Stochastic Models for Spatial Data

Diggle and Ribeiro (2007) and Mase (2010) describe geostatistics as a branch of spatial statistics that deals with statistical methods for the analysis of spatially referenced data with the following properties. Firstly, values Y_i, $i = 1, \ldots, n$, are observed at a discrete set of sampling locations $\boldsymbol{x}_i$ within some spatial region $\mathcal{S} \subset \mathbb{R}^d$, $d \geq 2$. Secondly, each observed value Y_i is either a measurement of, or is statistically related to, the value of an underlying continuous spatial phenomenon, $Z(\boldsymbol{x})$, at the corresponding sampling location $\boldsymbol{x}_i$. The term model-based geostatistics refers to geostatistical methods that rely on a stochastic model. The observed phenomenon is viewed as a realization of a continuous stochastic process in space, a so-called random field.

Such a random field $Z(\boldsymbol{x})$ is fully determined by specifying all multivariate distributions, i.e., $P(Z(\boldsymbol{x}_1) \leq z_1, \ldots, Z(\boldsymbol{x}_n) \leq z_n)$ for arbitrary $n \in \mathbb{N}$ and $\boldsymbol{x}_1, \ldots, \boldsymbol{x}_n \in \mathcal{S}$. Since a full characterization of a random field is usually hopeless, the mean function $m(\boldsymbol{x}) = E(Z(\boldsymbol{x}))$ and the covariance function $K(\boldsymbol{x}_i, \boldsymbol{x}_j) = Cov(Z(\boldsymbol{x}_i), Z(\boldsymbol{x}_j))$ play a prominent role. Thereby, $m(\boldsymbol{x})$ represents the trend while $K(\boldsymbol{x}_i, \boldsymbol{x}_j)$ defines the dependence structure of the random field. It is typical that the assumption of weak (second-order) isotropy is made about the random field, i.e., its mean function is constant and its covariance function $K(\boldsymbol{x}_1, \boldsymbol{x}_2)$ depends on $\boldsymbol{x}_1$ and $\boldsymbol{x}_2$ only through $h = \|\boldsymbol{x}_1 - \boldsymbol{x}_2\|_2$, where $\|.\|_2$ denotes the Euclidean distance. In this case K is called an isotropic autocovariance function. The covariance function is directly related to smoothness properties of the random field such as mean square continuity and differentiability. A widely used parametric family of isotropic autocovariance functions is the Matern family

$$K_{\sigma^2,\boldsymbol{\theta}}(h) = \sigma^2 \left((1 - \vartheta_2) + \frac{\vartheta_2}{2^{\kappa-1}\Gamma(\kappa)} \left(\frac{2\kappa^{\frac{1}{2}} h}{\vartheta_1} \right)^{\kappa} \mathcal{K}_{\kappa} \left(\frac{2\kappa^{\frac{1}{2}} h}{\vartheta_1} \right) \right),$$

where $\mathcal{K}_{\kappa}$ denotes the modified Bessel function of order $\kappa > 0$, $\vartheta_1 > 0$ is a called the "range parameter" controlling how fast the covariance decays as the distance h gets large, $\vartheta_2 \in [0,1]$ is called the "nugget parameter" and describes a measurement error, σ^2 controls the variance and $\boldsymbol{\theta} = (\vartheta_1, \vartheta_2, \kappa)$ denotes the vector of correlation parameters. The parameter κ controls the smoothness of the corresponding process. A thorough mathematical introduction to the theory of random fields is given in Stein (1999) and Yaglom (1987).

The most important geostatistical model is the linear Gaussian model

$$Y_i = \boldsymbol{f}(\boldsymbol{x}_k)^T \boldsymbol{\beta} + Z(\boldsymbol{x}_i), \quad i = 1, \ldots, n, \tag{1}$$

where $Z(\boldsymbol{x})$ is a weakly isotropic zero-mean Gaussian random field with autocovariance function $K_{\sigma^2,\boldsymbol{\theta}}$, $\boldsymbol{f}$ is a vector of location-dependent explanatory variables and $\boldsymbol{\beta} = (\beta_1, \ldots, \beta_p)^T$ is the vector of regression parameters. The

likelihood function for the linear Gaussian model is

$$p\left(\boldsymbol{Y} \mid \boldsymbol{\beta}, \sigma^2, \boldsymbol{\theta}\right) = (2\pi)^{-\frac{n}{2}} \left|\sigma^2 \boldsymbol{\Sigma}_{\boldsymbol{\theta}}\right|^{-\frac{1}{2}} \exp\left\{-\frac{1}{2\sigma^2}\left(\boldsymbol{Y} - \boldsymbol{F}\boldsymbol{\beta}\right)^T \boldsymbol{\Sigma}_{\boldsymbol{\theta}}^{-1}\left(\boldsymbol{Y} - \boldsymbol{F}\boldsymbol{\beta}\right)\right\},$$

where $\boldsymbol{\Sigma}_{\boldsymbol{\theta}}$ denotes the correlation matrix, $\boldsymbol{F}$ is the design matrix and $\boldsymbol{Y} = (Y_1, \ldots, Y_n)^T$ is the vector of observations. The maximum likelihood estimates for $\boldsymbol{\beta}$ and σ^2 in the linear Gaussian model are

$$\hat{\boldsymbol{\beta}} = \left(\mathbf{F}^T \boldsymbol{\Sigma}_{\boldsymbol{\theta}}^{-1} \mathbf{F}\right)^{-1} \mathbf{F}^T \boldsymbol{\Sigma}_{\boldsymbol{\theta}}^{-1} \mathbf{Y}, \tag{2}$$

$$\hat{\sigma}^2 = \frac{1}{n}\left(\mathbf{Z} - \mathbf{F}\hat{\boldsymbol{\beta}}\right)^T \boldsymbol{\Sigma}_{\boldsymbol{\theta}}^{-1}\left(\mathbf{Z} - \mathbf{F}\hat{\boldsymbol{\beta}}\right). \tag{3}$$

Plugging these estimates into the log-likelihood, we arrive at the so-called profiled log-likelihood, which just contains the parameters $\boldsymbol{\theta}$

$$\log p\left(\boldsymbol{Y} \mid \hat{\boldsymbol{\beta}}, \hat{\sigma}^2, \boldsymbol{\theta}\right) = -\frac{n}{2}\left(\log(2\pi) + 1\right) - \frac{1}{2}\log\left|\boldsymbol{\Sigma}_{\boldsymbol{\theta}}\right| - \frac{n}{2}\log\left(\hat{\sigma}^2\right).$$

To obtain $\hat{\boldsymbol{\theta}}$ we have to maximize the latter equation for $\boldsymbol{\theta}$ numerically. Note that this maximization problem is a lot simpler than the maximization of the complete likelihood where $\boldsymbol{\beta}$ and σ^2 are additional unknowns, especially when p is large. Spatial prediction, which is often the goal in geostatistics, is performed based on the estimated parameters. The plug-in predictive distribution for the value of the random field at an unobserved location $\boldsymbol{x}_0$ is Gaussian

$$Y_0 \mid \boldsymbol{Y}, \hat{\sigma}^2, \hat{\boldsymbol{\theta}} \sim \mathrm{N}\left(\boldsymbol{k}^T \boldsymbol{K}^{-1} \boldsymbol{Y} + \boldsymbol{s}^T \hat{\boldsymbol{\beta}}, \hat{\sigma}^2 - \boldsymbol{k}^T \boldsymbol{K}^{-1} \boldsymbol{k} + \hat{\sigma}^2 \boldsymbol{s}^T \left(\boldsymbol{F}^T \boldsymbol{K}^{-1} \boldsymbol{F}\right)^{-1} \boldsymbol{s}\right), \tag{4}$$

where $\boldsymbol{K} = \hat{\sigma}^2 \boldsymbol{\Sigma}_{\hat{\boldsymbol{\theta}}}, \boldsymbol{s} = \boldsymbol{f}(\boldsymbol{x}_0) - \boldsymbol{F}^T \boldsymbol{K}^{-1} \boldsymbol{k}, \boldsymbol{k} = Cov(\boldsymbol{Z}, Z(\boldsymbol{x}_0))$, $\boldsymbol{Z} = (Z(\boldsymbol{x}_1), \ldots, Z(\boldsymbol{x}_n))^T$.

Weak isotropy is a rather strong assumption and environmental processes are typically not direction independent but show an anisotropic behavior. A popular extension to isotropic random fields is to consider random fields that become isotropic after a linear transformation of the coordinates (Schabenberger and Gotway 2005). This special variant of anisotropy is called geometric anisotropy. Let $Z_1(\boldsymbol{x})$ be an isotropic random field on $\mathbb{R}^d$ with autocovariance function K_1 and mean μ. For the random field $Z(\boldsymbol{x}) = Z_1(\boldsymbol{T}\boldsymbol{x})$, where $\boldsymbol{T} \in \mathbb{R}^{d \times d}$, we get that $E(Z(\boldsymbol{x})) = \mu$ and the corresponding autocovariance function is $Cov(Z(\boldsymbol{x}_1), Z(\boldsymbol{x}_2)) = K_1\left(\|\boldsymbol{T}(\boldsymbol{x}_1 - \boldsymbol{x}_2)\|_2\right)$. When correcting for geometric anisotropy we need to revert the coordinate transformation. $Z\left(\boldsymbol{T}^{-1}\boldsymbol{x}\right)$ has the same mean as $Z(\boldsymbol{x})$ but isotropic autocovariance function K_1. When correcting for stretching and rotation of the coordinates we have

$$\boldsymbol{T}^{-1} = \begin{pmatrix} 1 & 0 \\ 0 & \lambda \end{pmatrix} \begin{pmatrix} \cos\varphi & -\sin\varphi \\ \sin\varphi & \cos\varphi \end{pmatrix}.$$

Here, λ and φ are called the anisotropy ratio and anisotropy angle, respectively. All the models that we consider in this chapter can be extended to account for geometric anisotropy by introducing these two parameters.

Bayesian Kriging

The first steps towards Bayesian modeling and prediction in geostatistics were made by Kitanidis (1986) and Omre (1987) who developed a Bayesian version of universal kriging. One of the advantages of the Bayesian approach, besides its ability to deal with the uncertainty about the model parameters, is the possibility to work with only a few measurements. Assume a Gaussian random field model in the form of the form Eq. 1 with known covariance matrix $\boldsymbol{K}$ but unknown parameter vector $\boldsymbol{\beta}$. From Bayesian analysis we know that it is natural to assume a prior of the form $\boldsymbol{\beta} \sim \mathrm{N}\left(\boldsymbol{m}_b, \sigma^2 \boldsymbol{V}_b\right)$ for $\boldsymbol{\beta}$, where $\boldsymbol{V}_b$ is a positive semidefinite matrix. It can be shown that the posterior distribution for $\boldsymbol{\beta}$ is

$$\boldsymbol{\beta} \mid \boldsymbol{Z} \sim \mathrm{N}\left(\tilde{\boldsymbol{\beta}}, \sigma^2 \boldsymbol{V}_{\tilde{\beta}}\right),$$

where $\tilde{\boldsymbol{\beta}} = \boldsymbol{V}_{\tilde{\beta}}\left(\sigma^2 \boldsymbol{F}^T \boldsymbol{K}^{-1} \boldsymbol{Z} + \boldsymbol{V}_b^{-1} \boldsymbol{m}_b\right)$ and $\boldsymbol{V}_{\tilde{\beta}} = \left(\sigma^2 \boldsymbol{F}^T \boldsymbol{K}^{-1} \boldsymbol{F} + \boldsymbol{V}_b^{-1}\right)^{-1}$. The predictive distribution of $Z(\boldsymbol{x}_0)$ is also Gaussian and given by

$$Z(\boldsymbol{x}_0) \mid \boldsymbol{Z} \sim \mathrm{N}\left(\boldsymbol{k}^T \boldsymbol{K}^{-1} \boldsymbol{Z} + \boldsymbol{s}^T \tilde{\boldsymbol{\beta}}, \sigma^2 - \boldsymbol{k}^T \boldsymbol{K}^{-1} \boldsymbol{k} + \sigma^2 \boldsymbol{s}^T \boldsymbol{V}_{\tilde{\beta}} \boldsymbol{s}\right),$$

where $\boldsymbol{F}$, $\boldsymbol{s}$ and $\boldsymbol{k}$ are defined as in Section "▶Stochastic Models for Spatial Data". From the above representation of the Bayesian kriging predictor it becomes clear that Bayesian kriging bridges the gap between simple and universal kriging. We get simple kriging in case of complete knowledge of the trend, which corresponds to $\mathbf{V}_b = \mathbf{0}$, whereas we get the universal kriging predictor if we have no knowledge of $\boldsymbol{\beta}$ ($\mathbf{V}_b^{-1} = \mathbf{0}$ in the sense that the smallest eigenvalue of $\mathbf{V}_b$ converges to infinity). Interestingly, the Bayesian universal kriging predictor has a smaller or equal variance than the classical universal kriging predictor (see Eq. 4) since $\left(\boldsymbol{F}^T \boldsymbol{K}^{-1} \boldsymbol{F} + \sigma^{-2} \boldsymbol{V}_b^{-1}\right)^{-1} \preceq \left(\boldsymbol{F}^T \boldsymbol{K}^{-1} \boldsymbol{F}\right)^{-1}$, where $\preceq$ denotes the Loewner partial ordering.

Bayesian universal kriging is not fully Bayesian because $\boldsymbol{K}$ is assumed known. Diggle and Ribeiro (2007) summarize the results for a fully Bayesian analysis of Gaussian random field models of the form Eq. 1, where $K_{\sigma^2,\theta} = \sigma^2 \Sigma_{\vartheta_1}$ and ϑ_1 is the range parameter of an isotropic autocorrelation function model.

Transformed Gaussian Kriging

Probably the most simple way to extend the Gaussian random field model is to assume that a differentiable transformation of the original random field, $Z_1(\boldsymbol{x}) = g(Z(\boldsymbol{x}))$, is Gaussian. The mean of the transformed field is unknown and parameterized by $\boldsymbol{\beta}$, $E(Z_1(\boldsymbol{x})) = \boldsymbol{f}(\boldsymbol{x})^T \boldsymbol{\beta}$. If we assume that the transformation function g and the covariance function K of $Y(\boldsymbol{x})$ are known, the optimal predictor for $Z(\boldsymbol{x}_0)$ can be derived using the results from Section "►Stochastic Models for Spatial Data". However, in practice neither K nor g is known and we have to estimate them from the data.

A family of one-parameter transformation functions g_λ that is widely used in statistics is the so-called Box-Cox family

$$g_\lambda(z) = \begin{cases} \frac{z^\lambda - 1}{\lambda}, & \lambda \neq 0, \\ \log(z), & \lambda = 0. \end{cases}$$

The ►Box-Cox transformation is valid for positive-valued random fields and is able to model moderately skewed, unimodal data.

The likelihood of the data $\boldsymbol{Y}$ in the transformed Gaussian model can be written as

$$p(\mathbf{Y} \mid \boldsymbol{\Theta}) = J_\lambda(\mathbf{Y}) (2\pi)^{-\frac{n}{2}} \left|\sigma^2 \boldsymbol{\Sigma}_{\boldsymbol{\theta}}\right|^{-\frac{1}{2}} \exp\left[-\frac{1}{2\sigma^2} (g_\lambda(\mathbf{Y}) - \boldsymbol{F}\boldsymbol{\beta})^T \boldsymbol{\Sigma}_{\boldsymbol{\theta}}^{-1} (g_\lambda(\mathbf{Y}) - \boldsymbol{F}\boldsymbol{\beta})\right],$$

where, $\boldsymbol{\Theta} = (\boldsymbol{\beta}, \boldsymbol{\theta}, \sigma^2, \lambda)$, $J_\lambda(\mathbf{Y})$ is the determinant of the Jacobian of the transformation, $g_\lambda(\boldsymbol{Y}) = (g_\lambda(Y_1), \ldots, g_\lambda(Y_n))$ and λ is the transformation parameter. De Oliveira et al. (1997) point out that the interpretation of $\boldsymbol{\beta}$ changes with the value of λ, and the same is true for the covariance parameters σ^2 and $\boldsymbol{\theta}$, to a lesser extent though. To estimate the parameters λ and $\boldsymbol{\theta}$, we make use of the profile likelihood approach that we have already encountered in Section "►Stochastic Models for Spatial Data". For fixed values of λ and $\boldsymbol{\theta}$, the maximum likelihood estimates for $\boldsymbol{\beta}$ and σ^2 are given by Eqs. 2 and 3 with $\boldsymbol{Y}$ replaced by $g_\lambda(\boldsymbol{Y})$. Again, the estimates for λ and $\boldsymbol{\theta}$ cannot be written in closed form and must be found numerically by plugging $\hat{\boldsymbol{\beta}}$ and $\hat{\sigma}^2$ in the likelihood for numerical maximization.

The estimated parameters $\hat{\boldsymbol{\Theta}}$ are subsequently used for spatial prediction. To perform a plug-in prediction we make use of the conditional distribution of the Gaussian variable $Y_0 \mid \boldsymbol{Y}, \hat{\boldsymbol{\Theta}}$ and back-transform it to the original scale by g_λ^{-1}. A Bayesian approach to spatial prediction in the transformed Gaussian model is proposed in De Oliveira et al. (1997).

The copula-based geostatistical model (Kazianka and Pilz 2009) also works with transformations of the marginal distributions of the random field and is a generalization of transformed Gaussian kriging. In this approach all multivariate distributions of the random field are described by a copula (Sempi 2010) and a family of univariate marginal distributions. Due to the additional flexibility introduced by the choice of the copula and of the marginal distribution, these models are able to deal with extreme observations and multi-modal data.

Generalized Linear Geostatistical Models

►Generalized linear models (McCullagh and Nelder 1989) provide a unifying framework for regression modeling of both continuous and discrete data. Diggle and Ribeiro (2007) extend the classical generalized linear model to what they call the generalized linear geostatistical model (GLGM). The responses Y_i, $i = 1, \ldots, n$, corresponding to location $\boldsymbol{x}_i$ are assumed to follow a family of univariate distributions indexed by their expectation, μ_i, and to be conditionally independent given $\boldsymbol{Z} = (Z(\boldsymbol{x}_1), \ldots, Z(\boldsymbol{x}_n))$. The μ_i are specified through

$$h(\mu_i) = \boldsymbol{f}(\boldsymbol{x}_i)^T \boldsymbol{\beta} + Z(\boldsymbol{x}_i),$$

where $Z(\boldsymbol{x})$ is a Gaussian random field with autocovariance function $K_{\boldsymbol{\theta}}$ and h is a pre-defined link function. The two most frequently applied GLGMs are the Poisson log-linear model, where Y_i is assumed to follow a Poisson distribution and the link function is the logarithm, and the binomial logistic-linear model, where Y_i is assumed to follow a Bernoulli distribution with probability $\mu_i = p(\boldsymbol{x}_i)$ and $h(\mu_i) = \log(p(\boldsymbol{x}_i) / (1 - p(\boldsymbol{x}_i)))$. These models are suitable for representing spatially referenced count data and binary data, respectively.

Since maximum likelihood estimation of the parameters is difficult, a Markov chain Monte Carlo (Robert and Casella 2004) approach (see ►Markov Chain Monte Carlo) is proposed to sample from the posteriors of the model parameters as well as from the predictive distributions at unobserved locations $\boldsymbol{x}_0$. The algorithm proceeds by sampling from $\boldsymbol{Z} \mid \boldsymbol{Y}, \boldsymbol{\beta}, \boldsymbol{\theta}$, from $\boldsymbol{\theta} \mid \boldsymbol{Z}$ and from $\boldsymbol{\beta} \mid \boldsymbol{Z}, \boldsymbol{Y}$ with the help of Metropolis-Hastings updates. At iteration $t+1$ and

actual sample $\left(\boldsymbol{Z}^t, \boldsymbol{\theta}^t, \boldsymbol{\beta}^t, Z^t(\boldsymbol{x}_0)\right)$, perform the following steps:

- Update $\boldsymbol{Z}$. For $i = 1, \ldots, n$, sample a new proposal $Z'(\boldsymbol{x}_i)$ from the conditional Gaussian distribution $p\left(Z(\boldsymbol{x}_i) \mid \boldsymbol{\theta}^t, \boldsymbol{Z}^t_{-i}\right)$, where $\boldsymbol{Z}^t_{-i}$ denotes $\boldsymbol{Z}^t = (Z^t(\boldsymbol{x}_1), \ldots, Z^t(\boldsymbol{x}_n))$ with its ith element removed. Accept $Z'(\boldsymbol{x}_i)$ with probability $r = \min\left\{1, \frac{p\left(Y_i \mid \boldsymbol{\beta}^t, Z'(\boldsymbol{x}_i)\right)}{p\left(Y_i \mid \boldsymbol{\beta}^t, Z^t(\boldsymbol{x}_i)\right)}\right\}$.
- Update $\boldsymbol{\theta}$. Sample a new proposal $\boldsymbol{\theta}'$ from a proposal distribution $J\left(\boldsymbol{\theta} \mid \boldsymbol{\theta}^t\right)$. Accept the new proposal with probability $r = \min\left\{1, \frac{p\left(\boldsymbol{Z}^{t+1} \mid \boldsymbol{\theta}'\right) J\left(\boldsymbol{\theta}^t \mid \boldsymbol{\theta}'\right)}{p\left(\boldsymbol{Z}^{t+1} \mid \boldsymbol{\theta}^t\right) J\left(\boldsymbol{\theta}' \mid \boldsymbol{\theta}^t\right)}\right\}$.
- Update $\boldsymbol{\beta}$. Sample a new proposal $\boldsymbol{\beta}'$ from a proposal distribution $J\left(\boldsymbol{\beta} \mid \boldsymbol{\beta}^t\right)$. Accept the new proposal with probability $r = \min\left\{1, \frac{\prod_{i=1}^n p\left(Y_i \mid Z^{t+1}(\boldsymbol{x}_i), \boldsymbol{\beta}'\right) J\left(\boldsymbol{\beta}^t \mid \boldsymbol{\beta}'\right)}{\prod_{i=1}^n p\left(Y_i \mid Z^{t+1}(\boldsymbol{x}_i), \boldsymbol{\beta}^t\right) J\left(\boldsymbol{\beta}' \mid \boldsymbol{\beta}^t\right)}\right\}$
- Draw a sample $Z^{t+1}(\boldsymbol{x}_0)$ from the conditional Gaussian distribution $Z(\boldsymbol{x}_0) \mid \boldsymbol{Z}^{t+1}, \boldsymbol{\theta}^{t+1}$.

If point predictions for $Z(\boldsymbol{x}_0)$ are needed, the Monte Carlo approximation to the expected value of $Z(\boldsymbol{x}_0) \mid \boldsymbol{Y}$ can be used, i.e., $E\left(\boldsymbol{Z}(\boldsymbol{x}_0) \mid \boldsymbol{Y}\right) \approx \frac{1}{M} \sum_{t=1}^M Z^t(\boldsymbol{x}_0)$, where M is the number of simulations.

Modeling Count Data

Joseph M. Hilbe
Emeritus Professor
University of Hawaii, Honolulu, HI, USA
Adjunct Professor of Statistics
Arizona State University, Tempe, AZ, USA
Solar System Ambassador
California Institute of Technology, Pasadena, CA, USA

Count models are a subset of discrete response regression models. Count data are distributed as non-negative integers, are intrinsically heteroskedastic, right skewed, and have a variance that increases with the mean. Example count data include such situations as length of hospital stay, the number of a certain species of fish per defined area in the ocean, the number of lights displayed by fireflies over specified time periods, or the classic case of the number of deaths among Prussian soldiers resulting from being kicked by a horse during the Crimean War.

►Poisson regression is the basic model from which a variety of count models are based. It is derived from the Poisson probability mass function, which can be expressed as

$$f(y_i; \lambda_i) = \frac{e^{-t_i \lambda_i} (t_i \lambda_i)^{y_i}}{y_i!}, \qquad y = 0, 1, 2, \ldots; \ \mu > 0 \quad (1)$$

with y_i as the count response, λ_i as the predicted count or rate parameter, and t_i the area or time in which counts enter the model. When λ_i is understood as applying to individual counts without consideration of size or time, $t_i = 1$. When $t_i > 1$, it is commonly referred to as an exposure, and is modeled as an offset.

Estimation of the Poisson model is based on the log-likelihood parameterization of the Poisson probability distribution, which is aimed at determining parameter values

making the data most likely. In exponential family form it is given as:

$$L(\mu_i; y_i) = \sum_{i=1}^{n} \{y_i \ln(\mu_i) - \mu_i - \ln(y_i!)\}, \quad (2)$$

where μ_i is typically used to symbolize the predicted counts in place of λ_i. Equation 2, or the deviance function based on it, is used when the Poisson model is estimated as a generalized linear model (*GLM*) (*see* ►Generalized Linear Models). When estimation employs a full maximum likelihood algorithm, μ_i is expressed in terms of the linear predictor, $x'\beta$. As such it appears as

$$\mu_i = \exp(x_i\beta). \quad (3)$$

In this form, the Poisson log-likelihood function is expressed as

$$L(\beta; y_i) = \sum_{i=1}^{n} \{y_i(x_i\beta) - \exp(x_i\beta) - \ln(y_i!)\}. \quad (4)$$

A key feature of the Poisson model is the equality of the mean and variance functions. When the variance of a Poisson model exceeds its mean, the model is termed overdispersed. Simulation studies have demonstrated that overdispersion is indicated when the Pearson χ^2 dispersion is greater than 1.0 (Hilbe 2007). The dispersion statistic is defined as the Pearson χ^2 divided by the model residual degrees of freedom. Overdispersion, common to most Poisson models, biases the parameter estimates and fitted values. When Poisson overdispersion is real, and not merely apparent (Hilbe 2007), a count model other than Poisson is required.

Several methods have been used to accommodate Poisson overdispersion. Two common methods are quasi-Poisson and negative binomial regression. Quasi-Poisson models have generally been understood in two distinct manners. The traditional manner has the Poisson variance being multiplied by a constant term. The second, employed in the glm() function that is downloaded by default when installing R software, is to multiply the standard errors by the square root of the Pearson dispersion statistic. This method of adjustment to the variance has traditionally been referred to as scaling. Using R's quasipoisson() function is the same as what is known in standard GLM terminology as the scaling of standard errors.

The traditional negative binomial model is a Poisson-gamma mixture model with a second ancillary or heterogeneity parameter, α. The mixture nature of the variance is reflected in its form, $\mu_i + \alpha\mu_i^2$, or $\mu_i(1 + \alpha\mu_i)$. The Poisson variance is μ_i, and the two parameter gamma variance is μ_i^2/ν. ν is inverted so that $\alpha = 1/\nu$, which allows for a direct relationship between μ_i, and ν. As a Poisson-gamma mixture model, counts are Poisson distributed as they enter into the model. α is the shape (gamma) of the manner counts enter into the model as well as a measure of the amount of Poisson overdispersion in the data.

The negative binomial probability mass function (*see* ►Geometric and Negative Binomial Distributions) may be formulated as

$$f(y_i; \mu_i, \alpha) = \binom{y_i + 1/\alpha - 1}{1/\alpha - 1} (1/(1 + \alpha\mu_i))^{1/\alpha} (\alpha\mu_i/(1 + \alpha\mu_i))_i^y, \quad (5)$$

with a log-likelihood function specified as

$$L(\mu_i; y_i, \alpha) = \sum_{i=1}^{n} \left\{ y_i \ln\left(\tfrac{\alpha\mu_i}{1+\alpha\mu_i}\right) - \left(\tfrac{1}{\alpha}\right) \ln(1 + \alpha\mu_i) + \ln\Gamma\left(y_i + \tfrac{1}{\alpha}\right) - \ln\Gamma(y_i + 1) - \ln\Gamma\left(\tfrac{1}{\alpha}\right) \right\}. \quad (6)$$

In terms of $\mu = \exp(x'\beta)$, the parameterization employed for maximum likelihood estimation, the negative binomial log-likelihood appears as

$$L(\beta; y_i, \alpha) = \sum_{i=1}^{n} \left\{ y_i \ln\left(\frac{\alpha \exp(x_i'\beta)}{1 + \alpha \exp(x_i'\beta)}\right) - \left(\frac{1}{\alpha}\right) \ln\left(1 + \alpha \exp(x_i'\beta)\right) + \ln\Gamma\left(y_i + \frac{1}{\alpha}\right) - \ln\Gamma(y_i + 1) - \ln\Gamma\left(\frac{1}{\alpha}\right) \right\}. \quad (7)$$

This form of negative binomial has been termed *NB2*, due to the quadratic nature of its variance function. It should be noted that the *NB2* model reduces to the Poisson when $\alpha = 0$. When $\alpha = 1$, the model is geometric, taking the shape of the discrete correlate of the continuous negative exponential distribution. Several fit tests exist that evaluate whether data should be modeled as Poisson or *NB2* based on the degree to which α differs from 0.

When exponentiated, Poisson and *NB2* parameter estimates may be interpreted as incidence rate ratios. For example, given a random sample of 1,000 patient observations from the German Health Survey for the year 1984, the following Poisson model output explains the years expected number of doctor visits on the basis of gender and marital status, both recorded as binary (1/0) variables, and the continuous predictor, age.

Docvis	IRR	OIM std. err.	z	P > |z|	[95% Conf. interval]	
Female	1.516855	0.054906	11.51	0.000	1.41297	1.628378
Married	0.8418408	0.0341971	−4.24	0.000	0.7774145	0.9116063
Age	1.018807	0.0016104	11.79	0.000	1.015656	1.021968

The estimates may be interpreted as

- Females are expected to visit the doctor some 50% more times during the year than males, holding marital status and age constant.

  Married patients are expected to visit the doctor some 16% fewer times during the year than unmarried patients, holding gender and age constant.

  For a one year increase in age, the rate of visits to the doctor increases by some 2%, with marital status and gender held constant.

It is important to understand that the canonical form of the negative binomial, when considered as a *GLM*, is not *NB2*. Nor is the canonical negative binomial model, *NB-C*, appropriate to evaluate the amount of Poisson overdispersion in a data situation. The NB-C parameterization of the negative binomial is directly derived from the negative binomial log-likelihood as expressed in Eq. 6. As such, the link function is calculated as $\ln(\alpha\mu/(1+\alpha\mu))$. The inverse link function, or mean, expressed in terms of $x'\beta$, is $1/(\alpha(\exp(-x'\beta)-1))$.

When estimated as a *GLM*, *NB-C* can be amended to *NB2* form by substituting $\ln(\mu)$ and $\exp(x'\beta)$ respectively for the two above expressions. Additional amendments need to be made to have the *GLM*-estimated *NB2* display the same parameter standard errors as are calculated using full maximum likelihood estimation. The *NB-C* log-likelihood, expressed in terms of μ, is identical to that of the *NB2* function. However, when parameterized as $x'\beta$, the two differ, with the *NB-C* appearing as

$$L(\beta;y_i,\alpha)=\sum_{i=1}^{n}\{y_i(x_i\beta)+(1/\alpha)\ln(1-\exp(x_i\beta)) + \ln\Gamma(y_i+1/\alpha)-\ln\Gamma(y_i+1)-\ln\Gamma(1/\alpha)\} \quad (8)$$

The *NB-C* model better fits certain types of count data than *NB2*, or any other variety of count model. However, since its fitted values are not on the log scale, comparisons cannot be made to Poisson or *NB2*.

The *NB2* model, in a similar manner to the Poisson, can also be overdispersed if the model variance exceeds its nominal variance. In such a case one must attempt to determine the source of the extra correlation and model it accordingly.

The extra correlation that can exist in count data, but which cannot be accommodated by simple adjustments to the Poisson and negative binomial algorithms, has stimulated the creation of a number of enhancements to the two base count models. The differences in these enhanced models relates to the attempt of identifying the various sources of overdispersion.

For instance, both the Poisson and negative binomial models assume that there exists the possibility of having zero counts. If a given set of count data excludes that possibility, the resultant Poisson or negative binomial model will likely be overdispersed. Modifying the loglikelihood function of these two models in order to adjust for the non-zero distribution of counts will eliminate the overdispersion, if there are no other sources of extra correlation. Such models are called, respectively, zero-truncated Poisson and zero-truncated negative binomial models.

Likewise, if the data consists of far more zero counts that allowed by the distributional assumptions of the Poisson or negative binomial models, a zero-inflated set of models may need to be designed. Zero-inflated models are ▶mixture models, with one part consisting of a 1/0 binary response model, usually a ▶logistic regression, where the probability of a zero count is estimated in difference to a non-zero-count. A second component is generally comprised of a Poisson or negative binomial model that estimates the full range of count data, adjusting for the overlap in estimated zero counts. The point is to (1) determine the estimates that account for zero counts, and (2) to estimate the adjusted count model data.

Hurdle models are another type mixture model designed for excessive zero counts. However, unlike the zero-inflated models, the hurdle-binary model estimates the probability of being a non-zero count in comparison to a zero count; the hurdle-count component is estimated on the basis of a zero-truncated count model. Zero-truncated, zero-inflated, and hurdle models all address abnormal

Modeling Count Data. Table 1 Models to adjust for violations of Poisson/NB distributional assumptions

Response	Example models
1: no zeros	Zero-truncated models (*ZTP*; *ZTNB*)
2: excessive zeros	Zero-inflated (*ZIP*; *ZINB*; *ZAP*; *ZANB*); hurdle models
3: truncated	Truncated count models
4: censored	Econometric and survival censored count models
5: panel	*GEE*; fixed, random, and mixed effects count models
6: separable	Sample selection, finite mixture models
7: two-responses	Bivariate count models
8: other	Quantile, exact, and Bayesian count models

Modeling Count Data. Table 2 Methods to directly adjust the variance (from Hilbe 2007)

Variance function	Example models
0: μ	Poisson
1: $\mu(\Phi)$	Quasi-Poisson; scaled SE; robust SE
2: $\mu(1+\alpha)$	Linear *NB* (*NB1*)
3: $\mu(1+\mu)$	Geometric
4: $\mu(1+\alpha\mu)$	Standard *NB* (*NB2*); quadratic *NB*
5: $\mu(1+(\alpha v)\mu)$	Heterogeneous *NB* (*NH-H*)
6: $\mu(1+\alpha\mu^{\rho})$	Generalized *NB* (*NB-P*)
7: $V[R]V'$	Generalized estimating equations

zero-count situations, which violate essential Poisson and negative binomial assumptions.

Other violations of the distributional assumptions of Poisson and negative binomial probability distributions exist. Table 1 below summarizes major types of violations that have resulted in the creation of specialized count models.

Alternative count models have also been constructed based on an adjustment to the Poisson variance function, μ. We have previously addressed two of these. Table 2 provides a summary of major types of adjustments.

