percentage that ultimately participates in a flow is called its quantum.

Data Cleaning and Careful Description

Cleaning the data of incorrect and inaccurate records is part of a demographer's preparation for analysis (Booth 2001). Demographers have always put great store on bringing out the facts, and this continues to be important in demographic investigations, while deeper explanation is often left to members of other disciplines despite any aspiration demographers may have toward the use (and development) of substantive theory. In this vein, demographers have a long tradition of careful description of empirical

regularities, mostly based on macro-data, but lately also covering patterns of individual-level behavior.

New Statistical Methods

To analyze demographic (vital) processes as dependent "variables," demographers have developed or adopted a number of statistical methods also used in other disciplines, notably public health and epidemiology. One can get an overview of the range of such methods as seen by demographers by consulting the various entries under 'demographic techniques' in Smelser and Baltes (2001). Entries under 'population dynamics' in the same source cover stable population theory, which is much used in demography. It is essentially based on extensions of branching-process theory.

The advent of event-history techniques has recently induced a change in the way many demographers approach their investigations. Demographers have increasingly turned to individual-level analyses of multi-process models and to multi-level modeling. The latter has opened the way for the inclusion of population-level features as determinants in investigations of individual behavior. It has also become possible to incorporate a feature like unobserved heterogeneity and thus to pick up selectivity in demographic behavior. These new possibilities have strengthened the tendency to use probabilistic thinking in demographic investigations and thus to make the field more recognizable to mathematical statisticians.

Transition Rates of Type 1 and Type 2

To give an impression of how demographic methodology fits into the world of statistical theory but have a flavor of its own, let us first note that just like in any application of event-history analysis in a transition model with a piecewise-constant hazard specification, a count of event occurrences $\{D_j\}$ and exposures $\{R_j\}$ (time-units of exposure) for the various subgroups $\{j\}$ of a population can be seen as a statistically sufficient set of statistics for the model risk parameters $\{\mu_j\}$. In such a situation, the occurrence/exposure rate $\hat{\mu}_j = D_j/R_j$ is a maximum-likelihood estimator of the parameter μ_j, and demographers would call it a *rate of the first kind*. Suppose, for instance, that the subscript j stands for a combination of (discrete) age x attained and civil status c, where $c = 0$ stands for "never married," say. Then $\mu_{x,0}$ can be the "risk" of entering first marriage at age x (for someone who has never been married before that age) and the first-marriage rate of the first kind will be $\hat{\mu}_{x,0} = D_{x,0}/R_{x,0}$. When the occurrences can be fully sub-specified but the population cannot be subdivided by marital status but only by age attained, say, a first-marriage rate $\mu^*_x = D_{x,0}/R_x$ of *the second kind* can still be computed for a given birth cohort, where $R_x = \sum_c R_{x,c}$ is an aggregate over all marital statuses c. (Note that μ^*_x is not an occurrence/exposure rate, because the denominator R_x includes the person-years $\sum_{c\neq 0} R_{x,c}$ also of individuals who are not under risk of first marriage in addition to the exposures $R_{x,0}$ for those who *are* under the risk of first marriage.) Demographers put rates of the second kind to uses of their own, but to a statistician, the main advantage of such rates is probably that in *cohort* data they can be converted into estimates rates of the first kind by means of the following formula:

$$\hat{\mu}_{x,0} = \mu^*_x \Big/ \left(1 - \sum_{y<x} \mu^*_y\right).$$

For a proof, see the argument by Calot (2001) leading up to his formula (3). (Note that all quantities in this formula refer to the same birth cohort. No corresponding conversion formula seems to exist for period data.)

About the Author

Dr. Jan Hoem is a Past President of the Scandinavian Demographic Society (1973–1974). He was Professor of Insurance Mathematics at Copenhagen University (1974–1981), Professor of Statistical Demography, Stockholm (1981–1999), where he is Guest Professor since 2009. He was Director of the Max Planck Institute for Demographic Research (1999–2007), and is Director Emeritus since 2007. Dr. Hoem was Section Editor for Demography of the International Encyclopedia of the Social and Behavioral Sciences (1998–2001). He was Editor of the electronic journal *Demographic Research* (1999–2006). Professor Hoem is Laureate of the International Union for the Scientific Study of Population (2006). He has authored and co-authored well over a hundred publications. He has initiated the use of Markov chains in life insurance mathematics, and has been instrumental in the development of event-history analysis in demography.

Density Ratio Model

Konstantinos Fokianos
Associate Professor
University of Cyprus, Nicosia, Cyprus

The problem of comparing two (or more samples) appears in several and diverse applications. The parametric theory resolves the problem by appealing to the well-known t-test. To carry out the t-test both samples are assumed to be normally distributed with common unknown variance and unknown means. The two-sample t-test enjoys several optimality properties, for instance, it is uniformly the most powerful unbiased test. Occasionally some (or all) of the needed assumptions fail; for instance, when there exists a group of observations with skewed distribution, then both assumptions of normality and equality of variances do not hold true. Hence, application of the ordinary two-sample t-test is questionable. The problem is usually bypassed after a suitable transformation but the comparison needs to be carried out in the transformed scale. Alternatively, we can appeal to the nonparametric theory, which approaches the problem of comparing two samples by the so-called Mann–Whitney–Wilcoxon test (see ►Wilcoxon–Mann–Whitney Test).

We consider a quite different approach to the two-sample comparison problem. The methodology is relatively new and depends on the so-called *density ratio model* for *semiparametric* comparison of two samples. To be more specific, assume that

$$\begin{aligned} X_1, \ldots, X_{n_0} &\sim f_0(x) \\ X_{n_0+1}, \ldots, X_n &\sim f_1(x) = \exp(\alpha + \beta h(x)) f_0(x). \end{aligned} \tag{1}$$

where $f_i(x)$, $i = 0, 1$ are probability densities, h is a *known* function, and α, β are two unknown parameters. In principle, $h(x)$ can be *multivariate* but we assume for simplicity that it is a univariate function.

Model (1) is motivated by means of the standard ►logistic regression and the equivalence between prospective and retrospective sampling, Prentice and Pyke (1979). Suppose that Y is a binary response variable and let X be a covariate. The simple logistic regression model is of the form

$$\mathrm{P}[Y = 1 \mid X] = \frac{\exp(\alpha^\star + \beta h(x))}{1 + \exp(\alpha^\star + \beta h(x))}, \tag{2}$$

where $\alpha^\star$ and β are scalar parameters. Notice that the marginal distribution of X is left completely unspecified. Assume that $X_1, \ldots, X_{n_0}$ is a random sample from $F(x \mid Y = 0)$. Independent of the X_i, assume that $X_{n_0+1}, \ldots, X_n$ is a random sample from $F(x \mid Y = 1)$, and let $n_1 = n - n_0$. Put $\pi = P(Y = 1) = 1 - P(Y = 0)$ and assume that $f(x \mid Y = i) = dF(x \mid Y = i)/dx$ exists and represents the conditional density function of X given $Y = i$ for $i = 0, 1$. A straightforward application of ►Bayes' theorem shows that

$$\frac{f(x \mid Y = 1)}{f(x \mid Y = 0)} = \exp(\alpha + \beta h(x))$$

with $\alpha = \alpha^* + \log[(1 - \pi)/\pi]$. In other words, model (2) is equivalent to (1) with $\alpha = \alpha^* + \log[(1 - \pi)/\pi]$.

We refer to (1) as the density ratio model since it specifies a parametric function of the log likelihood ratio of two densities without assuming any specific form about them. Hence, it is a semiparametric model and it is easy to see that, under the hypothesis $\beta = 0$, both of the distributions are identical. In other words, both density functions are assumed unknown but are related, however, through an exponential tilt–or distortion–which determines the difference between them. Notice that model (1) is quite general and includes examples such as the exponential and

partial exponential families of distributions. Model (1) provides a compromise between the fully parametric and nonparametric approaches to the problem of testing equality of two distribution, see Qin et al. (2002), Kedem et al. (2004), and Fokianos et al. (2005), among others, for applications of the density ratio model to real data problems.

It is also important to note that (1) is a biased sampling model with weights depending upon parameters. Inference regarding biased sampling models has been discussed by Vardi (1982, 1985), Gill et al. (1988), and Bickel et al. (1998), in the case of completely known weight functions, while Qin and Zhang (1997), Qin (1998), Gilbert et al. (1999), Gilbert (2000), and Fokianos et al. (2001) consider weight functions unknown up to a parameter.

It is easy to see that (1) generalizes to the m–samples comparison problem. Consider m unknown densities that are related by an exponential tilt of the following form

$$\begin{aligned} X_{11},\ldots,X_{1n_1} &\sim f_1(x) = \exp\left(\alpha_1 + \beta_1 h(x)\right) f_m(x),\\ X_{21},\ldots,X_{2n_2} &\sim f_2(x) = \exp\left(\alpha_2 + \beta_2 h(x)\right) f_m(x),\\ &\ldots \quad \ldots \quad \ldots \\ X_{m1},\ldots,X_{mn_m} &\sim f_m(x), \end{aligned} \tag{3}$$

where the notation follows (1). Estimation of $\beta_1,\ldots,\beta_{m-1}$ as well as inference regarding the cumulative distribution functions that correspond to $f_1(.),\ldots,f_m(.)$ has been considered by Fokianos et al. (2001), who also propose some test statistics for the hypotheses $\beta_1 = \ldots = \beta_{m-1} = 0$, that is, all the samples are identically distributed. In this sense, model (3) is also referred to as a *semiparametric one-way ANOVA*.

In conclusion, the density ratio model for two and m samples avoids the normal theory by specifying that the log ratio of two unknown densities is of some parametric form. Hence, it provides another way of testing the equality of several distributions without resorting to transformations or any other techniques. The last comment is particularly useful since there are examples of data that show that populations follow skewed distributions and therefore classical estimation theory might yield questionable results. The suggested model accommodates skewed data and provides desirable results such as consistent estimators of means, test statistics, and so on.

About the Author

Konstantinos Fokianos received his Ph.D. in Statistics from the University of Maryland at College Park in 1996 and is currently an Associate Professor with the Department of Mathematics and Statistics, University of Cyprus. His research interests include time series, bioinformatics, and semiparametric statistical inference. He has authored/coauthored 40 papers and the book *Regression Models for Time Series Analysis* (Wiley, 2002 with B. Kedem). He has been an elected member of the International Statistical Institute since 2005. He serves as an associate editor for the *Journal of Environmental Statistics, Statistics* and *Probability Letters* and *Computational Statistics & Data Analysis*.

Design for Six Sigma

Rick L. Edgeman
Professor and Chair & Six Sigma Black Belt
University of Idaho, Moscow, ID, USA

►Six Sigma can be defined as *a highly structured strategy for acquiring, assessing, and applying customer, competitor, and enterprise intelligence in order to produce superior product, system or enterprise innovation and designs*

(Klefsjö et al. 2006). Six Sigma originated approximately three decades ago as a means of generating near-perfect products via focus on associated manufacturing processes and while initially applied almost exclusively in manufacturing environments, its inherent sensibilities and organization facilitated migration to service operations. Similarly, while Six Sigma was at the outset used to generate significant innovation in and improvement of existing products, those same sensibilities led to its adaptation to new product and process design environments and it is on use of Six Sigma in design applications that the present contribution is focused.

There is a distinction between using Six Sigma principles in design or innovation applications versus a process operating at a level of six sigma. In terms of performance, a process operating at a "true" six sigma level produces an average of only 3.4 defects per million opportunities (DPMO) for defects where this figure is associated with a process with a 12 standard deviation spread between lower and upper specification limits, but wherein the 3.4 DPMO figure is based on allowance for a 1.5 standard deviation non-centrality factor or shift away from "perfect centering" so that, in essence, one specification limit is 4.5 standard deviations away from the targeted or ideal performance level whereas the other specification limit is 7.5 standard deviations away from that performance level. In practice, of course, a process may operate (typically) at lower or (rarely) higher sigma levels – that is, with less or more spread in standard deviation units between specification limits.

Herein we are not focused on the "sigma level" per se, but rather on the design approach leading to the process or product in question that operates at some sigma level. This approach is called *Design for Six Sigma* (DFSS) and is conducive to higher sigma levels – that is, nearer to perfect results – while at the same time aligning with customer demands and desires or, in more customary language, the Voice of the Customer (VOC) expressed as "customer needs and wants".

While multiple DFSS approaches exist, a few similar ones dominate the application arena with the two most prevalent ones being referred to as I^2DOV (Innovation, Invention, Design, Optimization and Verification) and DMADV (Define, Measure, Analyze, Design, Verify) Algorithm with DMADV being more commonly applied of the two and hence emphasized herein.

It should be emphasized that whichever DFSS approach is used, whether DMADV, I^2DOV, or another, that the approach provides freedom within structure rather than rigidity. That is to say that each phase in the chosen approach has a particular intent, that the phases are generally sequential and linked, and that together they are complete, but that within a given phase many and differing tools and techniques can be brought to bear with those used potentially differing substantially from one application to the next.

Turning now to the DMADV approach to DFSS we can provide the following brief descriptions of each portion of the algorithm.

Define (D): A primary goal of the *Define* phase of DFSS is to acquire and access the VOC and subsequently align goals for the product, process, or service with the VOC. We note here that the customers considered should be both internal and external ones, as applicable. Among methods for acquiring the VOC are focus groups, sample surveys, and examination of customer complaints. Another method of value is to directly observe customer use of similar to products, processes or services so that unspoken, more implicit information can be gathered. In goal-setting it is recommended that these be so-called "SMART" goals, where SMART is an acronym for Specific, Measurable, Attainable, Relevant, and Time-bound. Further, while these goals should be attainable, they should not be "easily" attained, but should rather represent stretch goals, ones that are more likely to position the product, process, or service at the leading edge.

Measure (M): In the DFSS context this requires that we measure and match performance to customer requirements. Fundamentally this is a *quantification* of the VOC and the alignment of this quantification with organizational and management goals.

Analyze (A): This phase demands that the *design* for any existing relevant product, process or service be analyzed and assessed to determine its suitability, performance, error or defect sources, and any corrective or innovative actions that may be taken. Various tools are of potential value in this phase, including *Design Failure Modes and Effects Analysis* (DFMEA), a tool whose name belies its intent. Other useful tools and methods include *Concept Generation and Selection*, and the *Theory of Inventive Problem Solving* (TRIZ).

Design (D): In this phase the array of corrective or innovative actions identified in the analyze phase are embedded in the design and subsequent deployment of new processes required to activate the VOC while simultaneously fulfilling organizational and management goals. While various tools may be of value here, a few of the more advanced approaches that are useful include many from *experimental design and response surface analysis* (Myers et al. 2009) along with more rigorous quality oriented approaches such as *Quality Function Deployment* (QFD). As a way of relating and integrating these latter approaches various customer needs and wants (the VOC) that are critical to QFD and its so-called *House of Quality*

(HOQ) can be regarded as response variables (Y's) whose selected or joint optimization is attained through deployment of identified product or process design attributes are controllable variables $X_1, X_2, \ldots X_P$ so that we have

$$Y = f(X_1, X_2, \ldots X_P) + \varepsilon$$

Where the optimal combination of settings of $X_1, X_2, \ldots X_P$ – called "engineering attributes" in the parlance of QFD – can be determined through use of, e.g., response surface methods, steepest ascent methods, and evolutionary operations or EVOP (Myers et al. 2009). It is important to note that it is not sufficient to simply identify the optimal combination of these variables as it is their specific means of deployment – the process – that ultimately actualizes the VOC.

Verify (V): In the *Verify* phase the objective is to assess performance of the design via such means as prototyping, simulation, or direct observation of the designed product or process in use prior to marketplace deployment. In this way design performance is verified.

From the description of DMADV it is easily concluded that a variety of statistical and other methods can be used to support its effectiveness and a few of these have been suggested herein. That said, it should be evident that the specific methods applied are almost boundless, being limited only as they are primarily by the knowledge and imagination of the design team. In all DMADV offers a logical and highly structured, yet versatile approach to product, process, or service design.

Design of Experiments: A Pattern of Progress

D. R. Cox
Honorary Fellow
Nuffield College, Oxford, UK

The article **Experimental Design, Introduction to** (Hinkelman 2010) sets out the basic statistical principles of experimental design. This supplementary note comments on the historical development of the subject.

Careful experimentation has a long history, perhaps especially in the physical sciences. There is, however, a long history also of experimentation in fields as diverse as agriculture and clinical medicine. The first systematic discussion of experimental design in the presence of substantial haphazard variation seems to be that of Fisher (1926), later developed in his book (Fisher 1935). He set out four principles:

- error control, for example by some form of matching to compare like with like
- independent replication to improve precision and allow its estimation
- randomization to achieve a number of aims, notably avoidance of selection biases
- factorial design to improve the efficiency of experimentation and to allow the exploration of interactions.

The relative importance of these four principles varies between subject-matter fields. This accounts to some extent for differences in how the subject has developed when directed toward, say, agricultural field trials as contrasted with some other fields of application.

In the period up to 1939 these ideas were extensively developed, notably by Fisher's friend and colleague, F. Yates, whose monograph (Yates 1937) is a little known masterpiece of the statistical literature. The focus and impact of this work was primarily but by no means exclusively agricultural.

In the 1950's a strand of new ideas entered from the chemical process industries notably with the work of G.E.P.

Box and his associates; see, for example, Box and Draper (1987). The differences were not so much that factors in a factorial experiment mostly had quantitative levels as that emphasis shifted from the estimation of factorial effects to the response surface of mean outcome considered as a smooth function of the factor level. This led to a richer family of designs and to an emphasis on exploring the form of the response surface in the neighborhood of an optimum. In some of the applications error was relatively small and experiments could be completed quite quickly allowing for a developing sequence of designs.

Carefully designed clinical trials have a long history but the period from about 1970 onward saw their application and development on a large scale. Here typically there a very small number of possible treatments, often just two, and error is large, so that substantial replication is essential. Avoidance of various forms of selection bias by concealment achieved by ►randomization is often crucial. See Piantadosi (1997) for a systematic account.

Two more recent areas of development are applications to matters of public policy, for example in education and criminology. Here an issue concerns the extent to which a parallel with randomized clinical trials is appropriate. The second and very different application concerns the systematic sensitivity analysis of complex computer models involving many adjustable parameters and computationally highly intensive individual runs. Models of climate change are an example.

In all these areas choice of a specific design in a particular context typically involves largely qualitative considerations of balancing the primary requirements of achieving precision and clarity and security of interpretation with practical constraints that are always present, although taking different forms in different fields. There may also be a number of distinct somewhat conflicting objectives. This often makes formal theoretical analysis of design choice difficult. Nevertheless a formal theory of design choice as an optimization problems has appeal both in the sense of showing the formal optimality of standard designs in specific circumstances and in guiding how to proceed in unusual situations, as for example there are specific technical constraints on the factor combinations that may be studied in a complex factorial experiment. A landmark result in such a theory of optimal design is the General Equivalence Theorem of Kiefer and Wolfowitz (1959).

Designs for Generalized Linear Models

André I. Khuri
Professor Emeritus
University of Florida, Gainesville, FL, USA

Introduction

►Generalized linear models (GLMs) represent an extension of the class of linear models. They are used to fit models in general situations where the response data under consideration can be discrete or continuous. Thus, GLMs provide a unified approach for the analysis of such data. Nelder and Wedderburn (1972) are credited for having introduced these models.

Three components are needed to define GLMs. These components are:

(a) The response data are values of a random variable, denoted by y, whose distribution is of the exponential type. Its density function (or probability mass function for a discrete distribution) is of the form

$$\ell(y,\theta,\phi) = \exp\left[\frac{\theta y - b(\theta)}{a(\phi)} + c(y,\phi)\right], \qquad (1)$$

where $a(.)$, $b(.)$, and $c(.)$ are known functions, θ is a so-called *canonical parameter*, and ϕ is a *dispersion parameter*.

(b) The mean response, μ, is related to the so-called *linear predictor*, η, through a function, denoted by h, such that $\mu = h(\eta)$, which is assumed to be monotone and differentiable. The inverse function of h, denoted by g, is called the *link function*. Thus,

$$\eta = g(\mu). \tag{2}$$

The value of the mean response at a point, $\boldsymbol{x} = (x_1, x_2, \ldots, x_k)'$, in a k-dimensional Euclidean space is denoted by $\mu(\boldsymbol{x})$, and the corresponding value of η is denoted by $\eta(\boldsymbol{x})$. Here, $x_1, x_2, \ldots, x_k$ represent control variables that affect the response variable y.

(c) The linear predictor is represented in terms of a linear model of the form

$$\eta(\boldsymbol{x}) = \boldsymbol{f}'(\boldsymbol{x})\beta, \quad \boldsymbol{x} \in \mathcal{R}, \tag{3}$$

where $\mathcal{R}$ is a certain region of interest in the k-dimensional space, $\boldsymbol{f}(\boldsymbol{x})$ is a known function of $\boldsymbol{x}$, and β is a vector of p unknown parameters. It follows that the mean response value at $\boldsymbol{x}$ is given by

$$\begin{aligned}\mu(\boldsymbol{x}) &= h[\eta(\boldsymbol{x})] \\ &= h[\boldsymbol{f}'(\boldsymbol{x})\beta].\end{aligned} \tag{4}$$

Given a set of n independent observations on the response y, namely $y_1, y_2, \ldots, y_n$, at n distinct locations in $\mathcal{R}$, an estimate of β in (3) is obtained by using the method of maximum likelihood. This method maximizes the likelihood function given by

$$\mathcal{L}(\theta, \phi, \boldsymbol{y}) = \prod_{i=1}^{n} \ell(y_i, \theta_i, \phi), \tag{5}$$

with respect to β, where θ_i is a canonical parameter corresponding to y_i $(i = 1, 2, \ldots, n)$, $\boldsymbol{\theta} = (\theta_1, \theta_2, \ldots, \theta_n)'$, and $\boldsymbol{y} = (y_1, y_2, \ldots, y_n)'$. The dispersion parameter, ϕ, is considered to have a fixed value that does not change over the values of y_i $(i = 1, 2, \ldots, n)$. The *maximum likelihood estimate* (MLE) of β is denoted by $\hat{\beta}$. Details about the computation of $\hat{\beta}$ can be found in McCullagh and Nelder (1989, Chap. 2), McCulloch and Searle (2001, Chap. 5), and Dobson (2002, Chap. 4).

The variance–covariance matrix of $\hat{\beta}$ is approximately equal to (see, for example, McCulloch and Searle 2001:143)

$$\mathrm{Var}(\hat{\beta}) \approx (\boldsymbol{X}'\boldsymbol{W}^{-1}\boldsymbol{X})^{-1}, \tag{6}$$

where $\boldsymbol{X}$ is the model matrix for the linear predictor in (3) based on the design matrix used to generate the response data, $y_1, y_2, \ldots, y_n$, and $\boldsymbol{W}$ is the diagonal matrix,

$$\boldsymbol{W} = \bigoplus_{i=1}^{n} \{[g'(\mu_i)]^2 a(\phi) b''(\theta_i)\}. \tag{7}$$

In formula (7), $\oplus$ is the direct sum notation, $g'(\mu_i)$ is the derivative of $g(\mu)$ with respect to μ evaluated at μ_i, and $b''(\theta_i)$ is the second derivative of $b(\theta)$ with respect to θ evaluated at θ_i $(i = 1, 2, \ldots, n)$.

An estimate of the linear predictor, $\eta(\boldsymbol{x})$, in (3) is given by

$$\hat{\eta}(\boldsymbol{x}) = \boldsymbol{f}'(\boldsymbol{x})\hat{\beta}. \tag{8}$$

Using (6), the variance of $\hat{\eta}(\boldsymbol{x})$ is approximately equal to

$$\mathrm{Var}[\hat{\eta}(\boldsymbol{x})] \approx \boldsymbol{f}'(\boldsymbol{x})(\boldsymbol{X}'\boldsymbol{W}^{-1}\boldsymbol{X})^{-1}\boldsymbol{f}(\boldsymbol{x}). \tag{9}$$

The mean response, $\mu(\boldsymbol{x})$, in (4) can then be estimated by using the expression,

$$\hat{\mu}(\boldsymbol{x}) = h[\boldsymbol{f}'(\boldsymbol{x})\hat{\beta}]. \tag{10}$$

This estimate is called the *predicted response* at $\boldsymbol{x}$. From (9) and (10) it follows that the variance of $\hat{\mu}(\boldsymbol{x})$ is approximately equal to

$$\mathrm{Var}[\hat{\mu}(\boldsymbol{x})] \approx \{h'[\eta(\boldsymbol{x})]\}^2 \boldsymbol{f}'(\boldsymbol{x})(\boldsymbol{X}'\boldsymbol{W}^{-1}\boldsymbol{X})^{-1}\boldsymbol{f}(\boldsymbol{x}), \tag{11}$$

where $h'[\eta(\boldsymbol{x})]$ is the derivative of h with respect to η evaluated at $\boldsymbol{x}$. Formula (11) results from taking the variance of the first-order Taylor's series approximation of $h[\hat{\eta}(\boldsymbol{x})]$ in a neighborhood of $\eta(\boldsymbol{x})$. The expression on the right-hand side of (11) is called the *prediction variance*.

It should be noted that $\hat{\mu}(\boldsymbol{x})$ is a biased estimator of $\mu(\boldsymbol{x})$. A measure of closeness of $\hat{\mu}(\boldsymbol{x})$ to $\mu(\boldsymbol{x})$ is given by its mean-squared error, namely,

$$\mathrm{MSE}[\hat{\mu}(\boldsymbol{x})] = \mathrm{E}[\hat{\mu}(\boldsymbol{x}) - \mu(\boldsymbol{x})]^2,$$

which can be partitioned as

$$\mathrm{MSE}[\hat{\mu}(\boldsymbol{x})] = \mathrm{Var}[\hat{\mu}(\boldsymbol{x})] + \{\mathrm{E}[\hat{\mu}(\boldsymbol{x})] - \mu(\boldsymbol{x})\}^2. \tag{12}$$

The second expression, $\mathrm{E}[\hat{\mu}(\boldsymbol{x})] - \mu(\boldsymbol{x})$, on the right-hand side of (12) is called the *bias* associated with estimating $\mu(\boldsymbol{x})$, and is denoted by $\mathrm{Bias}[\hat{\mu}(\boldsymbol{x})]$. We thus have

$$\mathrm{MSE}[\hat{\mu}(\boldsymbol{x})] = \mathrm{Var}[\hat{\mu}(\boldsymbol{x})] + \{\mathrm{Bias}[\hat{\mu}(\boldsymbol{x})]\}^2. \tag{13}$$

This is called the *mean-squared error of prediction* (MSEP) evaluated at $\boldsymbol{x}$. A second-order approximation of $\mathrm{Bias}[\hat{\mu}(\boldsymbol{x})]$ is described in Robinson and Khuri (2003).

Choice of Design for GLMs

By a choice of design, it is meant the determination of the settings of the control variables, $x_1, x_2, \ldots, x_k$, that yield an estimated (or predicted) response with desirable properties. Desirability is assessed by having small values for the prediction variance in (11), or small values for the MSEP in (13). Thus, we can have designs that minimize the prediction variance, or designs that minimize the MSEP. The

former designs utilize criteria similar to those used in linear models, such as *D-optimality* and *G-optimality*, and are therefore referred to as *variance-related criteria*. However, because of the bias in estimating $\mu(\boldsymbol{x})$, it would be more appropriate to adopt a design criterion based on minimizing the MSEP in (13).

The Design Dependence Problem

One problem that faces the actual construction of a design for GLMs is the dependence of the design on β, the vector of unknown parameters in the linear predictor in (3). This is true since $\eta(\boldsymbol{x})$, and hence $\mu(\boldsymbol{x})$, depends on β. Consequently, the elements of the matrix $\boldsymbol{W}$ in (7), which is used in the formulation of both the prediction variance and the MSEP, also depend on β. Thus, to minimize any design criterion function, some knowledge of β is required. This is quite undesirable since the purpose of any design is to estimate β in order to estimate the mean response $\mu(\boldsymbol{x})$.

Common approaches to solving this design dependence problem include the following:

(a) The specification of "guessed", or initial, values of the unknown parameters involved. These values are used in the determination of the so-called *locally-optimal design*. Some references that discuss this approach include those by Mathew and Sinha (2001), Wu (1988), and Sitter and Wu (1993).

(b) The *sequential approach* which starts by using initial values for the unknown parameters. The design derived from these values is then utilized to obtain estimates of the parameters which are then used as updated values leading to another design, and so on. Sequential designs were proposed by Wu (1985), Sitter and Forbes (1997), and Sitter and Wu (1999).

(c) The *Bayesian approach* which assumes a prior distribution on the elements of β. This distribution is then incorporated into an appropriate design criterion by integrating it over the prior distribution. This approach was discussed by several authors. See, for example, Chaloner and Verdinelli (1995) and Atkinson and Haines (1996).