Three texts specifically devoted to describing the theory and variety of count models are regarded as the standard resources on the subject. Other texts dealing with discrete response models in general, as well as texts on generalized linear models (*see* Generalized Linear Models), also have descriptions of many of the models mentioned in this article.

L. J. Savage (1980) and others understood the importance of better computational tools for utilizing Bayesian insights data in real life applications long ago. Such computational tools and software are now available that use subjective (or soft) data as well as quantitative (or hard) data. But

despite the availability of new tools and buildup of massive databases, the increased complexity and integration of economic and other systems involving people poses a significant challenge to a solely statistical driven view of the system. More importantly, evidence suggests that relying solely on standard statistical models is inadequate to represent real life systems effectively for management insights and decisions.

Unpredictability characterizes most real life systems due to non-linear relationships and multiple time-delayed feedback loops between interconnected elements. Senge (1990) describes it as *dynamic complexity* – *"situations* where the cause and effect are subtle, and the effects over time of interventions are not obvious." As a result, such systems are unsuitable for quantitative "only" representations without some subjective expert views. System Dynamics models offer a helpful alternative to modeling randomness that is based on hard data and soft data that models a real world system; see for example Sterman (2000) and his references.

According to , Forrester (1980) three types of data are required to develop the foundation of an effective model: numerical, written and mental data; compare, also, Sterman (2000) discussion on these points. In most cases, however, only a small fraction of the data needed to model a real world system may be available in the form of numerical data. Perhaps, the most important data to build a model, namely the mental data, is difficult to represent only numerically. But due to heavy influence of quantitative bias in model development, some modelers disregard key qualitative information in favor of information that can be estimated statistically. Sterman (2000) considers this reasoning counterintuitive and counterproductive in practice with realistic systems. He states that "omitting structures and variables known to be important because numerical data are unavailable is actually less scientific and less accurate than using your best judgment to estimate their values." This is in line with Forrester's views (1961) asserting that, "to omit such variables is equivalent to saying they have zero effect - probably the only value that is known to be wrong!" A suitable approach in such cases is to iteratively improve the accuracy and reliability of data by leveraging deeper insights into the system and interaction between various variables over time, along with sensitivity analysis of various contingencies.

A key to understanding a dynamic real world system is to identify and study the causal loops (or sub-systems) of the system. An analysis of the structure-behavior relationship in a model can uncover causal loops that are primarily responsible for the observed behavior of the model, i.e., identify the "dominant" loop. The dominant loop is the most influential structure in determining the overall behavior of a system depending on the specific conditions of a system. It is possible for any loop to be the dominant loop at a point in time but then as conditions change the same loop can be displaced by another loop as the dominant loop in a different time frame. Due to the shifting dominance of the loops in determining system performance over time, it is necessary that a system is explored to isolate the interactions between the variables that form various causal loops. Clearly, collecting such information is challenging on many fronts. First, the sheer volume of data required to map a real world system is a challenge; secondly, this kind of information is often qualitative in nature (mental, experiential or judgment) and hence not easy to capture; and thirdly, the information keeps changing over time.

Viewing system performance as a series of connected dominant loop behaviors is a fundamentally different way to study a system. In effect, this point of view suggests that it may not be possible or necessary to find the "one best" single representation to describe the system's performance over time. Instead, we can now treat the system as a composite structure that may be formed by the amalgamation of a number of different sub representations that collectively describe the system performance. This perspective alleviates the unnecessary difficulty that is imposed on a single representation to capture the logic of possibly disconnected patterns. Indeed, this approach has its own challenges in terms of how to superimpose the various patterns to model reality.

Note both Bayesian and System Dynamics have very helpful roles to play in the analysis of real life systems that do not yield easily to purely hard data or classical models. Accordingly, one can consider an integrated approach where a Bayesian model provides specific input to a System Dynamics model to complement the capabilities of the two approaches. A System Dynamics model enhanced by Bayesian inference will allow modelers to iteratively incorporate various data types into a comprehensive model and study the behavior of a system over time. This approach allows for the inclusion of both hard data and soft data into the model. Since the modeling process is iterative, the subjective views can be augmented or replaced with hard data as such information is acquired and improved over time. When appropriate data are available, it can be used as input to the System Dynamics model of various contingencies, such as "fear" curves, "hope" curves, or mixtures of them from a Bayesian perspective. When such data are not available, varied contingencies can still be incorporated as subjective expert views, but with the advantage that sensitivity analyses can be done to measure the impact on the system

performance over time under different assumptions. One can test better which subjective views might lead to more realistic insights using a system dynamic model. Software that helps in such modeling includes Vensim, Powersim, and ithink; compare Sterman (2000).

Modeling Survival Data

Edward L. Melnick
Professor of Statistics
New York University, New York, NY, USA

►Survival Data are measurements in time from a well defined origin until a particular event occurs. The event is usually death (e.g., lifetime from birth to death), but it could also be a change of state (e.g., occurrence of a disease or time to failure of an electrical component).

Of central importance to the study of risk is the probability that a system will perform and maintain its function (remain in a state) during a specified time interval $(0, t)$. Let $F(t) = P(T \le t)$ be the cumulative distribution function for the probability that a system fails before time t and conversely $R(t) = 1 - F(t)$ be the survival function for the system. Data from survival studies are often censored (the system has not failed during the study) so that survival times are larger than censored survival times. For example, if the response variable is the lifetime of an individual (or component), then the censored data are represented as (y_i, δ_i) where the indicator variable δ is equal to 1 if the event occurred during the study, and 0 if the event occurred after the study; i.e., $t_i = y_i$ if $\delta_i = 1$ and $t_i > y_i$ if $\delta_i = 0$. Further, if $f(t)dt$ is the probability of failure in the infinitesimal interval $(t, t + dt)$, then rate of a failure among items that have survived to time t is

$$h(t) = \frac{f(t)}{R(t)} = \frac{-d \ln R(t)}{dt}. \quad (1)$$

The function $h(t)$ is called the hazard function and is the conditional probability of failure, conditioned upon survival up to time t. The log likelihood function of (y_i, δ_i) is

$$\ln L = \delta_i \ln f(y_i) + (1 - \delta_i) \ln R(y_i), \quad (2)$$

and the cumulative hazard rate is

$$H(t) = \int_0^t h(x)dx. \quad (3)$$

The survival rate, $R(t)$, is equivalent to $R(t) = \exp(-H(t))$.

Examining the hazard function, it follows that

1. If $h(t)$ increases with age, $H(t)$ is an increasing failure rate. This would be the case for an object that wears out over time.
2. If $h(t)$ decreases with age, $H(t)$ is a decreasing failure rate. Examples of these phenomena include infant mortality and burn-in periods for engines.
3. If $h(t)$ is constant with age, $H(t)$ is a constant failure rate. In this situation failure time does not depend on age.

Note that $h(t)$ is a conditional probability density function since it is the proportion of items in *service* that fail per unit time. This differs from the probability density function $f(t)$, which is the proportion of the *initial* number of items that fail per unit time.

Distributions for failure times are often determined in terms of their hazard function. The exponential distribution function has a constant hazard function. The lognormal distribution function with standard deviation greater than 1 has a hazard function that increases for small t, and then decreases. The lognormal hazard function for standard deviation less than 1 has maximum at $t = 0$ and is often used to describe length of time for repairs (rather than modeling times to failure).

The ►Weibull distribution is often used to describe failure times. Its hazard function depends on the shape parameter m. The hazard function decreases when $m < 1$, increases when $m > 1$ and is constant when $m = 1$. Applications for this model include structured components in a system that fails when the weakest components fail, and for failure experiences that follow a bathtub curve. A bathtub failure time curve (convex function) has three stages: decreasing (e.g., infant mortality), constant (e.g., useful region), and increasing (e.g., wear out region). This curve is formed by changing m over the three regions. The basic

Modeling Survival Data. Table 1 Basic probability functions used to model survival data

Parametric		
Name	**Cumulative distribution function**	**Hazard function**
Exponential	$F(t) = 1 - \exp(-\lambda t) \quad \lambda > 0$	λ
Weibull	$F(t) = 1 - \exp(-\lambda t^m) \quad \lambda > 0$	$m\lambda$
Gumbel	$F(t) = 1 - \exp(-m(\exp(\lambda t) - 1)) \quad \lambda, m > 0$	$m\lambda \exp(\lambda t)$
Gompertz	$F(t) = 1 - \exp\left(\frac{m}{\lambda}(1 - \exp(\lambda t))\right) \quad \lambda, m > 0$	$m \exp(\lambda t)$
Nonparametric		
[a]Piecewise constant rates of change		$\sum_{i=1}^{n} \lambda_i I\{t_{i-1} < t < t_i\}$
[b]Kaplan–Meier	$\hat{F}(t) = 1 - \prod_{t_i \le t} \left(1 - \frac{d_i}{r_i}\right)$	$\frac{d_i}{r_i(t_{i+1} - t_i)}$
[c]Nelson–Aalen		$\hat{H}(t) = \sum_{t_i \le t} \left(1 - \frac{d_i}{r_i}\right)$

[a]The time axis is split into intervals such that $t_1 < t_2 < \ldots < t_n$ resulting in a non-continuous hazard function with jumps at the interval end points. The notation $I\{A\}$ is 1 if an event occurs in interval A, and is zero otherwise.
[b]The set $t_i \le \ldots \le t_n$ are the ordered event times where r_i are the number of individuals at risk at time t_i and d_i are the total number of individuals either experiencing the event or were censored at time t_i.
[c]The Nelson-Aalen statistic is an estimate of the cumulative hazard rate. It is based on the Poisson distribution.

probability functions used to model ▶survival data are in Table 1. These distributions are left skewed with support on $(0, \infty)$ for continuous distributions and support on the counting numbers $(0, n]$ for discrete distributions.

Nonparametric approaches have also been developed for estimating the survival function. A first approach might be the development of an empirical function such as:

$$\widehat{R}(t) = \frac{\text{Number of individuals with event times} \ge t}{\text{Number of individuals in the data set}}. \quad (4)$$

Unfortunately, this estimate requires that there are no censored observations. For example, an individual whose survival time is censored before time t cannot be used when computing the empirical function at t. This issue is addressed by introducing the ▶Kaplan–Meier estimator [see Kaplan and Meier (1958)]. Further, the variance of the Kaplan–Meier statistic can be estimated and confidence intervals can be constructed based on the normal distribution. Closely related to the Kaplan-Meier estimator is the Nelson–Aalen estimator (Nelson 1972; Aalen 1978) of the cumulative hazard rate function. The estimated variance and confidence interval can also be computed for this function.

Although the models already discussed assume that the occurrences of hazards are independent and identically distributed, often there are known risk factors such as environmental conditions and operating characteristics that affect the quality of a system.

In many problems a researcher is not only interested in the probability of survival, but how a set of explanatory variables affect the survival rate. Cox (1972) proposed the proportional hazard model that allows for the presence of covariates and the partial likelihood estimation procedure for estimating the parameters in the model. The proportional hazard model is of the form:

$$\lambda(t|\underline{Z}) = \lambda_0(t) \exp(\underline{Z}^T \underline{\beta}) \quad (5)$$

where

$\lambda_0(t)$ is the hazard function of unspecified shape (the subscript 0 implies all covariates are zero at time t).

$\underline{Z}$ is a vector of risk factors measured on each individual.

$\underline{\beta}$ is a vector of parameters describing the relative risk associated with the factors.

$\lambda(t|\underline{Z})$ is the hazard function at time t conditioned on the covariates.

The proportional hazard model is semi-parametric because no assumptions are made about the base hazard function but the effect of the risk factors is assumed to be linear on the log of the hazard function; i.e., $\lambda_0(t)$ is an infinite dimensional parameter and $\underline{\beta}$ is finite dimensional.

The proportionality assumption implies that if an individual has a risk of an event twice that of another individual, then the level of risk will remain twice as high for all time. The usual application of the model is to study the effect of the covariates on risk when absolute risk is less important. For example, consider a system where two types of actions can be taken, let

$$Z = \begin{cases} 1 & \text{if the high risk action is taken} \\ 0 & \text{if the low risk action is taken} \end{cases}$$

and let β be the relative risk associated with Z. The relative risk of the two types of actions is computed from the hazard ratio:

$$\frac{\lambda(t|Z=1)}{\lambda(t|Z=0)} = \exp\beta, \tag{6}$$

the instantaneous risk conditioned on survival at time t. In this problem the model describes relative risks and removes the effect of time. In a more general context, the ratio of hazards is the difference of covariates assuming the intercept is independent of time.

In many applications $\lambda_0(t)$ is unknown and cannot be estimated from the data. For example, the proportional hazard model is often used in credit risk modeling for corporate bonds based on interest rates and market conditions. A nonparametric estimation procedure for the conditional proportional hazard function is based on the exponential regression model:

$$\frac{\lambda(t|Z)}{\lambda_0(t)} = \exp(\underline{Z}^T\underline{\beta})$$

where the underlying survival function is estimated with a Kaplan–Meier estimator, a measure of time until failure.

If, however, the absolute risk is also important (usually in prediction problems), then the Nelson–Aalen estimate is preferred over the Kaplan–Meier estimator. The state space time series model [see Commandeur and Koopman (2007)] is useful for predicting risk over time and by using the Kalman Filter, can also include time varying covariates.

The proportional hazard model assumes event times are independent, conditioned on the covariates. The ▶frailty model relaxes this assumption by allowing for the presence of unknown covariates (random effects model). In this model event times are conditionally independent when values are given for the frailty variable. A frailty model that describes unexplained heterogeneity resulting from unobserved risk factors has a hazard function of the form

$$\lambda_{T_{ji}}(t) = w_{ji}\lambda_0(t)\exp\left(\underline{Z}_i^T\underline{\beta}_i\right) \tag{7}$$

where

T_{ji} is the time to failure (event) j for individual i, and

w_{ji} is the frailty variable.

In this model the frailty variable is constant over time, is shared by subjects within a subgroup, and acts multiplicatively on the hazard rates of all members of the subgroup. The two sources of variation for this model are:

1. Individual random variation described by the hazard function.
2. Group variation described by the frailty variable.

The log likelihood function, Eq. 2, for this model can be expressed in simple form if the hazard function has a Gompertz distribution and the frailty variable has a ▶gamma distribution. Other commonly used distributions for the frailty variable are the gamma, compound Poisson, and the lognormal. Estimators for situations where the likelihood function does not have an explicit representation are derived from the penalized partial likelihood function or from algorithms such as EM or Gibbs sampling.

Survival models have also been extended to multivariate conditional frailty survival functions. In the univariate setting, frailty varies from individual to individual whereas in the multivariate setting, frailty is shared with individuals in a subgroup. Consider, for example, the multivariate survival function conditioned on the frailty variable w:

$$s(t_1,\ldots,t_k|w) = \exp\left[-w(\Lambda_1(t_1),\ldots,\Lambda_k(t_k))\right], \tag{8}$$

where $\Lambda_i(t_i)$ is the cumulative hazard rate for group i. By integrating over w, the survival function is:

$$s(t_1,\ldots,t_k) = E\exp\left[-w(\Lambda_1(t_1),\ldots,\Lambda_k(t_k))\right], \tag{9}$$

the Laplace transform of w. Because of the simplicity of computing derivatives from the Laplace transform, this method is often used to derive frailty distributions. The most often assumed distributions are those from the gamma family. See Hougaard (2008) for a complete discussion on modeling multivariate survival data.

Conclusion

This paper presents a discussion for analyzing and modeling time series survival data. The models are then extended to include covariates primarily based upon regression modeling, and finally generalized to include multivariate models. Current research is focused on the development of multivariate time series models for survival data.

About the Author

Edward Melnick is Professor of Statistics and former Chair of the Department of Statistics and Operations Research at

Leonard N. Stern School of Business, New York University. He is an editor (with Brian Everitt) of the four volume *Encyclopedia of Quantitative Risk Analysis and Assessment* (Wiley Blackwell 2008), "valuable reference work ... and a rather beautiful work" (David Hand, *International Statistical Review*, Volume 77, Issue 2, p. 314). The number and impact of his publications were recognized by the American Statistical Association (ASA) when he became Fellow of the ASA. He is also Fellow of the Royal Statistical Society, and Elected Member of the International Statistical Institute. He was Chairman of the Risk Analysis section of the American Statistical Association (2004). Professor Melnick has won 16 teaching awards at NYU including the NYU Distinguished Teaching Award. Currently, he is an Associate Editor of the *Journal of Forecasting*.

Models for Z_+-Valued Time Series Based on Thinning

Emad-Eldin A. A. Aly
Professor
Kuwait University, Safat, Kuwait

Introduction

Developing models for integer-valued time series has received increasing attention in the past two decades. Integer-valued time series are useful in modeling dependent count data. They are also useful in the simulation of dependent discrete random variables with specified distribution and correlation structure.

Lawrance and Lewis (1977) and Gaver and Lewis (1980) were the first authors to construct autoregressive processes with non-Gaussian marginals. This has essentially motivated all the research on integer-valued time series. The present review is far from being exhaustive. Our focus is on models for Z_+-valued first-order autoregressive processes $INAR(1)$. We will consider five approaches which are based on "thinning" for developing these models.

First construction

To introduce integer-valued autoregressive moving average processes, McKenzie (1986, 1988) and Al-Osh and Alzaid (1987) used the binomial thinning operator $\odot$ of Steutel and van Harn (1979). The operation $\odot$ is defined as follows: if X is a Z_+−valued random variable (rv) and $\alpha \in (0,1)$, then

$$\alpha \odot X = \sum_{i=1}^{X} Y_i,$$

where $\{Y_i\}$ is a sequence of *i.i.d.* Bernoulli(α) $rv's$ independent of X. A sequence $\{X_n\}$ is said to be an $INAR(1)$ process if for any $n \in Z$,

$$X_n = \alpha \odot X_{n-1} + \varepsilon_n, \tag{1}$$

where $\odot$ is as in (1) and $\{\varepsilon_n\}$ is a sequence of *i.i.d.* Z_+−valued $rv's$ such that ε_n is independent of $\eta \odot X_{n-1}$ and the thinning $\eta \odot X_{n-1}$ is performed independently for each n. McKenzie (1986) constructed stationary Geometric

and Negative Binomial $INAR(1)$ processes and Al-Osh and Alzaid (1987) and independently McKenzie (1988) studied the Poisson $INAR(1)$ process.

Second Construction

Du and Li (1991) generalized the model (1) by introducing the $INAR(p)$ process

$$X_n = \sum_{i=1}^{p} \alpha_i \odot X_{n-i} + \varepsilon_n, \tag{2}$$

where all the thinning processes are independent and for $j < n$,

$$\operatorname{cov}(X_j, \varepsilon_n) = 0.$$

They proved that (2) has a unique stationary Z_+−valued solution $\{X_n\}_{n\in Z}$ if the roots of

$$\lambda^p - \sum_{i=1}^{p} \alpha_i \lambda^{p-i} = 0$$

are inside the unit circle. The main feature of the work of Du and Li (1991) is that it allows for models whose autocorrelation function (ACF) mimics that of the Normal *ARIMA* models.

Latour (1998) generalized Du and Li (1991) model by introducing the general $INAR(p)$ process ($GINAR(p)$),

$$X_n = \sum_{i=1}^{p} \alpha_i \circ X_{n-i} + \varepsilon_n,$$

where

$$\alpha_i \circ X_{n-i} = \sum_{i=1}^{X_{n-i}} Y_i^{(n,i)}$$

$\left\{Y_j^{(n,j)}\right\}$ is a sequence of nonnegative *i.i.d.rv's* independent of the *X's* with finite mean $\alpha_j > 0, j = 1, 2, \ldots, p$ and finite variance β_j and the innovation, ε_n, is assumed to have a finite mean μ_ε and finite variance σ_ε^2. Latour (1998) proved the existence of a stationary $GINAR(p)$ process if $\sum_{j=1}^{p} \alpha_j < 1$. He also showed that a stationary $GINAR(p)$ process, centered around its mean μ_X, admits a standard $AR(p)$ representation with the spectral density

$$f(\lambda) = \frac{\mu_X \sum_{j=1}^{p} \beta_j + \sigma_\varepsilon^2}{2\pi \left|\alpha\left(\exp(-i\lambda)\right)\right|^2}, \lambda \in [-\pi, \pi],$$

where

$$\alpha(t) = 1 - \sum_{j=1}^{p} \alpha_j t^j.$$

Third Construction

In the third approach the $INAR(1)$ stationary time series model takes the form

$$X_n = A_n(X_{n-1}, \eta) + \varepsilon_n, \tag{3}$$

where $\{\varepsilon_n\}$ are *i.i.d.r.v.'s* from the same family as the marginal distribution of $\{X_n\}$ and $A_n(X_{n-1}, \eta)$ is a random contraction operation performed on X_{n-1} which reduces it by the "amount η." Let $G_\theta(\cdot; \lambda_i)$ be the distribution of $Z_i, i = 1, 2$ and assume that Z_1 and Z_2 are independent and $G_\theta(\cdot; \lambda_1) * G_\theta(\cdot; \lambda_2) = G_\theta(\cdot; \lambda_1 + \lambda_2)$, where $*$ is the convolution operator. Let $G(\cdot; x, \lambda_1, \lambda_2)$ be the conditional distribution of Z_1 given $Z_1 + Z_2 = x$. The distribution of the random operator $A(X, \eta)$ given $X = x$, is defined as $G(\cdot; x, \eta\lambda, (1-\eta)\lambda)$. The distribution of $A(X, \eta)$ is $G_\theta(\cdot; \eta\lambda)$ when the distribution of X is $G_\theta(\cdot; \lambda)$. Now, if the distributions of X_0 and ε_1 are respectively $G_\theta(\cdot; \lambda)$ and $G_\theta(\cdot; (1-\eta)\lambda)$, then $\{X_n\}$ of (3) is stationary with marginal distribution $G_\theta(\cdot; \lambda)$. This construction was employed by Al-Osh and Alzaid (1991) for the Binomial marginal and Alzaid and Al-Osh (1993) for the Generalized Poisson marginal. This construction was generalized to the case when X_0 is infinitely divisible by Joe (1996) and to the case when X_0 is in the class of Exponential Dispersion Models by Jørgensen and Song (1998).

Fourth Construction

This construction is based on the expectation thinning operator $K(\eta)\circledast$ of Zhu and Joe (2003). The expectation thinning operator $K(\eta)\circledast$ is defined as follows: if X is a Z_+−valued *rv* and $\eta \in (0,1)$, then

$$K(\eta) \circledast X = \sum_{i=1}^{X} K_i(\eta),$$

where $K_i(\eta)$ are *i.i.d.r.v.'s* and the family $\{K(\alpha) : 0 \le \alpha \le 1\}$ is self-generalized, i.e., $E\{K(\eta) \circledast X | X = x\} = \eta x$ and $K(\eta') \circledast K(\eta) = K(\eta\eta')$. The corresponding $INAR(1)$ stationary time series model takes the form

$$X_n \overset{d}{=} K(\eta) \circledast X_{n-1} + \epsilon(\eta) = \sum_{i=1}^{X_{n-1}} K_i(\eta) + \epsilon(\eta).$$

The marginal distribution of X_n must be generalized discrete self-decomposable with respect to K, that is, $P_{X_n}(z)/P_{X_n}(P_{K(\alpha)}(z))$ must be a proper probability generating function (PGF) for every $\alpha \in [0,1]$. The ACF at lag$k$ is $\rho(k) = \eta^k$. The expectation thinning $K(\eta)\circledast$ governs the serial dependence. Several families of self-generalized *r.v.'s* $\{K(\eta)\}$ are known and the corresponding stationary distributions of $\{X_n\}$ are overdispersed with respect to Poisson (e.g., Generalized Poisson, Negative Binomial, Poisson-Inverse Gaussian). When a marginal distribution is possible for more than one self-generalized family then different $\{K(\eta)\}$ lead to differing amounts of conditional heteroscedasticity.

Fifth Construction

The fifth approach makes use of the thinning operator $\odot_{\mathcal{F}}$ of van Harn et al. (1982) and van Harn and Steutel (1993) which is defined as follows. Let $\mathcal{F} := (F_t, t \geq 0)$ be a continuous composition semigroup of PGF's such that $F_t(0) \neq 1, \delta = \delta(\mathcal{F}) = -\ln F_1'(1) > 0, F_{0+}(z) = z.$ and $F_{\infty-}(z) = 1.$ The infinitesimal generator U of $\mathcal{F}$ is given for $|z| \leq 1$ by

$$U(z) = \lim_{t \to 0+} \frac{F_t(z) - z}{t} = a\{H(z) - z\},$$

where a is a constant and $H(z) = \sum_{n=0}^{\infty} h_n z^n$ is a PGF of a Z_+ valued rv with $h_1 = 0$ and $H'(1) \leq 1$. For a Z_+ valued rv X and $\eta \in (0,1)$

$$\eta \odot_{\mathcal{F}} X = \sum_{i=1}^{X} Y_i,$$

where $\{Y_i\}$ is a sequence of *i.i.d.r.v.'s* independent of X with common PGF $F_{-\ln \eta} \in \mathcal{F}$. The corresponding $\mathcal{F}-$first order integer-valued autoregressive $(\mathcal{F}-INAR(1))$ model takes the form

$$X_n = \eta \odot_{\mathcal{F}} X_{n-1} + \varepsilon_n, \tag{4}$$

where $\{\varepsilon_n\}$ is a sequence of *i.i.d.* Z_+ valued *rv's* such that ε_n is independent of $\eta \odot_{\mathcal{F}} X_{n-1}$ and the thinning $\eta \odot_{\mathcal{F}} X_{n-1}$ is performed independently for each n. Note that $\{X_n\}$ is a Markov chain (see ▶Markov Chains). In terms of PGF's (4) reads

$$P_{X_n}(z) = P_{X_{n-1}}(F_{-\ln \eta}(z)) P_{\varepsilon}(z). \tag{5}$$

A distribution on Z_+ with PGF $P(z)$ is $\mathcal{F}$-self-decomposable (van Harn et al. (1982)) if for any t there exists a PGF $P_t(z)$ such

$$P(z) = P(F_t(z)) P_t(z).$$

Aly and Bouzar (2005) proved that any $\mathcal{F}$-self-decomposable distribution can arise as the marginal distribution of a stationary $\mathcal{F}-INAR(1)$ model. On assuming that the second moments of each of $H(\cdot), \varepsilon$ and X_n are finite for any $n \geq 0$, Aly and Bouzar (2005) proved that (1) the regression of X_n on X_{n-1} is linear, (2) the variance of X_n given X_{n-1} is linear, (3) the ACF at lag k, $\rho(X_{n-k}, X_n) = \eta^{\delta k} \sqrt{V(X_{n-k})/V(X_n)}$. Moreover, if $\{X_n\}$ is stationary, then $\rho(k) = \rho(X_{n-k}, X_n) = \eta^{\delta k}$.

We consider some important stationary time series models based on the composition semigroup

$$F_t^{(\theta)}(z) = 1 - \frac{\overline{\theta} e^{-\overline{\theta} t}(1-z)}{\overline{\theta} + \theta(1 - e^{-\overline{\theta} t})(1-z)}, t \geq 0, |z| \leq 1,$$
$$\overline{\theta} = 1 - \theta, 0 \leq \theta < 1$$

of van Harn et al. (1982). Note that when $\theta = 0$, $F_t^{(0)}(z) = 1 - e^{-t} + e^{-t} z$ and the corresponding thinning is the Binomial thinning of Steutel and van Harn (1979). In this case (4) becomes

$$P_X(z) = P_X(1 - \eta + \eta z) P_{\varepsilon}(z). \tag{6}$$

Particular $INAR(1)$ of (6) are the Poisson (Al-Osh and Alzaid 1987; McKenzie 1988), the Geometric and the Negative Binomial (McKenzie 1986), the Mittag-Leffler (Pillai and Jayakumar 1995) and the discrete Linnik (Aly and Bouzar 2000). Particular $INAR(1)$ time series models when $0 < \theta < 1$ are the Geometric, the Negative Binomial and the Poisson Geometric (Aly and Bouzar 1994) and the Negative Binomial (Al-Osh and Aly 1992).

Remarks

We mention some methods of parameter estimation. The most direct approach is using moment estimation based on the Yule-Walker equations. The conditional least squares method with some modifications, e.g., a two-stage procedure, in order to be able to estimate all the parameters (see, for example, Brännäs and Quoreshi 2004) may be used. Joe and Zhu (2006) used the method of maximum likelihood after using a recursive method to calculate the probability mass function of the innovation. Neal and Subba Rao (2007) used the MCMC approach for parameter estimation. For additional references on parameter estimation we refer to Brännäs (1994), Jung and Tremayne (2006), Silva and Silva (2009) and the references contained therein. Finally, we note that Hall and Scotto (2006) studied the extremes of integer-valued time series.

About the Author

Dr Emad-Eldin A. A. Aly is a Professor since 1994 at the Department of Statistics and Operations Research, Kuwait University, Kuwait. He was the Chair of the Department (2002–2006), and the Vice Dean for Academic Affairs of the Faculty of Graduate Studies, Kuwait University (1996–2002). He was a Faculty member at The University of Alberta, Edmonton, Alberta, Canada (1984–1995) and the Chair of the Department of Statistics and Applied Probability, The University of Alberta (1991–1994). He has authored and co-authored more than 75 papers. He was an Associate Editor of the *Journal of Nonparametric Statistics*. He was awarded (jointly with Professor A. Alzaid of King Saud University) the 1995 Kuwait Prize of the Kuwait Foundation for the Advancement of Sciences for his research in Mathematical Statistics.

Moderate Deviations

Moderate Deviations

Consider the familiar simple set up for the central limit theorem (CLT, see ►Central Limit Theorems). Let $X_1, X_2, \ldots$ be independently and identically distributed real random variables with common distribution function $F(x)$. Let $Y_n = \frac{1}{n}(X_1 + \cdots + X_n)$, $n = 1, 2, \ldots$. Suppose that

$$\int xF(dx) = 0, \int x^2 F(dx) = l \tag{1}$$

Then the central limit theorem states that

$$P\left(|Y_n| > \frac{a}{\sqrt{n}}\right) \to 2[1 - \Phi(a)] \tag{2}$$

where $\Phi(x) = \frac{1}{\sqrt{2\pi}} \int_{-\infty}^{x} \exp(-t^2/2)dt$ and $a > 0$.

In other words, the CLT gives an approximation to the two-sided deviation of size $\frac{a}{\sqrt{n}}$ of Y_n and the approximation is a number in $(1/2, 1)$. Deviations of the this type are called *ordinary deviations*.

However, one needs to study deviations larger than ordinary deviations to understand finer properties of the distributions of Y_n and to approximate expectations of other functions of Y_n. Thus a deviation of magnitude λ_n will be called a *excessive deviation* if $n\lambda_n^2 \to \infty$. In the particular case of $\lambda_n = \lambda$ where λ is a constant, it is called a *large deviation* (see also ►Large Deviations and Applications).

The following, due to Cramér (1938), Chernoff (1952), Bahadur and Rao (1960), etc., is a classical result on large deviations. Let

$$\int \exp(tx)F(dx) < \infty \text{ for } t \text{ in some neighborhood of } 0. \tag{3}$$

Then

$$\frac{1}{n}\log P(|Y_n| > \lambda) \to -I(\lambda) \tag{4}$$

where

$$I(\lambda) = \sup_t(t\lambda - \log\phi(t)) \tag{5}$$

and $0 < I(\lambda) \leq \infty$. This result is usually read as "the probability of large deviations tends to zero exponentially." For sequences of random variables $\{Y_n\}$ distributed in more general spaces like $R^k, C([0,1]), D([0,1])$, etc. (i.e., ▶stochastic processes), there is no preferred direction for deviations. The appropriate generalization of the large deviation result (4) is the *large deviation principle*, which states that for all Borel sets A

$$-I(A^0) \leq \underline{\lim}_n \frac{1}{n}\log P(Y_n \in A) \leq -I(\overline{A}) \tag{6}$$

where $A^0, \overline{A}$ denote the interior and closure of A, and

$$I(A) = \inf_{\lambda \in A} I(\lambda) \tag{7}$$

for some function $I(\lambda)$ whose level sets $\{\lambda : I(\lambda) \leq K\}$ are compact for $K < \infty$. The function $I(x)$ is called the *large deviation rate function*.

When the moment generating function condition (3) holds, Cramér (1938) has further shown that

$$P(|Y_n| > \lambda_n) \sim \frac{2}{\sqrt{2\pi n\lambda_n^2}}\exp\left(\frac{-n\lambda_n^2}{2}\right) \tag{8}$$

when $n\lambda_n^3 \to 0$ and $n\lambda_n^2 \to \infty$. This excludes large deviations ($\lambda_n = \lambda$), but it gives a rate for the probability (and not just the logarithm of the probability) of a class of excessive deviations and is therefore called a *strong excessive deviation result*.

Rubin and Sethuraman (1965a) called deviations λ_n with $\lambda_n = c\sqrt{\frac{\log n}{n}}$ where c is a constant as *moderate deviations*. Moderate deviations found their first applications in Bayes risk efficiency which was introduced in Rubin and Sethuraman (1965b). Cramér's result in (8) reduces to

$$P(|Y_n| > c\sqrt{\frac{\log n}{n}}) \sim \frac{2}{c\sqrt{2\pi\log n}}n^{-c^2/2} \tag{9}$$

and holds under the moment generating function condition (3). Rubin and Sethuraman (1965a) showed that the moderate deviation result (9) holds under the weaker condition

$$E(|X_1|^{c^2+2+\delta}) < \infty \text{ for some } \delta > 0. \tag{10}$$

They also showed that when (9) holds we have

$$E(|X_1|^{c^2+2-\delta}) < \infty \text{ for all } \delta > 0. \tag{11}$$

Slastnikov (1978) showed that the strong moderate deviation result (9) if and only if

$$\lim_{t\to\infty} t^{2+c}(\log(t))^{-(1+c)/2}P(|X_1| > t) = 0. \tag{12}$$

Since (8) was called a strong excessive deviation result, we should call (9) as a *strong moderate deviation result*. Analogous to the logarithmic large deviation result (4) is the *logarithmic moderate deviation result* which states that

$$\frac{1}{\log(n)}\log P(|Y_n| \geq c\sqrt{\frac{\log(n)}{n}}) \sim n^{-c^2/2} \tag{13}$$

which may be the only possible result for more complicated random variables $\{Y_n\}$ than are not means of i.i.d. random variables,

For random variables $\{Y_n\}$ which take values in $R^k, C([0,1]), D([0,1])$ etc., we can, under some conditions, establish the *moderate deviation principle* which states

$$-J(A^0) \leq \underline{\lim}_n \frac{1}{\log(n)}P(\sqrt{\frac{n}{\log(n)}}Y_n \in A) \leq -J(\overline{A}) \tag{14}$$

where $J(A) = \inf_{x\in A} J(x)$ for some function $J(x)$ whose level sets are compact. The function $J(x)$ is then called the *moderate deviation rate function*. This is analogous to the large deviation principle (6).