(d) The use of the *quantile dispersion graphs* approach. This more recent approach considers the MSEP in (13) as a criterion for comparing designs rather than selecting an optimal design. More specifically, quantiles of $\mathrm{MSE}[\hat{\mu}(\boldsymbol{x})]$ values in (13) are obtained on several concentric surfaces inside a region of interest, $\mathcal{R}$, which is a subset of the k-dimensional Euclidean space (recall that k is the number of control variables in the linear predictor model in (3)). Let $\mathcal{R}_\nu$ denote the surface of a region obtained by reducing $\mathcal{R}$ using a shrinkage factor, ν $(0 < \nu \leq 1)$. Furthermore for a given design, D, let $Q_D(p, \beta, \nu)$ denote the p^{th} quantile of the distribution of the values of $\mathrm{MSE}[\hat{\mu}(\boldsymbol{x})]$ on $\mathcal{R}_\nu$. Several concentric surfaces can be so obtained by varying the values of ν.

In order to assess the dependence of the design D on β, a certain parameter space, $\mathcal{C}$, to which β is assumed to belong, is specified. Then, the minimum and maximum values of $Q_D(p, \beta, \nu)$ with respect to β are computed over the parameter space $\mathcal{C}$. This results in the following extrema of $Q_D(p, \beta, \nu)$ for each ν and a given p:

$$Q_D^{min}(p, \nu) = \min_{\beta \in \mathcal{C}} \{Q_D(p, \beta, \nu)\}$$

$$Q_D^{max}(p, \nu) = \max_{\beta \in \mathcal{C}} \{Q_D(p, \beta, \nu)\}.$$

Plotting these values against p produces the so-called *quantile dispersion graphs* (QDGs) of the MSEP over the surface $\mathcal{R}_\nu$ for the design D. By repeating this process using several values of ν we obtain plots that depict the prediction capability of the design D throughout the region $\mathcal{R}$. Several plots can be so constructed for each of several candidate designs for the model in (3). A preferred design is one that has small values of Q_D^{min} and Q_D^{max} over the range of p $(0 \leq p \leq 1)$. More details concerning this approach with examples can be found in Khuri and Mukhopadhyay (2006). The approach itself was first introduced in Robinson and Khuri (2003).

The general problem of design dependence along with the aforementioned four approaches were discussed in detail by Khuri et al. (2006).

Detecting Outliers in Time Series Using Simulation

Abdalla M. El-Habil
Head of the Department of Applied Statistics, Faculty of Economics and Administrative Sciences
Al-Azhar University, Gaza, Palestine

Introduction

►Outliers have recently been studied more in the statistical time series literature and this interest is also growing in econometrics. Usually, time series outliers are informally defined as somehow unexpected or surprising values in relation to the rest of the series.

Data of potential value in the formulation of public and private policy frequently occur in the form of time series. Most time series data are observational in nature. In addition to possible gross errors, time series data are often subject to the influence of some uncontrolled or unexpected interventions, for example, implementations of a new regulation, major changes in political or economic policy, or occurrence of a disaster. Consequently, discordant observations and various types of structural changes occur frequently in time series data. Whereas the usual time series model is designed to grasp the homogeneous memory pattern of a time series, the presence of outliers, depending on their nature, may have a moderate to substantial impact on the effectiveness of the standard methodology for time series analysis with respect to model identification, estimation, and forecasting. Therefore, there is a clear need to have available methods to detect or accommodate them.

Simulation data are derived from a sequence of pseudorandom numbers. These pseudorandom numbers are created by a random number generator. The generator requires an initial seed value from which to generate its first value. The random number generator creates both a random number and a new seed for the next value.

The SIMULATE paragraph in the Scientific Computing Associate Corporation (SCA) program may be used to estimate an ARIMA model or a transfer function model. The use of the SIMULATE paragraph for the estimation of a transfer function model is identical as its use for the estimation of an ARIMA model, except for the presence of input series. The SIMULATE paragraph will first generate a noise sequence using a pseudorandom number generator. This sequence is then used according to a transfer function model specified lately using the TSMODEL paragraph.

Detecting Outliers of a Simulated $AR(1)$ Time Series

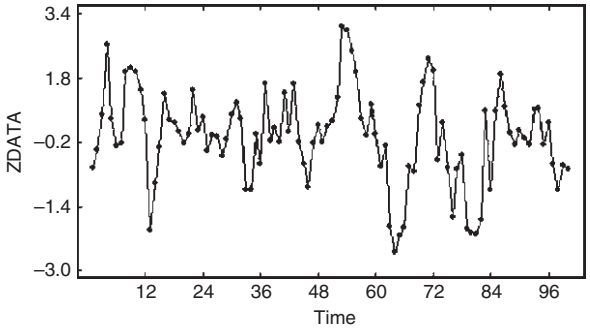
To facilitate our understanding of detecting outliers and their effects, for example, on the values of a simulated $AR(1)$ process, we will assume that the constant of the proposed model is equal to zero. For this purpose, 100 observations are simulated from the model $z_t = [1/(1-0.6B)]a_t$ with $\sigma_a = 1.0$. The data are shown in Fig. 1.

To illustrate, for example, the effect of an AO on the base $AR(1)$ model, we include an AO at time $t = 42$ with $\omega A = 6$ (the value ωA represents the amount of deviation from the "true" value of ZT). The new shape of data is shown in Fig. 2.

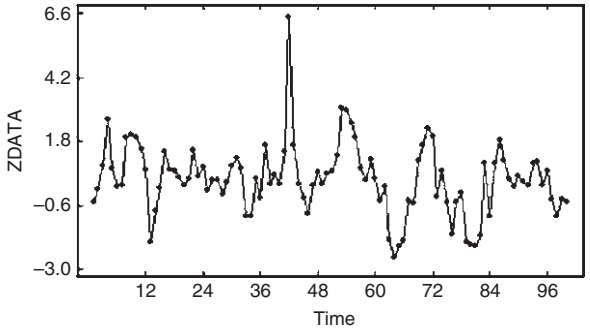
By using the SCA program, only AO has been detected at $t = 42$, and we obtain the estimation results for an $AR(1)$ fit of the simulated $AR(1)$ process as the following:

Case	φ estimate	S. E. of φ estimate	σ_a estimate
Without outlier	0.5921	0.0810	0.9783
AO at time $t = 42$	0.4683	0.0888	1.2177

From the table, with the additive outlier at time $t = 42$, we can see that the parameter estimate is decreased



Detecting Outliers in Time Series Using Simulation. Fig. 1
Zdata



Detecting Outliers in Time Series Using Simulation. Fig. 2
Zdata 1

by approximately 0.13, the estimated residual variance is inflated, and in consequence the prediction intervals can be too wide. In turn, it will affect the model identification, estimation, and forecasting.

Simulation of a Single-Equation Transfer Function Model (with Two-Input Variables)

To detect outliers and study their effects on the values of a simulated single-equation transfer function model (with two-input variables), 300 observations are simulated from the model

$$\text{zdata} = 12.0 + (0.6)\text{xdata} + (0.7)\text{ydata} + \text{at},$$

where the model of xdata is

$$(1 - 0.66B)\text{xdata} = 12.0 + \text{at},$$

and the model of ydata is

$$(1 - 0.7B)\text{ydata} = 11.0 + (1 - 0.6B)\text{at}, \text{ with } \sigma_a = 2.25.$$

We select only the last 250 values of xdata, ydata, and zdata to ensure that any potential irregularities in the beginning of the recursive computation of values are eliminated.

By using the SCA program, we estimated the model

$$\text{zdata} = 12.0 + (\omega 1)\text{xdata} + (\omega 2)\text{ydata} + \text{at},$$

AO has been detected at $t = 50, 82, 106$ and *TC* at $t = 160$. We obtain estimation results for a single-equation transfer function model (with two-input variables) fit of the simulated single-equation transfer function model (with two-input variables) process as the following:

Case	Estimate of $\omega 1$	S. E. of estimate of $\omega 1$	Estimate of $\omega 2$	S. E. of estimate of $\omega 2$	Estimate of σ_a
Without outlier	0.5741	0.0463	0.7416	0.0518	2.3085
AO at $t = 50$, 82, 106 and *TC* at $t = 160$	0.5494	0.0424	0.7448	0.0476	2.3096

As we see from the table, the parameter estimates are moderately changed, and the estimated residual variance is inflated. Thus, the presence of those extraordinary events could easily mislead the conventional time series analysis.

Simulation of Simultaneous Transfer Function (STF) Model

In order to detect outliers and study their effects on the values of a simulated simultaneous transfer function model, 150 observations are simulated from the models

$$\text{Z1data} = 17.0 + (1 - 0.5B)\text{at},$$
$$\text{Z2data} = 25.0 + (1 - 0.6B)\text{at},$$

with $\sigma_a = 2.25$.

By using the SCA program, we estimated the two models simultaneously using the STFMODEL JOINTMDL paragraph. *TC* has been detected at $t = 112$ and *IO* at $t = 126$. We get estimation results for simultaneous transfer

function model fit of the simulated simultaneous transfer function process as the following:

Estimation results for the simultaneous transfer function fit of the simulated transfer function process (first model)

Case	Estimate of z1data	S. E. of estimate of z1data	Estimate of z2data	S. E. of estimate of z2data
Without outlier	0.4579	0.0726	0.0702	0.0811
TC at $t = 112$	0.4786	0.0671	0.0786	0.0794

Estimation results for the simultaneous transfer function fit of the simulated transfer function process (second model)

Case	Estimate of z1data	S. E. of estimate of z1data	Estimate of z2data	S. E. of estimate of z2data
Without outlier	0.0061	0.0369	0.7262	0.0568
TC at $t = 126$	−0.0079	0.0706	0.7452	0.0553

As we see from the above two tables, the parameters estimates are changed, and the estimated residual variance is inflated. So, those outliers could easily mislead the conventional time series analysis.

Summary

In this entry, simulations for detecting outliers and studying their effects on the values of $AR(1)$ time series, transfer function model with one-input variable, transfer function model with two-input variables processes, and simultaneous transfer function (STF) are conducted using the STFMODEL JOINTMDL paragraph in the Scientific Computing Associate Corporation (SCA) program. The conclusion, which we come up with, is that the presence of outliers, depending on their nature, may have a moderate to substantial impact on the effectiveness of the standard methodology for time series analysis with respect to model identification, estimation, and forecasting.

About the Author

Dr. Abdalla El-Habil is Professor of Statistics, and Head of the Department of Applied Statistics at the Faculty of Economics & Admin. Sciences, Al-Azhar University – Gaza, Palestine. He is Past Dean of the Faculty of Economics & Admin. Sciences (2006–2008). He is a member of The International Association for Statistical Education and The International Biometrics Society. He is a member of The Consultative Council of Professional Statistics for Palestine. He was a Chairman of the Palestinian Economists and Statisticians Association (1993–2000).

Detection of Turning Points in Business Cycles

Marianne Frisén
Professor, Statistical Research Unit
University of Gothenburg, Gothenburg, Sweden

Turns in Business Cycles

A turn in a business cycle is a change from a phase of expansion to one of recession (or vice versa). Both government and industry need to have systems for predicting the future state of the economy, for example in order to timely predict the shift from a period of expansion to one of recession. Warnings of a turn can be given by using information from one or several time series that are leading in relation to the actual business cycle. A system for detecting the turning points of a leading indicator can give us early indications on the future behavior of the business cycle.

As pointed out for example by Diebold and Rudebusch (1996), Kim and Nelson (1998) and Birchenhall et al. (1999), two distinct but related approaches to the characterisation and dating of the business cycle can be discerned. One approach emphasizes the common movements of several variables. This approach is pursued for example by Stock and Watson (1993). The other approach, the

regime shift, is the one pursued in the works by Neftci (1982), Diebold and Rudebusch (1989), Hamilton (1989), Jun and Joo (1993), Lahiri and Wang (1994), Layton (1998), Birchenhall et al. (1999), Koskinen and Öller (2003) and Andersson et al. (2005, 2006).

An important issue is which characteristic of the leading index best predicts a turn in the business cycle. The question remains whether the most useful predictor is the level, as in Birchenhall et al. (1999), the transition and level, as in Hamilton (1989) and Koskinen and Öller (2003), or the transition and change in monotonicity, as in Andersson et al. (2005, 2006).

The Detection Problem

There is a need for methods for early warning, i.e., methods for the timely detection of a regime shift in a leading index. For reviews and general discussions on the importance of timeliness in the detection of turning points, see for example Neftci (1982), Zarnowitz and Moore (1982), Hackl and Westlund (1989), Zellner et al. (1991), Li and Dorfman (1996) and Layton and Katsuura (2001).

The inference situation can be described as one of ►*surveillance*, since a time series is continuously observed with the goal of detecting the turning point in the underlying process as soon as possible. Repeated decisions are made, the sample size is increasing and no null hypothesis is ever accepted. Thus, the inference situation is different from that where we have a fixed number of observations.

The aim of statistical surveillance is the timely detection of important changes in the process that generates the data. A process X (a leading economic indicator) is under surveillance, where X is often measured monthly or quarterly. Based on the available observations, we decide whether the observations made so far indicate a turn.

Thus at every decision time s, we use the alarm system to decide whether there has been a turn or not. This can be formulated as discriminating between two events at each decision time: D = "the turn has not occurred yet" and C = "the turn has occurred".

Models

An important question is which assumptions can be made about the process.

Economic time series often exhibit seasonal variation. Unfortunately, most data-driven filters can seriously alter the turning point times.

Autocorrelation can be a problem when the sampling intervals are short (Luceno and Box (2000)). When this is expected to be a problem, methods that adjust for autocorrelation should be used. Ivanova et al. (2000) argue that the effect of the autoregressive parameters will largely be captured by the probabilities of remaining in the current state.

Many macroeconomic variables can be characterized as cyclical movements around a trend. In order to distinguish the movements and make the time series stationary in relation to the cycle it is sometimes judged necessary to adjust for the trend. Adjusting for the trend by data transformation may result in a distortion of the characteristics of the original series. Canova (1999) points out that the trend may interact with the cyclical component, and therefore it may be difficult to isolate.

In the common movement approach, a business cycle is characterized as the cyclical movement of several economic activities. This is one example of how multivariate data are used. The common movement approach demonstrates that important information is contained in the relation between the turns of various indices. This information can be utilized either by transforming the problem to a univariate one (by using a composite index of leading indicators) or by applying a special method for surveillance of multivariate data. See for example Ryan (2000), Frisén (2010) and Frisén et al. (2010).

When estimating the parameters of the monitoring system, historical data are often used. The user of a system for on-line detection is faced with the paradox that the parameters in the surveillance system may be estimated using previous data, which means that it is assumed that previous patterns will repeat themselves. However, the aim of the surveillance method is to detect changes, and by estimating parameters from previous data, the ability to detect changes in the current cycle might be diminished. Sarlan (2001) examines the change in intensity and duration of US business cycles and concludes that the modern business cycle is different from the historical one.

The approach described by Andersson et al. (2005, 2006) of a non-parametric method may be preferred in order to avoid the risk of misleading results. The non-parametric method does not assume that all phases are of the same type or have the same level and parametric shape. In practice, this varies a lot. At time τ there is a turn in the expected value, μ. Different assumptions can be made about μ, conditional on D (expansion) and C (recession), and at a turn. Instead of assuming that the parametric shape is known, we can use monotonicity restrictions to define μ under C and D. Then the aim (at the detection of a peak) is to discriminate between the following two events: $D(s): \mu(1) \leq \ldots \leq \mu(s)$ and $C(s)$: "$\mu(1) \leq \ldots \leq \mu(\tau-1)$ and $\mu(\tau-1) \geq \mu(\tau) \geq \ldots \geq \mu(s)$". The monotonicity restrictions for a trough are the opposite. In such situations the exact parametric shape of μ is unknown. We only know that μ is monotonic within each phase.

Methods

In recent years, methods based on likelihood have been in focus. The performance of three methods for turning point detection in leading indicators is compared in detail by Andersson et al. (2005, 2006). All three methods are based on likelihood, but there are differences in model specifications, the amount of information used and parameter estimation. The Hidden Markov Model (HMM) is suggested for business cycle modeling for example by Hamilton (1989), Lahiri and Moore (1991), Lahiri and Wang (1994), Layton (1996), Gregoir and Lenglart (2000) and Koskinen and Öller (2003). The HMlin method is based on regime switching and has a model which is piecewise linear. In many ways it is similar to, for example, the method presented by Koskinen and Öller (2003). The SRlin method is based on the Shiryaev-Roberts (SR) technique under the assumption of a piecewise linear model. The SRnp method is a generalized version of the SR method. It is a non-parametric version of the SRlin method with no parametric assumption on the shape of the curve. It uses only the monotonicity change and not the level. The safe way of the SRnp method was recommended since there is no major loss of efficiency.

Andersson et al. (2005, 2006) illustrated the methods by monitoring a period of Swedish industrial production. Evaluation measures that reflect timeliness were used.

Dickey-Fuller Tests

David A. Dickey
William Neal Reynolds Professor
North Carolina State University, Raleigh, NC, USA

One of the most basic and useful of the time series models is the order 1 (1 lag) autoregressive model, denoted $AR(1)$ and given by $Y_t - \mu = \rho(Y_{t-1} - \mu) + e_t$ where Y_t is the observation at time t, μ is the long run mean of the time series and e_t is an independent sequence of random variables. We use this venerable model to illustrate the Dickey–Fuller test then mention that the results extend to a broader collection of models.

When written as $Y_t = \mu(1-\rho) + \rho Y_{t-1} + e_t$, or more convincingly as $Y_t = \lambda + \rho Y_{t-1} + e_t$, with e independent and identically distributed as $N(0, \sigma^2)$, the $AR(1)$ model looks like a regression with errors satisfying the usual assumptions. Indeed the least squares estimators of the coefficients are asymptotically unbiased and normally distributed under one key condition, namely that the true ρ satisfies $|\rho| < 1$. It appears that this assumption is quite often violated. Many prominent time series appear to have $\rho = 1$, in which case $Y_t - \mu = \rho(Y_{t-1} - \mu) + e_t$ becomes $Y_t = Y_{t-1} + e_t$ or $Y_t - Y_{t-1} = e_t$. That is to say there are many series whose first differences $Y_t - Y_{t-1}$ seem to form a sequence of independent shocks, as the e's are often called. For estimation of the parameters, only mild assumptions on e are required. Normality is not necessary as long as the sample size is reasonable and $|\rho| < 1$. Two things are worth noting. The first is that the long term mean μ has dropped from this equation, that is, there is no tendency to move toward a long term mean, no mean reversion. A series that is high at time t is just as likely to move up as to move down. There is nothing to be gained by assessing the distance from the historic mean. The second point is a recommendation to write the model as $Y_t - \mu = \rho(Y_{t-1} - \mu) + e_t$. The representation $Y_t = \lambda + \rho Y_{t-1} + e_t$ masks the relationship $\lambda = \mu(1-\rho)$. The uninformed analyst may not realize that the intercept disappears when $\rho = 1$. The case when $|\rho| < 1$ falls into the category of stationary autoregressive models whereas the model with $\rho = 1$ is an example of a nonstationary model. For reasons discussed later, the $\rho = 1$ case is also called a unit root model and sometimes an integrated model.

There are many series of economic interest for which a test of the hypothesis $H_0 : \rho = 1$ is desired. The interest in such tests can be explained with a hypothetical scenario. Suppose an autoregressive order 1 model $Y_t = 5.00 + 0.8(Y_{t-1} - 5.00) + e_t$ describes the price of a stock over some time index t. Now if the current price is $Y = 5.50$ then the expected value of the next observation is $5.00 + 0.8(5.50 - 5.00) + 0 = 5.40$, closer than the current 5.50 to the mean 5. Likewise we'd predict a rise to 4.60, were we currently at 4.50, that is, the strategy of selling high and buying low would make money in the long run. The ability to forecast the direction of the stock market would cast doubt on the assumption that it was a quickly responding market with fully informed participants so we think that 0.8 is an estimate of $\rho = 1$ and expect that the null hypothesis will not be rejected. In contrast, we might expect the ratio of short term to long term bond yields or interest rates to be stable, that is, we expect some long term equilibrium ratio and we expect movement of the ratio toward that number in the long run. Here we expect to *reject* $H_0 : \rho = 1$ in favor of $H_1 : \rho < 1$. On a logarithmic scale, we want to test $Y_t = \log(\text{short term rate}) - \log(\text{long term rate})$ for stationarity. When two individual series are nonstationary but their difference is stationary, the series are said to be "cointegrated." Some of the most interesting hypothesis tests in economics concern constructed variables, as does this test for cointegration.

Having established an interest in testing the hypothesis $H_0 : \rho = 1$, we return to the statement that the least squares estimator is not normal under this hypothesis. How can this be when the errors satisfy all the usual regression assumptions? The answer lies in the assumption on the independent (X) variables. In usual regression theory, these X variables are assumed fixed and measured without error. Extensions to random X cases typically involve a conditioning argument, that is, we consider what would happen if we only looked at repeated samples that have the same X values that we observed. There is no way to make that argument here, where the X variables are just the Y (dependent) variables at a different time.

When $\rho = 1$ and μ is known to be 0, the theory of weak convergence as in Billingsley (1968) implies that the least squares estimator $\hat{\rho}$ satisfies a limit in terms of a standard Wiener process $W(t)$:

$$n(\hat{\rho} - 1) = \frac{\sum_{t=2}^{n} Y_{t-1} e_t}{\sum_{t=2}^{n} Y_{t-1}^2} \xrightarrow{L} \frac{1}{2} \frac{W^2(1) - 1}{\int_0^1 W^2(t)dt}.$$

This is known as the "normalized bias" statistic. This is an appealing mathematical representation, but is nevertheless a random quantity. Knowing this expression does not lead directly to a distribution and resulting table of critical values for testing. With simulation, empirical percentiles for various sample sizes n can be computed, however it is not clear how large an n will get the simulations close

enough to the limit so that no further n values need be considered. In addition to running rather large simulations as just mentioned, Dickey and Fuller (1979) calculated the eigenvalues of the limits of the numerator and denominator quadratic forms in the above normalized bias and from those directly simulated the limit distribution. They were then able to see how large an n was required to get close to that limit. This resulted in critical values for the normalized bias $n(\hat{\rho}-1)$ for finite n and the limit. Statistical programs that do least squares regression also produce t tests. Dickey and Fuller looked at the t statistic associated with the 0 mean regression. Its limit is the same as that of $\left(\sigma^2\sum_{t=2}^{n}Y_{t-1}^2\right)^{-1/2}\sum_{t=2}^{n}Y_{t-1}e_t$. They gave percentiles for that statistic as well and called it τ to indicate that it did not behave like the usual t, even in the limit.

At this point two distributions, one for the normalized bias and one for τ have been discussed, but the underlying assumption that μ is 0 makes this result of little practical interest. Suppose you have a stationary ($|\rho| < 1$) $AR(1)$ time series whose values range between 1000 and 1100. With no intercept in the model, the estimator $\frac{\sum_{t=2}^{n}Y_{t-1}Y_t}{\sum_{t=2}^{n}Y_{t-1}^2} \approx 1-0.5\frac{\sum_{t=2}^{n}(Y_t-Y_{t-1})^2}{\sum_{t=2}^{n}Y_{t-1}^2}$, where the sum of squared differences can be no greater than $(n-1)(100^2)$ and the denominator is no less than $(n-1)(1000^2)$ so the estimate of ρ is between 0.995 and 1. Simulations (Dickey 1984) verify that, as the algebra suggests, stationary series with positive means give tests that rarely reject the (false) null hypothesis when no intercept is included in the regression. It thus becomes of interest to study the mean adjusted estimator $n(\hat{\rho}_\mu-1) = \frac{\sum_{t=2}^{n}(Y_{t-1}-\overline{Y})e_t}{\sum_{t=2}^{n}(Y_{t-1}-\overline{Y})^2}$, where $\overline{Y} = \sum_{t=1}^{n}\frac{Y_t}{n}$, and its associated studentized statistic τ_μ. An asymptotically equivalent estimator and τ_μ statistic are obtained by regressing Y_t on an intercept and Y_{t-1}. Dickey and Fuller show that the addition of an intercept changes even the asymptotic distribution rather dramatically. This can be demonstrated either through their quadratic form approach or the Wiener Process limit representation.

Applying the same logic to a series that appears to be moving upward or downward at a rather steady long run rate, a fair test for "trend stationarity" as the alternative hypothesis is called, one that gives a chance to both the null and alternative hypothesis, must use a model that can capture the trend under both hypotheses. A logical candidate is a model with linear trend and $AR(1)$ error. The model can be expressed in two ways:

$$Y_t-\alpha-\beta t=\rho(Y_{t-1}-\alpha-\beta(t-1))+e_t$$

or

$$Y_t=\alpha+\beta t+Z_t,\qquad Z_t=\rho Z_{t-1}+e_t.$$

The first of these models most easily demonstrates that under our null hypothesis $\rho = 1$, we have

$$Y_t=\beta+Y_{t-1}+e_t$$

a random walk with drift β. The former slope is now called a drift and algebraically appears as an intercept term but in reality, it represents the long term monotone trend regardless of the ρ value. It is, after all, the mean change in Y_t per unit change in t. Its inclusion accomplishes our purpose of allowing both the null and alternative model to capture the long term trend, thus separating the alternative hypothesis case of stationary errors around a linear trend from the null hypothesis case of random walk with drift. The alternative hypothesis defines the concept of trend stationarity. The model can be fit by regressing Y_t on an intercept, t, and Y_{t-1} or, in an asymptotically equivalent way, by regressing Y_t on 1 and t, obtaining residuals r_t, and then regressing r_t on r_{t-1} with no intercept. This second approach is motivated by the second form of the model above. As with the mean adjusted case, this results in further changes in the distributions of the estimate and its studentized statistic τ_τ, even asymptotically. Since this last model subsumes the others, why not always use an intercept and time trend? The answer lies in a substantial loss of power when unnecessary parameters are added to the model.

We now summarize a few numerical results from the literature. Tables of critical values for the normalized bias and studentized statistics are developed in Dickey and Fuller (1979, 1981) and reported in detail in Fuller (1996). The 1% and 5% critical values from Fuller's text are reported below for the smallest tabulated sample size $n = 25$ and for the limit distribution.

The studentized statistics (top 3 rows of Table 1) have the more stable percentiles over different sample sizes, especially at the 5% level and are more often used in practice. Dickey (1984, Table 6.1) shows what happens when there are nonzero intercept or trend parameters in the generated data that are not in the model. For even modest values of these omitted parameters, there are almost no rejections of the (false) null hypothesis when $|\rho| < 1$. In Table 6.2 of that paper we find empirical powers for 2000 replicates of these tests for data generated by $Y_t = \rho Y_{t-1} + e_t$, $t = 1, 2, \ldots, 50$. Substantial loss of power results when unneeded intercept or trend parameters are added to the model as in columns 3,4,6, and 7 of Table 2, which displays a few entries from the power study.

Clearly inclusion of either too many or too few deterministic terms in the model can cause power loss. Failing

Dickey-Fuller Tests. Table 1 Left tailed unit root test percentiles

Model	1%, $n = 25$	1%, limit	5%, $n = 25$	5%, limit
No intercept τ	−2.65	−2.58	−1.95	−1.95

to reject unit roots when a model without trend is fit to trending data may do less damage than rejecting. Forecasting future values to be the same as the present value may be less damaging than giving mean reverting forecasts that go in the opposite direction of the trend.

The autoregressive order 1 model is common but is not rich enough to fit all time series. Consider an autoregressive model of order 3,

$$Y_t - \mu = 1.1(Y_{t-1} - \mu) - 0.3(Y_{t-2} - \mu) + 0.2(Y_{t-3} - \mu) + e_t$$

or, written in terms of the backshift operator $B(Y_t) = Y_{t-1}$,

$$(1 - 1.1B + 0.3B^2 - 0.2B^3)(Y_t - \mu) = e_t$$

Because $1 - 1.1 + 0.3 - 0.2 = 0$ and μ is constant over time, μ drops out of the equation. The factored form $(1 + 0.4B)(1 - 0.5B)(1 - B)(Y_t - \mu) = e_t$, shows that the first differences, $(1 - B)(Y_t - \mu) = Y_t - Y_{t-1}$, form a stationary process $(1 + 0.4B)(1 - 0.5B)(Y_t - Y_{t-1}) = e_t$. The characteristic polynomial is the backshift polynomial with B considered an algebraic variable. An autoregressive series is stationary if the roots of its characteristic polynomial all exceed 1 in magnitude. The order 3 autoregressive example here has a root 1, a "unit root." It is therefore nonstationary but its differences form a stationary (roots $1/0.5 = 2$ and $-1/0.40 = -2.25$) autoregressive order 2 series.

Dickey and Fuller proved that if the first difference $Y_t - Y_{t-1}$ of a unit root autoregressive process is regressed on the lagged level Y_{t-1} of the process (and possibly an intercept and trend) and enough lagged differences to produce the appropriate lag structure, the studentized statistic on the lag level term will have the same limit distribution as in the autoregressive order 1 case. The tables discussed above can thus be used. In contrast, the distribution of the normalized bias is altered by the presence of the lagged differences which is one reason the studentized statistics are preferred despite the power advantage of the normalized bias test in the simplest $AR(1)$ cases.