Following the paper of Rubin and Sethuraman (1965a), there is a vast literature on moderate deviations for a large class of random variables $\{Y_n\}$ that arise in a multitude of contexts. The asymptotic distribution of $\{Y_n\}$ can be more general than Gaussian. We will give just a brief summary below.

We stated the definition of two-sided moderate deviations and quoted Slastnikov's necessary and sufficient condition. One can also consider one-sided moderate deviations results and the necessary and sufficient conditions are slightly different and these are given in Slastnikov (1978). Without assuming á priori that the mean and variance of the i.i.d. random variables $X_1, X_2 \ldots$ are 0 and 1 respectively, one can ask for necessary and sufficient conditions for moderate deviations. This problem has been completely addressed in Amosova (1979). Another variant of moderate deviations has been studied in Davis (1968).

The case where $\{Y_n\}$ is the sum of triangular arrays of independent random variables or a U-statistic were begun in Rubin and Sethuraman (1965). Ghosh (1974) studied moderate deviations for sums of m-dependent random variables. Michel (1974) gave results on rates of convergence in the strong moderate deviation result (9). Gut (1980) considered moderate deviations for random variables with multiple indices. Dembo (1996) considered moderate deviations for ▶martingales.

Moderate deviations in general topological spaces with applications in Statistical Physics and other areas can be found in Borovkov and Mogulskii (1978), (1980), Deo and Babu (1981), De Acosta (1992), Liming (1995), Djellout and Guillin (2001).

About the Author

Professor Jayaram Sethuraman earned a Ph.D. in statistics from the Indian Statistical Institute in 1962. Professor Sethuraman has received many recognitions for his contributions to the discipline of statistics: the U.S. Army S. S. Wilks Award (1994), the Teaching Incentive Program Award, FSU (1995), the Professorial Excellence Award, FSU (1996), an ASA Service Award (2001), the President's Continuing Education Award, FSU (2002), and the Bhargavi and C. R. Rao Prize, Pennsylvania State University (2005).

"Sethuraman has been a superior researcher throughout his career, making important contributions in many areas including asymptotic distribution theory, large deviations theory, moderate deviations theory for which he was the pioneer, limit theory, nonparametric statistics, Dirichlet processes and Bayesian nonparametrics, stopping times for sequential estimation and testing, order statistics, stochastic majorization, Bahadur and Pitman efficiency, Markov chain Monte Carlo, reliability theory, survival analysis and image analysis." (Myles Hollander (2008). A Conversation with Jayaram Sethuraman, *Statistical Science* 23, 2, 272–285).

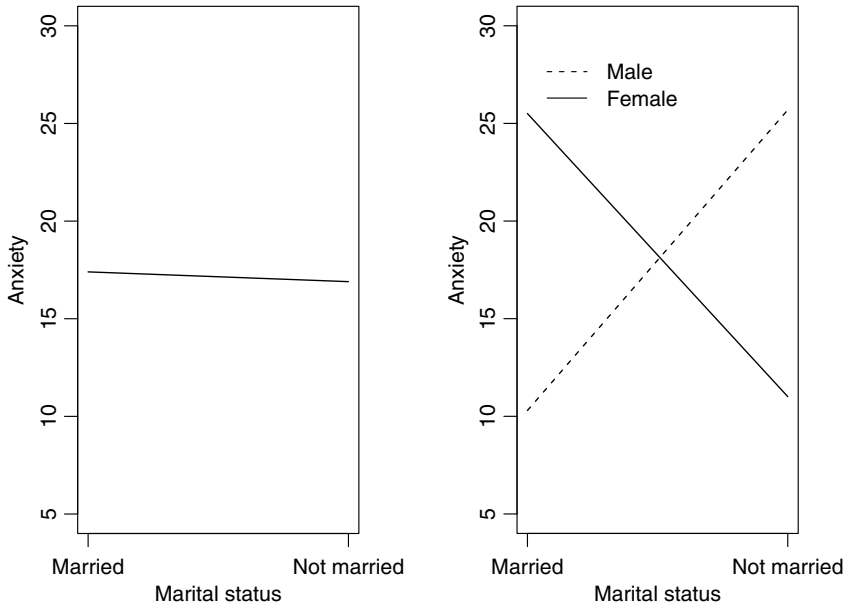
Moderating and Mediating Variables in Psychological Research

Petar Milin[1], Olga Hadžić[2]
[1]Associate Professor
University of Novi Sad, Novi Sad, Serbia
[2]Professor
University of Novi Sad, Novi Sad, Serbia

Moderating and mediating variables, or simply *moderators* and *mediators*, are related but distinct concepts in both general statistics and its application in psychology. A moderating variable is a variable that affects the relationship between two other variables. This effect is usually referred to as an *interaction*. The simplest case of an interaction can occur in ▶analysis of variance (ANOVA).



Moderating and Mediating Variables in Psychological Research. Fig. 1 The main effect of one categorical variable on a continuous dependent variable (*left-hand panel*), and how it is moderated by the third categorical variable (*right-hand panel*)

For example, we tested whether there is a significant difference in the *level of anxiety* (as measured with an appropriate standardized psychological test) between married and unmarried participants (i.e., variable *marital status*). The effect was not statistically significant. However, when we enter the third variable – *gender* (female/male) – it appears that, on average, unmarried males are significantly more anxious than married males, while for females the effect is the reverse. Figure 1 represents the results from two models described above. In the left-hand panel, we can see that, on average, there are no differences between married and unmarried participants in the level of anxiety. From the right-hand panel, we can conclude that gender moderates the effect of marital status on the level of anxiety: married males and unmarried females are significantly less anxious than the other two groups (unmarried males and married females).

We can generalize the previous example to more complex models, with two independent variables having more than just two levels for comparison, or even with more than two independent variables. If all variables in the model are continuous variables, we would apply multiple regression analysis, but the phenomenon of a moderating effect would remain the same, in essence. For example, we confirmed a positive relationship between the *hours of learning* and the *result in an assessment test*. Yet, *music loudness* during learning can moderate test results. We can imagine this as if a hand on the volume knob of an amplifier rotates clockwise and turns the volume up, students get all the worse results the longer they learn. Depending on the music volume level, the relationship between the hours of learning and the knowledge assessment changes continuously. This outcome is presented in Fig. 2. On the left-hand side, we can observe a positive influence of the hours of learning on the results in the assessment test, while on the right-hand side, we can see how music loudness moderates this relationship.

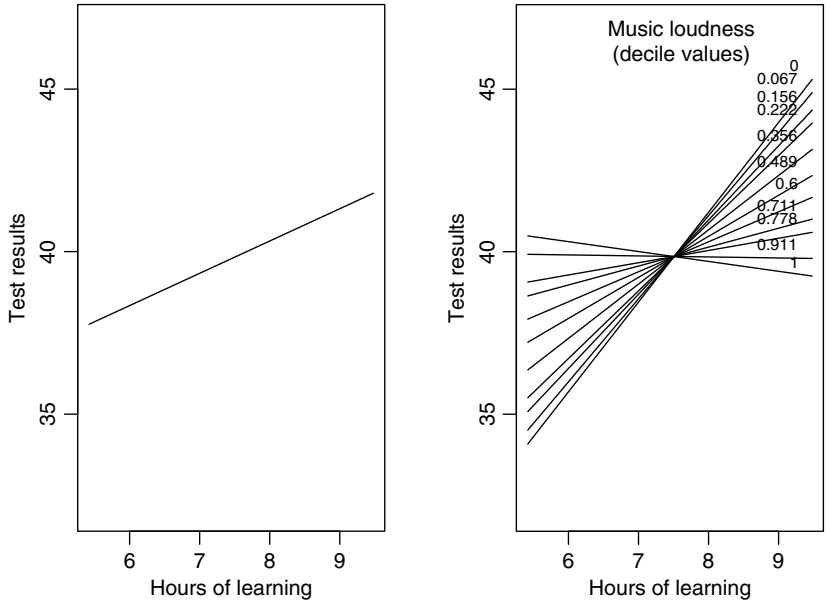
The general linear form with one dependent, one independent, and one moderating variable is as follows:

$$Y = \beta_0 + \beta_1 X_1 + \beta_2 X_2 + \beta_3 (X_1 \times X_2) + \varepsilon,$$

where β_3 evaluates the interaction between X_1 and X_2.

Mediating variables typically emerge in multiple regression analysis, where the influence of some independent variable (*predictor*) on the dependent variable (*criterion*) is not direct, but mediated through the third variable. For example, the correlation between *ageing* and the *number of work accidents* in the car industry appears to be strong and negative. Nevertheless, the missing link in this picture is *work experience*: it affects injury rate, and is itself affected by the age of worker.

In regression modeling, one can distinguish between *complete mediation* and *incomplete mediation*. In practice, if the effects of ageing on the number of work injuries



Moderating and Mediating Variables in Psychological Research. Fig. 2 The main effect of one continuous variable on another (*left-hand panel*), and how it is moderated by a third continuous variable (*right-hand panel*). Lines on the right panel represent decile values for the moderator variable

would not differ statistically from zero when work experience is included in the model, then mediation is complete. Otherwise, if this effect still exists (in the statistical sense), then mediation is incomplete. Complete and incomplete mediation are presented in Fig. 3.

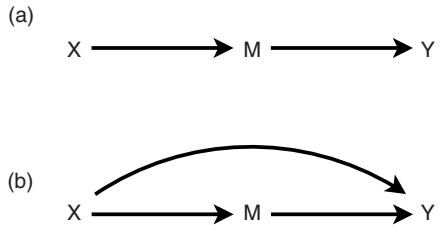
In principle, a mediating variable flattens the effect of an independent variable on the dependent variable. The opposite phenomenon would occur if the mediator variable would increase the effect. This is called *suppression*. It is a controversial concept in statistical theory and practice, but contemporary applied approaches take a more neutral position, and consider that suppression may provide better insights into the relationships between relevant variables.

The simplest case of linear regression with one dependent, one independent, and one mediating variable is defined by the following equations:

$$Y = \beta_0 + \beta_1 X + \varepsilon_1$$
$$M = \gamma_0 + \gamma_1 X + \varepsilon_2$$
$$Y = \beta_0' + \beta_1' X + \beta_2 M + \varepsilon_3,$$

where of particular interest are β_1, which is called the *total effect*, and β_1', named the *direct effect*. If suppression does not take place, which would occur if $\beta_1' > \beta_1$, then we can continue the analysis with a standard regression model. First, we ascertain whether mediation is complete or incomplete, depending on whether the direct effect drops to zero ($\beta_1' \approx 0$). The most important step in the analysis is the inference about the *indirect effect*, or the *amount of mediation*. It is defined as the reduction in the effect of the initial variable on the model outcome ($\beta_1 - \beta_1'$). In simple hierarchical regression models, the difference of the coefficients is exactly the same as the product of the effect of the independent variable on the mediating variable multiplied by the effect of the mediating variable on the dependent variable. In the general case, this equality only approximately holds.

Mediation and moderation can co-occur in statistical models. This is often the case in psychology. *Mediated moderation* takes place when the independent variable is actually an interaction ($X = X_A \times X_B$). Thus, the mediator acts between interacting variables (X_A and X_B) and the dependent variable (Y). For example, the effect of interacting variable *hours of learning* and *music loudness* on the dependent variable *result in an assessment test* can be mediated by the *importance of the test*, as rated by the participants. Conversely, *moderated mediation* is realized in two forms: (a) the effect of the independent variable on the mediator is affected by a moderator (γ_1 varies; as if the effect of *ageing* on *work experience* is moderated by a particular personality trait, like H. J. Eysenck's *Neuroticism*), or (b) a moderator may interact with the mediating variable (β_2 varies; as if the *work experience* and the *level of anxiety* would interact and mediate between *ageing* and *number of*



Moderating and Mediating Variables in Psychological Research. Fig. 3 Schematic representation of a complete mediation effect (panel a, *upper*), and an incomplete mediation effect (panel b, *lower*)

work accidents). If moderated mediation exists, inference about its type must be given.

Finally, special attention is required in moderation and mediation analyses since both can be influenced by ►*multicollinearity*, which makes estimates of regression coefficients unstable. In addition, in an analysis with a moderating term – i.e., an interaction effect – the product of the variables can be strongly related to either the independent or the moderating variable, or both of them. If two variables are collinear, one of them can be centred to its mean. In this way, half of its value will become negative, and consequently, collinearity will decrease. Another possibility is to regress the independent variable with a moderator or mediator, and then to use the *residuals* or unexplained values, of the independent variable in the main analysis. Thus, the independent variable will be orthogonal to the moderating or mediating variable, with zero correlation, which will bring collinearity under control. However, in applying the previous two remedies, and others that are available, one must choose a conservative approach. The risk of emphasizing, or even inventing, what is not present in the data ought to be as little as possible. In any circumstances, the ultimate way of securing more reliable estimates is simply to obtain enough data.

Acknowledgment

We would like to thank Professor David Kenny for reading a draft of this article, and providing us with comments and suggestions which resulted in many improvements.

About the Author

Moment Generating Function

Jan Beran[1], Sucharita Ghosh[2]
[1]Professor
University of Konstanz, Konstanz, Germany
[2]Scientific Staff Member
Swiss Federal Research Institute WSL, Birmensdorf, Switzerland

The moment generating function (mgf) of a real valued random variable X with distribution $F(x) = P(X \leq x)$ is defined by

$$M_X(t) = E\left[e^{tX}\right] = \int e^{tx} dF(x). \qquad (1)$$

For distributions with a density function $f = F'$, M_X can also be interpreted as a (two-sided) Laplace transform of f. In order that M_X exists and is finite for $t \in (-a, a)$ and some $a > 0$, all moments $\mu_j = E\left[X^j\right]$ must be finite and such that $\sum \mu_j t^j/j!$ is a convergent series. We then have

$$M_X(t) = \sum_{j=0}^{\infty} \frac{\mu_j}{j!} t^j \tag{2}$$

so that

$$\mu_j = M_X^{(j)}(0) = \frac{d^j}{dt^j} M_X(t) \mid_{t=0} \tag{3}$$

which explains the name moment generating function. A counter example where M_X does not exist in any open neighborhood of the origin is the Cauchy distribution, since there even μ_1 is not defined. The lognormal distribution is an example where all μ_j are finite but the series in (2) does not converge. In cases where $X > 0$ and $M_X(t) = \infty$ for $t \neq 0$, the mgf of $-X$ may be used (see e.g., Severini (2005) for further results). Related to M_X are the characteristic function $\phi_X(t) = M_X(it)$ and the probability generating function $H_X(z) = E(z^X)$ for which $M_X(t) = H_X(e^t)$. Note however that, in contrast to M_X, $\phi_X(t) = E\left[\exp(itX)\right]$ always exists. A furhter important function is the cumulant generating function $K_X(t) = \log M_X(t)$ which can be written as power series

$$K_X(t) = \sum_{j=1}^{\infty} \frac{\kappa_j}{j!} t^j \tag{4}$$

where κ_j are cumulants. The first two cumulants are $\kappa_1 = \mu = E(X)$ and $\kappa_2 = \sigma^2 = var(X)$. In contrast to the raw moments μ_j, higher order cumulants κ_j ($j \geq 3$) do not depend on the location μ and scale σ^2. For vector valued random variables $X = (X_1, ..., X_k)' \in \mathbb{R}^k$, M_X is defined in an analogous manner by $M_X(t) = E\left[\exp\left(t'X\right)\right] = E\left[\exp\left(\sum_{j=1}^k t_j X_j\right)\right]$. This implies

$$\frac{\partial^{j_1+j_2+\cdots+j_k}}{\partial t_1^{j_1} \partial t_1^{j_2} \cdots \partial t_1^{j_k}} M_X(0) = E\left[X_1^{j_1} X_2^{j_2} \cdots X_k^{j_k}\right] \tag{5}$$

and corresponding expressions for joint cumulants as derivatives of K_X. In particular,

$$\frac{\partial^2}{\partial t_i \partial t_j} K_X(0) = cov(X_i, X_j). \tag{6}$$

An important property is uniqueness: if $M_X(t)$ exists and is finite in an open interval around the origin, then there is exactly one distribution function with this moment generating function. For instance, if $\kappa_j = 0$ for $j \geq 3$, then $X \in \mathbb{R}$ is normally distributed with expected value $\mu = \kappa_1$ and variance $\sigma^2 = \kappa_2$. The moment generating function is very practical when handling sums of independent random variables. If X and Y are independent with existing moment generating function, then $M_{X+Y}(t) = M_X(t) M_Y(t)$ (and vice versa). For the cumulant generating function this means $K_{X+Y}(t) = K_X(t) + K_Y(t)$. For limit theorems, the following result is useful: Let X_n be a sequence of random variables with moment generating functions $M_{X_n}(t)$ which converge to the moment generating function $M_X(t)$ of a random variable X. Then X_n converges to X in distribution. This together with the additivity property of the cumulant generating function can be used for a simple proof of the central limit theorem (see ►Central Limit Theorems).

Moment Generating Function. Table 1 $M_X(t)$ for some important distributions

Distribution	$M_X(t)$
Binomial with n trials, success probability $p = 1 - q$	$[q + pe^t]^n$
Geometric distribution with success probability $p = 1 - q$	$pe^t (1 - qe^t)^{-1}$
Poisson with expected value λ	$\exp[\lambda (e^t - 1)]$
Uniform on $[a, b]$	$t^{-1}(b-a)^{-1}\left(e^{tb} - e^{ta}\right)$
Normal $N(\mu, \sigma^2)$	$\exp\left(\mu t + \frac{1}{2}\sigma^2 t^2\right)$
Multivariate Normal $N(\mu, \Sigma)$	$\exp\left(\mu' t + \frac{1}{2} t' \Sigma t\right)$
Chi-square χ_k^2	$(1 - 2t)^{-\frac{k}{2}}$
Exponential with expected value λ^{-1}	$\left(1 - t\lambda^{-1}\right)^{-1}$
Cauchy distribution	not defined

The empirical counterparts of M_X, K_X and ϕ_X, defined by

$$m_n(t) = n^{-1} \sum_{i=1}^{n} \exp(tX_i), \tag{7}$$

$k_n(t) = \log m_n(t)$ and $\varphi_n(t) = \log m_n(it)$, are often useful for statistical inference. For instance, testing the null hypothesis that X and Y are independent can be done by testing $M_{X+Y} \equiv M_X M_Y$ or $\varphi_{X+Y} \equiv \varphi_X \varphi_Y$ (see e.g., Csörgő 1985; Feuerverger 1987). Testing normality of a random sample $X_1, ..., X_n$ is the same as testing $H_o : \partial^3/\partial t^3 K_X(t) \equiv 0$ (see Ghosh 1996; Fang et al. 1998). For further applications of empirical moment and cumulant generating functions see e.g., Csörgő (1982, 1986), Epps et al. (1982),

Monte Carlo Methods in Statistics

Christian Robert
Professor of Statistics
Université Paris-Dauphine, CEREMADE, Paris, France

Monte Carlo methods are now an essential part of the statistician's toolbox, to the point of being more familiar to graduate students than the measure theoretic notions upon which they are based! We recall in this note some of the advances made in the design of Monte Carlo techniques towards their use in Statistics, referring to Robert and Casella (2004, 2010) for an in-depth coverage.

The Basic Monte Carlo Principle and Its Extensions

The most appealing feature of Monte Carlo methods [for a statistician] is that they rely on sampling and on probability notions, which are the bread and butter of our profession. Indeed, the foundation of Monte Carlo approximations is identical to the validation of empirical moment estimators in that the average

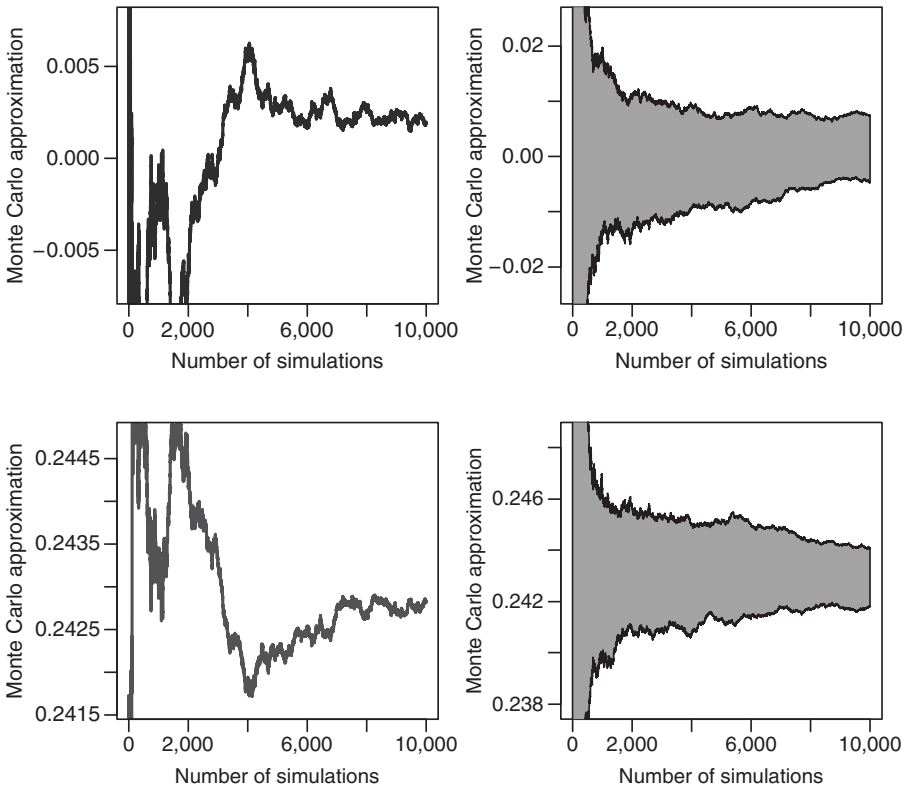
$$\frac{1}{T}\sum_{t=1}^{T} h(x_t), \quad x_t \sim f(x), \tag{1}$$

is converging to the expectation $\mathbb{E}_f[h(X)]$ when T goes to infinity. Furthermore, the precision of this approximation is exactly of the same kind as the precision of a statistical estimate, in that it usually evolves as $O(\sqrt{T})$. Therefore, once a sample $x_1, \ldots, x_T$ is produced according to a distribution density f, all standard statistical tools, including bootstrap (see ►Bootstrap Methods), apply to this sample (with the further appeal that more data points can be produced if deemed necessary). As illustrated by Fig. 1, the variability due to a single Monte Carlo experiment must be accounted for, when drawing conclusions about its output and evaluations of the overall variability of the sequence of approximations are provided in Kendall et al. (2007). But the ease with which such methods are analyzed and the systematic resort to statistical intuition explain in part why Monte Carlo methods are privileged over numerical methods.

The representation of integrals as expectations $\mathbb{E}_f[h(X)]$ is far from unique and there exist therefore many possible approaches to the above approximation. This range of choices corresponds to the importance sampling strategies (Rubinstein 1981) in Monte Carlo, based on the obvious identity

$$\mathbb{E}_f[h(X)] = \mathbb{E}_g[h(X)f(X)/g(X)]$$

provided the support of the density g includes the support of f. Some choices of g may however lead to appallingly poor performances of the resulting Monte Carlo estimates, in that the variance of the resulting empirical average may be infinite, a danger worth highlighting since often neglected while having a major impact on the quality of the approximations. From a statistical perspective, there exist some natural choices for the importance function



Monte Carlo Methods in Statistics. Fig. 1 Monte Carlo evaluation (1) of the expectation $\mathbb{E}[X^3/(1+X^2+X^4)]$ as a function of the number of simulation when $X \sim \mathcal{N}(\mu,1)$ using (*left*) one simulation run and (*right*) 100 independent runs for (*top*) $\mu = 0$ and (*bottom*) $\mu = 2.5$

g, based on Fisher information and analytical approximations to the likelihood function like the Laplace approximation (Rue et al. 2008), even though it is more robust to replace the normal distribution in the Laplace approximation with a t distribution. The special case of Bayes factors (Andrieu et al. 2005) (Andrieu et al. 2005)

$$B_{01}(x) = \int_\Theta f(x|\theta)\pi_0(\theta)\mathrm{d}\theta \Big/ \int_\Theta f(x|\theta)\pi_1(\theta)\mathrm{d}\theta,$$

which drive Bayesian testing and model choice, and of their approximation has led to a specific class of importance sampling techniques known as *bridge sampling* (Chen et al. 2000) where the optimal importance function is made of a mixture of the posterior distributions corresponding to both models (assuming both parameter spaces can be mapped into the same Θ). We want to stress here that an alternative approximation of marginal likelihoods relying on the use of *harmonic means* (Gelfand and Dey 1994; Newton and Raftery 1994) and of direct simulations from a posterior density has repeatedly been used in the literature, despite often suffering from infinite variance (and thus numerical instability). Another potentially very efficient approximation of Bayes factors is provided by Chib's (1995) representation, based on parametric estimates to the posterior distribution.

MCMC Methods

Markov chain Monte Carlo (MCMC) methods (see ►Markov Chain Monte Carlo) have been proposed many years (Metropolis et al. 1953) before their impact in Statistics was truly felt. However, once Gelfand and Smith (1990) stressed the ultimate feasibility of producing a Markov chain (see ►Markov Chains) with a given stationary distribution f, either via a Gibbs sampler that simulates each conditional distribution of f in its turn, or via a Metropolis–Hastings algorithm based on a proposal $q(y|x)$ with acceptance probability [for a move from x to y]

$$\min\left\{1, f(y)q(x|y)\big/f(x)q(y|x)\right\},$$

then the spectrum of manageable models grew immensely and almost instantaneously.

Due to parallel developments at the time on graphical and hierarchical Bayesian models, like generalized linear mixed models (Zeger and Karim 1991), the wealth of multivariate models with available conditional distributions (and hence the potential of implementing the Gibbs sampler) was far from negligible, especially when the availability of latent variables became quasi universal due to the slice sampling representations (Damien et al. 1999; Neal 2003). (Although the adoption of Gibbs samplers has primarily taken place within ►Bayesian statistics, there is nothing that prevents an artificial augmentation of the data through such techniques.)

For instance, if the density $f(x) \propto \exp(-x^2/2)/(1 + x^2 + x^4)$ is known up to a normalizing constant, f is the marginal (in x) of the joint distribution $g(x,u) \propto \exp(-x^2/2)\mathbb{I}(u(1 + x^2 + x^4) \leq 1)$, when u is restricted to $(0,1)$. The corresponding slice sampler then consists in simulating

$$U|X = x \sim \mathcal{U}(0, 1/(1 + x^2 + x^4))$$

and

$$X|U = u \sim \mathcal{N}(0,1)\mathbb{I}(1 + x^2 + x^4 \leq 1/u),$$

the later being a truncated normal distribution. As shown by Fig. 2, the outcome of the resulting Gibbs sampler perfectly fits the target density, while the convergence of the expectation of X^3 under f has a behavior quite comparable with the iid setting.

While the Gibbs sampler first appears as *the* natural solution to solve a simulation problem in complex models if only because it stems from the true target f, as exhibited by the widespread use of BUGS (Lunn et al. 2000), which mostly focus on this approach, the infinite variations offered by the Metropolis–Hastings schemes offer much more efficient solutions when the proposal $q(y|x)$ is appropriately chosen. The basic choice of a random walk proposal (see ►Random Walk) $q(y|x)$ being then a normal density centered in x) can be improved by exploiting some features of the target as in Langevin algorithms (see Andrieu et al. 2005 Sect. 7.8.5) and Hamiltonian or hybrid alternatives (Duane et al. 1987; Neal 1999) that build upon gradients. More recent proposals include particle learning about the target and sequential improvement of the proposal (Douc et al. 2007; Rosenthal 2007; Andrieu et al. 2010). Fig. 3 reproduces Fig. 2 for a random walk Metropolis–Hastings algorithm whose scale is calibrated towards an acceptance rate of 0.5. The range of the convergence paths is clearly wider than for the Gibbs sampler, but the fact that this is a generic algorithm applying to any target (instead of a specialized version as for the Gibbs sampler) must be borne in mind.

Another major improvement generated by a statistical imperative is the development of variable dimension generators that stemmed from Bayesian model choice requirements, the most important example being the reversible jump algorithm in Green (1995) which had a significant impact on the study of graphical models (Brooks et al. 2003).

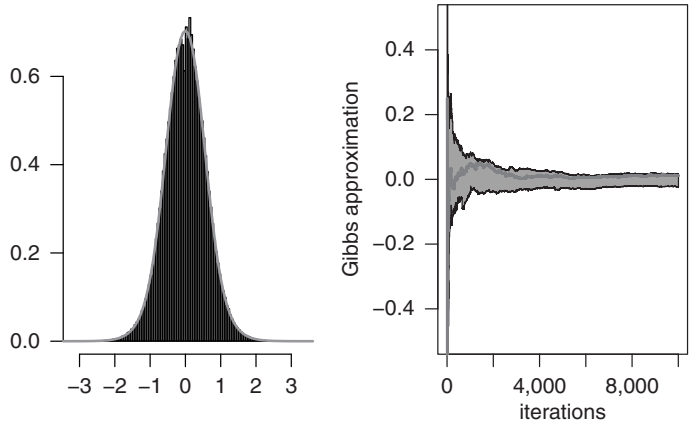
Some Uses of Monte Carlo in Statistics

The impact of Monte Carlo methods on Statistics has not been truly felt until the early 1980s, with the publication of Rubinstein (1981) and Ripley (1987), but Monte Carlo methods have now become invaluable in Statistics because they allow to address optimization, integration and exploration problems that would otherwise be unreachable. For instance, the calibration of many tests and the derivation of their acceptance regions can only be achieved by simulation techniques. While integration issues are often linked with the Bayesian approach – since Bayes estimates are posterior expectations like

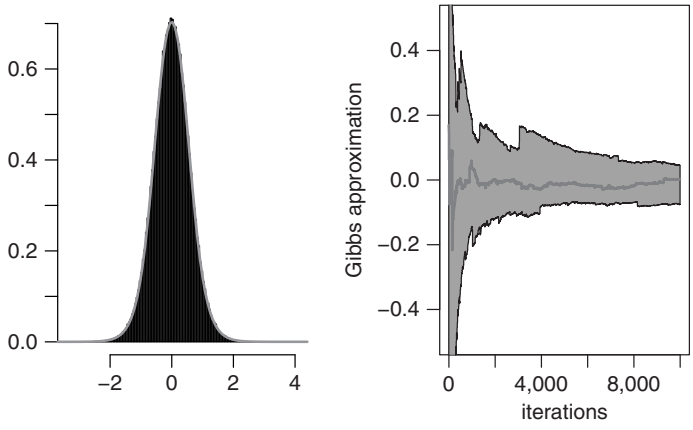
$$\int h(\theta)\pi(\theta|x)\,\mathrm{d}\theta$$

and Bayes tests also involve integration, as mentioned earlier with the Bayes factors, and optimization difficulties with the likelihood perspective, this classification is by no way tight – as for instance when likelihoods involve unmanageable integrals – and all fields of Statistics, from design to econometrics, from genomics to psychometry and environmics, have now to rely on Monte Carlo approximations. A whole new range of statistical methodologies have entirely integrated the simulation aspects. Examples include the bootstrap methodology (Efron 1982), where multilevel resampling is not conceivable without a computer, indirect inference (Gouriéroux et al. 1993), which construct a pseudo-likelihood from simulations, MCEM (Cappé and Moulines 2009), where the E-step of the EM algorithm is replaced with a Monte Carlo approximation, or the more recent approximated Bayesian computation (ABC) used in population genetics (Beaumont et al. 2002), where the likelihood is not manageable but the underlying model can be simulated from.

In the past fifteen years, the collection of real problems that Statistics can [afford to] handle has truly undergone a quantum leap. Monte Carlo methods and in particular MCMC techniques have forever changed the emphasis from "closed form" solutions to algorithmic ones, expanded our impact to solving "real" applied problems while convincing scientists from other fields that statistical solutions were indeed available, and led us into a world



Monte Carlo Methods in Statistics. Fig. 2 (*left*) Gibbs sampling approximation to the distribution $f(x) \propto \exp(-x^2/2)/(1+x^2+x^4)$ against the true density; (*right*) range of convergence of the approximation to $\mathbb{E}_f[X^3] = 0$ against the number of iterations using 100 independent runs of the Gibbs sampler, along with a single Gibbs run



Monte Carlo Methods in Statistics. Fig. 3 (*left*) Random walk Metropolis–Hastings sampling approximation to the distribution $f(x) \propto \exp(-x^2/2)/(1+x^2+x^4)$ against the true density for a scale of 1.2 corresponding to an acceptance rate of 0.5; (*right*) range of convergence of the approximation to $\mathbb{E}_f[X^3] = 0$ against the number of iterations using 100 independent runs of the Metropolis–Hastings sampler, along with a single Metropolis–Hastings run

where "exact" may mean "simulated." The size of the data sets and of the models currently handled thanks to those tools, for example in genomics or in climatology, is something that could not have been conceived 60 years ago, when Ulam and von Neumann invented the Monte Carlo method.

Monty Hall Problem : Solution

Richard D. Gill
Professor, Faculty of Science, President of the Dutch Society for Statistics and Operations Research
Leiden University, Leiden, Netherlands

Introduction

The *Three Doors Problem*, or *Monty Hall Problem*, is familiar to statisticians as a paradox in elementary probability theory often found in elementary probability texts (especially in their exercises sections). In that context it is usually meant to be solved by careful (and elementary) application of ►Bayes' theorem. However, in different forms, it is much discussed and argued about and written

about by psychologists, game-theorists and mathematical economists, educationalists, journalists, lay persons, blog-writers, wikipedia editors.

In this article I will briefly survey the history of the problem and some of the approaches to it which have been proposed. My take-home message to you, dear reader, is that one should distinguish two levels to the problem.

There is an informally stated problem which you could pose to a friend at a party; and there are many concrete *versions* or *realizations* of the problem, which are actually the result of mathematical or probabilistic or statistical *modeling*. This modeling often involves adding supplementary assumptions chosen to make the problem well posed in the terms of the modeler. The modeler finds those assumptions perfectly natural. His or her students are supposed to guess those assumptions from various key words (like: "indistinguishable," "unknown") strategically placed in the problem re-statement. Teaching statistics is often about teaching the students to read the teacher's mind. Mathematical (probabilistic, statistical) modeling is, unfortunately, often solution driven rather than problem driven.