The characteristic polynomial here has the form $(1-a_1B)(1-a_2B)(1-a_3B)$ with roots $1/a_i$, $i = 1, 2, 3$. If (and only if) $B = 1$ is a root, we will have $(1-a_1)(1-a_2)(1-a_3) = 0$. These expressions are algebraically equivalent:

(I) $(1 - a_1B)(1 - a_2B)(1 - a_3B)(Y_t - \mu) = e_t$

(II) $Y_t - \mu = (a_1 + a_2 + a_3)(Y_{t-1} - \mu) - (a_1a_2 + a_2a_3 + a_1a_3)(Y_{t-2} - \mu) + a_1a_2a_3(Y_{t-3} - \mu) + e_t$

(III) $Y_t - Y_{t-1} = -(1-(a_1+a_2+a_3)+(a_1a_2+a_2a_3+a_1a_3)-a_1a_2a_3)(Y_{t-1} - \mu) + (a_1a_2 + a_2a_3 + a_1a_3 - a_1a_2a_3)(Y_{t-1} - Y_{t-2}) + a_1a_2a_3(Y_{t-2} - Y_{t-3}) + e_t$

Expression (III) is the motivation for the regression approach. The coefficient on $(Y_{t-1} - \mu)$ is $-(1 - a_1)(1 - a_2)(1 - a_3)$, the negative of the characteristic polynomial evaluated at $B = 1$ so a unit root (any $a_i = 1$) makes this coefficient 0 and removes μ from the model. There is, then, no mean reversion. The lagged differences are known as augmenting terms and the resulting tests are known as *ADF* or augmented Dickey Fuller tests. Focusing on one of the three factors in $(1-a_1)(1-a_2)(1-a_3)$, clearly it is multiplied by the other two. Under the null hypothesis that one a_i value is 1, the coefficient on Y_{t-1} in (III) is an estimate of 0 but is scaled by the other two factors. This affects the distribution of the coefficient, but not that of its τ statistic. As in any regression, division of the estimate by its standard error makes τ a self normalizing statistic. Some estimate of those other two factors is needed to scale the normalized bias so that it is asymptotically equivalent to the $AR(1)$ case.

Other results worth mentioning include the work of S. E. Said (Said and Dickey 1984). Said showed that even if a time series contained an invertible moving average part, one could use an augmented autoregressive model. Given a number of augmenting lagged differences that increases with n at the proper rate, the studentized statistic has the same limit distribution as in the autoregressive

order 1 model. One can simply fit a model with augmenting lagged differences to test for unit roots. Park and Fuller (1995) use a weighted regression resulting in considerable power improvement. Elliott et al. (1996) incorporate a generalized least squares trend and intercept estimator that results in a test with similar power increase. Pantula et al. (1994) compare a test of Gonzalez-Farias, based on maximization of the exact stationary likelihood, and these other two. They all have competitive power. Phillips and his students have made many contributions in the area. Among them, Phillips and Perron (1988) suggest a different adjustment for the higher order models and show that the tables described herein can be used for the test under weak assumptions on the errors.

About the Author

Professor David Dickey, with Wayne Fuller, developed a *Unit Root Test*, in 1979. His paper "opened-up a new way research agenda in time series econometrics, the investigation and identification of nonstationary processes" (Lex Oxley, The "Top 10" Papers in Econometrics, 1980–2000). He was Program Chair, Business and Economics section American Statistical Association (2007). He is an elected Fellow (2000) of the American Statistical Association. In addition to writing four books, Dr. Dickey has been published in numerous papers and has given over 50 presentations at a variety of professional events and organizations. He has also been recognized as a member of the Academy of Outstanding Teachers at North Carolina State University.

Discriminant Analysis: An Overview

Barry J. Babin
Max P. Watson, Jr. Professor and Department Head
Louisiana Tech University, Ruston, LA, USA

Discriminant analysis is a multivariate technique that helps the user explain group membership as a function of multiple independent variables. In particular, discriminant analysis is appropriate when the user is faced with a situation involving a categorical (nominal or ordinal) dependent variable and independent variables that are primarily continuous (interval or ratio) although categorical independent variables can be included under some conditions. This would typically involve dummy coding of the categorical variables. In many cases, a dichotomous dependent variable is employed although it can be multichotomous.

The variate takes the familiar form:

$$V = w_1x_1 + w_2x_2 + \ldots + w_ix_i + e_i$$

where x represents the independent variables, w represents an empirically derived parameter estimate that weights the extent to which the independent variable determines group membership, and V represents the resulting variate value which determines group membership. The variate takes on the form of a Z score. This metric value is ultimately the key indicator of which group an observation should belong to based on the corresponding set of independent variable values. Groups are formed based on these Z-values by determining a cutting score which is used to separate observations into two groups. Discriminant analysis applies the fundamental logic that observations that produce similar Z-values (based on values for the set of independent variables) should be grouped together and observations with dissimilar Z-values are different and should not be grouped together. Thus, for a dichotomous dependent variable, the cutting score can be thought of as:

$$Z_{CS} = \frac{N_AZ_B + N_BZ_A}{N_A + N_B}$$

Where, Z_{cs} is the cutting score and N represents the sample size in groups A and B, respectively. Z_A and Z_B represent the centroids of groups A and B formed by splitting all observations into groups using the cutting score.

Considering the dichotomous case, the observed values for each independent variable can be used to predict whether each observed value for a dependent variable is a "1" or "0." The values for the independent variables are multiplied by derived parameter estimates just as in multiple regression. In other words, the analysis determines which group an observation should belong to based upon the calculated value? A classification matrix is created which shows how accurately the model can actually place these observations into categories. This matrix is formed by taking a conditional frequency of predicted group membership against actual observed group membership. The contingency table takes a form as follows:

Actual Group Membership	Predicted Group Membership	
	Group 1	Group 2
Group 1	Correctly classified	Incorrectly classified
Group 2	Incorrectly classified	Correctly classified

The percent of observations correctly classified becomes one measure of a discriminant function's effectiveness. Consider that if group 1 had two times as many respondents as group 2, correct classification could be 67 percent simply by placing all observations into group 1. Therefore, the discriminant analysis should be able to produce better than 67 percent correct classifications if it is to be useful. In fact, a t-test is available to determine the significance level for classification accuracy:

$$t = \frac{p - g}{\sqrt{\frac{g(1.0 - g)}{N}}}$$

Where, p = percent correctly classified, N = sample size, and g represents the proportion of observations actually observed in the largest group (0.67 in the example above and 0.5 if group sizes are equal, for instance).

The pattern of discriminant weights or discriminant loadings determines which variables most predict or explain group membership (i.e., via the Z-values). Discriminant loadings are sometimes called structure correlations and they are directly analogous to factor loadings in the multivariate technique known as factor analysis (see ►Factor Analysis and Latent Variable Modeling). They represent the correlation between an observation and the discriminant function (i.e., variate). Thus, the relative magnitude of a loading shows how influential a variable is to the grouping variable. If causal terms are appropriate, it would show relatively speaking, how much a variable caused observations to be in one group or another. The number of discriminant factors that can be recovered is equal to one less than the number of groups so that for a dichotomous dependent variable, only one discriminant function, or factor, is possible. In the three group case two factors are possible.

Thus, two key results are (1) how accurately a discriminant function can classify observations and (2) which variables are most responsible for the classifying. As the cross-classification suggests that the model predicts membership at better than a chance rate, the discriminant function has validity. As loadings are greater in magnitude, they are predictive of group membership. In a very real way, the mathematics of discriminant analysis mirrors that of MANOVA, another multivariate technique. Both MANOVA and discriminant analysis will each produce a Wilkes Λ that indicates whether or not the observed group membership accounts for differences in the means of the independent variables. Discriminant validity is often used in combination with other techniques like cluster analysis (see ►Cluster Analysis: An Introduction) and also is conceptually similar to techniques like ►logistic regression that also predict categorical dependent variables.

Here, a simple illustration of discriminant analysis is described. The observations represent records of academic journal submissions forming a sample of the larger population of submissions. The dependent variable is whether or not the submission was rejected. Thus, there are two groups of observations. One hundred and eighteen papers were rejected and 40 were not rejected. Group membership constitutes the dependent variable and was coded 0 = Rejected and 1 = Not Rejected. The independent variables represent the paper's review scores based on:

(a) topical relevance,
(b) theoretical development,
(c) research approach,
(d) analytical competence,
(e) writing quality,
(f) contribution potential.

Each independent variable was scored on a 5 point scale with higher scores being better. Here is a brief overview of the results. The Wilkes' Λ is 56.9 which suggests the means for the independent variables differ significantly based on group membership ($p < .001$). The resulting cross-classification matrix is shown below:

Actual Group Membership	Predicted Group Membership	
	Rejected	Not Rejected
Rejected	109	9
Not Rejected	16	24

133 of 158 observations, or 84.2 percent, are correctly classified. This can be compared to the 75 percent of observations that would be correctly classified if all 158 observations were predicted to be rejected. The discriminant analysis improves predictability significantly over chance ($p < .001$). Additionally, the discriminant loadings are as follows:

Variable	Function 1
Theoretical development	0.83
Research methods	0.76
Writing quality	0.71
Analytical competence	0.62
Contribution potential	0.62
Topical relevance	0.37

Thus, theoretical development is the most influential independent variable helping explain why papers get rejected from this particular journal. In contrast, topical relevance does very little to distinguish papers that are rejected from others. Perhaps the reason for this is that most submissions receive similar high scores for relevance. Practically, the results suggest that stronger theory is a route to avoiding rejection.

As you can see, discriminant analysis can be a very useful tool for explaining why observations end up in one group or another (Hair et al. 2010). Some applications of discriminant analysis include a study predicting cohort group membership as the dependent variable with personal value scores as a independent variables (Noble and Schewe 2003), a study trying to explain differences between small firms and firms that grow into large firms (Culpan 1989), and a study explaining groups of consumers based on how they respond to poor performance in a retail setting. This idea involves explaining why someone might be an irate consumer, an active consumer or a passive consumer, for instance, using a variety of demographic, lifestyle and situational independent variables (Singh 1990).

Discriminant Analysis: Issues and Problems

Carl J. Huberty
Professor Emeritus
University of Georgia, Athens, GA, USA

Introduction

It was in the mid 1930s when Sir Ronald A. Fisher (1890–1962) formally introduced the notion of "discriminant analysis" (DA) in writing. His introduction involved prediction of group membership in a two-group context – a predictive discriminant analysis (PDA). The notion of "discriminant analysis" became of interest to researchers in various areas of study in the 1950s and 1960s (e.g., Cooley and Lohnes 1962). That is when the variant which may be termed "descriptive discriminant analysis" (DDA) "caught on."

PDA Versus DDA

The mixing of PDA and DDA is fairly common in many books and journal articles. The distinction of PDA from

Discriminant Analysis: Issues and Problems. Table 1 PDA versus DDA

	PDA	DDA
Research context	Prediction of group membership	Description of group separation
Variable roles		
Predictor(s)	Response variables	Grouping variable(s)
Criterion(ia)	Grouping variable	Response variables
Response variable set	Hodgepodge	System
Response variable composite	LCF/QCF	LDF
Number of composites	k	$\min(p, k-1)$
Preliminary analysis concerns		
Equality of covariance matrices	Yes	Yes
MANOVA	No	Yes
Analysis aspects of typical concern		
Variable construct(s)	No	Yes(!)
Response variable deletion	Yes (!)	Maybe
Response variable ordering	Yes	Yes
Criterion for variable deletion/ordering	Classification accuracy	Group separation
Research purpose	Practical/theoretical	Theoretical

DDA is, to the current writer, fairly important for description, interpretation, and reporting purposes. A PDA is used to determine a "rule" for predicting membership in one of k groups of analysis units based on measures on p predictor variables. The rule, then, consists of k composites of the p predictors. These composites may be of linear form (if the k $p \times p$ covariance matrices are judged to be approximately equal) or of quadratic form (if the k covariance matrices are clearly unequal). For the former, one has k linear classification functions (LCFs). For the latter, one has k quadratic classification functions (QCFs). For details, see Huberty and Olejnik (2006, Chap. 13).

A DDA is considered in the context of comparing k group mean vectors of the p outcome variables. A DDA would be applicable when a ►multivariate analysis of variance (MANOVA) is conducted and the k mean vectors of the p outcome variables are judged to be unequal. [In a MANOVA context, it is assumed that the k covariance matrices are "in the same ballpark." See Huberty and Olejnik (2006, Chap. 3).] One obtains a set of $\min(p, k-1)$ linear discriminant functions (LDFs). These linear composites comprise the essence of a DDA. [Such composites are analogous to "factors" in a factor analysis.]

An issue/problem in DA is the lack of distinction between PDA and DDA. This lack results in the misuse of terms, and some misinterpretations of computer output. [The computer output often leads to misuse of terms.] See Table 1 for a summary of PDA versus DDA. In sum, it is classification (PDA) versus separation (DDA).

Terms

It should be clear from the stated purpose of an empirical study involving $k \geq 2$ groups of analysis units and $p \geq 2$ attributes/variables pertaining to the units, whether one is interested in group membership prediction or in group comparison description. For the former analysis (PDA), one would be interested in prediction, and, therefore, related term use should be utilized. Similarly for applications of DDA. Issues in term use in PDA and in DDA are reviewed by Huberty and Olejnik (2006, Chap. 22).

More specifically, proper use of terms in reporting the use, and results, of a PDA and DDA is given by Huberty and Olejnik (2006, Chaps. 7 and 20). Also, reliance on terms found in computer output is *not* strongly recommended.

More Issues and Problems

Five issues in PDA are discussed by Huberty and Olejnik (2006, Chap. 22): (1) linear versus quadratic classification

rules; (2) nonnormal classification rules; (3) prior probabilities; (4) misclassification costs; and (5) hit-rate estimation. Also discussed in that chapter are three issues in DDA: (1) stepwise analyses (yuk!); (2) standardized LDF weights versus structure *r*'s; and (3) data-based structure. All of these issues involve the use of researcher judgment – of course, consultation with respected "experts" would help in making some judgment calls.

There are, also, some additional problems in the use of both PDA and DDA – see Huberty and Olejnik (2006, Chap. 23). Three of these problems involve missing data, outliers, and misclassification costs. A detailed discussion of these problems will not be presented herein. With regard to the first two problems, a recommendation is to "look at your data" (via graphs).

About the Author

Dr. C. J. Huberty is a Professor Emeritus, Department of Research, Measurement, and Statistics, University of Georgia, USA. He served UGA from 1969 to 2002, and was Department Head (1992–1999). He was given the College of Education Faculty Research Award in 1998, and the Career Center Award in 2002. He was also given recognition by being nominated for 27 national academic awards. In 2004, he was recognized as a Fulbright Senior Specialist. He was an ASA member for 32 years. He authored two books: *Applied Discriminant Analysis* (Wiley 1994) and *Applied MANOVA and Discriminant Analysis* (Wiley, 2006, with Stephen Olejnik). He was the sole/senior author of 15 invited book chapters, 58 journal articles, 13 book reviews, and 93 papers presented at professional meetings. He conducted 42 workshops on multivariate statistics at professional meetings in Australia, Belgium, Egypt, and USA. He served as a statistical consultant for 18 grants. Dr. Huberty served on 12 journal editorial boards, including the founding board of the *Journal of Educational Statistics*. Finally, he sponsored academic visitors from Canada (2), Egypt (16), Iran (1), Italy (1), Japan (1), South Korea (1), St. Lucia (1), and Sweden (1).

Dispersion Models

Bent Jørgensen
Professor
University of Southern Denmark, Odense M, Denmark

Introduction

A *dispersion model,* denoted $Y \sim \mathrm{DM}(\mu, \sigma^2)$, is a two-parameter family of distributions with probability density functions on $\mathbb{R}$ of the form

$$f(y;\mu,\sigma^2) = a(y;\sigma^2)\exp\left\{-\frac{1}{2\sigma^2}d(y;\mu)\right\}. \qquad (1)$$

Here μ and σ^2 are real parameters with domain $(\mu,\sigma^2) \in \Omega \times \mathbb{R}_+$ (Ω being an interval), called the *position* and *dispersion* parameters, respectively. Also a and d are suitable functions such that (1) is a probability density function for all parameter values. In particular, d is assumed to be a *unit deviance*, satisfying $d(\mu;\mu) = 0$ for $\mu \in \Omega$ and $d(y;\mu) > 0$ for $y \neq \mu$. Dispersion models were introduced by Sweeting (1981) and Jørgensen (1983; 1987b) who extended the analysis of deviance for ►generalized linear models in the sense of Nelder and Wedderburn (1972) to non-linear regression models with error distribution $\mathrm{DM}(\mu,\sigma^2)$.

In many cases, the unit deviance d is *regular,* meaning that it is twice continuously differentiable and $\partial^2 d/\partial\mu^2(\mu;\mu) > 0$ for $\mu \in \Omega$. We then define the *unit variance function* for $\mu \in \Omega$ by

$$V(\mu) = \frac{2}{\frac{\partial^2 d}{\partial\mu^2}(\mu;\mu)}. \qquad (2)$$

For example, the normal distribution $\mathrm{N}(\mu,\sigma^2)$ corresponds to the unit deviance $d(y;\mu) = (y-\mu)^2$ on $\mathbb{R}^2$, with unit variance function $V(\mu) \equiv 1$ and $a(y;\sigma^2) = \left(2\pi\sigma^2\right)^{-1/2}$. Note that for $0 < \rho < 2$ the unit deviance $d(y;\mu) = |y-\mu|^\rho$, with $a(y;\sigma^2)$ constant (not depending on y) provides an example of a dispersion model where d is not regular.

The *renormalized saddlepoint approximation* for a dispersion model with regular unit deviance d is defined for $y \in \Omega$ by

$$f(y;\mu,\sigma^2) \sim a_0(\mu,\sigma^2)V^{-\frac{1}{2}}(y)\exp\left\{-\frac{1}{2\sigma^2}d(y;\mu)\right\}, \quad (3)$$

where $a_0(\mu,\sigma^2)$ is a normalizing constant, making the right-hand side of (3) a probability density function on Ω with respect to Lebesgue measure. The ordinary saddlepoint approximation is obtained by the asymptotic approximation $a_0(\mu,\sigma^2) \sim (2\pi\sigma^2)^{-1/2}$ as $\sigma^2 \downarrow 0$, and correspondingly, the distribution $\mathrm{DM}(\mu,\sigma^2)$ is asymptotically normal $\mathrm{N}\{\mu,\sigma^2V(\mu)\}$ for σ^2 small, so that μ and $\sigma^2V(\mu)$ are the asymptotic mean and variance of Y, respectively. In this way, dispersion models have properties that resemble those of the normal distribution. In particular the unit deviance $d(y;\mu)$ is often a measure of squared distance between y and μ.

There are two main classes of dispersion models, namely *proper dispersion models* (PD) and *reproductive exponential dispersion models* (ED), as defined below. The class of *additive exponential dispersion models* (ED*) is not of the dispersion model form (1), but is closely related to reproductive exponential dispersion models. These three types of models cover a comprehensive range of non-normal distributions, and as shown in Table 1 they include many standard statistical families as special cases. The exponential and Poisson families are examples of natural exponential families, which correspond to exponential dispersion models with $\sigma^2 = 1$.

Proper Dispersion Models

Jørgensen (1997a) proposed a special case of (1), called a *proper dispersion model*, which corresponds to a density of the form

$$f(y;\mu,\sigma^2) = a(\sigma^2)V^{-\frac{1}{2}}(y)\exp\left\{-\frac{1}{2\sigma^2}d(y;\mu)\right\}, \quad (4)$$

where d is a given regular unit deviance with unit variance function $V(\mu)$. We denote this model by $Y \sim \mathrm{PD}(\mu,\sigma^2)$. Note that the unit deviance d characterizes the proper dispersion model (4), because the unit variance function (2) is a function of d, while $a(\sigma^2)$, in turn, is a normalizing constant. It also follows that the normalizing constant of (3) is $a_0(\mu,\sigma^2) = a(\sigma^2)$, making the the two sides of (3) identical in this case. Conditions under which a given unit deviance gives rise to a proper dispersion model, and the connection with exactness of Barndorff-Nielsen's p^*-formula, are discussed by Jørgensen (1997b, Chap. 5).

Many proper dispersion models are transformation models when σ^2 is known. For example, unit deviances of the form $d(y;\mu) = h(y-\mu)$ on $\Omega = \mathbb{R}$, for a suitable function h, give rise to so-called *location-dispersion models*, where the unit variance function is constant. A specific example is given by the unit deviance $d(y;\mu) = \log\{1+(y-\mu)^2\}$, which corresponds to the Student t location family. Another important case corresponds to unit deviances of the form $d(y;\mu) = h(y/\mu)$ on $\Omega = \mathbb{R}_+$, which give rise to so-called *scale-dispersion models*. For example, Jørgensen (1997b, Chap. 5) showed that the generalized ▶inverse Gaussian distribution is a family of scale-dispersion models with unit deviances

$$d_\beta(y;\mu) = 2\beta\log\frac{\mu}{y} + (1+\beta)\frac{y}{\mu} + (1-\beta)\frac{\mu}{y} - 2, \quad (5)$$

for $y,\mu > 0$, where $\beta \in [-1,1]$ is an additional parameter. In particular, the values $\beta = \pm 1$ correspond to the gamma and reciprocal gamma families, respectively, and $\beta = 0$ to the one-dimensional hyperboloid distribution. The von Mises distribution, corresponding to the unit deviance $d(y;\mu) = 2\{1-\cos(y-\mu)\}$ on $\Omega = (0,2\pi)$ is also a transformation model when σ^2 is known, corresponding to the group of additions modulo 2π.

The class of *simplex distributions* of Barndorff-Nielsen (1991) contains several proper dispersion models as special cases. The simplest example is given by the probability density function

$$f(y;\mu,\sigma^2) = \frac{1}{\sigma\sqrt{2\pi}}\{y(1-y)\}^{-3/2} \times \exp\left\{-\frac{(y-\mu)^2}{2\sigma^2y(1-y)\mu^2(1-\mu)^2}\right\}, \quad (6)$$

where $y,\mu \in (0,1)$ and $\sigma^2 > 0$. The *transformed Leipnik distribution*, defined by the unit deviance

$$d(y;\mu) = \log\left\{1+\frac{(y-\mu)^2}{y(1-y)}\right\} \text{ for } y,\mu \in (0,1)$$

provides a further examples of proper dispersion models. This and the simplex distribution are examples of proper dispersion models that are not transformation models when σ^2 is known.

Exponential Dispersion Models

Exponential dispersion models are two-parameter extensions of natural exponential families. A *natural exponential family* has densities of the form

$$f(x;\theta) = c(x)\exp\{\theta x - \kappa(\theta)\}, \quad (7)$$

with respect to a suitable measure ν, usually Lebesgue or counting measure. Here $c(x)$ is a given function and $\kappa(\theta) = \log\int c(x)e^{\theta x}\,\nu(dx)$ is the corresponding *cumulant function*. The *canonical parameter* θ has domain Θ; the

Dispersion Models. Table 1 Main examples of univariate dispersion models

Data type	Support	Examples	Type
Real data	$\mathbb{R}$	Normal, generalized hyperbolic secant	ED
Positive data	$\mathbb{R}_+$	Exponential, gamma, inverse Gaussian	ED
Positive data with zeros	$\mathbb{R}_0 = [0, \infty)$	Compound Poisson distribution	ED
Proportions	$(0,1)$	Simplex, Leipnik distributions	PD
Directional data	$[0, 2\pi)$	von Mises distribution	PD
Count data	$\mathbb{N}_0 = \{0,1,2,\dots\}$	Poisson, negative binomial distributions	ED*
Binomial count data	$\{0,1,\dots,m\}$	Binomial distribution	ED*

largest interval for which $\kappa(\theta)$ is finite. The mean of a random variable X with distribution (7) is $\mu = \tau(\theta)$, where $\tau(\theta) = \kappa'(\theta)$ (a one-to-one function of θ), and the domain for μ is $\Omega = \tau(\text{int}\Theta)$, where $\text{int}\Theta$ denotes the interior of the domain Θ. If necessary, we define the value of μ by continuity at boundary points of Θ. Examples of natural exponential families include the exponential, geometric, Poisson, and logarithmic families.

The variance of X is $V(\mu) = \tau'\{\tau^{-1}(\mu)\}$, where V is known as the *variance function* of the family (7). This function characterizes (7) among all natural exponential families, see for example Morris (1982), and V is an important convergence and characterization tool for natural exponential families, see, e.g., Jørgensen (1997b, Chap. 2).

An *additive exponential dispersion model* is a two-parameter extension of natural exponential families with densities of the form

$$f^*(x;\theta,\lambda) = c^*(x;\lambda)\exp\{\theta x - \lambda\kappa(\theta)\}, \qquad (8)$$

where the *index parameter* λ has domain Λ consisting of those values of $\lambda > 0$ for which $\lambda\kappa(\theta)$ is a cumulant function of some function $c^*(x;\lambda)$. The mean and variance of a random variable X with distribution (8) are $\lambda\mu$ and $\lambda V(\mu)$, respectively. Many discrete distributions are additive exponential dispersion models, for example the binomial and negative binomial families. An additive exponential dispersion model is denoted $X \sim \text{ED}^*(\mu,\lambda)$.

A *reproductive exponential dispersion model* is defined by applying the transformation $Y = X/\lambda$ to (8), known as the *duality transformation*. The reproductive form is denoted $Y \sim \text{ED}(\mu,\sigma^2)$, corresponding to densities of the form

$$f(y;\theta,\lambda) = c(y;\lambda)\exp[\lambda\{\theta y - \kappa(\theta)\}] \qquad (9)$$

for a suitable function $c(y;\lambda)$. Here μ (with domain Ω) is the mean of Y, $\sigma^2 = 1/\lambda$ is the dispersion parameter, and the variance of Y is $\sigma^2 V(\mu)$. Reproductive exponential dispersion models were proposed by Tweedie (1947), and again by Nelder and Wedderburn (1972) as the class of error distributions for generalized linear models. The inverse duality transformation $X = \lambda Y$ takes (9) back into the form (8) so that each exponential dispersion model has, in principle, an additive as well as a reproductive form. Both (9) and (8) are natural exponential families when the index parameter λ is known.

To see the connection with dispersion models as defined by (1), we introduce the unit deviance corresponding to (9),

$$d(y;\mu) = 2\left[\sup_\theta\{\theta y - \kappa(\theta)\} - y\tau^{-1}(\mu) + \kappa\{\tau^{-1}(\mu)\}\right], \qquad (10)$$

which is a Kullback-Leibler distance, see Hastie (1987). Defining

$$a(y;\sigma^2) = c(y;\sigma^{-2})\exp\left[\sup_\theta\{\theta y - \kappa(\theta)\}\right],$$

we may write the density (9) in the dispersion model form (1). Consequently, reproductive exponential dispersion models form a sub-class of dispersion models, whereas additive exponential dispersion models are not in general of the form (9).

The overlap between exponential and proper dispersion models is small; in fact the normal, gamma and inverse Gaussian families are the only examples of exponential dispersion models that are also proper dispersion models.

An additive exponential dispersion model satisfies a convolution formula, defined as follows. If $X_1,\dots,X_n$ are independent random variables, and $X_i \sim \text{ED}^*(\mu,\lambda_i)$ with

$\lambda_i \in \Lambda$ for $i = 1, \ldots, n$, then the distribution of $X_+ = X_1 + \ldots + X_n$ is

$$X_+ \sim \mathrm{ED}^*(\mu, \lambda_1 + \ldots + \lambda_n), \tag{11}$$

where in fact $\lambda_1 + \cdots + \lambda_n \in \Lambda$. This is called the *additive property* of an additive exponential dispersion model.

An additive exponential dispersion model $\mathrm{ED}^*(\mu, \lambda)$ gives rise to a stochastic process $\{X(t) : t \in \Lambda \cup \{0\}\}$ with stationary and independent increments, called an *additive process*. This process is defined by assuming that $X(0) = 0$, along with the following distribution of the increments:

$$X(t+s) - X(t) \sim \mathrm{ED}^*(\mu, s),$$

for $s, t \in \Lambda$. An additive process with time domain $\Lambda = \mathbb{N}$ (the positive integers) is a random walk, the simplest example being the Bernoulli process. An additive process with time domain $\Lambda = \mathbb{R}_+$ (which requires the distribution to be infinitely divisible), is a Lévy process (see ►Lévy Processes), including examples such as Brownian motion with drift and the Poisson process (see ►Poisson Processes). Note, in particular, that the average of the process over the interval $(0, t)$ has distribution $X(t)/t \sim \mathrm{ED}(\mu, t^{-1})$, which follows by an application of the duality transformation.