The very same criticism can, and should, be leveled at this very article! By cunningly presenting the history of *The Three Doors Problem* from my rather special point of view, I have engineered complex reality so as to convert the *Three Doors Problem* into an illustration of my personal Philosophy of Science, my Philosophy of Statistics.

This means that I have re-engineered the *Three Doors Problem* into an example of the point of view that Applied Statisticians should always be wary of the lure of *Solution-driven Science*. Applied Statisticians are trained to know Applied Statistics, and are trained to know how to convert real world problems into statistics problems. That is fine. But the best Applied Statisticians know that Applied Statistics is not the only game in town. Applied Statisticians are merely some particular kind of Scientists. They know lots about modeling uncertainty, and about learning from more or less random data, but probably not much about anything else. The Real Scientist knows that there is not a universal *disciplinary* approach to every problem. The *Real Statistical Scientist* modestly and persuasively and realistically offers what his or her discipline has to offer in synergy with others.

To summarize, we must distinguish between:

(0) the *Three-Doors-Problem Problem* [sic], which is to make sense of some real world question of a real person.
(1) a large number of solutions to this *meta*-problem, i.e., the many Three-Doors-Problem *Problems*, which are competing mathematizations of the meta-problem (0).

Each of the solutions at level (1) can well have a number of different solutions: nice ones and ugly ones; correct ones and incorrect ones. In this article, I will discuss three level (1) solutions, i.e., three different Monty Hall problems; and try to give three short correct and attractive solutions.

Now read on. Be critical, use your intellect, don't believe anything on authority, and certainly not on mine. Especially, don't forget the problem at meta-level (−1), not listed above.

C'est la vie.

Starting Point

I shall start not with the historical roots of the problem, but with the question which made the Three Doors Problem famous, even reaching the front page of the *New York Times*.

Marilyn vos Savant (a woman allegedly with the highest IQ in the world) posed the *Three Door Problem* or *Monty Hall Problem* in her "Ask Marilyn" column in *Parade* magazine (September 1990:16), as posed to her by a correspondent, a Mr. Craig Whitaker. It was, quoting vos Savant literally, the following:

> *Suppose you're on a game show, and you're given the choice of three doors: Behind one door is a car; behind the others, goats. You pick a door, say No. 1, and the host, who knows what's behind the doors, opens another door, say No. 3, which has a goat. He then says to you, "Do you want to pick door No. 2?" Is it to your advantage to switch your choice?*

Apparently, the problem refers to a real American TV quiz-show, with a real presenter, called Monty Hall.

The literature on the Monty Hall Problem is enormous. At the end of this article I shall simply list two references which for me have been especially valuable: a paper by Jeff Rosenthal (2008) and a book by Jason Rosenhouse (2009). The latter has a huge reference list and discusses the pre- and post-history of vos Savant's problem.

Briefly regarding the pre-history, one may trace the problem back through a 1975 letter to the editor in the journal *The American Statistician* by biostatistician Steve Selkin, to a problem called *The Three Prisoners Problem* posed by Stephen Gardner in his Mathematical Games column in *Scientific American* in 1959, and from there back to *Bertrand's Box Problem* in his 1889 text on Probability Theory. The internet encyclopedia `wikipedia.org` discussion pages (in many languages) are a fabulous though every-changing resource. Almost everything that I write here was learnt from those pages.

Despite making homage here to the two cited authors Rosenthal (2008) and Rosenhouse (2009) for their wonderful work, I emphasize that I strongly disagree with

both Rosenhouse ("the canonical problem") and Rosenthal ("the original problem") on what the essential Monty Hall problem is. I am more angry with certain other authors, who will remain nameless but for the sake of argument I'll just call Morgan et al. for unilaterally declaring in *The American Statistician* in 1981 *their* Monty Hall problem to be the only possible sensible problem, for calling everyone who solved different problems stupid, and for getting an incorrect theorem (I refer to their result about the situation when we do not know the quiz-master's probability of opening a particular door when he has a choice, and put a uniform prior on this probability.) published in the peer-reviewed literature.

Deciding unilaterally (Rosenhouse 2009) that a certain formulation is *canonical* is asking for a schism and for excommunication. Calling a particular version *original* (Rosenthal 2008) is asking for a historical contradiction. In view of the pre-history of the problem, the notion is not well defined. Monty Hall is part of folk-culture, culture is alive, the Monty Hall problem is not owned by a particular kind of mathematician who looks at such a problem from a particular point of view, and who adds for them "natural" extra assumptions which merely have the role of allowing their solution to work. Presenting any "canonical" or "original" Monty Hall problem together with a solution, is an example of *solution driven science* – you have learnt a clever trick and want to show that it solves lots of problems.

Three Monty Hall Problems

I will concentrate on three different particular Monty Hall problems. One of them (Q-0) is simply to answer the question literally posed by Marilyn vos Savant, "would you switch?". The other two (Q-1, Q-2) are popular mathematizations, particularly popular among experts or teachers of elementary probability theory: one asks for the unconditional probability that "always switching" would gets the car, the other asks for the conditional probability given the choices made so far. Here they are:

Q-0: Marilyn vos Savant's (or Craig Whitaker's) question "*Is it to your advantage to switch?*"

Q-1: A mathematician's question "*What is the unconditional probability that switching gives the car?*"

Q-2: A mathematician's question "*What is the conditional probability that switching gives the car, given everything so far?*"

The free, and freely editable, internet encyclopedia Wikipedia is the scene of a furious debate as to which mathematization Q-1 or Q-2 is the right starting point for answering the verbal question Q-0 (to be honest, many of the actors claim another "original" question as *the* original question). Alongside that, there is a furious debate as to which supplementary conditions are obviously implicitly being made. For each protagonist in the debate, those are the assumptions which ensure that his or her question has a unique and nice answer. My own humble opinion is "neither Q-1 nor Q-2, though the unconditional approach comes closer." I prefer Q-0, and I prefer to see it as a question of *game theory* for which, to my mind, [almost] no supplementary conditions need to be made.

Here I admit that I will suppose that the player knows game-theory and came to the quiz-show prepared. I will also suppose that the player wants to get the Cadillac while Monty Hall, the quizmaster, wants to keep it.

My analysis below of both problems Q-1 and Q-2 yields the good answer "2/3" under minimal assumptions, and almost without computation or algebraic manipulation. I will use Israeli (formerly Soviet Union) mathematician Boris Tsirelson's proposal on Wikipedia talk pages to use symmetry to deduce the conditional probability from the unconditional one. (Boris graciously gave me permission to cite him here, but this should not be interpreted to mean that anything written here also has his approval).

You, the reader, may well prefer a calculation using Bayes' theorem, or a calculation using the definition of conditional probability; I think this is a matter of taste.

I finally use a game-theoretic point of view, and von Neumann's minimax theorem, to answer the question Q-0 posed by Marilyn vos Savant, on the assumptions just stated.

Let the three doors be numbered in advance 1, 2, and 3. I add the universally agreed (and historically correct) additional assumptions: Monty Hall knows in advance where the car is hidden, Monty Hall always opens a door revealing a goat.

Introduce four random variables taking values in the set of door-numbers $\{1, 2, 3\}$:

C: the quiz-team hides the Car (a Cadillac) behind door C,
P: the Player chooses door P,
Q: the Quizmaster (Monty Hall) opens door Q,
S: Monty Hall asks the player if she'ld like to Switch to door S.

Because of the standard story of the Monty Hall show, we certainly have:

$Q \neq P$, the quizmaster *always* opens a door different to the player's first choice,
$Q \neq C$, opening that door *always* reveals a goat,
$S \neq P$, the player is *always* invited to switch to another door,
$S \neq Q$, *no* player wants to go home with a goat.

It does not matter for the subsequent mathematical analysis whether probabilities are subjective (Bayesian) or objective (frequentist); nor does it matter whose probabilities they are supposed to be, at what stage of the game. Some writers think of the player's initial choice as fixed. For them, P is degenerate.

I simply merely down some mathematical assumptions and deduce mathematical consequences of them.

Solution to Q-1: Unconditional Chance That Switching Wins

By the rules of the game and the definition of S, if $P \neq C$ then $S = C$, and vice-versa. A "switcher" would win the car if and only if a "stayer" would lose it. Therefore:

If $\Pr(P = C) = 1/3$ *then* $\Pr(S = C) = 2/3$, *since the two events are complementary.*

Solution to Q-2: Probability Car is Behind Door 2 Given You Chose Door 1, Monty Hall Opened 3

First of all, suppose that P and C are uniform and independent, and that given (P, C), suppose that Q is uniform on its possible values (unequal to those of P and of C). Let S be defined as before, as the third door-number different from P and Q. The joint law of C, P, Q, S is by this definition invariant under renumberings of the three doors. Hence $\Pr(S = C|P = x, Q = y)$ is the same for all $x \neq y$. By the law of total probability, $\Pr(S = C)$ (which is equal to 2/3 by our solution to Q-1) is equal to the weighted average of all $\Pr(S = C|P = x, Q = y), x \neq y \in \{1, 2, 3\}$. Since the latter are all equal, all these six conditional probabilities are equal to their average 2/3.

Conditioning on $P = x$, say, and letting y and y' denote the remaining two door numbers, we find the following corollary:

Now take the door chosen by the player as fixed, $P \equiv 1$, say. We are to compute $\Pr(S = C|Q = 3)$. *Assume that all doors are equally likely to hide the car and assume that the quizmaster chooses completely at random when he has a choice.* Without loss of generality we may as well pretend that P was chosen in advance completely at random. Now we have embedded our problem into the situation just solved, where P and C are uniform and independent.

▶ *If* $P \equiv 1$ *is fixed,* C *is uniform, and* Q *is symmetric, then "switching gives car" is independent of quizmaster's choice, hence*

$$\Pr(S = C|Q = 3) = \Pr(S = C|Q = 2') = \Pr(S = C) = 2/3.$$

Some readers may prefer a direct calculation. Using Bayes' theorem in the form "posterior odds equal prior odds times likelihoods" is a particularly efficient way to do this. The probabilities and conditional probabilities below are all conditional on $P = 1$, or if your prefer with $P \equiv 1$.

We have uniform prior odds

$$\Pr(C = 1) : \Pr(C = 2) : \Pr(C = 3) = 1 : 1 : 1.$$

The likelihood for C, the location of the car, given data $Q = 3$, is (proportional to) the discrete density function of Q given C (and P)

$$\Pr(Q = 3|C = 1) : \Pr(Q = 3|C = 2) : \Pr(Q = 3|C = 3) = \frac{1}{2} : 1 : 0.$$

The posterior odds are therefore proportional to the likelihood. It follows that the posterior probabilities are

$$\Pr(Q = 3|C = 1) = \frac{1}{3}, \quad \Pr(Q = 3|C = 2) = \frac{2}{3},$$
$$\Pr(Q = 3|C = 3) = 0.$$

Answer to Marilyn Vos Savant's Q-0: Should *You* Switch Doors?

Yes. Recall, *You only know that Monty Hall always opens a door revealing a goat.* You didn't know what strategy the quiz-team and quizmaster were going to use for their choices of the distribution of C and the distribution of Q given P and C, so naturally (since you know elementary Game Theory) you had picked your door uniformly at random. Your strategy of choosing C uniformly at random guarantees that $\Pr(C = P) = 1/3$ and hence that $\Pr(S = C) = 2/3$.

It was easy for you to find out that this combined strategy, which I'll call "symmetrize and switch," is your so-called minimax strategy.

On the one hand, "symmetrize and switch" guarantees you a 2/3 (unconditional) chance of winning the car, whatever strategy used by the quizmaster and his team.

On the other hand, if the quizmaster and his team use their "symmetric" strategy "hide the car uniformly at random and toss a fair coin to open a door if there is choice", then you cannot win the car with a *better* probability than 2/3.

The fact that your "symmetrize and switch" strategy gives you "at least" 2/3, while the quizmaster's "symmetry" strategy prevents you from doing better, proves that these are the respective minimax strategies, and 2/3 is the game-theoretic value of this two-party zero-sum game. (Minimax strategies and the accompanying "value" of the game exist by virtue of John von Neumann's (1929) minimax theorem for finite two-party zero-sum games).

There is not much point for you in worrying about your conditional probability of winning conditional on

your specific initial choice and the specific door opened by the quizmaster, say doors 1 and 3 respectively. You don't know this conditional probability anyway, since you don't know the strategy used by quiz-team and the quizmaster. (Even though you know probability theory and game theory, they maybe don't). However, it is maybe comforting to learn, by easy calculation, that if the car is hidden uniformly at random, then your conditional probability cannot be *smaller* than 1/2. So in that case at least, it certainly never *hurts* to switch door.

Discussion

Above I tried to give short clear mathematical solutions to three mathematical problems. Two of them were problems of elementary probability theory, the third is a problem of elementary game theory. As such, it involves not much more than elementary probability theory and the beautiful minimax theorem of John von Neumann (1928). That a finite two-party zero-sum game has a saddle-point, or in other words, that the two parties in such a game have matching minimax strategies (if ►randomization is allowed), is not obvious. It seems to me that probabilists ought to know more about game theory, since every ordinary non-mathematician who hears about the problem starts to wonder whether the quiz-master is trying to cheat the player, leading to an infinite regress: if I know that he knows that I know that....

I am told that the literature of mathematical economics and of game theory is full of Monty Hall examples, but no-one can give me a nice reference to a nice game-theoretic solution of the problem. Probably game-theorists like to keep their clever ideas to themselves, so as to make money from playing the game. Only losers write books explaining how the reader could make money from game theory.

It would certainly be interesting to investigate more complex game-theoretic versions of the problem. If we take Monty Hall as a separate player to the TV station, and note that TV ratings are probably helped if nice players win while annoying players lose, we leave elementary game theory and must learn the theory of Nash equilibria.

Then there is a sociological or historical question: who "owns" the Monty Hall problem? I think the answer is obvious: no-one. A beautiful mathematical paradox, once launched into the real world, lives it own life, it evolves, it is re-evaluated by generation after generation. This point of view actually makes me believe that Question 0: *would you switch* is the right question, and no further information should be given beyond the fact that you know that the quizmaster knows where the car is hidden, and always opens a door exhibiting a goat. Question 0 is a question you can ask a non-mathematician at a party, and if they have not heard of the problem before, they'll give the wrong answer (or rather, one of the two wrong answers: *no* because nothing is changed, or *it doesn't matter* because it's now 50–50). My mother, who was one of Turing's computers at Bletchley Park during the war, but who had had almost no schooling and in particular never learnt any mathematics, is the only person I know who immediately said: *switch*, by immediate intuitive consideration of the 100-door variant of the problem. The problem is a *paradox* since you can next immediately convince anyone (except lawyers, as was shown by an experiment in Nijmegen), that their initial answer is wrong.

The mathematizations Questions 1 and 2 are not (in my humble opinion!) *the* Monty Hall problem; they are questions which probabilists might ask, anxious to show off Bayes' theorem or whatever. Some people intuitively try to answer Question 0 via Questions 1 and 2; that is natural, I do admit. And sometimes people become very confused when they realize that the answer to Question 2 can only be given its pretty answer "2/3" under further conditions. It is interesting how in the pedagogical mathematical literature, the further conditions are as it were held under your nose, e.g., by saying "three *identical* doors," or replacing Marilyn's "say, door 1" by the more emphatic "door 1."

It seems to me that adding into the question explicitly the remarks that the three doors are equally likely to hide the car, and that when the quizmaster has a choice he secretly tosses a fair coin to decide, convert this beautiful paradox into a probability puzzle with little appeal any more to non experts.

It also converts the problem into one version of the three prisoner's paradox. The three prisoners problem is isomorphic to the conditional probabilistic three doors problem. I always found it a bit silly and not very interesting, but possibly that problem too should be approached from a sophisticated game theoretic point of view.

By the way, Marilyn vos Savant's original question is semantically ambiguous, though this might not be noticed by a non-native English speaker. Are the mentioned door numbers, huge painted numbers on the front of the doors *a priori*, or are we just for convenience *naming* the doors by the choices of the actors in our game *a posteriori*. Marilyn stated in a later column in *Parade* that she had originally been thinking of the latter. However, her own offered solutions are not consistent with a single unambiguous formulation. Probably she did not find the difference very interesting.

This little article contains nothing new, and only almost trivial mathematics. It is a plea for future generations to preserve the life of *The True Monty Hall paradox*, and not

let themselves be misled by probability purists who say "you *must* compute a conditional probability."

Mood Test

Justice I. Odiase[1], Sunday M. Ogbonmwan[2]
[1]University of Benin, Benin City, Nigeria
[2]Professor and Dean, The Faculty of Physical Sciences University of Benin, Benin City, Nigeria

In 1954, A.M. Mood developed the square rank test for dispersion known as Mood test. It is based on the sum of squared deviations of the ranks of one sample from the mean rank of the combined samples. The null hypothesis is that there is no difference in spread against the alternative hypothesis that there is some difference. The Mood test assumes that location remains the same. It is assumed that differences in scale do not cause a difference in location. The samples are assumed to be drawn from continuous distributions.

In two-sample scale tests, the population distributions are usually assumed to have the same location with different spreads. However, Neave and Worthington (1988) cautioned that tests for difference in scale could be severely impaired if there is a difference in location as well.

In a two-sample problem composed of $X = \{x_1, x_2, \ldots, x_m\}$ with distribution $F(X)$ and $Y = \{y_1, y_2, \ldots, y_n\}$ with distribution $G(Y)$, arrange the combined samples in ascending order of magnitude and rank all the $N = m + n$ observations from 1 (smallest) to N (largest). Let W be the sum of squares of the deviations of one of the samples' (say X) ranks from the mean rank of the combined samples,

$$W = \sum_{i=1}^{m} \left(r_i - \frac{m+n+1}{2} \right)^2,$$

where r_i is the rank of the i^{th} X observation. The table of exact critical values can be found in Odiase and Ogbonmwan (2008).

Under the null hypothesis ($F = G$), the layout of the ranks of the combined samples is composed of N independent and identically distributed random variables, and hence conditioned on the observed data set, the mean and variance of W are $m(N^2-1)/12$ and $mn(N+1)(N^2-4)/180$, respectively. The large sample Normal approximation of W is

$$\frac{W - \frac{m(N^2-1)}{12}}{\sqrt{\frac{mn(N+1)(N^2-4)}{180}}}.$$

The efficiency of the two-sample Mood test against the normal alternative to the null hypothesis is $\frac{15}{2\pi^2} \cong 76\%$.

A Monte Carlo study of several nonparametric test statistics to obtain the minimum sample size requirement for large sample approximation was carried out by Fahoome (2002). Adopting Bradley's (1978) liberal criterion of robustness, Fahoome (2002) recommends the asymptotic approximation of the Mood test when $\min(m, n) = 5$ for the level of significance $\alpha = 0.05$ and $\min(m, n) = 23$ for $\alpha = 0.01$. However, Odiase and Ogbonmwan (2008) generated the exact distribution of the Mood test statistics by the permutation method and therefore provided the table of exact critical values at different levels of significance.

The idea of a general method of obtaining an exact test of significance originated with Fisher (1935). The essential feature of the method is that all the distinct permutations of the observations are considered, with the property that each permutation is equally likely under the hypothesis to be tested.

About the Authors

Dr. Justice Ighodaro Odiase is a Senior Lecturer, Department of Mathematics, University of Benin, Nigeria. He is the Scientific Secretary of the Statistics Research Group (SRG), Department of Mathematics, University of Benin. He is a member of the Nigerian Statistical Association (NSA), International Association for Statistical Computing (IASC), and The Society for Imprecise Probability:

Theories and Applications (SIPTA). He has authored and coauthored more than 30 papers.

Sunday Martins Ogbonmwan is a Professor of Statistics, Department of Mathematics, University of Benin, Benin City, Nigeria. He is the President of the Statistics Research Group (SRG), Department of Mathematics, University of Benin. He was the Head of Department of Mathematics, University of Benin (2006–2009). He is currently the Dean of the Faculty of Physical Sciences, University of Benin. He is a member of the Institute of Mathematical Statistics (IMS). He is also a member of the Nigerian Statistical Association (NSA). He has authored and coauthored more than 50 papers. He was the Editor-in-Chief of the *Journal of the Nigerian Statistical Association* (JNSA (1990–1995)). Professor Ogbonmwan was an award winner in a competition organized by the International Statistical Institute for young statisticians in developing countries (Madrid, Spain, 1983).

Most Powerful Test

Czesław Stępniak
Professor
Maria Curie-Skłodowska University, Lublin, Poland
University of Rzeszów, Rzeszów, Poland

This notion plays a key role in testing statistical hypotheses. Testing is a two-decision statistical problem.

Case Study

A producer of hydraulic pumps applies plastic gaskets purchased from a deliverer. The gaskets are supplied in batches of 5,000. Since the cost of repairing a pump found to be faulty is far higher than the cost of the gasket itself, each batch is subject to testing. Not only the testing is costly but also any gasket used in the process is practically damaged. Thus the producer decides to verify 50 gaskets taken randomly from each batch.

Assume the deliverer promised that the fraction of defective gaskets would not exceed 5%. Suppose 4 defective gaskets were disclosed in a sample of size 50. Is this enough to reject the batch? The situation is illustrated by the following table

Batch\decision	Accept	Reject
Good	+	Type I Error
Bad	Type II Error	+

Since the decision is taken on the basis of a random variable (the number of defective gaskets), the quality of test may be expressed in terms of the probabilities of these two errors. We would like to minimize these probabilities simultaneously. However, any decrease of one of these probabilities causes increase of the second one. Consequences of these two errors should also be taken into consideration. Similarly as in law, one presumes that the tested hypothesis is true. Thus the probability of the error of the first type should be under control. Theory of testing statistical hypotheses, regarding these postulates, was formalized in 1933 by Neyman and Pearson.

Neyman-Pearson Theory

Let X be a random variable (or: random vector) taking values in a sample space $(\mathcal{X}, \mathcal{A})$ with a distribution P belonging to a class $\mathcal{P} = \{P_\theta : \theta \in \Theta\}$ and let Θ_0 be a proper subset of Θ. We are interested in deciding, on the basis of observation X, whether $\theta \in \Theta_0$ (decision d_0) or not (decision d_2).

Any statement of the form $H : \theta \in \Theta_0$ is called a statistical hypothesis. We consider also the alternative hypothesis $K : \theta \notin \Theta_0$, i.e., $\theta \in \Theta \setminus \Theta_0$. A criterion of rejecting H (called a test) may be assigned by a *critical region* $S \subseteq \mathcal{X}$, according to the rule: reject H if $X \in S$ and accept otherwise.

When performing a test one may arrive at the correct decision, or one may commit one of two errors: rejecting H when it is true or accepting when it is false. The upper bound of the probability $P_\theta(d_0(X))$ for all $\theta \in \Theta_0$ is called

the *size* while the function $\beta(\theta) = P_\theta(d_0)$ for $\theta \in \Theta \setminus \Theta_0$ is called the power function of the test.

The general principle in Neyman-Pearson theory is to find such a procedure that maximizes $\beta(\theta)$ for all $\theta \in \Theta \backslash \Theta_0$ under assumption that $P_\theta(d_0(X)) \leq \alpha$ (significance level) for all $\theta \in \Theta_0$. Any such test (if exists) is called to be *uniformly most powerful* (UMP). The well known Neyman-Pearson fundamental lemma (see ▶Neyman-Pearson Lemma) states that for any two-element family of densities or mass probabilities $\{f_0, f_1\}$ such test always exists and it can be expressed by the likelihood ratio $r(x) = \frac{f_1(x)}{f_0(x)}$. In this case the power function β reduces to a scalar and the word *uniformly* is redundant.

It is worth to add that in the continuous case the size of the UMP test coincides with its significance level. However, it may not be true in the discrete case. The desired equality can be reached by considering the *randomized* decision rules represented by functions $\phi = \phi(x)$, taking values in the interval $[0,1]$ and interpreted as follows:

"If $X = x$ then reject H with probability $\phi(x)$
and accept it with probability $1 - \phi(x)$"

The size of the MP randomized test coincides with its significance level and its power may be greater than for the nonrandomized one. According to the Neyman-Pearson lemma, the randomized MP test has the form

$$\phi(x) = \begin{cases} 1, & \text{if} \quad p_1(x) > kp_0(x) \\ \gamma, & \text{if} \quad p_1(x) = kp_0(x \\ 0, & \text{if} \quad p_1(x) < kp_0(x \end{cases}$$

for some k induced by the significance level. If $\gamma = 0$ then it is non-randomized.

One-Side Hypothesis and Monotone Likelihood Ratio

In practical situations distribution of the observation vector depends on one or more parameters and we make use of composite hypotheses $\theta \in \Theta_0$ against $\theta \in \Theta \setminus \Theta_0$. Perhaps one of the simple situations of this type is testing one-side hypothesis $\theta \leq \theta_0$ or $\theta \geq \theta_0$ in a scalar parameter family of distributions.

We say that a family of densities $\{f_\theta : \theta \in \Theta\}$ has *monotone likelihood ratio* if there exists a statistic $T = t(X)$ such that for any $\theta < \theta'$ the ratio $\frac{f_{\theta'}(x)}{f_\theta(x)}$ is a monotone function of T. It appears that for testing a hypothesis $H : \theta \leq \theta_0$ against $K : \theta > \theta_0$ in such a family of densities there exists a UMP test of the form

$$\phi(x) = \begin{cases} 1 & \text{when } T(x) > C \\ \gamma & \text{when } T(x) = C \\ 0 & \text{when } T(x) < C. \end{cases}$$

An important class of families with monotone likelihood ratio are one-parameter exponential families with densities of type $f_\theta(x) = C(\theta)e^{Q(\theta)T(x)}h(x)$. In a discrete case with integer parameter instead the mononotonity condition it suffices to verify that the ratio $\frac{P_{k+1}(x)}{P_k(x)}$ is a monotone function of T for all k.

Example 1 (Testing expectation in a simple sample from normal distribution with known variance). Let $X_1, ..., X_n$ be independent and identically distributed. Random variables with distribution $N(\mu, \sigma^2)$, where σ^2 is known. Consider the hypothesis $H : \mu \leq \mu_0$ under the alternative $K : \mu > \mu_0$. The family of distributions has a monotone likelihood ratio with respect to the statistic $T = \sum_{i=1}^n X_i$. Therefore there exists a UMP test which rejects H if $\sum_{i=1}^n X_i$. is too large.

Example 2 (Statistical control theory). From a great number (N) of elements with an unknown number D of defective ones we draw without replacement a sample of size n. Then the potential number X of defective elements in the sample has the hypergeometric distribution

$$P_D(X = x) = \begin{cases} \frac{\binom{D}{x}\binom{N-D}{n-x}}{\binom{N}{n}}, & \text{if } \max(0, n+D-N) < \\ & x < \min(n, D) \\ 0, & \text{otherwise.} \end{cases}.$$

One can verify that

$$\frac{P_{D+1}(x)}{P_D(x)} = \begin{cases} 0, & \text{if } x = n + D - N \\ \frac{D+1}{N-D}\frac{N-D-n+x}{D+1-x}, & \text{if } n + D + 1 - N \leq x \leq D \\ \infty & \text{if } x = D + 1 \end{cases}$$

is a monotone function of x. Therefore there exists a UMP test for the hypothesis $H : D \leq D_0$ against $K : D > D_0$, which rejects H if x is too large.

Invariant and Unbiased Tests

If distribution of the observation vector depends on several parameters, some of them may be out of our interest and play the role of nuisance parameters. Such a situation occurs, for instance, in testing linear hypotheses. In this case the class of all unbiased estimators is usually too large for handle. Then we may seek for a test with maximum power in a class of tests which are invariant with respect to some transformations of observations or their powers do not depend on the nuisance parameters. This is called the

most powerful invariant test. The class of tests under consideration may be also reduced by unbiasedness condition. A member of this class with maximum power is then called the most powerful unbiased test. The standard tests for linear hypotheses in a linear normal model are most powerful in each of these classes.

Moving Averages

Rob J. Hyndman
Professor of Statistics
Monash University, Melbourne, VIC, Australia

A moving average is a time series constructed by taking averages of several sequential values of another time series. It is a type of mathematical convolution. If we represent the original time series by $y_1, \ldots, y_n$, then a *two-sided moving average* of the time series is given by

$$z_t = \frac{1}{2k+1} \sum_{j=-k}^{k} y_{t+j}, \qquad t = k+1, k+2, \ldots, n-k.$$

Thus $z_{k+1}, \ldots, z_{n-k}$ forms a new time series which is based on averages of the original time series, $\{y_t\}$. Similarly, a *one-sided moving average* of $\{y_t\}$ is given by

$$z_t = \frac{1}{k+1} \sum_{j=0}^{k} y_{t-j}, \qquad t = k+1, k+2, \ldots, n.$$

More generally, weighted averages may also be used. Moving averages are also called running means or rolling averages. They are a special case of "filtering", which is a general process that takes one time series and transforms it into another time series.

The term "moving average" is used to describe this procedure because each average is computed by dropping the oldest observation and including the next observation. The averaging "moves" through the time series until z_t is computed at each observation for which all elements of the average are available.

Note that in the above examples, the number of data points in each average remains constant. Variations on moving averages allow the number of points in each average to change. For example, in a cumulative average, each value of the new series is equal to the sum of all previous values.

Moving averages are used in two main ways: Two-sided (weighted) moving averages are used to "smooth" a time series in order to estimate or highlight the underlying trend; one-sided (weighted) moving averages are used as simple forecasting methods for time series. While moving averages are very simple methods, they are often building blocks for more complicated methods of time series smoothing, decomposition and forecasting.

Smoothing Using Two-Sided Moving Averages

It is common for a time series to consist of a smooth underlying trend observed with error:

$$y_t = f(t) + \varepsilon_t,$$

where $f(t)$ is a smooth and continuous function of t and $\{\varepsilon_t\}$ is a zero-mean error series. The estimation of $f(t)$ is known as smoothing, and a two-sided moving average is one way of doing so:

$$\hat{f}(t) = \frac{1}{2k+1} \sum_{j=-k}^{k} y_{t+j}, \qquad t = k+1, k+2, \ldots, n-k.$$

The idea behind using moving averages for smoothing is that observations which are nearby in time are also likely to be close in value. So taking an average of the points near an observation will provide a reasonable estimate of the trend at that observation. The average eliminates some of the randomness in the data, leaving a smooth trend component.

Moving averages do not allow estimates of $f(t)$ near the ends of the time series (in the first k and last k periods). This can cause difficulties when the trend estimate is used for forecasting or analyzing the most recent data.

Each average consists of $2k+1$ observations. Sometimes this is known as a $(2k+1)$ MA smoother. The larger the value of k, the flatter and smoother the estimate of $f(t)$ will be. A smooth estimate is usually desirable, but a flat estimate is biased, especially near the peaks and troughs in $f(t)$. When ε_t is a white noise series (i.e., independent and identically distributed with zero mean and variance σ^2), the bias is given by $\mathrm{E}[\hat{f}(x)] - f(x) \approx \frac{1}{6} f''(x)k(k+1)$ and the variance by $\mathrm{V}[\hat{f}(x)] \approx \sigma^2/(2k+1)$. So there is a trade-off between increasing bias (with large k) and increasing variance (with small k).

Centered Moving Averages

The simple moving average described above requires an odd number of observations to be included in each average. This ensures that the average is centered at the middle of the data values being averaged. But suppose we wish to calculate a moving average with an even number of observations. For example, to calculate a 4-term moving average, the trend at time t could be calculated as

$$\hat{f}(t-0.5) = (y_{t-2} + y_{t-1} + y_t + y_{t+1})/4$$

or

$$\hat{f}(t+0.5) = (y_{t-1} + y_t + y_{t+1} + y_{t+2})/4$$

That is, we could include two terms on the left and one on the right of the observation, or one term on the left and two terms on the right, and neither of these is centered on t. If we now take the average of these two moving averages, we obtain something centered at time t.

$$\begin{aligned}\hat{f}(t) &= \frac{1}{2}\left[(y_{t-2} + y_{t-1} + y_t + y_{t+1})/4\right] \\ &\quad + \frac{1}{2}\left[(y_{t-1} + y_t + y_{t+1} + y_{t+2})/4\right] \\ &= \frac{1}{8}y_{t-2} + \frac{1}{4}y_{t-1} + \frac{1}{4}y_t + \frac{1}{4}y_{t+1}\frac{1}{8}y_{t+2}\end{aligned}$$

So a 4 MA followed by a 2 MA gives a *centered moving average*, sometimes written as 2×4 MA. This is also a weighted moving average of order 5, where the weights for each period are unequal. In general, a $2 \times m$ MA smoother is equivalent to a weighted MA of order $m+1$ with weights $1/m$ for all observations except for the first and last observations in the average, which have weights $1/(2m)$.

Centered moving averages are examples of how a moving average can itself be smoothed by another moving average. Together, the smoother is known as a *double moving average*. In fact, any combination of moving averages can be used together to form a double moving average. For example, a 3×3 moving average is a 3 MA of a 3 MA.

Moving Averages. Table 1 Weight functions a_j for some common weighted moving averages

Moving Averages with Seasonal Data

If the centered 4 MA was used with quarterly data, each quarter would be given equal weight. The weight for the quarter at the ends of the moving average is split between the two years. It is this property that makes 2×4 MA very useful for estimating a trend in the presence of quarterly seasonality. The seasonal variation will be averaged out exactly when the moving average is computed. A slightly longer or a slightly shorter moving average will still retain some seasonal variation. An alternative to a 2×4 MA for quarterly data is a 2×8 or 2×12 which will also give equal weights to all quarters and produce a smoother fit than the 2×4 MA. Other moving averages tend to be contaminated by the seasonal variation.

More generally, a $2 \times (km)$ MA can be used with data with seasonality of length m where k is a small positive integer (usually 1 or 2). For example, a 2×24 MA may be used for estimating a trend in monthly seasonal data (where $m = 12$).

Weighted Moving Averages

A weighted k-point moving average can be written as

$$\hat{f}(t) = \sum_{j=-k}^{k} a_j y_{t+j}.$$

For the weighted moving average to work properly, it is important that the weights sum to one and that they are symmetric, that is $a_j = a_{-j}$. However, we do not require that the weights are between 0 and 1. The advantage of weighted averages is that the resulting trend estimate is much smoother. Instead of observations entering and leaving the average abruptly, they can be slowly downweighted. There are many schemes for selecting appropriate weights. Kendall et al. (1983, Chap. 46) give details.