A reproductive exponential dispersion model $\mathrm{ED}(\mu, \sigma^2)$ satisfies the following *reproductive property*, which follows as a corollary to (11). Assume that $Y_1, \ldots, Y_n$ are independent and $Y_i \sim \mathrm{ED}\left(\mu, \sigma^2/w_i\right)$ for $i = 1, \ldots, n$, where $w_1, \ldots, w_n$ are positive weights such that $w_i/\sigma^2 \in \Lambda$ for all i. Then, with $w_+ = w_1 + \ldots + w_n$,

$$\frac{1}{w_+}\sum_{i=1}^{n} w_i Y_i \sim \mathrm{ED}\left(\mu, \frac{\sigma^2}{w_+}\right). \tag{12}$$

Tweedie Exponential Dispersion Models

The class of *Tweedie models,* denoted $\mathrm{Tw}_p(\mu, \sigma^2)$, consist of reproductive exponential dispersion models corresponding to the unit variance functions $V(\mu) = \mu^p$, where p is a parameter with domain $(-\infty, 0] \cup [1, \infty]$ and Ω is defined in Table 2. Here we let $p = \infty$ correspond to the variance function $V(\mu) = e^{\beta\mu}$ for some $\beta \in \mathbb{R}$. These models were introduced independently by Tweedie (1984), Morris (1981), Hougaard (1986) and Bar-Lev and Enis (1986). As shown in Table 2, the Tweedie class contains several well-known families of distributions. For $p < 0$ or $p > 2$, the Tweedie models are natural exponential families generated by extreme or positive stable distributions with index $\alpha = (p-2)/(p-1)$. For $p \neq 0, 1, 2$, the unit deviance of the family $\mathrm{Tw}_p(\mu, \sigma^2)$ is given by

$$d_p(y; \mu) = 2\left[\frac{\{\max(y, 0)\}^{2-p}}{(1-p)(2-p)} - \frac{y\mu^{1-p}}{1-p} + \frac{\mu^{2-p}}{2-p}\right],$$

where y belongs to the support, see Table 2.

The Tweedie models are characterized by the following scaling property:

$$b\,\mathrm{Tw}_p(\mu, \sigma^2) \sim \mathrm{Tw}_p(b\mu, b^{2-p}\sigma^2). \tag{13}$$

for all $b > 0$, see Jørgensen et al. (1994) and Jørgensen (1997b, Chap. 4). The former authors showed that the scaling property implies a kind of central limit theorem (see ►Central Limit Theorems) for exponential dispersion models, where Tweedie models appear as limiting distributions.

For $1 < p < 2$, the Tweedie models are compound Poisson distributions, which are continuous non-negative distributions with an atom at zero. Such models are useful for measurements of for example precipitation, where wet periods show positive amounts, while dry periods are recorded as zeros. Similarly, the total claim on an insurance policy over a fixed time interval (Renshaw 1993; Jørgensen and Souza 1994), may be either positive if claims were made in the period or zero if no claims were made. Other values of p (except $p = 1$) correspond to continuous distributions with support either $\mathbb{R}_+$ or $\mathbb{R}$.

Dispersion Models. Table 2 Summary of Tweedie exponential dispersion models

Distribution family	p	Support	Ω	Θ
Extreme stable exponential family	$p < 0$	$\mathbb{R}$	$\mathbb{R}_+$	$\mathbb{R}_0$
Normal distribution	$p = 0$	$\mathbb{R}$	$\mathbb{R}$	$\mathbb{R}$
Poisson distribution	$p = 1$	$\mathbb{N}_0$	$\mathbb{R}_+$	$\mathbb{R}$
Compound Poisson distribution	$1 < p < 2$	$\mathbb{R}_0$	$\mathbb{R}_+$	$\mathbb{R}_-$
Gamma distribution	$p = 2$	$\mathbb{R}_+$	$\mathbb{R}_+$	$\mathbb{R}_-$
Positive stable exponential family	$p > 2$	$\mathbb{R}_+$	$\mathbb{R}_+$	$-\mathbb{R}_0$
Inverse Gaussian distribution	$p = 3$	$\mathbb{R}_+$	$\mathbb{R}_+$	$-\mathbb{R}_0$
Extreme stable exponential family	$p = \infty$	$\mathbb{R}$	$\mathbb{R}$	$\mathbb{R}_-$

Notation: $-\mathbb{R}_0 = (-\infty, 0]$

Let us apply the inverse duality transformation $X = \lambda Y$ to the Tweedie variable $Y \sim \mathrm{Tw}_p(\mu, 1/\lambda)$, in order to obtain the additive form of the Tweedie distribution. By the scaling property (13) this gives $X \sim \mathrm{Tw}_p(\lambda\mu, \lambda^{1-p})$, which shows that the Tweedie exponential dispersion models have an additive as well as a reproductive form. The additive form of the Tweedie model gives rise to a class of additive processes $\{X(t) : t \geq 0\}$, defined by the following distribution of the increments:

$$X(t+s) - X(t) \sim \mathrm{Tw}_p\left(s\mu, s^{1-p}\right),$$

for $s, t > 0$. This class of *Hougaard Lévy processes* was introduced by Jørgensen (1992) and Lee and Whitmore (1993). Brownian motion (see ►Brownian Motion and Diffusions) with drift ($p = 0$) and the Poisson process ($p = 1$) mentioned above are examples of Hougaard processes, and other familiar examples include the gamma process ($p = 2$) and the inverse Gaussian process ($p = 3$). The Hougaard processes corresponding to $1 < p < 2$ are compound Poisson processes with gamma distributed jumps.

Multivariate Dispersion Models

One way to generalize (1) to the multivariate case is to consider a probability density function of the form

$$f(\boldsymbol{y}; \boldsymbol{\mu}, \sigma^2) = a(\boldsymbol{y}; \sigma^2) \exp\left\{-\frac{1}{2\sigma^2} d(\boldsymbol{y}; \boldsymbol{\mu})\right\} \text{ for } \boldsymbol{y} \in \mathbb{R}^k, \tag{14}$$

where $(\boldsymbol{\mu}, \sigma^2) \in \Omega \times \mathbb{R}_+$, and Ω is now a domain in $\mathbb{R}^k$. Here a is a suitable function such that (14) is a probability density function, and d is again a unit deviance satisfying $d(\boldsymbol{\mu}; \boldsymbol{\mu}) = 0$ for $\boldsymbol{\mu} \in \Omega$ and $d(\boldsymbol{y}; \boldsymbol{\mu}) > 0$ for $\boldsymbol{y} \neq \boldsymbol{\mu}$. The multivariate exponential dispersion models of Jørgensen (1986; 1987a) provide examples of (14). Other examples include the multivariate von Mises-Fisher distribution, the multivariate hyperboloid distribution (see Jensen 1981), and some special cases of the multivariate simplex distributions of Barndorff-Nielsen (1991).

A more flexible definition of multivariate dispersion models is obtained by considering models of the form

$$f(\boldsymbol{y}; \boldsymbol{\mu}, \boldsymbol{\Sigma}) = a(\boldsymbol{y}; \boldsymbol{\Sigma}) \exp\left[-\frac{1}{2} g\left\{r^\top(\boldsymbol{y}; \boldsymbol{\mu}) \boldsymbol{\Sigma}^{-1} r(\boldsymbol{y}; \boldsymbol{\mu})\right\}\right], \tag{15}$$

where $\boldsymbol{\Sigma}$ is a symmetric positive-definite $k \times k$ matrix, g is an increasing function satisfying $g(0) = 0$ and $g'(0) > 0$, and $r(\boldsymbol{y}; \boldsymbol{\mu})$ is a suitably defined k-vector of residuals satisfying $r(\boldsymbol{\mu}; \boldsymbol{\mu}) = \mathbf{0}$ for $\boldsymbol{\mu} \in \Omega$, see Jørgensen and Lauritzen (2000). An example is the ►multivariate normal distributions $\mathrm{N}_k(\boldsymbol{\mu}, \boldsymbol{\Sigma})$, which is obtained for $r(\boldsymbol{y}; \boldsymbol{\mu}) = \boldsymbol{y} - \boldsymbol{\mu}$ and g the identity function. Further examples include the multivariate Laplace and t distributions, along with the class of elliptically contoured distributions of Fang (1997). Further generalizations and examples may be found in Jørgensen and Lauritzen (2000), see also Jørgensen and Rajeswaran (2005).

About the Author

Bent Jørgensen is Professor of Mathematical Statistics at the University of Southern Denmark, Odense. He has also held positions at the Institute of Pure and Applied Mathematics, Rio de Janeiro, and the University of British Columbia, Vancouver. He is an Elected member of the International Statistical Institute. Professor Jørgensen has authored or co-authored more than 45 papers and three books, including *The Theory of Dispersion Models* (Chapman & Hall, 1997).

Distance Measures

Bojana Dalbelo Basic
Professor, Faculty of Electrical Engineering and Computing
University of Zagreb, Zagreb, Croatia

Distance is a key concept in many statistical and pattern recognition methods (e.g., clustering, ►multidimensional scaling, ►correspondence analysis, ►principal component analysis, k-nearest neighbors, etc.). From the mathematical point of view, any set X (whose elements are called points) is said to be a *metric space* (Rudin 1976) if for any two points $\boldsymbol{a}, \boldsymbol{b} \in X$ there is an associated real number $d(\boldsymbol{a}, \boldsymbol{b})$ called *distance* if the following properties hold true:

1. $d(\boldsymbol{a}, \boldsymbol{b}) \geq 0$, (non-negativity)
2. $d(\boldsymbol{a}, \boldsymbol{b}) = 0 \iff \boldsymbol{a} = \boldsymbol{b}$ (definiteness)
3. $d(\boldsymbol{a}, \boldsymbol{b}) = d(\boldsymbol{b}, \boldsymbol{a})$ (symmetry)
4. $d(\boldsymbol{a}, \boldsymbol{c}) \leq d(\boldsymbol{a}, \boldsymbol{b}) + d(\boldsymbol{b}, \boldsymbol{c})$, for any $\boldsymbol{b} \in X$ (triangle inequality)

Any function with these properties is called a *distance function*, a *distance measure*, or a *metric*.

An example of the distance measure in metric space R^n is the so-called *Minkowski distance* (L_n) defined by:

$$d_n(\boldsymbol{a}, \boldsymbol{b}) = \sqrt[n]{\sum_{i=1}^{n} (a_i - b_i)^n},$$

where $\boldsymbol{a}$ and $\boldsymbol{b}$ are vectors, elements of R^n.

The Minkowski metric for $n = 1$ is called the *Manhattan* or the *Cityblock distance* (L_1) and is given by:

$$d_1(\boldsymbol{a}, \boldsymbol{b}) = \sum_{i=1}^{n} |a_i - b_i|.$$

For binary vectors (whose components are restricted to values 0 or 1) this metric is called the *Hamming distance*. A special case of the Minkowski metric for the $n = 2$ metric is called the Euclidian distance (L_2) and it is the most popular metric:

$$d_2(\boldsymbol{a}, \boldsymbol{b}) = \sqrt{\sum_{i=1}^{n} (a_i - b_i)^2}.$$

For $n \to \infty$, we have the *distance* $(\boldsymbol{L_\infty})$ defined by:

$$d_\infty(\boldsymbol{a}, \boldsymbol{b}) = \max_{1 \leq i \leq n} \{|a_i - b_i|\}.$$

As an example, consider a set of points $\boldsymbol{x}$ in R^2 that have a constant distance r from the origin, that is, $(0, 0)$ point in R^2. Then, a set of points $\boldsymbol{x} \in R^2$ having the property $d_2(0, \boldsymbol{x}) = r$ is a circle with radius r and origin $(0, 0)$; a set of points $\boldsymbol{x} \in R^2$ having $d_1(0, \boldsymbol{x}) = r$ is a "diamond" having vertices at $(r, 0), (0, r), (-r, 0)$ and $(0, -r)$; and a set of points $\boldsymbol{x} \in R^2$ having the property $d_\infty(0, \boldsymbol{x}) = r$ is a square having vertices at $(r, r), (-r, r), (-r, -r), (r, -r)$.

Although the Euclidean distance is the most widely used, it is not an appropriate measure when the statistical properties of variables (attributes of the items) are being explicitly considered because it assumes that the variables are uncorrelated.

Also, if we measure the distance between two items, the Euclidean distance could change with a change in the scale of different variables. For that purpose, the *statistical distance* is used, since it is not affected by a change in scale.

An example of such *scale-invariant distance* measures is the squared (weighted) Euclidean distance for standardized data and the Mahalanobis distance. The *squared Euclidean distance for standardized data* is weighted by $1/s_i^2$, where s_i^2 is the standard deviation of the i^{th} variable:

$$d^2(\boldsymbol{a}, \boldsymbol{b}) = \sum_{i=1}^{n} \frac{(a_i - b_i)^2}{s_i^2}.$$

This distance is also called the *Karl Pearson distance*.

Another example of a weighted Euclidean distance is the *chi-squared distance* used in the ►correspondence analysis. A very important statistical measure that is scale invariant is the *Mahalanobis distance* (Mardia and Kent 1982), defined by:

$$d^2_{Mahalanobis}(\boldsymbol{a}, \boldsymbol{b}) = (\boldsymbol{a} - \boldsymbol{b})' \Sigma^{-1} (\boldsymbol{a} - \boldsymbol{b}),$$

where $\boldsymbol{a}$ and $\boldsymbol{b}$ are two multivariate observations, Σ^{-1} is the inverse of the variance-covariance matrix and $(\boldsymbol{a}-\boldsymbol{b})'$ is the transpose of vector $(\boldsymbol{a}-\boldsymbol{b})$.

The Mahalanobis distance is designed to take into account the correlation between all variables (attributes) of the observations under consideration. For uncorrelated variables, the Mahalanobis distance reduces to the Euclidean distance for standardized data.

As an example, consider a set of points $\boldsymbol{x}$ in R^2 that have the constant distance r from the origin, that is, $(0,0)$. Then, the set of points having the property $d^2_{Mahalanobis}(0,\boldsymbol{x}) = r$ is an ellipse. The Mahalanobis distance is a positive definite quadratic form $\boldsymbol{x}'\mathbf{A}\boldsymbol{x}$, where the matrix $\mathbf{A} = \Sigma^{-1}$.

Distance measures or metrics are members of a broader concept called *similarity measures* (or *dissimilarity measures*) (Theodoridis and Koutroumbas 2009) that measure likeness (or affinity) in the case of the similarity measure, or difference (or lack of affinity) in the case of dissimilarity between objects. Similarity measures can be converted to dissimilarity measures using a monotone decreasing transformation and vice versa.

The main difference between metrics and broader concepts of similarity/dissimilarity measures is that some of the properties (1)–(4) do not hold for similarity/dissimilarity measures. For example, definiteness, or the triangle inequality, usually do not hold for similarity/dissimilarity measures.