Some sets of weights are widely used and have been named after their proposers. For example, Spencer (1904) proposed a $5 \times 4 \times 4$ MA followed by a weighted 5-term moving average with weights $a_0 = 1$, $a_1 = a_{-1} = 3/4$, and $a_2 = a_{-2} = -3/4$. These values are not chosen arbitrarily, but because the resulting combination of moving averages can be shown to have desirable mathematical properties. In this case, any cubic polynomial will be undistorted by the averaging process. It can be shown that Spencer's MA is equivalent to the 15-point weighted moving average whose weights are −.009, −.019, −.016, .009, .066, .144, .209, .231, .209, .144, .066, .009, −.016, −.019, and −.009. Another Spencer's MA that is commonly used is the 21-point weighted moving average. Henderson's weighted moving averages are also widely used, especially as part of seasonal adjustment methods (Ladiray and Quenneville 2001). The set of weights is known as the *weight function*. Table 1 shows some common weight functions. These are all symmetric, so $a_{-j} = a_j$.

Weighted moving averages are equivalent to kernel regression when the weights are obtained from a kernel function. For example, we may choose weights using the quartic function

$$Q(j,k) = \begin{cases} \left\{1 - [j/(k+1)]^2\right\}^2 & \text{for } -k \le j \le k; \\ 0 & \text{otherwise.} \end{cases}$$

Then a_j is set to $Q(j,k)$ and scaled so the weights sum to one. That is,

$$a_j = \frac{Q(j,k)}{\sum_{i=-k}^{k} Q(i,k)}. \quad (1)$$

Forecasting Using One-Sided Moving Averages

A simple forecasting method is to average the last few observed values of a time series. Thus

$$\hat{y}_{t+h|t} = \frac{1}{k+1} \sum_{j=0}^{k} y_{t-j}$$

provides a forecast of y_{t+h} given the data up to time t.

As with smoothing, the more observations included in the moving average, the greater the smoothing effect. A forecaster must choose the number of periods $(k+1)$ in a moving average. When $k = 0$, the forecast is simply equal to the value of the last observation. This is sometimes known as a "naïve" forecast.

An extremely common variation on the one-sided moving average is the exponentially weighted moving average. This is a weighted average, where the weights decrease exponentially. It can be written as

$$\hat{y}_{t+h|t} = \sum_{j=0}^{t-1} a_j y_{t-j}$$

where $a_j = \lambda(1-\lambda)^j$. Then, for large t, the weights will approximately sum to one. An exponentially weighted moving average is the basis of simple exponential smoothing. It is also used in some process control methods.

Moving Average Processes

A related idea is the moving average process, which is a time series model that can be written as

$$y_t = e_t - \theta_1 e_{t-1} - \theta_2 e_{t-2} - \cdots - \theta_q e_{t-q},$$

where $\{e_t\}$ is a white noise series. Thus, the observed series y_t, is a weighted moving average of the unobserved e_t

series. This is a special case of an Autoregressive Moving Average (or ARMA) model and is discussed in more detail in the entry ►Box-Jenkins Time Series Models. An important difference between this moving average and those considered previously is that here the moving average series is directly observed, and the coefficients $\theta_1, \ldots, \theta_q$ must be estimated from the data.

Multicollinearity

Vlasta Bahovec
Professor, Faculty of Economics and Business
University of Zagreb, Zagreb, Croatia

One of the assumptions of the standard regression model $y = X\beta + \varepsilon$ is that there is no exact linear relationship among the explanatory variables, or equivalently, that the matrix X of explanatory variables has a full rank. The problem of multicollinearity occurs if two or more explanatory variables are linearly dependent, or near linearly dependent (including the variable $x_0' = [1, 1, \cdots, 1]$, which generates a constant term). There are two types of multicollinearity: perfect and near multicollinearity.

Perfect multicollinearity occurs if at least two explanatory variables are linearly dependent. In that case, the determinant of matrix $X'X$ equals zero (the $X'X$ matrix is singular), and therefore ordinary least squares (OLS) estimates of regression parameters $\beta' = (\beta_0, \beta_1, \cdots, \beta_k)$

$$\hat{\beta} = (X'X)^{-1}X'y = \frac{adj(X'X)}{\det(X'X)} \cdot X'y$$

are not unique. This type of multicollinearity is rare, but may occur if the regression model includes qualitative explanatory variables, whose effect is taken into account by ►dummy variables. Perfect multicollinearity occurs in a regression model with an intercept, if the number of dummy variables for each qualitative variable is not less than the number of groups of this variable. Perfect multicollinearity can easily be revealed. A more difficult problem is near or imperfect multicollinearity. This problem arises if at least two regressors are highly intercorrelated. In that case, $\det(X'X) \approx 0$, the matrix $X'X$ is ill conditioned, and therefore the estimated parameters are numerically imprecise. Furthermore, since the covariance matrix of estimated parameters is calculated by the formula $Cov(\hat{\beta}) = \hat{\sigma}^2(X'X)^{-1}$, the variances and covariances of the estimated parameters will be large. Large standard errors $SE(\hat{\beta}_j) = \hat{\sigma}\sqrt{(X'X)^{-1}_{jj}}$ imply that empirical t-ratios $\left(t_j = \hat{\beta}_j / SE\left(\hat{\beta}_j\right)\right)$ could be insignificant, which may lead to an incorrect conclusion that some explanatory variables have to be omitted from the regression model. Also, large standard errors make interval parameter estimates imprecise.

Imperfect multicollinearity often arises in the time series regression model (see ►Time Series Regression), especially in data involving economic time series, while variables over time tend to move in the same direction.

The simplest way to detect serious multicollinearity problems is to analyze variances of estimated parameters, which are calculated with the following formula:

$$var(\hat{\beta}_j) = \sigma^2(X'X)^{-1}_{jj} = \frac{\hat{\sigma}^2}{\sum_{i=1}^{n}(x_{ij} - \bar{x}_j)^2 \cdot \left(1 - R_j^2\right)},$$

where R_j^2 is the coefficient of determination in the regression, variable x_j is the dependent, and the remaining x's are explanatory variables. If variable x_j is highly correlated with other regressors, R_j^2 will be large (near to 1), and therefore the variance of $\hat{\beta}_j$ will be large. There are some measures of multicollinearity included in standard statistical software: the variance inflation factor (VIF), tolerance (TOL), condition number (CN), and condition indices (CI). VIF and TOL are calculated with the following formulas:

$$VIF_j = \frac{1}{1 - R_j^2} \quad j = 1, 2, \cdots, k \quad TOL_j = \frac{1}{VIF_j} = 1 - R_j^2.$$

The multicollinearity problem is serious if $R_j^2 > 0.8$, consequently if $VIF_j > 5$, or equivalently if $TOL_j < 0.2$.

More sophisticated measures of multicollinearity are condition number, CN, and condition indices, CI_i, based on the use of eigenvalues of the $X'X$ matrix. CN is the square root of the ratio of the largest eigenvalue to the smallest eigenvalue, and CI_i, $i = 1, 2, \ldots, k$, are square roots of the ratio of the largest eigenvalue to each individual eigenvalue. These measures, which are calculated with the formulas

$$CN = \sqrt{\frac{\lambda_{\max}}{\lambda_{\min}}} \qquad CI_i = \sqrt{\frac{\lambda_{\max}}{\lambda_i}} \quad i = 1, 2, \cdots, k,$$

are measures of sensitivity of parameter estimates to small changes in data. Some authors, such as Belsley et al. (1980), suggested that a condition index of 30–100 indicates moderate to strong multicollinearity.

Several solutions have been suggested to rectify the multicollinearity problem. Some are the following: (1) increasing the sample size to reduce multicollinearity, as multicollinearity is a problem of the sample, and not the population; (2) dropping one or more variables suspected of causing multicollinearity; (3) transforming data as the first differences $\Delta X_t = X_t - X_{t-1}$ or ratios X_t/X_{t-1} $t = 2, 3, \ldots, n$ to eliminate linear or exponential trends; (4) ridge regression (see ►Ridge and Surrogate Ridge Regressions); and (5) principal component regression.

The problem of multicollinearity is approached differently by econometricians depending on their research goal. If the goal is to forecast future values of the dependent variable, based on the determined regression model, the problem of multicollinearity is neglected. In all other cases, this problem is approached more rigorously.

Multicriteria Clustering

Anuška Ferligoj
Professor, Head of the Center of Informatics and Methodology, Faculty of Social Sciences
University of Ljubljana, Ljubljana, Slovenia

Some clustering problems cannot be appropriately solved with classical clustering algorithms because they require optimization over more than one criterion. In general, solutions optimal according to each particular criterion are not identical. Thus, the problem arises of how to find the best solution satisfying as much as possible all criteria considered. In this sense the set of Pareto efficient clusterings was defined: a clustering is Pareto efficient if it cannot be improved on any criterion without sacrificing some other criterion.

A multicriteria clustering problem can be approached in different ways:

- By reduction to a clustering problem with a single criterion obtained as a combination of the given criteria;
- By constrained clustering algorithms where a selected criterion is considered as the clustering criterion and all others determine the constraints;
- By direct algorithms: Hanani (1979) proposed an algorithm based on the dynamic clusters method using the concept of the kernel, as a representation of any given criterion. Ferligoj and Batagelj (1992) proposed modified relocation algorithms and modified agglomerative hierarchical algorithms.

Usual Clustering Problems

Cluster analysis (known also as classification and taxonomy) deals mainly with the following general problem: given a set of units, $\mathcal{U}$, determine subsets, called clusters, C, which are homogeneous and/or well separated according to the measured variables (e.g., Sneath and Sokal 1973; Hartigan 1975; Gordon 1981). The set of clusters forms a clustering. This problem can be formulated as an optimization problem:

Determine the clustering $\mathbf{C}^*$ for which

$$P(\mathbf{C}^*) = \min_{\mathbf{C} \in \Phi} P(\mathbf{C})$$

where $\mathbf{C}$ is a clustering of a given *set of units*, $\mathcal{U}$, Φ is the set of all feasible clusterings and $P : \Phi \to \mathbb{R}$ a *criterion function*.

As the set of feasible clusterings is finite a solution of the clustering problem always exists. Since this set is usually large it is not easy to find an optimal solution.

A Multicriteria Clustering Problem

In a *multicriteria clustering problem* $(\Phi, P_1, P_2, \ldots, P_k)$ we have several criterion functions $P_t, t = 1, \ldots, k$ over the same set of feasible clusterings Φ, and our aim is to determine the clustering $\mathbf{C} \in \Phi$ in such a way that

$$P_t(\mathbf{C}) \to \min, \quad t = 1, \ldots, k.$$

In the ideal case, we are searching for the dominant set of clusterings. The solution $\mathbf{C}_0$ is the *dominant* solution if for each solution $\mathbf{C} \in \Phi$ and for each criterion P_t, it holds that

$$P_t(\mathbf{C}_0) \le P_t(\mathbf{C}), \quad t = 1, \ldots, k.$$

Usually the set of dominant solutions is empty. Therefore, the problem arises of finding a solution to the problem that is as good as is possible according to each of the given criteria. Formally, the *Pareto-efficient* solution is defined as follows:

For $\mathbf{C}_1, \mathbf{C}_2 \in \Phi$, solution $\mathbf{C}_1$ *dominates* solution $\mathbf{C}_2$ if and only if

$$P_t(\mathbf{C}_1) \le P_t(\mathbf{C}_2), \quad t = 1, \ldots, k,$$

and for at least one $i \in 1, \ldots, k$ the strict inequality $P_i(\mathbf{C}_1) < P_i(\mathbf{C}_2)$ holds. We denote the dominance relation by $\prec$. $\prec$ is a strict partial order. The set of Pareto-efficient solutions, Π, is the set of minimal elements for the dominance relation:

$$\Pi = \{\mathbf{C} \in \Phi : \neg\exists \mathbf{C}' \in \Phi : \mathbf{C}' \prec \mathbf{C}\}$$

In other words, the solution $\mathbf{C}^* \in \Phi$ is *Pareto-efficient* if there exists no other solution $\mathbf{C} \in \Phi$ such that

$$P_t(\mathbf{C}) \le P_t(\mathbf{C}^*), \quad t = 1, \ldots, k,$$

with strict inequality for at least one criterion. A *Pareto-clustering* is a Pareto-efficient solution of the multicriteria clustering problem (Ferligoj and Batagelj 1992).

Since the optimal clusterings for each criterion are Pareto-efficient solutions the set Π is not empty. If the set of dominant solutions is not empty then it is equal to the set of Pareto-efficient solutions.

Solving Discrete Multicriteria Optimization Problems

Multicriteria clustering problems can be approached as a multicriteria optimization problem, that has been treated by several authors (e.g., Chankong and Haimes 1983; Ferligoj and Batagelj 1992). In the clustering case, we are dealing with discrete multicriteria optimization (the set of feasible solutions is finite), which means that many very useful theorems in the field of multicriteria optimization do not hold, especially those which require convexity. It was proven that if, for each of the given criteria, there is a unique solution, then the minimal number of Pareto-efficient solutions to the given multicriteria optimization problem equals the number of different minimal solutions of the single criterion problems.

Although several strategies haven been proposed for solving multicriteria optimization problems explicitly, the most common is the conversion of the multicriteria optimization problem to a single criterion problem.

Direct Multicriteria Clustering Algorithms

The multicriteria clustering problem can be approached efficiently by using direct algorithms. Two types of direct algorithms are known: a version of the relocation algorithm, and the modified agglomerative (hierarchical) algorithms (Ferligoj and Batagelj 1992).

Modified Relocation Algorithm

The idea of the *modified relocation* algorithm for solving the multicriteria clustering problem follows from the definition of a Pareto-efficient clustering. The solutions obtained by the proposed procedure can be only *local Pareto clusterings*. Therefore, the basic procedure should be repeated *many* times (at least hundreds of times) and the obtained solutions should be reviewed. An efficient review of the obtained solutions can be systematically done with an appropriate *metaprocedure* with which the true set of Pareto clusterings can be obtained.

Modified Agglomerative Hierarchical Approach

Agglomerative hierarchical clustering algorithms usually assume that all relevant information on the relationships between the n units from the set $\mathcal{U}$ is summarized by a symmetric pairwise dissimilarity matrix $D = [d_{ij}]$. In the case of multicriteria clustering we assume we have k dissimilarity matrices $D^t, t = 1, \ldots, k$, each summarizing all relevant information obtained, for example, in the k different situations. The problem is to find the best hierarchical solution which satisfies as much as is possible all k dissimilarity matrices.

One approach to solving the multicriteria clustering problem combines the given dissimilarity matrices (at each step) into a composed matrix. This matrix $D = [d_{ij}]$ can, for example, be defined as follows:

$$d_{ij} = \max\left(d_{ij}^t; t = 1, \ldots, k\right)$$
$$d_{ij} = \min\left(d_{ij}^t; t = 1, \ldots, k\right)$$
$$d_{ij} = \sum_{t=1}^{k} \alpha_t d_{ij}^t \ , \ \sum_{t=1}^{k} \alpha_t = 1$$

Following this approach, one of several *decision rules* (e.g., pessimistic, optimistic, Hurwicz, Laplace) for making decisions under uncertainty (Chankong and Haimes 1983) can be used at the composition and selection step of the agglomerative procedure.

Conclusion

The multicriteria clustering problem can be treated with the proposed approaches quite well if only a few hundreds units are analysed. New algorithms have to be proposed for large datasets.

Multicriteria Decision Analysis

Theodor J. Stewart
Emeritus Professor

University of Manchester, Manchester, UK

Basic Definitions

The field variously described as *multicriteria decision making (MCDM)* or *multicriteria decision analysis* or *aid (MCDA)* is that branch of operational research/management science (OR/MS) that deals with the explicit modeling of multiple conflicting goals or objectives in management decision making. Standard texts in OR/MS typically do include identification of objectives (often stated as plural) as a key step in the decision-making process, but the ensuing discussion appears to assume that such objectives are easily aggregated into a single measure of achievement which can formally be optimized. The field of MCDA, however, arose from a recognition that systematic and coherent treatment of multiple objectives requires structured decision support to ensure that all interests are kept in mind and that an informed balance is achieved. See, for example, the discussions and associated references in Chap. 2 of Belton and Stewart (2002) and Chap. 1 of Figueira et al. (2005).

The starting point of MCDA is the identification of the critical *criteria* according to which potential courses of action (choices, policies, strategies) may be compared and evaluated. In this sense, each *criterion* is a particular point of view or consideration according to which preference orders on action outcomes can (more-or-less) unambiguously be specified. Examples of such criteria may include issues such as investment costs, job creation, levels of river pollution etc., as well as more subjective criteria such as aesthetic appeal. With careful selection of the criteria, preference ordering according to each could be essentially self-evident apart from some fuzziness around the concept equality of performance.

Selection of criteria is a profound topic in its own right, but is perhaps beyond the scope of the present article. Some discussion may be found in Keeney and Raiffa (1976); Keeney (1992); Belton and Stewart (2010). In essence, the analyst needs to ensure that values and aspirations of the decision maker(s) have been fully captured by the chosen criteria, while still retaining a manageably small number of criteria (typically, one strives for not much more than 15 or 25 criteria in most applications). Care needs to be taken not

to double-count issues, and that preference orders can be understood on each criterion independently of the others.

Suppose then that say m criteria have been defined as above. For any specified course of action, say $a \in \mathscr{A}$ (the set of all possible actions), we define $z_i(a)$ to be a measure of performance of a according to the perspective of criterion i, for $i = 1, \ldots, m$. The scaling at this stage is not important, the only requirement being that action a is preferred to action b in terms of criterion i ($a \succ_i b$) if and only if $z_i(a) > z_i(b) + \epsilon_i$ for some tolerance parameter ϵ_i. Apart from the brief comments in the final section, we assume that these measures of performance are non-stochastic.

The primary aim of MCDA is to support the decision maker in aggregating the single-criterion preferences into an overall preference structure, in order to make a final selection which best satisfies all criteria, or to select a reduced subset of $\mathscr{A}$ for further discussion and evaluation. It is important to recognize that this aggregation phase contains fundamentally subjective elements, namely the value judgments and tradeoffs provided by the decision maker. We shall briefly review some of the support processes which are used. A comprehensive overview of these approaches may be found in Figueira et al. (2005).

Methods of Multicriteria Analysis

It is important to recognize that two distinct situations may arise in the context described above, and that these may lead to broadly different forms of analysis:

- *Discrete choice problems:* In this case, $\mathscr{A}$ consists of a discrete set of options, e.g., alternative locations for a power station. The discrete case arises typically at the level of high level strategic choices, within which many of the criteria may require subjective evaluation of alternatives.
- *Multiobjective optimization problems:* These problems are often defined in mathematical programming terms, i.e., an option will be defined in terms of a vector of *decision variables*, say $\mathbf{x} \in \mathbb{X} \subset \mathbb{R}^n$. The measures of performance for each criterion typically need to be defined quantitatively in terms of functions $f_i(\mathbf{x})$ mapping $\mathbb{R}^n \to \mathbb{R}$ for each i.

The methods adopted can be characterized in two ways:

- By the underlying paradigm for modeling human preferences (*preference modeling*);
- By the stage of the analysis at which the decision makers' judgments are brought into play (*timing of preference statements*).

We deal with each of these in turn.

Preference Modeling

At least four different paradigms can be identified.

1. **Value scoring or utility methods:** The approach is first to re-scale the performance measures $z_i(a)$ so as to be commensurate in some way, typically by means of transformation through a *partial value function*, say $v_i(z_i)$. This rescaling needs to ensure that equal-sized intervals in the transformed scale represent the same importance to the decision maker (in terms of trade-offs with other criteria) irrespective of where they occur along the scale. Relatively mild assumptions (under conditions of deterministic performance measures) imply that an overall value of a can be modeled additively, i.e., as $V(a) = \sum_{i=1}^{m} w_i v_i(z_i(a))$. The assessment of the partial values and weights (w_i) may be carried out by direct assessment (e.g., Dyer 2005), indirectly such as by the analytic hierarchy process approach (Saaty 2005), or by learning from previous choices (Siskos et al. 2005).
2. **Metric methods:** In this approach, some form of goal or aspiration is specified (by the decision maker) for each criterion, say G_i for each i. A search (discrete or by mathematical optimization) is then conducted to find the option for which the performance levels $z_1(a), z_2(a), \ldots, z_m(a)$ approach the goal levels $G_1, G_2, \ldots, G_m$ as closely as possible. Typically, L_1, L_2, or L_∞ metrics are used to define closeness, with provision for differential weighting of criteria. Differences do also arise in terms of whether over-achievement of goals adds additional benefits or not. Such approaches are termed (generalized) goal programming, and are reviewed in Lee and Olson; Wierzbicki (1999; 1999). Goal programming is primarily applied in the context of the multiobjective optimization class of model.
3. **Outranking methods:** These methods consider action alternatives pairwise in terms of their performance levels on all criteria, in order to extract the level of evidence in the data provided by the performance measures which either support (are concordant with) or oppose (are discordant with) a conclusion that the one action is better than the other. These considerations generate partial rankings of the actions, or at least a classification of the actions into ordered preference classes. Descriptions of different outranking approaches may be found in Part III of Figueira et al. (2005).
4. **Artificial intelligence:** Greco et al. (2005) describe how observed choices by the decision maker(s) can

be used to extract decision rules for future multicriteria decisions, without explicit or formal preference modeling along the lines described above.

Timing of Preference Statements

Three possible stages of elicitation of values and preferences from the decision maker may be recognized as described below (although in practice no one of these is used completely in isolation).

1. **Elicitation prior to analysis of options:** In this approach, a complete model of the decision maker preferences is constructed from a sequence of responses to questions about values, trade-offs, relative importance, etc. The resulting model is then applied to the elements of $\mathscr{A}$ in order to select the best alternative or a shortlist of alternatives. This approach is perhaps most often used with value scoring methods, in which a simple and transparent preference model (e.g., the additive value function) is easily constructed and applied.
2. **Interactive methods:** Here a tentative preference model, incomplete in many ways, is used to generate a small number of possible choices which are presented to the decision maker, who may either express strong preferences for some or dislike of others. On the basis of these stated preferences, models are refined and a new set of choices generated. Even in the prior elicitation approach, some degree of interaction of this nature will occur, where in the application of value scoring or outranking approaches to discrete choice problems, results will inevitably be fed back to decision makers for reflection on the value judgements previously specified. However, it is especially with continuous multiobjective optimization problems that the interaction becomes firmly designed and structured into the process. See Chap. 5 of Miettinen (1999) for a comprehensive coverage of such structured interaction.
3. **Posterior value judgements:** If each performance measure is to be maximized, then an action a is said to *dominate* action b if $z_i(a) \geq z_i(b)$ for all criteria, with strict inequality for at least one criterion. With discrete choice problems, the removal of dominated actions from $\mathscr{A}$ may at times reduce the set of options to such a small number that no more analysis is necessary – decision makers can make a holistic choice. In some approaches to multiobjective optimization (see also Miettinen 1999), a similar attempt is made to compute the "efficient frontier," i.e., the image in criterion space of all non-dominated options, which can be displayed to the decision maker for a holistic choice. In practice, however, this approach is restricted to problems with two or three criteria only which can be displayed graphically (although there have been attempts at graphical displays for slightly higher dimensionality problems).

Stochastic MCDA

As indicated at the start, we have focused on deterministic problems, i.e., in which a fixed (even if slightly "fuzzy") performance measure $z_i(a)$ can be associated with each action-criterion combination. However, there do of course exist situations in which each $z_i(a)$ will be a *random variable*.

The introduction of stochastic elements into the multicriteria decision making problem introduces further complications. Attempts have been made to adapt value scoring methods to be consistent with the von Neumann/Morgenstern axioms of expected utility theory, to link multicriteria decision analysis with scenario planning, and to treat probabilities of achieving various critical outcomes as separate "criteria." Discussion of these extensions is beyond the scope of space available for this short article, but a review is available in Stewart (2005).

About the Author

Professor Stewart is Past-President of both the Operations Research Society of South Africa (1978) and the South African Statistical Association (1989). He was Vice President of IFORS (International Federation of Operational Research Societies) for the period 2004–2006, and President of the International Society on Multiple Criteria Decision Making for the period 2004–2008. He is currently Editor-in-Chief of the *Journal of Multi-Criteria Decision Analysis*, and African Editor of *International Transactions in Operations*. He is a Member of the Academy of Science of South Africa. In 2008 Professor Stewart was awarded the Gold medal of the International Society on Multiple Criteria Decision Making (for marked contributions to theory, methodology and practice in the field), and has been awarded ORSSA's Tom Roszwadowski Medal (for written contributions to OR) on five occasions.

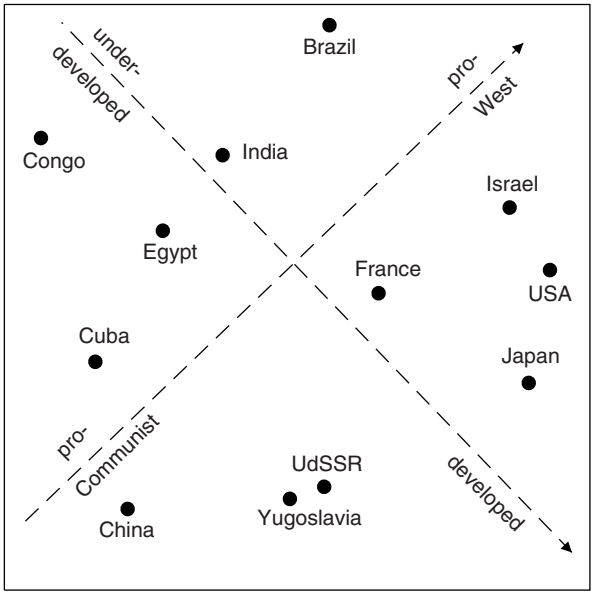
Multidimensional Scaling

Ingwer Borg
Professor of Applied Psychological Methods
University of Giessen, Giessen, Germany
Scientific Director
GESIS, Mannheim, Germany

►Multidimensional scaling (MDS) is a family of methods that optimally map *proximity indices* of objects into distances between points of a multidimensional space with a given dimensionality (usually two or three dimensions). The main purpose for doing this is to visualize the data so that the user can test structural hypotheses or discover patterns "hidden" in the data.



Multidimensional Scaling. Fig. 1 MDS configuration for country similarity data

Historically, MDS began as a psychological model for judgments of (dis)similarity. A typical example of this early era is the following. Wish (1971) was interested to find out how persons generate overall judgments on the similarity of countries. He asked a sample of subjects to assess each pair of twelve countries with respect to their global similarity. For example, he asked "How similar are Japan and China?", offering a 9-point answer scale from "very dissimilar" to "very similar" for the answer. On purpose, "there were no instructions concerning the characteristics on which these similarity judgments were to be made; this was information to discover rather than to impose" (Kruskal and Wish 1978:30). The resulting numerical ratings were averaged over subjects, and then mapped via MDS into the distances among 12 points of a Euclidean plane. The resulting MDS configuration (Fig. 1) was interpreted to show that the ratings were essentially generated from two underlying dimensions.

As an MDS model, Wish (1971) used *ordinal MDS*, the most popular MDS model. It maps the proximities of the n objects (δ_{ij}) into distances d_{ij} of the $n \times m$ configuration $\mathbf{X}$ such that their ranks are optimally preserved. Hence, assuming that the δ_{ij}'s are dissimilarities, the function $f : \delta_{ij} \rightarrow d_{ij}(\mathbf{X})$ is monotone so that $f : \delta_{ij} < \delta_{kl} \rightarrow d_{ij}(\mathbf{X}) \leq d_{kl}(\mathbf{X})$, for all pairs (i,j) and (k,l) for which

data are given. Missing data impose no constraints onto the distances.

Another popular MDS model is *interval MDS*, where $f : \delta_{ij} \rightarrow a + b \cdot \delta_{ij} = d_{ij}(\mathbf{X})$. This model assumes that the data are given on an interval scale. Hence, both a and $b(\neq 0)$ can be chosen arbitrarily. In particular, they can be chosen such that the re-scaled proximities are equal to the distances of a given MDS configuration $\mathbf{X}$.

A second facet of an MDS model is the distance function that it uses. In psychology, the family of *Minkowski distances* has been studied extensively as a model of judgment. Minkowski distances can be expressed by the formula

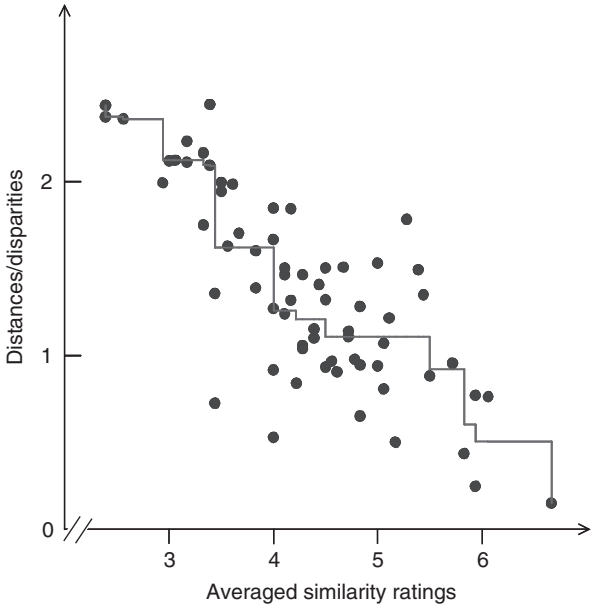
$$d_{ij}^{(p)}(\mathbf{X}) = \left(\sum_{a=1}^{m} |x_{ia} - x_{ja}|^p \right)^{1/p}, p \geq 1. \quad (1)$$

Setting $p = 1$ results in the *city-block metric*, setting $p = 2$ in the *Euclidean distance*. If p grows, d_{ij} is quickly dominated by its largest intra-dimensional difference (out of the $a = 1, \ldots, m$ dimensions). Such metrics supposedly explain fast and frugal (dis)similarity judgments. The city-block metric, in contrast, models careful judgments with important consequences for the individual. When MDS is used for exploratory purposes, however, only $p = 2$ should be used, because all other choices imply geometries with non-intuitive properties.

The fit of the MDS representation to the data can be seen from its *Shepard diagram*. For our country-similarity example, this is shown in Fig. 2. The plot exhibits how the data are related to the distances. It also shows the monotone regression line. The vertical scatter of the points about this regression line corresponds to the model's loss or misfit. It is measured as $\sum_{i<j} e_{ij}^2 = \sum_{i<j} (d_{ij}(\mathbf{X}) - f(\delta_{ij}))^2$, for all points i und j. The $f(\delta_{ij})$'s here are *disparities*, i.e., proximities that are re-scaled using all admissible transformations of the chosen scale level to optimally approximate the corresponding distances of the MDS configuration $\mathbf{X}$. The optimization is done by ordinal or linear regression (or, generally, by regression of type f) so that $f(\delta_{ij}) = \widehat{d}_{ij}(\mathbf{X})$. In order to obtain an interpretable measure of model misfit, the error sum is normed to yield the standard MDS loss function

$$Stress = \sqrt{\sum_{i<j} (d_{ij}(\mathbf{X}) - \widehat{d}_{ij})^2 / \sum_{i<j} d_{ij}^2(\mathbf{X})}. \quad (2)$$

A perfect MDS solution has a Stress of zero. In this case, the distances of the MDS solution correspond perfectly to the disparities. For the above example, we get Stress = 0.19. Evaluating if this is an acceptably low value is complex. A minimum criterion is that the observed Stress value should be clearly smaller than the Stress that results for random data. Other criteria (such as the number of points (n), the number of missing data, the restrictiveness of the MDS model, or the dimensionality of the MDS space (m)), but also the interpretability of the solution have to be taken into account. Indeed, it may be true that Stress is high but the configuration is nevertheless stable over replications of the data. This case can result if the data have a large random error component. MDS, then, acts as a *data smoother* that irons out the error in the distance representation.



Multidimensional Scaling. Fig. 2 Shepard diagram of MDS solution in Fig. 1

MDS methods allow one to utilize many different proximity measures. One example is direct judgments of similarity or dissimilarity as in the example given above. Another example are intercorrelations of test items over a sample of persons. A third example are co-occurrence coefficients that assess how often an event X is observed together with another event Y.

MDS is also robust against randomly distributed missing data. Computer simulations show that some 80% of the proximities may be missing, provided the data contain little error and the number of points (n) is high relative to the dimensionality of the MDS space (m). The data can also be quite coarse and even dichotomous.

A popular variety of MDS is *Individual Differences Scaling* or INDSCAL (Carroll and Chang 1970). Here, we have N different proximity matrices, one for each of N persons. The idea of the model is that these proximities can

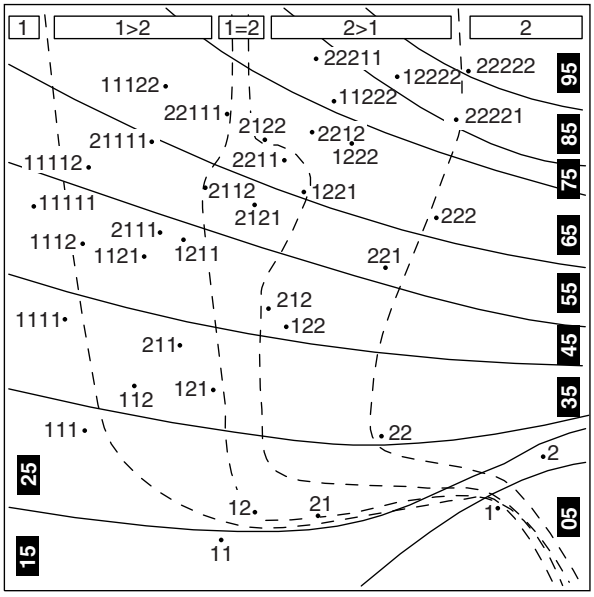
be explained by individually stretching or compressing a common MDS space along a fixed set of dimensions. That is,

$$d_{ij}^{(k)}(\mathbf{X}) = \sqrt{\sum_{a=1}^{m} w_a^{(k)} (x_{ia} - x_{ja})^2}, w_a^{(k)} \geq 0, \qquad (3)$$

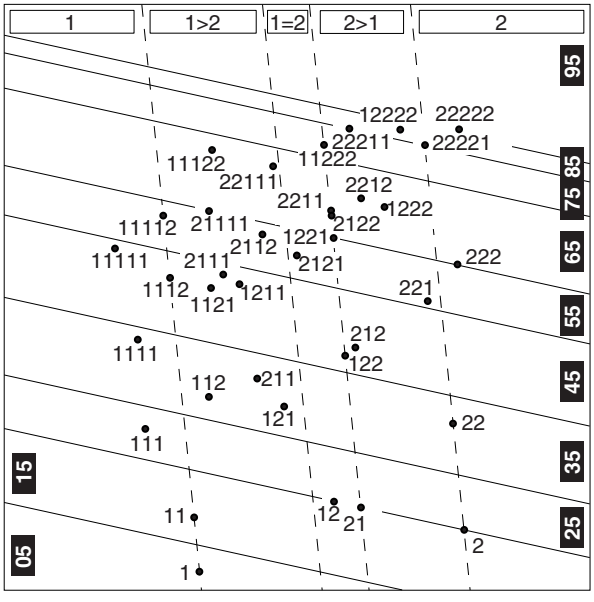
where $k = 1, \ldots, N$. The weight $w_a^{(k)}$ is interpreted as the salience of dimension a for individual k. Carroll and Wish (1974) used INDSCAL on the overall similarity ratings of different individuals for a set of countries, similar to the data discussed above. What they find is that one group of persons ("doves") pays much attention to economic development, while the other group ("falcons") emphasizes almost only political alignment of the countries with the West. Note, though, that these interpretations depend on the norming of $\mathbf{X}$. A more transparent way to analyze such data is to scale each individual's data matrix by itself, and then proceed by Procrustean fittings of the various solutions to each other, followed by finding optimal dimensions for an INDSCAL-type weighting model (Lingoes and Borg 1978).