The cosine similarity and the Pearson's product moment coefficient are two similarity measures that are not metric. The cosine similarity is the cosine of an angle between the vectors $\boldsymbol{x}$ and $\boldsymbol{y}$ from R^n and is given by:

$$s(\boldsymbol{x},\boldsymbol{y}) = \frac{\boldsymbol{x}'\boldsymbol{y}}{\|\boldsymbol{x}\|\,\|\boldsymbol{y}\|},$$

where $\|\boldsymbol{x}\|$ and $\|\boldsymbol{y}\|$ are norms of the vectors $\boldsymbol{x}$ and $\boldsymbol{y}$. This measure is very popular in information retrieval and text-mining applications.

In statistical analysis (especially when applied to ecology, natural language processing, social sciences, etc.) there are often cases in which similarity or the distance between two items (e.g., sets, binary vectors) is based on two-way contingency tables with elements a, b, c, and d, where a represents the number of elements (attribute values, variables values) present in both items, b is the number of elements present in the first but absent in the second item, c is the number of elements present in the second but absent in the first item, and d is number of elements absent simultaneously in both items. The numbers a, b, c, and d can be defined as properties of two sets or two binary vectors.

Similarity coefficients (Theodoridis and Koutroumbas 2009) or *associations measures* can be defined as a combination of numbers a, b, c, and d. Examples of associations measures are:

Simple matching coefficient	$(a+d)/n$,
Dice coefficient	$2a/(2a+b+c)$,
Jaccard (or *Tanimoto*) *coefficient*	$a/(a+b+c)$.

Although association measures, similarity measures, and correlation coefficients are not metric, they are applicable in the analysis where they are consistent with the objective of the study and where they have meaningful interpretation (Sharma 1996).

Distance sampling is a widely used methodology for estimating animal density or abundance. Its name derives from the fact that the information used for inference are the recorded distances to objects of interest, usually animals, obtained by surveying lines or points. The methods

are also particularly suited to plants or immotile objects, as the assumptions involved (see below for details) are more easily met. In the case of lines the perpendicular distances to detected animals are recorded, while in the case of points the radial distances from the point to detected animals are recorded. A key underlying concept is the detection function, usually denoted $g(y)$ (here y represents either a perpendicular distance from the line or a radial distance from the point). This represents the probability of detecting an animal of interest, given that it is at a distance y from the transect. This function is closely related to the probability density function (pdf) of the detected distances, $f(y)$, as

$$f(y) = \frac{g(y)\pi(y)}{\int_0^w g(y)\pi(y)dy}, \quad (1)$$

where $\pi(y)$ is the distribution of distances available for detection and w is a truncation distance, beyond which distances are not considered in the analysis. The above pdf provides the basis of a likelihood from which the parameters of the detection function can be estimated. An important and often overlooked consideration is that $\pi(y)$ is assumed known. This is enforced by design, as the random placement of transects, independently of the animal population, leads to a distribution which is uniform in the case of line transects and triangular in the case of point transects (Buckland et al. 2001).

Given the n distances to detected animals, density can be estimated by

$$\hat{D} = \frac{n\hat{f}(0)}{2L} \quad (2)$$

in the case of line transects with total transect length L, where $f^{(0)}$ is the estimated pdf evaluated at zero distance, and by

$$\hat{D} = \frac{n\hat{h}(0)}{2k\pi} \quad (3)$$

in the case of k point transects, where $h^{(0)}$ is the slope of the estimated pdf evaluated at zero distance (Buckland et al. 2001). This is a useful result because we can then use all the statistical tools that are available to estimate a pdf in order to obtain density estimates. So one can consider plausible candidate models for the detection function and then use standard maximum likelihood to obtain estimates for the corresponding parameters and therefore density estimates.

The most common software to analyze distance sampling data, Distance (Thomas et al. 2010), uses the semi-parametric key+series adjustment formulation from Buckland (1992), in which a number of parametric models are considered as a first approximation and then some expansion series terms are added to improve the fit to the data. Standard model selection tools and goodness-of-fit tests are available for assisting in ▶model selection.

Variance estimates can be obtained using a delta method approximation to combine the individual variances of the random components in the formulas above (i.e., n and either $f^{(0)}$ or $h^{(0)}$; for details on obtaining each component variance, see Buckland et al. 2001). In some of the more complex scenarios, one must use resampling methods based on the non-parametric bootstrap, which are also available in the software.

Given a sufficiently large number of transects randomly allocated independently of the population of interest, estimators are asymptotically unbiased if (1) all animals on the transect are detected, i.e., $g(0) = 1$, (2) sampling is an instantaneous process (typically it is enough if animal movement is slow relative to the observer movement), and (3) distances are measured without error. See Buckland et al. (2001) for discussion of assumptions. Other assumptions, for example that all detections are independent events, are strictly required as the methods are based on maximum likelihood, but the methods are extraordinarily robust to their failure (Buckland 2006). Failure of the $g(0) = 1$ assumption leads to underestimation of density. Violation of the movement and measurement error assumption have similar consequences. Underestimation of distances and undetected responsive movement toward the observers lead to overestimation of density, and overestimation of distances and undetected movement away from the observer lead to underestimation of density. Random movement and random measurement error usually leads to overestimation of density. Naturally the bias depends on the extent to which the assumptions are violated. Most of the current research in the field is aimed at relaxing or avoiding the need for such assumptions. As there are no free lunches in statistics, these come at the expense of more elaborate methods, additional data demands and additional assumptions.

Further details about conventional distance sampling, including dealing with clustered populations, cue counting methods and field methods aspects, can be found in Buckland et al. (2001), while advanced methods, including the use of multiple covariates in the detection function, double platform methods for when $g(0) < 1$, spatial models, automated survey design, and many other specialized topics, are covered in Buckland et al. (2004).

About the Authors

The authors have a wide experience in developing and applying methods for estimation of animal abundance. They have published collectively around one hundred papers in distance sampling methods and applications,

and are actively involved in dissemination of distance sampling methods through international workshops and consultancy. Three of them are also co-authors and editors of the following key books on distance sampling: *Introduction to Distance Sampling: Estimating Abundance of Biological Populations* (Oxford University Press, 2001) and *Advanced Distance Sampling: Estimating Abundance of Biological Populations* (Oxford University Press, 2004).

The distributions of order k are infinite families of probability distributions indexed by a positive integer k, which reduce to the respective classical probability distributions for $k = 1$, and they have many applications. We presently discuss briefly the geometric, negative binomial, Poisson, logarithmic series and binomial distributions of order k.

Geometric Distribution of Order *k*

Denote by T_k the number of independent Bernoulli trials with success (S) and failure (F) probabilities p and $q = 1 - p$ $(0 < p < 1)$, respectively, until the occurrence of the kth consecutive success. Philippou and Muwafi (1982) observed that a typical element of the event $\{T_k = x\}$ is an arrangement

$$a_1 a_2 \dots a_{x_1+x_2+\cdots+x_k} \underbrace{SS\dots S}_{k}, \tag{1}$$

such that x_1 of the a's are $E_1 = F$, x_2 of the a's are $E_2 = SF, \dots,$ x_k of the a's are $E_k = \underbrace{SS\dots S}_{k-1}F$, and proceeded to obtain the following exact formula for the probability mass function (pmf) of T_k, namely,

$$f(x) = P(T_k = x) = p^x \sum \binom{x_1 + x_2 + \cdots + x_k}{x_1, x_2, \dots, x_k} \left(\frac{q}{p}\right)^{x_1+x_2+\cdots+x_k}, \quad x \geq k, \tag{2}$$

where the summation is taken over all non-negative integers $x_1, x_2, \dots, x_k$ satisfying the condition $x_1 + 2x_2 + \cdots + kx_k = x - k$. Alternative simpler formulas have been derived. The following recurrence for example, due to Philippou and Makri (1985), is very efficient for computations

$$f(x) = f(x-1) - qp^k f(x-1-k), \quad x > 2k \tag{3}$$

with initial conditions $f(k) = p^k$ and $f(x) = qp^k$ for $k < x \leq 2k$. Furthermore, it shows that $f(x)$ attains its maximum p^k for $x = k$, followed by a plateau of height qp^k for $x = k+1, k+2, \dots, 2k$, and decreases monotonically to 0 for $x \geq 2k+1$.

Philippou et al. (1983) employed the transformation $x_i = m_i$ $(1 \leq m_i \leq k)$ and $x = m + \sum_{i=1}^{k}(i-1)m_i$ to show that $\sum_{x=k}^{\infty} f(x) = 1$ (and hence $f(x)$ is a proper pmf). They named the distribution of T_k *geometric distribution of order k with parameter p* and denoted it by $G_k(p)$, since for $k = 1$ it reduces to the classical geometric distribution with pmf $f(x) = q^{x-1}p$ $(x \geq 1)$. It follows from (2), by means of the above transformation and the multinomial theorem, that the probability generating function (pgf) of T_k is given by

$$\phi_k(w) = \sum_{x=k}^{\infty} x^w f(x) = \frac{p^k w^k (1 - pw)}{1 - w + qp^k w^{k+1}}, \quad |w| \leq 1. \tag{4}$$

The mean and variance of T_k readily follow from its pgf and they are given by

$$E(T_k) = \frac{1 - p^k}{qp^k}, \quad Var(T_k) = \frac{1 - (2k+1)qp^k - p^{2k+1}}{(qp^k)^2}. \tag{5}$$

A different derivation of (4) was first given by Feller (1968), who used the method of partial fractions on $\phi_k(w)$ to

derive the surprisingly good approximation

$$P(T_k > x) \simeq \frac{1 - pw_0}{(k + 1 - kw_0)q\, w_0^{x+1}}, \tag{6}$$

where w_0 is the unique positive root of $p^k w^k / \phi_k(w)$.

It is well known that the negative binomial distribution arises as the distribution of the sum of r independent rv's distributed identically as geometric. This fact motivated the genesis of the following distribution of order k.

Negative Binomial Distribution of Order k

Let $X_1, X_2, \ldots, X_r$ be independent rv's distributed identically as $G_k(p)$ and set $T_{r,k} = \sum_{i=1}^{r} X_i$. Then, relation (4) implies

$$\begin{aligned}\phi_{r,k}(w) &= \sum_{x=rk}^{\infty} x^w P(T_{r,k} = x) \\ &= \left(\frac{p^k w^k (1 - pw)}{1 - w + qp^k w^{k+1}}\right)^r, \quad |w| \le 1. \end{aligned} \tag{7}$$

Expanding $\phi_{r,k}(w)$ in a series around 0, Philippou et al. (1983) obtained the pmf of $T_{r,k}$ as

$$\begin{aligned}P(T_{r,k} = x) = p^x \sum \binom{x_1 + x_2 + \cdots + x_k + r - 1}{x_1, x_2, \ldots, x_k, r - 1} \\ \times \left(\frac{q}{p}\right)^{x_1 + x_2 + \cdots + x_k}, \quad x \ge rk, \end{aligned} \tag{8}$$

where the summation is taken over all non-negative integers $x_1, x_2, \ldots, x_k$ satisfying the condition $x_1 + 2x_2 + \cdots + kx_k = x - rk$. They called the distribution of $T_{r,k}$ *negative binomial distribution of order k with parameter vector* (r, p) and denoted it by $NB_k(r, p)$, since for $k = 1$ it reduces to the negative binomial distribution with pmf $f(x) = \binom{x-1}{r-1} p^r q^{x-r}$ $(x \ge r)$. For $r = 1$, it reduces to the geometric distribution of order k. Obviously, $T_{r,k}$ denotes the waiting time for the occurrence of the rth non-overlapping success run of length k. Alternative formulas, simpler than (8), have been derived by Godbole (1990) (see also Antzoulakos and Philippou (1999)) and Philippou and Georghiou (1989). The latter authors established also the following efficient recurrence

$$\begin{aligned}g(x) = P(T_{r,k} = x) = \frac{q/p}{x - rk} \sum_{i=1}^{k} [x - rk + i(r-1)] \\ \times p^i g(x - i), \quad x \ge rk + 1, \end{aligned} \tag{9}$$

with $g(x) = 0$ for $0 \le x \le rk - 1$ and $f(rk) = p^{rk}$, which recaptures (3) for $r = 1$.

Let $X_1, X_2, \ldots, X_n$ be independent rv's distributed identically as $NB_k(r, p)$, and set $\overline{X} = \frac{1}{n} \sum_{i=1}^{n} X_i$. Philippou (1984) observed that the moment estimator $\hat{p}$ of p is the unique admissible root of the equation $\frac{r(1-p^k)}{(1-p)p^k} = \overline{X}$. In particular, for $k = 2$, $\hat{p} = \frac{r + (r^2 + 4r\overline{X})^{1/2}}{2\overline{X}}$ and it is consistent for p.

The fact that the Poisson and the logarithmic series distributions arise as appropriate limits of the negative binomial distribution, motivated the following.

Poisson and Logarithmic Series Distributions of Order k

Let X be a rv distributed as $NB_k(r, p)$ and set $Y_r = X - rk$.

(a) Assume that $q \to 0$ and $rq \to \lambda$ (> 0) as $r \to \infty$. Then, for $y = 0, 1, \ldots,$

$$\lim_{r \to \infty} P(Y_r = y) = e^{-k\lambda} \sum \frac{\lambda^{y_1 + y_2 + \cdots + y_k}}{y_1! y_2! \ldots y_k!} = f_Y(y), \tag{10}$$

where the summation is taken over all non-negative integers $y_1, y_2, \ldots, y_k$ satisfying the condition $y_1 + 2y_2 + \cdots + ky_k = y$. The distribution of Y has been named *Poisson distribution of order k with parameter* λ.

(b) Assume that r is positive and real. Then, for $z = 1, 2, \ldots,$

$$\begin{aligned}\lim_{r \to 0} P(Y_r = z \mid Y_r \ge 1) = \alpha p^z \sum \frac{(z_1 + z_2 + \cdots + z_k - 1)!}{z_1! z_2! \ldots z_k!} \\ \times \left(\frac{q}{p}\right)^{z_1 + z_2 + \cdots + z_k} = f_Z(z), \end{aligned} \tag{11}$$

where $\alpha = -1/k \log p$, and the summation is taken over all non-negative integers $z_1, z_2, \ldots, z_k$ satisfying the condition $z_1 + 2z_2 + \cdots + kz_k = z$. This result is due to Aki et al. (1984) who extended the definition of $NB_k(r, p)$ to positive real r. They called the distribution of Z *logarithmic series distribution of order k with parameter p*.

We end this note with a few words on the binomial distribution of order k.

Binomial Distribution of Order k