A second popular variety of MDS is *Unfolding*. The prototypical data for this model are preference ratings of a set of persons for a set of objects. These data are mapped into distances between person-points and object-points in a "joint" space. The person-points are interpreted as "ideal" points that express the persons' points of maximal preference in the object space.

MDS solutions can be interpreted in different ways. The most popular approach is interpreting dimensions, but this is just a special case of interpreting regions. Regions are partitions of the MDS space which sort its points into subgroups that are equivalent in terms of substance. A systematic method for that purpose is *facet theory* (Borg and Shye 1995), an approach that offers methods to cross-classify the objects into substantively meaningful cells of a Cartesian product. The facets used for these classifications induce, one by one, partitions into the MDS space if they are empirically valid. The facets themselves are often based on theoretical considerations, but they can also be attributes that the objects possess by construction. Figure 3 shows an example. Here, (symmetrized) confusion probabilities of 36 Morse signals are represented as distances of a 2-dimensional MDS configuration. The space is partitioned by dashed lines into five regions that contain signals with only short beeps (coded as 1's); signals with more short than long (coded as 2's) beeps; etc. The solid lines cut the space into ten regions that each contain signals with equal duration (0.15 seconds to 0.95 seconds).



Multidimensional Scaling. Fig. 3 Exploratory MDS for confusion probabilities of 36 Morse signals



Multidimensional Scaling. Fig. 4 Confirmatory MDS for the Morse signals, enforcing linearized regions

The solution in Fig. 3 is found by *exploratory* ordinal MDS. There also exist various methods for *confirmatory* MDS that impose additional external constraints onto the MDS model. Figure 4 shows an example of an ordinal MDS with the additional constraint $\mathbf{X}$=$\mathbf{YC}$,

where **Y** is a 36 × 2 matrix of composition and duration codes, respectively, assigned to the 36 Morse signals; **C** is an unknown matrix of weights that re-scales **Y**'s columns monotonically. The confirmatory MDS procedure optimally represents the proximities in the sense of ordinal MDS while satisfying **X**=**YC**. The resulting configuration linearizes the regions of the MDS configuration which makes the solution easier to interpret. Provided its Stress is still acceptable, this is the preferred MDS representation, because it reflects a clear law of formation that is more likely to be replicable than an ad-hoc system of regions. Many alternative side constraints are conceivable. For example, an obvious modification is to require that **C** is diagonal. This enforces an orthogonal lattice of partitioning lines onto the solution in Fig. 4.

Many computer programs exist for doing MDS (for an overview, see Borg and Groenen (2005)). All large statistics packages offer MDS modules. One of the most flexible programs is Proxscal, one of the two MDS modules in Spss. The Spss package also offers Prefscal, a powerful program for unfolding. For R, De Leeuw and Mair (2009) have written a comprehensive MDS program called Smacof which can be freely downloaded from http://CRAN.R-project.org.

Multidimensional Scaling: An Introduction

Nataša Kurnoga Živadinović
Faculty of Economics and Business
University of Zagreb, Zagreb, Croatia

►Multidimensional scaling (MDS), also called perceptual mapping, is based on the comparison of objects (persons, products, companies, services, ideas, etc.). The purpose of MDS is to identify the relationships between objects and to represent them in geometrical form. MDS is a set of procedures that allows the researcher to map distances between objects in a multidimensional space into a lower-dimensional space in order to show how the objects are related.

MDS was introduced by Torgerson (1952). It has its origins in psychology where it was used to understand respondents' opinions on similarities or dissimilarities between objects. MDS is also used in marketing, management, finance, sociology, information science, political science, physics, biology, ecology, etc. For example, it can be used to understand the perceptions of respondents, to identify unrecognized dimensions, for segmentation analysis, to position different brands, to position companies, and so on (for descriptions of various examples, see Borg and Groenen 2005 and Hair et al. 2010).

MDS starts from the proximities between the objects that express the similarity between them. There are different types of MDS: metric MDS (the similarities data are quantitative; input and output matrices are metric) and nonmetric MDS (the similarities data are qualitative; input matrix is nonmetric).

The steps involved in conducting MDS consist of problem formulation, selection of MDS procedure, determination of the number of dimensions, interpretation, and

validation. Problem formulation includes several tasks. First, the objectives of MDS should be identified. The nature of the variables to be included in MDS should be specified. Also, an appropriate number of variables should be chosen as the number of variables influences the resulting solution. The selection of MDS procedure depends on the nature of the input data (metric or nonmetric). Nonmetric MDS procedures assume that the input data is ordinal, but the resulting output is metric. Metric MDS procedures assume that both input and output data are metric. MDS procedures estimate the relative position of each object in a multidimensional space. The researcher must decide on a number of dimensions. The objective is to achieve an MDS solution that best fits the data in the smallest number of dimensions. Though the fit improves as the number of dimensions increases, the interpretation becomes more complicated. The interpretation of the dimensions and the configuration require subjective judgment, including some elements of judgment on the part of both the researcher and the respondent. The objectives of MDS are not achieved if an appropriate interpretation is lacking. Ultimately, the researcher must consider the quality of the MDS solution. (For detailed descriptions of MDS steps, see Cox and Cox 2001, Hair et al. 2010, and Kruskal and Wish 1978.)

To apply MDS, the distances between objects must first be calculated. The Euclidean distance is the most commonly used distance measure. The distance between objects A and B is given by $d_{AB} = \sqrt{\sum_{i=1}^{v}(x_{Ai} - x_{Bi})^2}$. MDS begins with a matrix $(n \times n)$ consisting of the distances between objects. From the calculated distances, a graph showing the relationship among objects is constructed.

The graphical representation used in MDS is a perceptual map, also called a spatial map. It represents the respondent's perceptions of objectives and shows the relative positioning of all analyzed objects. Let us suppose that there are five objects, A, B, C, D, and E. If objects A and B are judged by the respondents as most similar in comparison to all other pairs of objects (AC, AD, AE, BC, BD, etc.), the MDS procedures will position the objects A and B so that their distance is smaller than the distance of any other two objects. A perceptual map is constructed in two or more dimensions. In a two-dimensional map, objects are represented by points on a plane. In the case of a higher number of dimensions, graphical representation becomes more complicated.

MDS can be conducted at the individual or group level. At the individual level, perceptual maps should be constructed on a respondent-by-respondent base. At the group level, the average judgment of all respondents within a group should be established and the perceptual maps of one or more groups constructed.

Statistical packages such as statistical analysis system (SAS), statistical package for the social sciences (SPSS), Stata, and STATISTICA are suitable for MDS.

Methods closely related to MDS are factor analysis (see ►Factor Analysis and Latent Variable Modelling), ►correspondence analysis, and cluster analysis (see Borg and Groenen 2005, Hair et al. 2010; see also the entry ►Cluster Analysis: An Introduction).

Multilevel Analysis, Hierarchical Linear Models

The term "Multilevel Analysis" is mostly used interchangeably with "Hierarchical Linear Modeling," although strictly speaking these terms are distinct. Multilevel Analysis may be understood to refer broadly to the methodology of

research questions and data structures that involve more than one type of unit. This originated in studies involving several levels of aggregation, such as individuals and counties, or pupils, classrooms, and schools. Starting with Robinson's (1950) discussion of the *ecological fallacy*, where associations between variables at one level of aggregation are mistakenly regarded as evidence for associations at a different aggregation level (see Alker 1969, for an extensive review), this led to interest in how to analyze data including several aggregation levels. This situation arises as a matter of course in educational research, and studies of the contributions made by different sources of variation such as students, teachers, classroom composition, school organization, etc., were seminal in the development of statistical methodology in the 1980s (see the review in Chap. 1 of de Leeuw and Meijer 2008). The basic idea is that studying the simultaneous effects of variables at the levels of students, teachers, classrooms, etc., on student achievement requires the use of regression-type models that comprise error terms for each of those levels separately; this is similar to mixed effects models studied in the traditional linear models literature such as Scheffé (1959).

The prototypical statistical model that expresses this is the *Hierarchical Linear Model*, which is a mixed effects regression model for nested designs. In the two-level situation – applicable, e.g., to a study of students in classrooms – it can be expressed as follows. The more detailed level (students) is called the lower level, or level 1; the grouping level (classrooms) is called the higher level, or level 2. Highlighting the distinction with regular regression models, the terminology speaks of *units* rather than cases, and there are specific types of unit at each level. In our example, the level-1 units, students, are denoted by i and the level-2 units, classrooms, by j. Level-1 units are nested in level-2 units (each student is a member of exactly one classroom) and the data structure is allowed to be unbalanced, such that j runs from 1 to N while i runs, for a given j, from 1 to n_j. The basic two-level hierarchical linear model can be expressed as

$$Y_{ij} = \beta_0 + \sum_{h=1}^{r} \beta_h x_{hij} + U_{0j} + \sum_{h=1}^{p} U_{hj} z_{hij} + R_{ij}; \qquad (1a)$$

or, more succinctly, as

$$\mathbf{Y} = \mathbf{X}\beta + \mathbf{Z}\ \mathbf{U} + \mathbf{R}. \qquad (1b)$$

Here Y_{ij} is the dependent variable, defined for level-1 unit i within level-2 unit j; the variables x_{hij} and z_{hij} are the explanatory variables. Variables R_{ij} are residual terms, or error terms, at level 1, while U_{hj} for $h = 0, \ldots, p$ are residual terms, or error terms, at level 2. In the case $p = 0$ this is called a *random intercept model*, for $p \geq 1$ it is called a *random slope model*. The usual assumption is that all R_{ij} and all vectors $U_j = (U_{0j}, \ldots, U_{pj})$ are independent, R_{ij} having a normal $\mathcal{N}(0, \sigma^2)$ and U_j having a multivariate normal $\mathcal{N}_{p+1}(\mathbf{0}, \mathbf{T})$ distribution. Parameters β_h are regression coefficients (fixed effects), while the U_{hj} are random effects. The presence of both of these makes (1) into a mixed linear model. In most practical cases, the variables with random effects are a subset of the variables with fixed effects ($x_{hij} = z_{hij}$ for $h \leq p$; $p \leq r$), but this is not necessary.

More Than Two Levels

This model can be extended to a three- or more-level model for data with three or more nested levels by including random effects at each of these levels. For example, for a three level structure where level-3 units are denoted by $k = 1, \ldots, M$, level-2 units by $j = 1, \ldots, N_k$, and level-1 units by $i = 1, \ldots, n_{ij}$, the model is

$$Y_{ijk} = \beta_0 + \sum_{h=1}^{r} \beta_h x_{hijk} + U_{0jk} + \sum_{h=1}^{p} U_{hjk} z_{hijk} + V_{0k} + \sum_{h=1}^{q} V_{hk} w_{hijk} + R_{ijk}, \qquad (2)$$

where the U_{hjk} are the random effects at level 2, while the V_{hk} are the random effects at level 3. An example is research into outcome variables Y_{ijk} of students (i) nested in classrooms (j) nested in schools (k), and the presence of error terms at all three levels provides a basis for testing effects of pupil variables, classroom or teacher variables, as well as school variables.

The development both of inferential methods and of applications was oriented first to this type of nested models, but much interest now is given also to the more general case where the restriction of nested random effects is dropped. In this sense, multilevel analysis refers to methodology of research questions and data structures that involve several sources of variation – each type of units then refers to a specific source of variation, with or without nesting. In social science applications this can be fruitfully applied to research questions in which different types of *actor* and *context* are involved; e.g., patients, doctors, hospitals, and insurance companies in health-related research; or students, teachers, schools, and neighborhoods in educational research. The word "level" then is used for such a type of units. Given the use of random effects, the most natural applications are those where each "level" is associated with some population of units.

Longitudinal Studies

A special area of application of multilevel models is longitudinal studies, in which the lowest level corresponds to repeated observations of the level-two units. Often the level-two units are individuals, but these may also be organizations, countries, etc. This application of mixed effects models was pioneered by Laird and Ware (1982). An important advantage of the hierarchical linear model over other statistical models for longitudinal data is the possibility to obtain parameter estimates and tests also under highly unbalanced situations, where the number of observations per individual, and the time points where they are measured, are different between individuals. Another advantage is the possibility of seamless integration with nesting if individuals within higher-level units.

Model Specification

The usual considerations for model specification in linear models apply here, too, but additional considerations arise from the presence in the model of the random effects and the data structure being nested or having multiple types of unit in some other way. An important practical issue is to avoid the ecological fallacy mentioned above; i.e., to attribute fixed effects to the correct level. In the original paper by Robinson (1950), one of the examples was about the correlation between literacy and ethnic background as measured in the USA in the 1930s, computed as a correlation at the individual level, or at the level of averages for large geographical regions. The correlation was .203 between individuals, and .946 between regions, illustrating how widely different correlations at different levels of aggregation may be.

Consider a two-level model (1) where variable X_1 with values x_{1ij} is defined as a level-1 variable – literacy in Robinson's example. For "level-2 units" we also use the term "groups." To avoid the ecological fallacy, one will have to include a relevant level-2 variable that reflects the composition of the level-2 units with respect to variable X_1. The mostly used composition variable is the group mean of X_1,

$$\bar{x}_{1.j} = \frac{1}{n_j} \sum_{i=1}^{n_j} x_{1ij}.$$

The usual procedure then is to include x_{1ij} as well as $\bar{x}_{1.j}$ among the explanatory variables with fixed effects. This allows separate estimation of the within-group regression (the coefficient of x_{1ij}) and the between-group regression (the sum of the coefficients of x_{1ij} and $\bar{x}_{1.j}$).

In some cases, notably in many economic studies (see Greene 2003), researchers are interested especially in the within-group regression coefficients, and wish to control for the possibility of unmeasured heterogeneity between the groups. If there is no interest in the between-group regression coefficients one may use a model with fixed effects for all the groups: in the simplest case this is

$$Y_{ij} = \beta_0 + \sum_{h=1}^{r} \beta_h x_{hij} + \gamma_j + R_{ij}. \qquad (3)$$

The parameters γ_j (which here have to be restricted, e.g., to have a mean 0 in order to achieve identifiability) then represent all differences between the level-two units, as far as these differences apply as a constant additive term to all level-1 units within the group. For example in the case of longitudinal studies where level-2 units are individuals and a linear model is used, this will represent all time-constant differences between individuals. Note that (3) is a linear model with only one error term.

Model (1) implies the distribution

$$\mathbf{y} \sim \mathcal{N}_p \left(\mathbf{X}\beta, \mathbf{Z}\,\mathbf{T}\,\mathbf{Z}' + \sigma^2 I \right).$$

Generalizations are possible where the level-1 residual terms R_{ij} are not i.i.d.; they can be heteroscedastic, have time-series dependence, etc. The specification of the variables Z having random effects is crucial to obtain a well-fitting model. See Chap. 9 of Snijders and Bosker (1999), Chap. 9 of Raudenbush and Bryk (2002), and Chap. 3 of de Leeuw and Meijer (2008).

Inference

A major reason for the take-off of multilevel analysis in the 1980s was the development of algorithms for maximum likelihood estimation for unbalanced nested designs. The EM algorithm (Dempster et al. 1981), Iteratively Reweighted Least Squares (Goldstein 1986), and Fisher Scoring (Longford 1987) were applied to obtain ML estimates for hierarchical linear models. The MCMC implementation of Bayesian procedures has proved very useful for a large variety of more complex multilevel models, both for non-nested random effects and for generalized linear mixed models; see Browne and Draper (2000) and Chap. 2 of de Leeuw and Meijer (2008).

Hypothesis tests for the fixed coefficients β_h can be carried out by Wald or Likelihood Ratio tests in the usual way. For testing parameters of the random effects, some care must be taken because the estimates of the random effect variances τ^2_{hh} (the diagonal elements of $\mathbf{T}$) are not approximately normally distributed if $\tau^2_{hh} = 0$. Tests for these parameters can be based on estimated fixed effects, using least squares estimates for U_{hj} in a specification where these are treated as fixed effects (Bryk and Raudenbush 2002, Chap. 3); based on appropriate distributions of the log likelihood ratio; or obtained as score tests (Berkhof and Snijders 2001).

About the Author

Professor Snijders is Elected Member of the European Academy of Sociology (2006) and Elected Correspondent of the Royal Netherlands Academy of Arts and Sciences (2007). He was awarded the Order of Knight of the Netherlands Lion (2008). Professor Snijders was Chairman of the Department of Statistics, Measurement Theory, and Information Technology, of the University of Groningen (1997–2000). He has supervised 52 Ph.D. students. He has been associate editor of various journals, and Editor of *Statistica Neerlandica* (1986–1990). Currently he is co-editor of *Social Networks*, Associate editor of *Annals of Applied Statistics*, and Associate editor of *Journal of Social Structure*. Professor Snijders has (co-)authored about 100 refereed papers and several books, including *Multilevel analysis. An introduction to basic and advanced multilevel modeling*. (with Bosker, R.J., London etc.: Sage Publications, 1999). In 2005, he was awarded an honorary doctorate in the Social Sciences from the University of Stockholm.

Multinomial Distribution

George A. F. Seber
Emeritus Professor of Statistics
Auckland University, Auckland, New Zealand

The Multinomial distribution arises as a model for the following experimental situation. An experiment or "trial" is carried out and the outcome occurs in one of k mutually exclusive categories with probabilities p_i, $i = 1, 2, \ldots, k$. For example, a person may be selected at random from a population of size N and their ABO blood phenotype recorded as A, B, AB, or O ($k = 4$). If the trial is repeated n times such that the trials are mutually independent, and if x_i is the frequency of occurrence in the ith category, then the joint probability function of the x_i is

$$P_1(x_1, x_1, \ldots, x_k) = \frac{n!}{x_1!x_2!\cdots x_k!} p_1^{x_1} p_2^{x_2} \cdots p_k^{x_k},$$

where $\sum_{i=1}^{k} x_i = n$ and $\sum_{1=1}^{k} p_i = 1$. This would be the correct probability function for the genetics example if further people were chosen with replacement. In practice, sampling is without replacement and the correct distribution is the multivariate hypergeometric, a difficult distribution to deal with. Fortunately, all is not lost, as when the sampling fraction $f = n/N$ is small enough (say less than 0.1 or preferably less than 0.05), the Multinomial distribution

is a good approximation and is used extensively in genetics (e.g., Greenwood and Seber 1992). We note that when $k = 2$ we have the ▶Binomial distribution. Also the terms of P_1 can be obtained by expanding $(p_1 + p_2 + \cdots + p_k)^n$.

Various properties of the Multinomial distribution can be derived using extensive algebra. However, they are more readily obtained by noting that any subset of a multinomial distribution is also Multinomial. We simply group the categories relating to the remaining variables into a single category. For example x_i will have a Binomial distribution as there are just two categories, the ith and the rest combined. Hence the mean and variance of x_i are

$$\mathrm{E}(x_i) = np_i \text{ and } \mathrm{var}(x_i) = np_iq_i,$$

where $q_i = 1 - p_i$. Also, if we combine the ith and jth category and then combine the rest into single category, we see that $x_i + x_j$ is Binomial with probability parameter $p_i + p_j$ and variance $n(p_i + p_j)(1 - p_i - p_j)$. Hence the covariance of x_i and x_j is

$$\mathrm{cov}(x_i, x_j) = \frac{1}{2}[\mathrm{var}(x_i + x_j) - \mathrm{var}(x_i) - \mathrm{var}(x_j)] = -np_ip_j.$$

Another useful result that arises in comparing proportions p_i and p_j in a ▶questionnaire is

$$\begin{aligned}\mathrm{var}(x_i - x_j) &= \mathrm{var}(x_i) + \mathrm{var}(x_j) - 2\mathrm{cov}(x_i, x_j)\\ &= n[p_i + p_j - (p_i - p_j)^2]. \end{aligned} \quad (1)$$

It should be noted that the Multinomial distribution given above is a "singular" distribution as the random variables satisfy the linear constraint $\sum_{i=1}^{k} x_i = n$, which leads to a singular variance-covariance matrix. We can instead use the "nonsingular" version

$$P_2(x_1, x_2, \ldots, x_{k-1}) = \frac{n!}{x_1!x_2!\cdots\left(n - \sum_{i=1}^{k-1} x_i\right)!} \times p_1^{x_1}p_2^{x_2}\cdots p_k^{n-\sum_{i=1}^{k-1} x_i}.$$

We note that the joint ▶moment generating function of $\boldsymbol{x}$ is

$$M(\boldsymbol{t}) = (p_1e^{t_1} + p_2e^{t_2} + \cdots + p_{k-1}e^{t_{k-1}} + p_k)^n,$$

which can also be used to derive the above properties of the Multinomial distribution as well as the ▶asymptotic normality properties described next.

Let $\hat{p}_i = x_i/n$ be the usual estimate of p_i. Given the vectors $\hat{\boldsymbol{p}} = (\hat{p}_1, \hat{p}_2, \ldots, \hat{p}_{k-1})'$ and $\boldsymbol{p} = (p_1, p_2, \ldots, p_{k-1})'$, then the mean of $\hat{\boldsymbol{p}}$ is $\boldsymbol{p}$ and its variance-covariance matrix is $n^{-1}\boldsymbol{V}$, where $\boldsymbol{V} = (\mathrm{diag}\,\boldsymbol{p} - \boldsymbol{p}\boldsymbol{p}')$ and $\mathrm{diag}\,\boldsymbol{p}$ is a diagonal matrix with diagonal elements $p_1, p_2, \ldots p_{k-1}$. In the same way that a Binomial random variable is asymptotically normal for large n, $\sqrt{n}(\hat{\boldsymbol{p}} - \boldsymbol{p})$ is asymptotically multivariate Normal with mean vector 0 and variance-covariance matrix $\boldsymbol{V}$. If $\boldsymbol{V}^{-1}$ is the inverse of $\boldsymbol{V}$, then $\boldsymbol{V}^{-1} = n^{-1}\left((\mathrm{diag}\,\boldsymbol{p})^{-1} + p_k^{-1}1_{k-1}'1_{k-1}\right)$, where 1_{k-1} is a column $k-1$ ones (cf. Seber, 2008, 15.7). From the properties of the multivariate Normal distribution (cf. Seber 2008, 20.25),

$$n(\hat{\boldsymbol{p}} - \boldsymbol{p})'\boldsymbol{V}^{-1}(\hat{\boldsymbol{p}} - \boldsymbol{p}) = \sum_{i=1}^{k} \frac{(x_i - np_i)^2}{np_i} \quad (2)$$

will be asymptotically distributed as the ▶Chi-square distribution with $k-1$ degrees of freedom. If we use the singular version and include x_k to expand $\boldsymbol{V}$ to $\boldsymbol{V}_k$, we can obtain the result more quickly using a generalized inverse (cf. Seber, 2008, 20.29b using $\boldsymbol{A} = \boldsymbol{V}_k^{-} = (\mathrm{diag}\,(\boldsymbol{p}', p_k)')^{-1}$). This link with the Chi-square distribution forms the basis of a number of tests involving the Multinomial distribution mentioned below.

We see that $P_1(\cdot)$ above can be regarded conceptually as a nonsingular distribution for the x_i $(i = 1, 2, \ldots, k)$ with probabilities π_i, but conditional on $\sum_{i=1}^{k} x_i = n$ with $p_i = \pi_i / \sum_{i=1}^{k} \pi_i$. It therefore follows that the joint distribution of any subset of multinomial variables conditional on their sum is also multinomial. For example, the distribution of x_1 and x_2 given $x_1 + x_2 = n$ is Binomial with probability parameter $p_1/(p_1 + p_2)$. We get a similar result in ecology where we have a population of plants divided up into k areas with x_i in the ith area being distributed as the Poisson distribution with mean μ_i. If the x_i are mutually independent, then the joint distribution of the x_i conditional on the sum $\sum_{i=1}^{k} x_i$ is Multinomial with probabilities $p_i = \mu_i / \sum_{j=1}^{k} \mu_j$.

The last topic I want to consider briefly is inference for the multinomial distribution. Estimating p_i by $\hat{p}_i = x_i/n$, using the normal approximation, and applying (1), we can obtain a confidence interval for any particular p_i or any particular difference $p_i - p_j$. Simultaneous confidence interval procedures are also available for all the p_i or all differences using the Bonferroni method. We can also test $\boldsymbol{p} = \boldsymbol{p}_0$ using (2).

A common problem is testing the hypothesis H_0 : $\boldsymbol{p} = \boldsymbol{p}(\boldsymbol{\theta})$, where $\boldsymbol{p}$ is a known function of some unknown t-dimensional parameter $\boldsymbol{\theta}$ (e.g., the genetics example above). This can be done using a derivation like the one that led to (2) above, giving the so-called "goodness of fit" statistic, but with $\boldsymbol{p}$ replaced by $\boldsymbol{p}(\hat{\boldsymbol{\theta}})$. Here $\hat{\boldsymbol{\theta}}$, the maximum likelihood estimate of $\boldsymbol{\theta}$, is asymptotically Normal so that $\boldsymbol{p}(\hat{\boldsymbol{\theta}})$ is also asymptotically Normal. Under H_0, it can be shown that the test statistic is approximately Chi-square with degrees of freedom now $k - 1 - t$.

One application of the above is to the theory of contingency tables. We have an $r \times c$ table of observations x_{ij}

$(i = 1, 2, \ldots, r; j = 1, 2, \ldots, c)$ and p_{ij} is the probability of falling in the (i, j)th category. Treating the whole array as a single Multinomial distribution, one hypothesis of interest is $H_0 : p_{ij} = \alpha_i \beta_j$, where $\sum_{i=1}^{r} \alpha_i = 1$ and $\sum_{j=1}^{c} \beta_j = 1$. In this hypothesis of row and column independence, we have $\boldsymbol{\theta}' = (\alpha_1, \ldots \alpha_{r-1}, \beta_1, \ldots, \beta_{c-1})$ with maximum likelihood estimates $\hat{\alpha}_i = R_i/n$ and $\hat{\beta}_j = c_j/n$, where r_i is the ith row sum of the table and c_j the jth column sum. The statistic for the test of independence is therefore

$$\sum_{i=1}^{r} \sum_{j=1}^{c} \frac{(x_i - r_i c_j/n)^2}{r_i c_j/n}, \tag{3}$$

which, under H_0, is approximately Chi-square with $rc - 1 - (r-1) - (c-1) = (r-1)(c-1)$ degrees of freedom. If the rows of the $r \times c$ table now represents r independent Multinomial distributions with $\sum_{j=1}^{c} p_{ij} = 1$ for $i = 1, 2, \ldots, r$, then the hypothesis that the distributions are identical is $H_0 : p_{ij} = \gamma_j$ for $i = 1, 2, \ldots, r$, where $\sum_{j=1}^{c} \gamma_j = 1$. Pooling the common distributions, the maximum likelihood estimate of γ_j is $\hat{\gamma}_j = c_j/n$ so that the term $np_{ij}(\hat{\theta})$ becomes $r_i \hat{\gamma}_j$ and the test statistic for testing homogeneity turns out to be the same as (3) with the same degrees of freedom.

The above chi-squared tests are not particularly powerful and need to be backed up with various confidence interval procedures. Other asymptotically equivalent tests are the likelihood ratio test and the so-called "score" (Lagrange multiplier) test. Log linear models can also be used. For further properties of the Multinomial distribution see Johnson et al. (1997, Chap. 35) and asymptotic background theory for the chi-squared tests is given by Bishop et al. (1975, Chap. 14). More recent developments are given by Agresti (2002).

Multi-Party Inference and Uncongeniality

Xiao-Li Meng
Professor, Chair
Harvard University, Cambridge, MA, USA

► *"Life is more complicated when you have three uncongenial models involved."*

The Multi-Party Inference Reality

Much of the statistical inference literature uses the familiar framework of "God's model versus my model." That is, an unknown model, "God's model," generates our data, and our job is to infer this model or at least some of its characteristics (e.g., moments, distributional shape) or implications (e.g., prediction). We first postulate one or several models, and then use an array of estimation, testing, selection, and refinement methods to settle on a model that we judge to be acceptable – according to some sensible criterion, hopefully pre-determined – for the inference goals at hand, even though we almost never can be sure that our chosen model resembles God's model in critical ways. Indeed, philosophically even the existence of God's model is not a universally accepted concept, just as theologically the existence of God is not an unchallenged notion.

Whether one does or does not adopt the notion of God's model, it is repeatedly emphasized in the literature that to select a reasonable model, an iterative process is necessary and hence multiple models are typically considered (e.g., see Box and Tiao 1973, Chap. 1; Gelman and Meng 1996). By *multiple models* we mean multiple sets of mathematically quantifiable assumptions (hence, not necessarily parametric models), which are compatible within each set but not across different sets. Indeed, if they are not incompatible across different sets then one is simply postulating a larger model; see McCullagh (2002). In this

sense we automatically take a "monotheistic" point of view that there is only one God's model; we assume God's model contains no self-contradiction (or at least none detectable by a human modeler). However, we do not go so far as to suggest that the modeler can always embed everything into one model, e.g., as in Bayesian model averaging, because contrasting models sometimes is as useful as, if not more so than, combining models.

Whereas many models may be entertained, the commonly accepted paradigm involves only two parties: the (hypothetical) God, and "me" – the modeler. Unfortunately, reality is far more complicated. To explain the complication, we must distinguish the *modeler's data* from *God's data*. The modeler's data are the data available to the modeler, whereas God's data are the realizations from God's model that the modeler's data were collected to *approximate*. Whereas any attempt to mathematically define such concepts is doomed to fail, it is useful to distinguish the two forms of data because the *approximation* process introduces an additional inference party (or parties).

For example, in the physical sciences, the modeler's data typically are results of a series of pre-processing steps to deal with limitations or irregularities in recording God's data (e.g., discarding "outliers" (see ►Outliers); recalibration to account for instrument drift), and typically the modeler at best only has partial information about this process. For the social and behavioral sciences, some variables are not even what we normally think they are, such as responses to a questionnaire survey. Rather, they are so-called "constructed variables," typically from a deterministic algorithm converting a set of answers to an index that indicates, say, whether a subject is considered to suffer major depression. The algorithm is often a black box, and in some cases it is pitch black because the modeler is not even informed of what variables were used as inputs to produce the output. In the context of public-use data files, virtually all data sets contain imputations of some sort (see ►Imputation) because of non-responses or other forms of missing data (e.g., missingness by design such as with matrix sampling), which means someone has "fixed the holes" in the data before they reach the modeler.

In all these examples, the key issue is not that there is data pre-processing step per se, but rather that during the journey from God's data to modeler's data, a set of assumptions has been introduced. There is no such thing as "assumption-free" pre-processing; any attempt to make the data "better" or "more usable" implies that a judgment has been made. Under the God-vs.-me paradigm, this intermediate "data cleaning" process has to be considered either as part of God's model, or of the modeler's model, or of both by somehow separating aspects of the process (e.g., one could argue that a refused answer to an opinion question is an opinion itself, whereas a refusal to an income question is a non-response). Regardless of how we conceptualize, we find ourselves in an extremely muddy – if not hopeless – situation. For example, if aspects of this intermediate process are considered to be part of God's model, then the modeler's inference is not just about God's model but also about someone else's assumptions about it. If we relegate the pre-processing to the modeler's model, then the modeler will need good information on the process. Whereas there has been an increasing emphasis on understanding the entire mechanism that leads to the modeler's data, the reality is that for the vast majority of real-life data sets, especially large-scale ones, it is simply impossible to trace back how the data were collected or pre-processed. Indeed, many such processes are nowhere documented, and some are even protected by confidentiality constraints (e.g., confidential information may be used for imputation by a governmental agency).

This intermediate "data cleaning" process motivates the *multi-party inference* paradigm. The term is self-explanatory: we acknowledge that there is more than one party involved in reaching the final inference. The key distinction between the multi-party paradigm and the God-vs.-me paradigm is not that the former involves more sets of assumptions, i.e., models – indeed under the latter we still almost always (should) consider multiple models. Rather, in the multi-party paradigm, we explicitly acknowledge the *sequential nature* of the parties' involvement, highlighted by how the intermediate party's assumptions impact the final inference, because typically they are necessarily incompatible with the modeler's assumptions, due both to the parties' having access to different amounts of information and to their having different objectives.

This situation is most vividly demonstrated by multiple imputation inference (Rubin 1987), where the intermediate party is the imputer. (There is often more than one intermediate party even in the imputation context, but the case of a single imputer suffices to reveal major issues.) In such a setting, the concept of *congeniality* (Meng 1994) is critical. In a nutshell, congeniality means that the imputation model and the analysis model are compatible for the purposes of predicting the missing data. In real life, this typically is not the case, even if the imputer and analyst are the same entity, because of the different aims of imputation (where one wants to use as many variables as possible even if causal directions are incorrectly specified) and of analysis (where one may be only interested in a subset of variables with specified causal directions). The next section demonstrates the importance

of recognizing *uncongeniality*, which directly affects the validity of the final inferences. The concept of uncongeniality was originally defined and has thus far been investigated in the context of multiple imputation inference, the most well-studied case of multi-party inference. However, its general implication is broad: to reach valid inference when more than one party is involved, we must consider the incompatibility/uncongeniality among their assumptions/models, even if each party has made assumptions that are consistent with God's model and has carried out its task in the best possible way given the information available at the time.

Uncongeniality in Multiple Imputation Inference

A common method for dealing with non-response in surveys and incomplete data in general is imputation (Little and Rubin 2002). Briefly, imputation is a prediction of the missing data from a posited (not necessarily parametric) model $p_I(Y_{mis}|Y_{obs})$, where Y_{mis} denotes the missing data and Y_{obs} the observed data. The trouble with single imputation, however sophisticated, is that the resulting data set cannot be analyzed in the same way as would an authentic complete data set, without sacrificing the validity of the inference. Multiple imputation (MI; Rubin 1987) attempts to circumvent this problem by providing multiple predictions from $p_I(Y_{mis}|Y_{obs})$, thereby permitting, via genuine replications, a direct assessment of uncertainties due to imputation.

Specifically, in the MI framework, we draw independently m times from $p_I(Y_{mis}|Y_{obs})$, resulting in m completed-data sets: $Y_{com}^{(\ell)} = \left\{Y_{obs}, Y_{mis}^{(\ell)}\right\}, \quad \ell = 1, \ldots, m.$ Suppose our complete-data analysis can be summarized by a point estimator $\hat{\theta}(Y_{com})$ and an associated variance estimator $U(Y_{com})$, where Y_{com} denotes $\{Y_{mis}, Y_{obs}\}$. The MI inference procedure consists of the following steps:

Step 1: Perform m complete-data analyses as if each $Y_{com}^{(\ell)}$ were real data:

$$\hat{\theta}_\ell \equiv \hat{\theta}\left(Y_{com}^{(\ell)}\right), \text{ and } U_\ell \equiv U\left(Y_{com}^{(\ell)}\right), \quad \ell = 1, \ldots, m.$$

Step 2: Use Rubin's Combining Rules:

$$\bar{\theta}_m = \frac{1}{m}\sum_{\ell=1}^{m} \hat{\theta}_\ell, \text{ and } T_m = \bar{U}_m + \left(1 + \frac{1}{m}\right) B_m,$$

where

$$\bar{U}_m = \frac{1}{m}\sum_{\ell=1}^{m} U_\ell \text{ and } B_m = \frac{1}{m-1}\sum_{\ell=1}^{m} (\hat{\theta}_\ell - \bar{\theta}_m)(\hat{\theta}_\ell - \bar{\theta}_m)^\top$$

are respectively the within-imputation variance and the between-imputation variance, to reach the MI inference $\{\bar{\theta}_m, T_m\}$, with T_m the variance estimator of $\bar{\theta}_m$.

The justification of Rubin's combining rules is most straightforward under strict congeniality, which means that both the analyst and the imputer use (effectively) Bayesian models, and their Bayesian models are compatible. That is, we assume:

(I) The complete-data analysis procedure can be embedded into a Bayesian model, with

$$\hat{\theta}(Y_{com}) = E_A(\theta|Y_{com}) \text{ and } U(Y_{com}) = \mathrm{V}_A(\theta|Y_{com}),$$

where the subscript A indexes expectation with respect to the embedded analysis model;

(II) The imputer's model and the (embedded) analysis model are the same for the purposes of predicting missing data:

$$P_I(Y_{mis}|Y_{obs}) = P_A(Y_{mis}|Y_{obs}), \quad \textit{for all } Y_{mis} \textit{ (but the given } Y_{obs}).$$

Then for $\bar{\theta}_m$ as $m \to \infty$, we have

$$\begin{aligned}\bar{\theta}_\infty &= \mathrm{E}_I\left[\hat{\theta}(Y_{com})\middle|Y_{obs}\right] \\ &< \text{by (I)} > = \mathrm{E}_I\left[\mathrm{E}_A(\theta|Y_{com})\middle|Y_{obs}\right] \\ &< \text{by (II)} > = \mathrm{E}_A\left[\mathrm{E}_A(\theta|Y_{com})\middle|Y_{obs}\right] = \mathrm{E}_A(\theta|Y_{obs}).\end{aligned}$$

That is, the MI estimator $\bar{\theta}_m$ simply is a consistent (Monte Carlo) estimator of the posterior mean under the analyst's model based on the observed data Y_{obs}. The critical role of (II) is also vivid in establishing the validity of $T_m = \bar{U}_m + (1 + m^{-1})B_m$ as $m \to \infty$:

$$\begin{aligned}\bar{U}_\infty + B_\infty &= E_I[U(Y_{com})|Y_{obs}] + \mathrm{V}_I[\hat{\theta}(Y_{com})|Y_{obs}] \\ &< by\ (I) > = E_I[\mathrm{V}_A(\theta|Y_{com})|Y_{obs}] \\ &\quad + \mathrm{V}_I[E_A(\theta|Y_{com})|Y_{obs}] \\ &< by\ (II) > = E_A[\mathrm{V}_A(\theta|Y_{com})|Y_{obs}] \\ &\quad + \mathrm{V}_A[E_A(\theta|Y_{com})|Y_{obs}] = \mathrm{V}_A(\theta|Y_{obs}).\end{aligned}$$

Therefore, as $m \to \infty$, $\{\bar{\theta}_m, T_m\}$ reproduces the posterior mean and posterior variance under the analyst's model given Y_{obs}, because $\bar{\theta}_\infty = E_A(\theta|Y_{obs})$ and $T_\infty = \mathrm{V}_A(\theta|Y_{obs})$.

When congeniality fails, either because the analyst's procedure does not correspond to any Bayesian model or because the corresponding Bayesian model is incompatible with the imputer's model, the MI variance estimator T_m can overestimate or underestimate the variance of $\bar{\theta}_m$ even as $m \to \infty$. However, depending on the relationships

among God's model, the analyst's model and the imputer's model, we may still reach valid inference under uncongeniality. For example, under the assumption that the analyst's complete-data procedure is self-efficient (Meng 1994), if God's model is nested in the analyst's model, which in turn is nested in the imputer's model, then the MI confidence interval based on $\{\bar{\theta}_\infty, T_\infty\}$ is valid (asymptotically with respect to the size of the observed data). However, the MI estimator $\bar{\theta}_\infty$ may not be as efficient as the analyst's estimator (e.g., MLE) directly based on the observed data, because the additional assumptions built into the analysis model are not used by the imputer. But this comparison is immaterial when the analyst is unable to analyze the observed data directly, and therefore multiple imputation inference is needed (see ►Multiple Imputation).

However, the situation becomes more complicated if we assume God's model is nested in the imputer's model, which in turn is nested in the analyst's model. In such cases, it is possible to identify situations where the multiple imputation interval estimator is conservative in its own right, yet it is narrower than analyst's interval estimator (with the correct nominal coverage) directly based on the observed data (Xie and Meng 2010). This seemingly paradoxical phenomenon is due to the fact the imputer has introduced "secret" model assumptions into the MI inference, making it more efficient than the analyst's inference directly based on the observed data, which does not benefit from the imputer's assumptions. At the same time, since the analyst's complete-data procedure $\{\hat{\theta}(Y_{com}), U(Y_{com})\}$ is determined irrespective of the imputer's model, the imputer's secret assumption introduces uncongenality, which leads to the conservativeness of the MI interval. However, this is not to suggest that MI tends to be conservative, but rather to demonstrate the impact of imputation models on the MI inference and hence to provide practical guidelines on how to regulate the imputation models.

Even more complicated are situations where the analyst's and imputer's models do not nest, or where at least one of them does not contain God's model as a sub-model. Consequences of such are virtually undetermined at the present time, but one thing is clear. These complications remind us the importance of recognizing the multi-party inference paradigm, because the God-vs.-me paradigm sweeps all of them under the rug, or more precisely buries our heads in the sand, leaving our posteriors exposed without proper coverage.

About the Author

Dr Xiao-Li Meng started his outstanding career in 1982 as Instructor of Mathematics in China Textile University and 22 years later has become Professor and Chair of Statistics at one of the most prestigious universities in the world, Harvard University (2004–Present), USA. In July 2007 he was appointed as Whipple V.N. Jones Professor of Statistics at his department. In 2001 he was awarded for "the outstanding statistician under the age of forty" by the Committee of Presidents of Statistical Societies. In 2002 he was ranked (by Science Watch) among the world top 25 most cited mathematicians for articles published and cited during 1991–2000. Professor Meng was Editor of *Bayesian Analysis* (2003–2005), and Co-Chair Editor, *Statistica Sinica* (2005–2008). He was an Associate editor for following journals: *Bernoulli* (2004–2005), *Biometrika* (2002–2005), The *Annals of Statistics* (1997–2003), *Journal of the American Statistical Association* (1996–2002) and *Statistica Sinica* (1992–1997). Currently, he is Editor of *Statistics Series, IMS Monograph and Textbook Series*. He is an Elected Fellow of the Institute of Mathematical Statistics (1997) and American Statistical Association (2004). Professor Meng is a recipient of the University of Chicago Faculty Award for Excellence in Graduate Teaching (1997–1998). He has published over 100 papers in leading statistical journals, and is widely known for his contributions in statistical analysis with missing data, Bayesian modeling, statistical computation, in particular Markov chain Monte Carlo and EM-type algorithms. Multiplicity Issues

Statistical evidence is obtained by rejecting the null hypothesis at a "small" prespecified significance level α, say 0.05 or 0.01, which is an acceptable level of probability of the type I error (the error of rejecting the "true" null hypothesis). If we have a family of multiple hypotheses in a confirmatory experiment and test them simultaneously at each level α, the *overall* or *familywise type I error rate* (*FWER*), i.e., the probability of rejecting at least one "true" null hypothesis in the family, may inflate and exceed α, even if there exist no treatment differences. We call such inflation of the *FWER* a *multiplicity issue*.

Usually there may be some correlation structure between test statistics, and the inflation of the *FWER* might not be so remarkable. However, if we have multiple hypotheses to be tested for confirmatory purpose, we should adjust for multiplicity so as to control the *FWER* within α. This is called *multiplicity adjustment*. Testing procedures for multiplicity adjustment are called *multiple comparison procedures* (*MCPs*) or more generally *multiple testing procedures* (*MTPs*).

Multiplicity issues may arise in (1) multiple treatments (multiple comparisons), (2) multiple response variables (multiple endpoints), (3) multiple time points (longitudinal analysis), (4) multiple subgroups (subgroup analysis), and (5) multiple looks (interim analysis with group sequential methods or adaptive designs).

Hereafter we mainly concentrate on the multiple treatment comparisons, i.e., multiple comparisons in a traditional sense.

Multiple Comparisons

In a two group comparison of treatments A and B on their response means μ_A and μ_B, we have just one null hypothesis $H_0 : \mu_A = \mu_B$ to be tested and there is no need to adjust for multiplicity. However, when we compare three treatment groups, e.g., there are three treatments A, B and C, we may typically want to compare their means pairwisely, i.e., μ_A vs μ_B, μ_A vs μ_C and μ_B vs μ_C. Then there are three test hypotheses to be adjusted for multiplicity; namely, we need multiple comparison procedures.

All Pairwise Comparisons

The method to exactly control the *FWER* by adjusting the critical value in the above "all" pairwise comparisons is called *Tukey's method* (or *Tukey's multiple comparison test*). The method was developed for equal sample sizes, but even if the sample sizes are different between groups, the same critical value could be used conservatively, and such a method is known as the *Tukey-Kramer method*. The nonparametric version of Tukey's method is called the *Steel-Dwass test*.

Comparisons with a Control

The above three treatment example may have a structure that A and B are two (high and low) doses of a drug and C is a placebo (zero-dose). Then main interest in a formal analysis may be focused on the comparisons between each active dose and the placebo, i.e., μ_A vs μ_C and μ_B vs μ_C. This type of multiple comparison on treatment means can be performed by *Dunnett's method* (or *Dunnett's multiple comparison test*), and the common reference C is called a *control* or *control group*. The nonparametric version of Dunnett's method is called *Steel's test*.

If we assume the monotonicity of response means, such as $\mu_A \geq \mu_B \geq \mu_C$ or $\mu_A \leq \mu_B \leq \mu_C$, then in the comparison with a control, we can apply the *Williams test*, which is more powerful than Dunnett's test when the monotone dose-response relationship holds. The nonparametric version of the Williams test is known as the *Shirley-Williams test*.

Any Contrast Comparisons

More generally in a $k(\geq 3)$ treatment comparison, various hypotheses on any contrasts, such as, $\sum_{i=1}^{k} c_i \mu_i = 0$ where $\sum_{i=1}^{k} c_i = 0$, can be tested using *Scheffe's method* to control the *FWER*. For all pairwise comparisons or comparisons with a control, Scheffe's method is not recommended because it is "too" conservative in such cases. A nonparametric version of the Scheffe type multiple comparison method can be easily constructed.

Fixed Number of Comparisons

When the number of comparisons is fixed, the *Bonferroni method* (or *Dunn's method*) is simpler and easier to apply. The method only adjusts the significance level to α/m for each single test, where m is the number of interested comparisons. It is known that the method controls the *FWER* because the well-known *Bonferroni inequality*, $Pr\left(\bigcup_{i=1}^{m} E_i\right) \leq \sum_{i=1}^{m} Pr(E_i)$ holds, where E_i is an event to reject hypothesis H_i. In the above three treatment example, the Bonferroni method could be applied with $m = 3$ for Tukey-type, and with $m = 2$ for Dunnett-type multiple comparisons, although it might be rather conservative.

Stepwise Procedures

All the methods described above (except the Williams test) are called "*simultaneous tests*" or "*single step tests*", because none of tests considered are affected by the results of others, and statistical testing for each hypothesis can be done simultaneously or in a single step manner. They control the *FWER* and can be used to easily construct the corresponding simultaneous confidence intervals, but there is some tradeoff in that they have a low statistical power in compensation for controlling the *FWER*.

Recently, more powerful test procedures than single step or simultaneous test procedures have been developed and become popular. Most of them are based on the *closed testing procedure* (*CTP*) proposed by Marcus, Peritz and Gabriel (1976) and they have a stepwise property in their nature. *CTPs* give a very general scheme of stepwise *MCPs* (or *MTPs*).

Closed Testing Procedures (CTPs)

Suppose that we have a family of m null hypotheses $F = \{H_1, H_2, \ldots, H_m\}$ to be tested and let $N = \{1, 2, \ldots, m\}$ be an *index set* that indicates the set of hypotheses considered. Then there are $2^m - 1$ possible intersections of null hypotheses H_i. We denote a set or family of such *intersection hypotheses* by $G = \{H_I = \bigcap_{i \in I} H_i : I \subseteq N,\ I \neq \emptyset\}$, where $\emptyset$ is an empty set and each intersection hypothesis H_I means that all hypotheses $H_i, i \in I$ hold simultaneously and thus H_I represents one possibility of the "true" null hypothesis. Because we do not know which H_I is true, a given *MCP* (or *MTP*) should control the *FWER* under any H_I. This is called a *strong control of the FWER*. If we control the *FWER* only under the *complete* or *global null hypothesis*, $H_N = \bigcap_{i \in N} H_i$, it is called a *weak control of the FWER*.

CTPs are testing procedures in which each *elementary hypothesis* $H_i, i = 1, \ldots, m$, is rejected only if all the intersection hypotheses including H_i, i.e., all $H_I = \bigcap_{j \in I} H_j, i \in I$, are rejected by the *size* α *test*. It is easily shown that any *CTP* controls the *FWER* in a strong sense. The procedure is equivalent to a test that starts with the test of *complete null hypothesis* H_N at level α and then proceeds in a stepwise manner that any *intersection hypothesis* H_I, $I \subset N$, is tested at level α only if all the intersection hypotheses $H_J = \bigcap_{i \in J} H_i$ which *imply* H_I, i.e., $J \supset I$, are rejected.

Some well known stepwise methods for the Tukey type multiple comparisons, e.g., *Fisher's protected LSD* (least significant difference) *test*, the *Newman-Keuls test*, and *Duncan's multiple range test*, control the *FWER* only in a weak sense, and should not be used. Instead, we can use the *Tukey-Welsch method* and *Peritz's method*. Also the *step-down Dunnett method* can be applied for the Dunnett type comparisons. They are *CTPs* and control the *FWER* in a strong sense. Note that the Williams test is also a *CTP*.

Modified Bonferroni Procedures (MBPs)

Modified Bonferroni procedures (*MBPs*) are extensions of the classical Bonferroni procedure, which use the Bonferroni's or similar criterion to test the intersection hypotheses H_I in *CTPs*. They use only *individual p-values* for multiplicity adjustment and are easy to apply. *Holm*, *Hochberg*, *Hommel* and *Rom procedures* are some of typical *MBPs*.

Gatekeeping Procedures (GKPs)

Most recently the new methods called the *gatekeeping procedures* (*GKPs*) have been rapidly developed. *GKPs* utilize the order and logical relationship between hypotheses or families of hypotheses and construct a *MTP* satisfying these relationships. They are usually based on *CTPs* and control the *FWER* in a strong sense. They include *serial GKP*, *parallel GKP*, *tree GKP*, and *truncated GKP*, etc. *GKPs* are especially useful for multiple endpoints and various combination structures of multiple comparisons, multiple endpoints and other multiplicities.

About the Authors

Dr. Toshihiko Morikawa is former professor of Kurume University, Japan. He is well-known as an author of the paper on a combined test of non-inferiority and superiority (Morikawa and Yoshida, *J. Biopharm. Statist.* 5, 297–306, 1995). He contributed to ICH as an expert working group (EWG) member of ICH E10 guideline. He is an elected member of ISI.

Dr. Takeharu Yamanaka is Chief Researcher in the Cancer Biostatistics Laboratory, National Kyushu Cancer Center, Japan. He has worked primarily on the design and analysis of clinical trials in areas including cancer. He has also served on the Data Safety Monitoring Boards for several international multi-center clinical trials.

A General Multiple Comparisons Problem

In this note, we examine a general multiple comparisons testing problem from a Bayesian viewpoint. Suppose we observe independent random samples from I normally distributed populations with equal variances. The goal of our problem is to determine which pairs of groups have equal means.

Write

$$\{X_{ij}\} \,|\, \{\mu_i\}, \sigma^2 \sim \text{ indep } N\left(\mu_i, \sigma^2\right). \tag{1}$$

We are interested in testing $H^{(a,b)}: \mu_a = \mu_b$ for each (a, b); a total of $I(I-1)/2$ distinct, but related hypotheses. A typical frequentist test is based on the decision rule of accept $H^{(a,b)}$ when

$$\left|\overline{X}_b - \overline{X}_a\right| \le Q_{a,b}. \tag{2}$$

The overall error rate is the probability of falsely rejecting any of the true hypotheses in the set $\left\{H^{(a,b)}\right\}$. The determination of $Q_{a,b}$ in (2) depends on how the overall error rate is to be controlled. A classical book featuring this multiple comparisons problem in detail is Scheffé (1959). For an applied review, see, for example, Kutner et al. (2004) or Montgomery (2008). A modern theoretical treatment is offered by Christensen (2002).

An overview to multiple comparisons under the Bayesian framework is given by Berry and Hochberg (1999). Westfall et al. (1997) consider the preceding problem of controlling the overall error rate from a Bayesian perspective. Here, our main focus is to show how a Bayesian approach can offer a logically pleasing interpretation of multiple comparisons testing.

A major point of difficulty to multiple comparisons procedures based on an accept / reject $H^{(a,b)}$ philosophy is illustrated by a case where one decides to accept $\mu_1 = \mu_2$ and $\mu_2 = \mu_3$, but reject $\mu_1 = \mu_3$. Such an outcome is possible under decision rule (2), but an interpretation is difficult to provide since the overall decision is not logically consistent. Employing a Bayesian philosophy, we may restate the goal of the problem as quantifying the evidence from the data in favor of each hypothesis $H^{(a,b)}$.

To implement this philosophy, we will require a measure of prior/posterior belief in $H^{(a,b)}$, represented by point mass probabilities. The construction of prior probabilities over the set of hypotheses $\left\{H^{(a,b)}\right\}$ must account for the fact that the collection does not consist of mutually exclusive events. For example, $H^{(1,2)}$ true $(\mu_1 = \mu_2)$ may occur with $H^{(2,3)}$ true $(\mu_2 = \mu_3)$ or with $H^{(2,3)}$ false $(\mu_2 \neq \mu_3)$. One cannot develop a prior by comparing relative beliefs in each of the pairwise hypotheses. Furthermore, certain combinations of hypotheses in the set $\left\{H^{(a,b)}\right\}$ represent impossibilities. For example, the event with $H^{(1,2)}$ true $(\mu_1 = \mu_2)$, $H^{(2,3)}$ true $(\mu_2 = \mu_3)$, $H^{(1,3)}$ false $(\mu_1 \neq \mu_3)$ should be assigned zero probability.

Allowable decisions can be reached through the formation of equal mean clusters among the I populations. For example, the clustering $\mu_1 = \mu_2$, $\mu_3 = \mu_4$ implies $H^{(1,2)}$ true, $H^{(3,4)}$ true, and all others false. Designating a clustering of equal means will define a model nested within (1). When two or more means are taken as equal, we merely combine all relevant samples into one. The smaller model is of the same form as (1), only for $I' < I$. The problem can now be stated in terms of Bayesian ►model selection, where each allowable combination of hypotheses will correspond to a candidate model.

We provide a short review of Bayesian model selection in the general setting using the notation of Neath

and Cavanaugh (1997). Let Y_n denote the observed data. Assume that Y_n is to be described using a model M_k selected from a set of candidate models $\{M_1, \ldots, M_L\}$. Assume that each M_k is uniquely parameterized by θ_k, an element of the parameter space $\Theta(k)$. In the multiple comparisons problem, the class of candidate models consists of all possible mean clusterings. Each candidate model is parameterized by the mean vector $\mu = (\mu_1, \ldots, \mu_I)$ and the common variance σ^2, with the individual means restricted by the model-defined clustering of equalities. That is, each model determines a corresponding parameter space where particular means are taken as equal.

Let $L(\theta_k|Y_n)$ denote the likelihood for Y_n based on M_k. Let $\pi(k)$, $k = 1, \ldots, L$, denote a discrete prior over the models $M_1, \ldots, M_L$. Let $g(\theta_k|k)$ denote a prior on θ_k given the model M_k. Applying Bayes' Theorem, the joint posterior of M_k and θ_k can be written as

$$f(k, \theta_k|Y_n) = \frac{\pi(k)g(\theta_k|k)L(\theta_k|Y_n)}{h(Y_n)},$$

where $h(Y_n)$ denotes the marginal distribution of Y_n.

The posterior probability on M_k is given by

$$\pi(k|Y_n) = h(Y_n)^{-1}\pi(k)\int_{\Theta(k)} g(\theta_k|k)L(\theta_k|Y_n)\,d\theta_k. \quad (3)$$

The integral in (3) requires numerical methods or approximation techniques for its computation. Kass and Raftery (1995) provide a discussion of the various alternatives. An attractive option is one based upon the popular Bayesian information criterion (Schwarz 1978). Define

$$B_k = -2\ln L(\hat{\theta}_k|Y_n) + dim(\theta_k)\ln(n),$$

where $\hat{\theta}_k$ denotes the maximum likelihood estimate obtained by maximizing $L(\theta_k|Y_n)$ over $\Theta(k)$. It can be shown under certain nonrestrictive regularity conditions (Cavanaugh and Neath 1999) that

$$\pi(k|Y_n) \approx \frac{\exp(-B_k/2)}{\sum_{l=1}^{L}\exp(-B_l/2)}. \quad (4)$$

The advantages to computing the posterior model probabilities as (4) include computational simplicity and a direct connection with a popular and well-studied criterion for Bayesian model selection. The justification of approximation (4) is asymptotic for the general case of prior $g(\theta_k|k)$, but Kass and Wasserman (1995) argue how the approximation holds under a noninformative prior on θ_k even for moderate and small sample sizes.

Regardless of which technique is used for computing $\pi(k|Y_n)$, we compute the probability on hypothesis $H^{(a,b)}$ by summing over the probabilities on those models for which $\mu_a = \mu_b$. This gives a nice approach to determining the evidence in favor of each of the pairwise equalities. The probability approach to presenting results for multiple comparisons testing provides more information than merely an accept / reject decision and is free of the potential contradictions alluded to earlier.

Example

We illustrate the Bayesian approach to multiple comparisons testing using data from Montgomery (2008). The $I = 5$ groups correspond to different cotton blends. Five fabric specimens are tested for each blend. The response measurements reflect tensile strength (in pounds per square inch). See Table 1 for the data and summary statistics. For ease of notation, treatments are identified in ascending order of the observed sample means.

A glance at the data suggests a potentially strong clustering of μ_1, μ_2 and a clustering to a lesser degree among μ_3, μ_4, μ_5. We shall see how these notions can be quantified by computing Bayesian posterior probabilities on the pairwise equalities. The top five most likely pairwise equalities are displayed in Table 2.

The hypothesis $\mu_1 = \mu_2$ is well-supported by the data ($P[H^{(1,2)}] \approx .8$), as was suspected. There is also some evidence in favor of $\mu_3 = \mu_4$ ($P[H^{(3,4)}] \approx .6$) and a non-negligible probability of $\mu_4 = \mu_5$ ($P[H^{(4,5)}] > .1$). Yet, there is good evidence against $\mu_3 = \mu_5$ ($P[H^{(3,5)}] < .02$).

Consider the clustering among μ_3, μ_4, μ_5. Tukey's multiple comparison procedure gives a critical range of $Q = 5.37$. A pair of means is deemed equal only if the corresponding sample difference is less than Q in magnitude. One reaches the decision of accept $\mu_3 = \mu_4$, accept $\mu_4 = \mu_5$, but reject $\mu_3 = \mu_5$. This decision is not logically consistent and is lacking any probabilistic detail. The proposed Bayesian approach bridges this probabilistic gap

Multiple Comparisons Testing from a Bayesian Perspective.

Table 1 Data for example

Group (cotton blend)	Response (tensile strength in lb/in^2)	Sample mean	Sample s.d.
1	7,7,9,11,15	9.8	3.35
2	7,10,11,11,15	10.8	2.86
3	12,12,17,18,18	15.4	3.13
4	14,18,18,19,19	17.6	2.07
5	19,19,22,23,25	21.6	2.61

Multiple Comparisons Testing from a Bayesian Perspective.

Table 2 Probabilities of pairwise equalities

Hypothesis	Posterior
$\mu_1 = \mu_2$	.7976
$\mu_3 = \mu_4$	.6015
$\mu_4 = \mu_5$	.1200
$\mu_2 = \mu_3$	.0242
$\mu_3 = \mu_5$	.0191

and provides a nice presentation for multiple comparisons. Bayesian inference has an advantage over traditional frequentist approaches to multiple comparisons in that degree of belief is quantified. One can avoid illogical conclusions which arise from an accept/reject decision process.

For computing details and continued analysis on this example, see Neath and Cavanaugh (2006).

Multiple Imputation

Christian Heumann
Ludwig-Maximilian University, Munich, Germany

Multiple Imputation and Combining Estimates

Missing data substantially complicates the statistical analysis of data. A common approach to circumvent the problem of analyzing a data set with missing data is to replace/impute the missing values by some estimates or auxiliary values. Subsequently, the data are then analyzed as if they would have been complete. While it is often straightforward to get a point estimate $\hat{\theta}$ for a quantity or parameter of interest, θ, an estimate for the variance of $\hat{\theta}$ is typically difficult to obtain, since the uncertainty due to the imputed values is not reflected correctly. This is exactly where multiple imputation (Rubin 1978, 1996) steps in: by creating several datasets by imputing several values for each missing position in the dataset, multiple imputation tries to reflect the uncertainty due to the imputed values. Note, that this uncertainty is additional to the usual uncertainty arising from the sampling process. Finally, the estimate $\hat{\theta}$ is computed for each of the completed datasets and these estimates are then combined into a single estimate for θ. In the following we give the algorithmic scheme for computing the combined point estimate and an estimated covariance matrix of it, that is, we directly address the case of a vector valued parameter θ. Strategies on how proper imputations can be created are discussed in the next paragraph.

Algorithm for inference under multiple imputation

1. Create m imputed datasets.
2. For each imputed dataset, $j = 1, \ldots, m$, compute the point estimate $Q^{(j)} = \hat{\theta}^{(j)}$ and its corresponding estimated (probably asymptotic) covariance matrix $U^{(j)} = \widehat{\mathrm{Cov}}(\hat{\theta}^{(j)})$. Usually, the "MI"-paradigm (Schafer 1999) assumes that $Q^{(j)}$ is asymptotically normal.
3. The multiple-imputation point estimate for θ is then

$$\overline{Q} = \frac{1}{m}\sum_{j=1}^{m} Q^{(j)} = \frac{1}{m}\sum_{j=1}^{m} \hat{\theta}^{(j)}. \qquad (1)$$

4. The estimated covariance matrix of $\overline{Q}$ consists of two components, the within-imputation covariance and the between-imputation covariance. The within-imputation covariance $\overline{U}$ is given by

$$\overline{U} = \frac{1}{m}\sum_{j=1}^{m} U^{(j)} = \frac{1}{m}\sum_{j=1}^{m} \widehat{\mathrm{Cov}}(\hat{\theta}^{(j)}). \qquad (2)$$

The between-imputation covariance B is given by

$$B = \frac{1}{m-1}\sum_{j=1}^{m}\left(Q^{(j)} - \overline{Q}\right)\left(Q^{(j)} - \overline{Q}\right)^{T}, \qquad (3)$$

where T means the transposed vector, i.e. B is a quadratic matrix where the dimensions are equal to the length of the vector θ. Now we can combine the two estimates to the total variance T which is our estimated covariance matrix of $\overline{Q}$:

$$T = \widehat{\mathrm{Cov}}(\overline{Q}) = \overline{U} + (1 + m^{-1})B. \qquad (4)$$

5. A problem is that while the distribution of $T^{-\frac{1}{2}}(\theta - \overline{Q})$ can be approximated by a t-distribution with ν degrees of freedom,

$$\nu = (m-1)\left[1 + \frac{\overline{U}}{1 + m^{-1}B}\right]^2, \qquad (5)$$

in the *scalar* case, the same is not trivial for the vector valued case, see Schafer (1997).

Approaches to Create Multiple Imputations

So far we have discussed how MI works in principal and how the estimates for the completed datasets can be combined. Now we address how the imputations can be generated. We assume a missing data process that is ignorable. This relates essentially to a missing at random mechanism (MAR) plus the assumption that the parameters of the data model and the parameters of the missing data process are distinct (in likelihood inference this means that the combined parameter space is the product of the two parameter spaces, in a Bayesian analysis this means roughly that the prior distributions are independent). We note, that extensions to the case of nonignorable data situations are possible (although in general this is not easy), especially if one uses a Bayesian approach. The following subsections cannot reflect the whole research which has been done in the past. They only represent a small number of methods selected by the authors.

MI from Parametric Bayesian Models

Let D^{obs} be the observed data and D^{mis} the missing part of a dataset D, with $D = (D^{\mathrm{obs}}, D^{\mathrm{mis}})$. Then, m proper multiple imputations can be obtained via the predictive posteriori distribution of the missing data given the observed data

$$p(D^{\mathrm{mis}}|D^{\mathrm{obs}}) = \int p(D^{\mathrm{mis}}|D^{\mathrm{obs}};\theta)\, p(\theta|D^{\mathrm{obs}})\, d\theta \qquad (6)$$

or an approximation thereof. Note, that $p(\theta|D^{\mathrm{obs}})$ denotes the posteriori distribution of θ. Typically, two distinct approaches are considered to generate multiple imputations from (6): joint modeling and fully conditional modeling. The first approach assumes that the data follow a specific multivariate distribution, e.g. $D \sim N(\mu, \Sigma)$. Under a Bayesian framework draws from $p(D^{\mathrm{mis}}|D^{\mathrm{obs}})$ can be either generated directly (in some trivial cases) or simulated via suitable algorithms (in most cases) such as the IP-algorithm (see, e.g., Schafer [1997]). The second approach specifies an individual conditional distribution $p(D_j|D_{-j}, \theta_j)$ for each variable $D_j \in D$ and creates imputations as draws from these univariate distributions. It can be shown that the process of iteratively drawing and updating the imputed values from the conditional distributions can be viewed as a Gibbs sampler, that converges to draws from the (theoretical) joint distribution (if it exists). Further discussions and details on these issues can be found, e.g., in Drechsler and Rässler (2008) and the references therein.

An additional important remark refers to the fact that the imputations are called improper if we only draw imputations from

$$p(D^{\mathrm{mis}}|D^{\mathrm{obs}}, \tilde{\theta}),$$

where $\tilde{\theta}$ is a reasonable point estimate of θ (such as maximum likelihood, posterior mode or posterior mean), see also section "Other Pragmatic Approaches". That is why the above mentioned IP algorithm always includes the P-Step which samples also a new value of θ from $p(\theta|D^{\mathrm{obs}})$ before using this value to create a new imputed data set.

Nonparametric Methods

Another method to create proper multiple imputations is the so-called ABB (Approximate Bayesian Bootstrap). We refer the reader to Litte and Rubin (2002, Chap. 5.4).

Bootstrap EM

If the EM (Expectation-Maximization) algorithm is applied to an incomplete dataset, then a common problem is that only a point estimate (maximum likelihood estimate) is generated, but not an estimated (co-)variance matrix of this estimate. A typical approach to handle that issue corresponds to the use of the bootstrap (see ▶Bootstrap Methods) to create multiple imputations which then can be used to calculate such an estimate as shown in section "Multiple

Imputation and Combining Estimates". The following steps are repeated for $j = 1, \ldots, m$:

1 Draw a bootstrap sample $D^{(j)}$ from the data with replacement (including all data, complete and incomplete) with the same sample size as the original data. Obtain the maximum likelihood estimate $\hat{\theta}^{(j)}$ from the EM algorithm applied to $D^{(j)}$.
2 Use $\hat{\theta}^{(j)}$ to create an imputed dataset j from $p(D^{\text{mis}}|D^{\text{obs}}; \hat{\theta}^{(j)})$.

Other Pragmatic Approaches

Since Rubin introduced the MI paradigm in the late 1970s, there have been proposed several more or less ad-hoc methods to create multiple imputations that do not rely directly on random draws of the predictive posteriori distribution (6). A common approach refers to types of regression imputation (see, e.g., Little and Rubin [2002]), whereby missing values are replaced by predicted values from a regression of the missing item on the items observed based upon the subsample of the complete cases. This may be interpreted as an approximation to $p(D^{\text{mis}}|D^{\text{obs}}; \theta)$ from (6) with the simple constraint, that the uncertainty due to estimation of θ is not sufficiently reflected and hence $p(\theta|D^{\text{obs}})$ is apparently neglected. As an approach to consider this source of uncertainty anyhow and generate pragmatic multiple imputations (PMI), one might add an stochastic error to the imputation value and/or draw a random value from the conditional estimated distribution resulting from the prediction of the regression. Further extensions on regression imputation, e.g. the use of flexible nonparametric models and a recursive algorithm (GAMRI, Generalized Additive Model based Recursive Imputation), are discussed in Schomaker et al. (2010). Of course, the combination of values form different single imputation procedures might be seen as another type of PMI as well. Various strategies, such as nearest neighbor imputation (Chen and Shao 2000), Hot Deck imputations (Little and Rubin 2002) and others can be used for that approach.

Proper Versus Pragmatic Multiple Imputation

We recommend to create proper multiple imputations based on the predictive posteriori distribution of the missing data given the observed data. As mentioned in section "Software", a variety of statistical software packages nowadays provide fast and reliable tools to create proper multiple imputations even for users with less statistical expertise in missing-data-procedures. In situations where numerical algorithms fail to do so (sparse data, small datasets) pragmatic multiple imputations can be seen as a first approach to model imputation uncertainty.

Problems and Extensions

A number of problems arise along with multiple imputation procedures. Often they are not exclusively related to multiple imputation but to the general problem of misspecification in statistical models. If, e.g., the data model is misspecified because it assumes independent observations on the sampling units, but the observations are temporally or/and spatially correlated, also the results based on MI may become erroneous. An additional problem is ►model selection in general, especially if it is applied on high dimensional data. Also fully Bayesian inference, which often takes a lot of time for one specific model, is often too time consuming to be realistically applied to such problems. The same applies to model averaging (Frequentist or Bayesian) which may be thought of being an alternative to model selection.

Software

Recent years have seen the emergence on software that not only allows for valid inference with multiple imputation but also enables users with less statistical expertise to handle missing-data problems. We shortly introduce two packages that highlight the important progresses that lately have been made in easy-to-use Open-Source-Software. A broader description, discussion and comparison on MI-software can be found in Horton and Kleinman (2007).

- `Amelia II` (Honaker et al. 2008) is a package strongly related to the statistical Software *R* (R Development Core Team 2009) and performs proper multiple imputations by using an new, bootstrapping-based EM-algorithm that is both fast and reliable. All imputations are created via the `amelia()` function. For valid inference the quantities of the m imputed data sheets can be combined (i) in *R* using the `zelig()` command of `Zelig` (Imai et al. 2006), (ii) by hand using (1) and (4), respectively, or (iii) in separate software such as SAS, Stata etc. The Amelia II Software (named after the famous "missing" pilot Amelia Mary Earhart) is exceedingly attractive as it provides many useful options, such as the analysis of time-series data, the specification of priors on individual missing cell values, the handling of ordinal and nominal variables, the choice of suitable transformations and other useful tools. For further details see King et al. (2001) and Honaker and King (2010).

- `MICE` (Multiple Imputations by Chained Equations, van Buuren and Oudshoorn (2007)) is another package provided for *R* and *S-Plus*. It implements the chained equation approach proposed from van Buuren et al. (1999), where proper multiple imputations are generated via Fully Conditional Specification and Gibbs Sampling. The imputation step is carried out using the `mice()` function. As bugs of earlier versions seem to be removed, the MICE software can be attractive especially to the advanced user since he/she may specify his/her own imputation functions without much additional effort.

Multiple Statistical Decision Theory

Deng-Yuan Huang
Professor
Fu Jen Catholic University, Taipei, Taiwan

In the theory and practice of statistical inference, multiple decision problems are encountered in many experimental situations. The classical methods for analyzing data customarily employ hypothesis testing in most situations. In such cases, when the hypothesis is rejected, one wants to know on which of a number of possible ways the actual situations fit our goal. If in the formulation of the problem, we consider only two decisions (reject or not reject the hypothesis), we will not only neglect to differentiate between certain alternative decisions but may also be using an inappropriate acceptance region for the hypothesis. Moreover, the traditional approach to hypothesis testing problems is not formulated in a way to answer the experimenter's question, namely, how to identify the hypothesis that satisfies the goal. Furthermore, when performing a test one may commit one of two errors: rejecting the hypothesis when it is true or accepting it when it is false. Unfortunately, when the number of observations is given, both probabilities cannot be controlled simultaneously by the classical approach (Lehmann 1959). Kiefer (1977) gave an example to show that for some sample values an appropriate test does not exhibit any detailed data-dependent measure of conclusiveness that conveys our strong feeling in favor of the alternative hypothesis. To enforce Kiefer's point, Schaafsma (1969) pointed out the Neyman–Pearson formulation is not always satisfactory and reasonable (Gupta and Huang 1981).

In the preceding paragraphs, we have discussed various difficulties associated with the hypothesis testing formulation. Thus, there arises the need for a modification of this theory and for alternative ways to attack such problems.

The approach in terms of Wald's decision theory (1950) provides an effective tool to overcome the above-mentioned difficulties in some reasonable ways. Actually, the problems of hypothesis testing can be formulated as general multiple decision problems. To this end, we first define that the space A of actions of the statistician consists of a finite number ($k \geq 2$) of elements, $A = \langle a_1, a_2, \ldots, a_k \rangle$. In practice, there are two distinct types of multiple decision problems. In one the parameter space Θ is partitioned into k subsets $\Theta_1, \Theta_2, \ldots, \Theta_k$, according to the increasing value of a real-valued function $r(\underline{\theta})$, $\underline{\theta} \in \Theta$. The action a_i is preferred if $\underline{\theta} \in \Theta_i$. This type of multiple decision problem is called monotone. This approach has been studied by Karlin and Rubin (1956) and Brown et al. (1976). For example, in comparing two treatments with means θ_1 and θ_2, an experimenter may have only a finite number of actions available, among these the experimenter might have preference based on the magnitudes of the differences of the means $\theta_2 - \theta_1$: A particular case occurs when one may choose from the three alternatives:

1. Prefer treatment 1 over treatment 2
2. Prefer treatment 2 over treatment 1
3. No preference (Ferguson 1967)

Another important class of multiple decision problems arises – selection problems where the treatments are classified into a superior category (the selected items) and an inferior one. In general, selection problems have been treated under several different formulations (Gupta and Panchapakesan 1979).

Recently, the modification of the classical hypothesis testing is considered the null hypothesis and several alternative hypotheses. Some multiple decision procedures are proposed to test the hypotheses. Under controlling the type I error, the type II error is the probability of incorrect decision. The type I and type II errors are given, the sample size can be determined. In general, one's interest is not just testing H_0 against the global alternative. Formulating the problem as one of choosing a subset of a set of alternatives has been studied (Lin and Huang 2007).

About the Author

Dr. Deng-Yuan Huang is Professor and Director, Institute of Applied Statistics, and Dean of the College of Management at Fu-Jen Catholic University in Taipei, Taiwan. He received his Ph.D. degree in Statistics from Purdue University in 1974. He is a renowned scholar in multiple decision theory, and has published numerous books and journal articles. Professor Huang has held positions of great honor in the research community of his country. He has also served as a member of the Committee on Statistics and the Committee on the Census of the Directorate General of Budget Accounting and Statistics of Taiwan. Before beginning his doctoral studies under Professor Shanti Gupta, he received the B.S. in mathematics from National Taiwan Normal University and the M.S. in Mathematics from National Taiwan University. Professor Huang is a member of the Institute of Mathematical Statistics, the Chinese Mathematical Association, and the Chinese Statistical Association. In 2002, he received the Distinguished Alumnus Award from Purdue University. In his honor, the International Conference on Multiple Decision Theory was held in Taiwan in 2007.

Multistage Sampling

David Steel
Professor, Director of Centre for Statistical and Survey Methodology
University of Wollongong, Wollongong, NSW, Australia

Probability and Single Stage Sampling

In probability sampling each unit in the finite population of interest has a known, non-zero, chance of selection, π_i. In

single stage sampling the units in the sample, *s*, are selected directly from the population and information is obtained from them. For example, the finite population of interest may consist of businesses and a sample of businesses is selected. In these cases the population units and sampling units are the same. To obtain a single stage sample a sampling frame consisting of a list of the population units and means of contacting them are usually required. Simple random sampling (SRS) can be used, in which each possible sample of a given size has the same chance of selection. SRS leads to each unit in the population having the same chance of selection and is an equal probability selection method (EPSEM). Other EPSEMs are available. A probability sampling method does not need to be an EPSEM. As long as the selection probabilities are known it is possible to produce an estimator that is design unbiased, that is unbiased over repeated sampling. For example the ►Horvitz-Thompson estimator of the population total can be used, $\hat{T}_y = \sum_{i \in s} \pi_i^{-1} y_i$.

Stratification is often used, in which the population is divided into strata according to the values of auxiliary variables known for all population units. An independent sample is then selected from each stratum. The selection probabilities may be the same in each stratum, but often they are varied to give higher sampling rates in strata that are more heterogeneous and/or cheaper to enumerate. Common stratification variables are geography, size and type, for example industry of a business.

Cluster and Multistage Sampling

Instead of selecting a sample of population units directly it may be more convenient to select sampling units which are groups that contain several population units. The sampling unit and the population unit differ. The groups are called Primary Sampling Units (PSUs). If we select all population units from each selected PSU we have ►cluster sampling. If we select a sample of the units in the selected PSUs we have multistage sampling. Each population unit must be uniquely associated with only one PSU through coverage rules. These methods are often used when there is some geographical aspect to the sample selection and there are significant travel costs involved in collecting data and/or when there is no suitable population list of the population units available. A common example of a PSU is a household, which contains one or more people (Clark and Steel 2002). Another common example is area sampling (see Kish 1963, Chap. 9).

In a multistage sample the sample is selected in stages, the sample units at each stage being sampled from the larger units chosen at the previous stage. At each successive stage smaller sampling units are defined within those selected at the previous stage and further selections are made within each of them. At each stage a list of units from which the selections are to be made is required only within units selected at the previous stage.

For example, suppose we wish to select a sample of visitors staying overnight in the city of Wollongong. No list of such people exists, but if we confine ourselves to people staying in hotels or motels then it would be possible to construct a list of such establishments. We could then select a sample of hotels and motels from this list and select all guests from the selected establishments, in which case we have a cluster sample. It would probably be better to select a sample from the guests in each selected establishment allowing selection of more establishments, in which case we have a multi-stage sampling scheme. The probability of a particular guest being selected in the sample is the product of the probability of the establishment being selected and the probability the guest is selected given the establishment is selected. Provided the selection of establishments and guests within selected establishments is done using probability sampling, the sampling method is a valid probability sample. It would also be worthwhile stratifying according to the size of the establishment and its type.

Cluster and multistage sampling are used because a suitable sampling frame of population units does not exist but a list of PSUs does, or because they are less costly than a single stage sample of the same size in terms of population units. In multistage sampling the probability a population unit is selected is the probability the PSU containing the unit is selected multiplied by the conditional probability that the unit is selected given that the PSU it is in is selected.

Cluster and multistage sampling are often cheaper and more convenient than other methods but there is usually an increase in standard errors for the same sample size in terms of number of finally selected population units. It is important that the estimation of sampling error reflects the sample design used (See Lohr 1999, Chap. 9).

In many situations, the problems of compiling lists of population units and travel between selected population units are present even within selected PSUs. Consideration is then given to selecting the sample of population units within a selected PSU by grouping the population units into second stage units, a sample of which is selected. The population units are then selected from selected second stage units. This is called three-stage sampling. This process can be continued to any number of stages. The set of all selected population units in a selected PSU is called an ultimate cluster.

Multistage sampling is very flexible since many aspects of the design have to be chosen including the number of

stages and, for each stage, the unit of selection, the method of selection and number of units selected. Stratification and ratio or other estimation techniques may be used. This flexibility means that there is large scope for meeting the demands of a particular survey in an efficient way.

For a multistage sample the sampling variance of an estimator of a mean or total has a component arising from each stage of selection. The contribution of a stage of selection is determined by the number of units selected at that stage and the variation between the units at that stage, within the units at the next highest level. The precise formula depends on the selection and estimation methods used (See Lohr 1999, Chaps. 5–6; Cochran 1977, Chaps. 9, 9A, 10–11; Kish 1963, Chaps. 5–7, 9–10).

If PSUs vary appreciably in size then it can be useful to control the impact of this variation using ratio estimation or Probability Proportional to Size (PPS) sampling using the number of units in the PSU. For two-stage sampling a common design involves PPS selection of PSUs and selection of an equal number of units in each selected PSU. This gives each population unit the same chance of selection, which is usually a sensible feature for a sample of people, and an equal workload within each selected PSU, which has operational benefits. The first stage component of variance is determined by the variation of the PSU means. To use PPS sampling we need to know the population size of each PSU in the population. For ratio estimation we only need to know the total population size.

Optimal Design in Multistage Sampling

One of the main problems in designing multistage samples is to determine what size sample within selected PSUs to take to optimally balance cost and sampling error. In a two stage sampling scheme in which m PSUs are to be selected and the average number of units selected in each PSU is $\overline{n}$ the sampling variance is minimized for fixed sample size when $\overline{n} = 1$, since then the sample includes the largest number of PSUs. However, costs will be minimized when as few PSUs as possible are selected. Costs and variances are pulling in opposite directions and we must try to optimally balance them. In a two-stage sample several types of costs can be distinguished: overhead costs, costs associated with the selection of PSUs and costs associated with the selection of 2nd stage units. This leads to specifying a cost function of the form

$$C_0 + C_1 m + C_2 m\overline{n}.$$

For some of the common two-stage sampling and estimation methods used in practice the variance of the estimator of total or mean can be written as

$$V_0^2 + \frac{V_1^2}{m} + \frac{V_2^2}{m\overline{n}}.$$

For fixed cost the variance is minimized by choosing

$$\overline{n} = \sqrt{\frac{C_1}{C_2}\frac{V_2^2}{V_1^2}}.$$

The optimum choice of $\overline{n}$ thus depends on the ratios of costs and variances. As the first stage costs increase relative to the second stage costs the optimum $\overline{n}$ increase, so we are led to a more clustered sample. As the second stage component of variance increases relative to the first stage we are also led to a more clustered design.

The optimum value of $\overline{n}$ can be expressed in terms of the measure of homogeneity $\delta = \frac{V_1^2}{V_1^2 + V_2^2}$, as $\overline{n} = \sqrt{\frac{C_1}{C_2}\frac{1-\delta}{\delta}}$. As δ increases the optimal choice of $\overline{n}$ decreases. For example if $C_1/C_2 = 10$ and $\delta = 0.05$ then the optimal $\overline{n} = 14$. To determine the optimal choice of $\overline{n}$ we only need to obtain an idea of the ratio of first stage to second stage cost coefficients and δ.

About the Author

Dr David Steel is a Professor in the School of Mathematics and Applied Statistics, University of Wollongong, Australia. He was the Head of the School of Mathematics and Applied Statistics (2000–2004) and Associate Dean (Research) for the Faculty of Informatics (2004–2006). He is foundation Director of the Center for Statistical and Survey Methodology (2007–). He has authored and co-authored more than 60 papers and books chapters. Professor Steel is currently an Associate Editor for the *Journal of the Royal Statistical Society (Series A)* and *Survey Methodology*. He is a foundation member of the Methodological Advisory Committee of the Australian Bureau of Statistics (1995–).

Multivariable Fractional Polynomial Models

Willi Sauerbrei[1], Patrick Royston[2]
[1]Professor
University Medical Center Freiburg, Freiburg, Germany
[2]Professor
University College London, London, UK

Fractional Polynomial Models

Suppose that we have an outcome variable, a single continuous covariate X, and a suitable regression model relating them. Our starting point is the straight line model, $\beta_1 X$ (for simplicity, we suppress the constant term, β_0). Often a straight line is an adequate description of the relationship, but other models must be investigated for possible improvements in fit. A simple extension of the straight line is a power transformation model, $\beta_1 X^p$. The latter model has often been used by practitioners in an *ad hoc* way, utilising different choices of p. Royston and Altman (1994) formalize the model slightly by calling it a first-degree fractional polynomial or FP1 function. The power p is chosen from a pragmatically chosen restricted set $S = \{-2, -1, -0.5, 0, 0.5, 1, 2, 3\}$, where X^0 denotes $\log X$.

As with polynomial regression, extension from one-term FP1 functions to the more complex and flexible two-term FP2 functions follows immediately. Instead of $\beta_1 X^1 + \beta_2 X^2$, FP2 functions with powers (p_1, p_2) are defined as $\beta_1 X^{p_1} + \beta_2 X^{p_2}$ with p_1 and p_2 taken from S. If $p_1 = p_2$ Royston and Altman proposed $\beta_1 X^{p_1} + \beta_2 X^{p_1} \log X$, a so-called repeated-powers FP2 model.

For a more formal definition, we use the notation from Royston and Sauerbrei (2008). An FP1 function or model is defined as $\varphi_1(X, p) = \beta_0 + \beta_1 X^p$, the constant (β_0) being optional and context-specific. For example, β_0 is usually included in a normal-errors regression model but is always excluded from a Cox proportional-hazards model. An FP2 transformation of X with powers $\mathbf{p} = (p_1, p_2)$, or when $p_1 = p_2$ with repeated powers $\mathbf{p} = (p_1, p_1)$ is the vector $X^{\mathbf{p}}$ with

$$X^{\mathbf{p}} = X^{(p_1,p_2)} = \begin{cases} (X^{p_1}, X^{p_2}), & p_1 \neq p_2 \\ (X^{p_1}, X^{p_1} \log X), & p_1 = p_2 \end{cases}$$

An FP2 function (or model) with parameter vector $\boldsymbol{\beta} = (\beta_1, \beta_2)^{\mathrm{T}}$ and powers $\mathbf{p}$ is $\varphi_2(X, \mathbf{p}) = \beta_0 + X^{\mathbf{p}}\boldsymbol{\beta}$. With the set S of powers as just given, there are 8 FP1 transformations, 28 FP2 transformations with distinct powers $(p_1 \neq p_2)$ and 8 FP2 transformations with equal powers $(p_1 = p_2)$. The best fit among the combinations of powers from S is defined as that with the highest likelihood.

The general definition of an FPm function with powers $\mathbf{p} = (p_1 \leq \cdots \leq p_m)$ is conveniently written as a recurrence relation. Let $h_0(X) = 1$ and $p_0 = 0$. Then

$$\varphi_m(X, \mathbf{p}) = \beta_0 + X^{\mathbf{p}}\beta = \beta_0 + \sum_{j=1}^{m} \beta_j h_j(X)$$

where for $j = 1, \ldots, m$

$$h_j(X) = \begin{cases} X^{p_j}, & p_{j-1} \neq p_j \\ h_{j-1}(X) \log X, & p_{j-1} = p_j \end{cases}$$

For example, for $m = 2$ and $\mathbf{p} = (-1, 2)$ we have $h_1(X) = X^{-1}$, $h_2(X) = X^2$. For $\mathbf{p} = (2, 2)$ we have $h_1(X) = X^2$, $h_2(X) = X^2 \log X$.

Figure 1 shows some FP2 curves, chosen to indicate the flexibility available with a few pairs of powers (p_1, p_2). The ability to fit a variety of curve shapes, some of which have asymptotes or which have both a sharply rising or falling portion and a nearly flat portion, to real data is a particularly useful practical feature of FP2 functions.

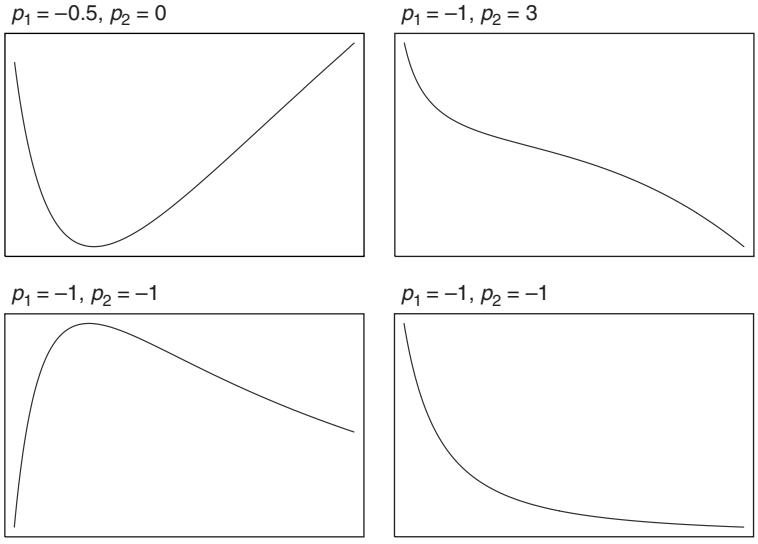
Function Selection Procedure (FSP)

Choosing the best FP1 or FP2 function by mininizing the deviance (minus twice the maximized log likelihood) is straightforward. However, having a sensible default function is important for increasing the parsimony, stability and general usefulness of selected functions. In most of the algorithms implementing FP modelling, the default function is linear – arguably, a natural choice. Therefore, unless the data support a more complex FP function, a straight line model is chosen. There are occasional exceptions; for example, in modelling time-varying regression coefficients in the Cox model, Sauerbrei et al. (2007a) chose a default time transformation of $\log t$ rather than t.

It is assumed in what follows that the null distribution of the difference in deviances between an FPm and an FP$(m-1)$ model is approximately central χ^2 on two degrees of freedom. Justification of this result is given in Sect. 4.9.1 of Royston and Sauerbrei (2008) and supported by simulation results (Ambler and Royston 2001).

For FP model selection, Royston and Sauerbrei (2008) proposed using the following closed test procedure (although other procedures are possible). It runs as follows:

1. Test the best FP2 model for X at the α significance level against the null model using four d.f. If the test is not significant, stop, concluding that the effect of X is "not significant" at the α level. Otherwise continue.



Multivariable Fractional Polynomial Models. Fig. 1 Examples of FP2 curves for different powers (p_1, p_2)

2. Test the best FP2 for X against a straight line at the α level using three d.f. If the test is not significant, stop, the final model being a straight line. Otherwise continue.
3. Test the best FP2 for X against the best FP1 at the α level using two d.f. If the test is not significant, the final model is FP1, otherwise the final model is FP2. End of procedure.

The test at step 1 is of overall association of the outcome with X. The test at step 2 examines the evidence for non-linearity. The test at step 3 chooses between a simpler or more complex non-linear model. Before applying the procedure, the analyst must decide on the nominal P-value (α) and on the degree (m) of the most complex FP model allowed. Typical choices are $\alpha = 0.05$ and FP2 ($m = 2$).

Multivariable Fractional Polynomial (MFP) Procedure

In many studies, a relatively large number of predictors is available and the aim is to derive an interpretable multivariable model which captures the important features of the data: the stronger predictors are included and plausible functional forms are found for continuous variables.

As a pragmatic strategy to building such models, a systematic search for possible non-linearity (provided by the FSP) is added to a backward elimination (BE) procedure. For arguments to combine FSP with BE, see Royston and Sauerbrei (2008). The extension is feasible with any type of regression model to which BE is applicable. Sauerbrei and Royston (1999) called it the multivariable fractional polynomial (MFP) procedure, or simply MFP. Using MFP successfully requires only general knowledge about building regression models.

The nominal significance level is the main tuning parameter required by MFP. Actually, two significance levels are needed: α_1 for selecting variables with BE, and α_2 for comparing the fit of functions within the FSP. Often, $\alpha_1 = \alpha_2$ is a good choice. A degree greater than 2 ($m > 2$) is rarely if ever needed in a multivariable context. Since the model is derived data-dependently, parameter estimates are likely to be somewhat biased.

As with any multivariable selection procedure checks of the underlying assumptions and of the influence of single observations are required and may result in model refinement. To improve robustness of FP models in the univariate and multivariable context Royston and Sauerbrei (2007) proposed a preliminary transformation of X. The transformation shifts the origin of X and smoothly pulls in extreme low and extreme high values towards the center of the distribution. The transformation is linear in the central bulk of the observations.

If available, subject-matter knowledge should replace data-dependent model choice. Only minor modifications are required to incorporate various types of subject-matter knowledge into MFP modelling. For the discussion of a detailed example, see Sauerbrei and Royston (1999).

For model-building by selection of variables and functional forms for continuous predictors, MFP has several advantages over spline-based models (the most important alternatives). For example, MFP models exhibit fewer

artefacts in fitted functions, and are more transportable, mathematically concise and generally more useful than spline models (Royston and Sauerbrei 2008; Sauerbrei et al. 2007b). Residual analysis with spline models may be used to check whether the globally defined functions derived by MFP analysis have missed any important local features in the functional form for a given continuous predictor (Binder and Sauerbrei 2010).

Recommendations for practitioners of MFP modelling are given in Royston and Sauerbrei (2008) and Sauerbrei et al. (2007b).

Extensions of MFP to Investigate for Interactions

MFP was developed to select main effects of predictors on the outcome. If a variable X_2 explains (at least partially) the relationship between a predictor X_1 and the outcome Y then confounding is present. Another important issue is interaction between two or more predictors in a multivariable model. An interaction between X_1 and X_2 is present if X_2 modifies the relationship between X_1 and the outcome. That means that the effect of X_1 is different in subgroups determined by X_2. Extensions of MFP have been proposed to handle two-way interactions involving at least one continuous covariate (Royston and Sauerbrei 2004). Higher order interactions, which typically play a role in factorial experiments, are a further extension, but not one that has yet been considered in the FP context.

To investigate for a possible interaction between a continuous predictor and two treatment arms in a randomized controlled trial, the multivariable fractional polynomial interaction (MFPI) procedure was introduced (Royston and Sauerbrei 2004). In a first step, the FP class is used to model the prognostic effect of the continuous variable separately in the two treatment arms, usually under some restrictions such as the same power terms in each arm. In a second step, a test for the equality of the prognostic functions is conducted. If significant, an interaction is present and the difference between two functions estimates the influence of the prognostic factor on the effect of treatment. The difference function is called a treatment effect function (and should be plotted). For interpretation, it is important to distinguish between the two cases of a predefined hypothesis and of searching for hypotheses (Royston and Sauerbrei 2004, 2008).

For more than two groups, extensions to investigate continuous by categorical interactions are immediate. Furthermore, MFPI allows investigation of treatment-covariate interactions in models with or without adjustment for other covariates. The adjustment for other covariates enables the use of the procedure in observational studies, where the multivariable context is more important than in an RCT.

Continuous-by-continuous interactions are important in observational studies. A popular approach is to assume linearity for both variables and test the multiplicative term for significance. However, the model may fit poorly if one or both of the main effects is non-linear. Royston and Sauerbrei (2008, Chap. 7) introduced an extension of MFPI, known as MFPIgen, in which products of selected main effect FP functions are considered as candidates for an interaction between a pair of continuous variables. Several continuous variables are usually available, and a test of interaction is conducted for each such pair. If more than one interaction is detected, interactions are added to the main-effects model in a step-up manner.

The MFPT(ime) algorithm (Sauerbrei et al. 2007a) combines selection of variables and of the functional form for continuous variables with determination of time-varying effects in a Cox proportional hazards model for ►survival data. A procedure analogous to the FSP was suggested for investigating whether the effect of a variable varies in time, i.e., whether a time-by-covariate interaction is present.

Further Contributions to Fractional Polynomial Modelling

Methods based on fractional polynomials have been reported recently, aiming to improve or extend the modelling of continuous covariates in various contexts. For example, Faes et al. (2007) applied model averaging to fractional polynomial functions to estimate a safe level of exposure; Lambert et al. (2005) considered time-dependent effects in regression models for relative survival; and Long and Ryoo (2010) used FPs to model non-linear trends in longitudinal data. For further topics and references, see Sect. 11.3 of Royston and Sauerbrei (2008).

About the Authors

Willi Sauerbrei, Ph.D., is a senior statistician and professor in medical biometry at the University Medical Center Freiburg. He has authored many research papers in biostatistics, and has published over 150 articles in leading statistical and clinical journals. He worked for more than 2 decades as an academic biostatistician and has extensive experience of cancer research. Together with Patrick Royston, he has written a book on modeling (*Multivariable model-building: a pragmatic approach to regression analysis based on fractional polynomials for modelling continuous variables*, Wiley 2008).

Patrick Royston, D.Sc., is a senior statistician at the MRC Clinical Trials Unit, London, an honorary professor of statistics at University College London and a Fellow of the Royal Statistical Society. He has authored many research papers in biostatistics, including over 150 articles in leading statistical journals. He is co-author (with Willi Sauerbrei, see above) of a book on multivariable modeling. He is also an experienced statistical consultant, Stata programmer and software author.

Multivariate Analysis of Variance (MANOVA)

Barbara G. Tabachnick, Linda S. Fidell
California State University, Northridge, CA, USA

ANOVA (►analysis of variance) tests whether mean differences among groups on a single DV (dependent variable) are likely to have occurred by chance. MANOVA (multivariate analysis of variance) tests whether mean differences among groups on a *combination* of DVs are likely to have occurred by chance. For example, suppose a researcher is interested in the effect of different types of treatment (the IV; say, desensitization, relaxation training, and a waiting-list control) on anxiety. In ANOVA, the researcher chooses one measure of anxiety from among many. With MANOVA, the researcher can assess several types of anxiety (say, test anxiety, anxiety in reaction to minor life stresses, and so-called free-floating anxiety). After random assignment of participants to one of the three treatments and a subsequent period of treatment, participants are measured for test anxiety, stress anxiety, and free-floating anxiety. Scores on all three measures for each participant serve as DVs. MANOVA is used to ask whether a combination of the three anxiety measures varies as a function of treatment. (MANOVA is statistically identical to discriminant analysis. The difference between the techniques is one of emphasis. MANOVA emphasizes the mean differences and statistical significance of differences among groups. Discriminant analysis (see ►Discriminant Analysis: An Overview, and ►Discriminant Analysis: Issues and Problems) emphasizes prediction of group membership and the dimensions on which groups differ.)

MANOVA developed in the tradition of ANOVA. Traditionally, MANOVA is applied to experimental situations where all, or at least some, IVs are manipulated and participants are randomly assigned to groups, usually with equal cell sizes. The goal of research using MANOVA is to discover whether outcomes, as reflected by the DVs, are changed by manipulation (or other action) of the IVs.

In MANOVA, a new DV is created from the set of DVs that maximizes group differences. The new DV is a linear combination of measured DVs, combined so as to separate the groups as much as possible. ANOVA is then performed on the newly created DV. As in ANOVA, hypotheses about means are tested by comparing variances between means relative to variances in scores within groups-hence multivariate analysis of variance.

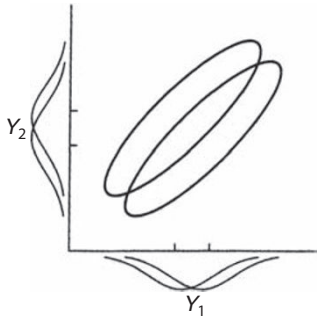
In factorial or more complicated MANOVA, a different linear combination of DVs is formed for each IV and

interaction. If gender of participant is added to type of treatment as a second IV, one combination of the three DVs maximizes the separation of the three treatment groups, a second combination maximizes separation of women and men, and a third combination maximizes separation of the six cells of the interaction. Further, if an IV has more than two levels, the DVs can be recombined in yet other ways to maximize the separation of groups formed by comparisons.

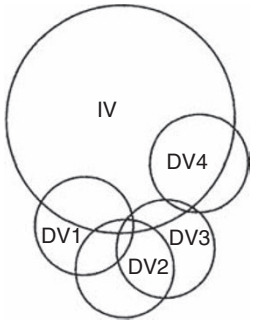
MANOVA has a number of advantages over ANOVA. First, by measuring several DVs instead of only one, the researcher improves the chance of discovering what it is that changes as a result of different IVs and their interactions. For instance, desensitization may have an advantage over relaxation training or waiting-list control, but only on test anxiety; the effect is missed in ANOVA if test anxiety is not chosen as the DV. A second advantage of MANOVA over a series of ANOVAs (one for each DV) is protection against inflated Type I error due to multiple tests of (likely) correlated DVs. (The linear combinations themselves are usually of interest in discriminant analysis, but not in MANOVA.)

Another advantage of MANOVA is that, under certain, probably rare conditions, it may reveal differences not shown in separate ANOVAs (Maxwell 2001). Such a situation is shown in Fig. 1 for a one-way design with two levels. In this figure, the axes represent frequency distributions for each of two DVs, Y_1 and Y_2. Notice that from the point of view of either axis, the distributions are sufficiently overlapping that a mean difference might not be found in ANOVA. The ellipses in the quadrant, however, represent the distributions of Y_1 and Y_2 for each group separately. When responses to two DVs are considered in combination, group differences become apparent. Thus, MANOVA, which considers DVs in combination, may occasionally be more powerful than separate ANOVAs.

The goal in MANOVA is to choose a small number of DVs where each DV is related to the IV, but the DVs are not related to each other. Good luck. In the usual situation there are correlations among the DVs, resulting in some ambiguity in interpretation of the effects of IVs on any single DV and loss of power relative to ANOVA. Figure 2 shows a set of hypothetical relationships between a single IV and four DVs. DV1is highly related to the IV and shares some variance with DV2 and DV3. DV2 is related to both DV1 and DV3 and shares very little unique variance with the IV. DV3 is somewhat related to the IV, but also to all of the other DVs. DV4 is highly related to the IV and shares only a little bit of variance with DV3. Thus, DV2 is completely redundant with the other DVs, and DV3 adds only a bit of unique variance to the set. (However, DV2 might be useful as a covariate if that use is conceptually viable because it reduces the total variances in DVs 1 and 3 that are not overlapping with the IV.)



Multivariate Analysis of Variance (MANOVA). Fig. 1 Advantage of MANOVA, which combines DVs, over ANOVA. Each axis represents a DV; frequency distributions projected to axes show considerable overlap, while ellipses, showing DVs in combination, do not



Multivariate Analysis of Variance (MANOVA). Fig. 2 Hypothetical relationships among a single IV and four DVs

Although computing procedures and programs for MANOVA and MANCOVA are not as well developed as for ANOVA and ANCOVA, there is in theory no limit to the generalization of the model. The usual questions regarding main effects of IVs, interactions among IVs, importance of DVs, parameter estimates (marginal and cell means), specific comparisons and trend analysis (for IVs with more than two levels), effect sizes of treatments, and effects of covariates, if any, are equally interesting with MANOVA as with ANOVA. There is no reason why all types of designs - one-way, factorial, repeated measures, nonorthogonal, and so on - cannot be extended to research with several DVs.

For example, multivariate analysis of covariance (MANCOVA) is the multivariate extension of ANCOVA. MANCOVA asks if there are statistically significant mean differences among groups after adjusting the newly created DV for differences on one or more covariates. To extend the example, suppose that before treatment participants are

pretested on test anxiety, minor stress anxiety, and free-floating anxiety; these pretest scores are used as covariates in the final analysis. MANCOVA asks if mean anxiety on the composite score differs in the three treatment groups, after adjusting for preexisting differences in the three types of anxieties.

MANOVA is also a legitimate alternative to repeated-measures ANOVA in which differences between pairs of responses to the levels of the within-subjects IV are simply viewed as separate DVs.

Univariate analyses are also useful following a MANOVA or MANCOVA. For example, if DVs can be prioritized, ANCOVA is used after MANOVA (or MANCOVA) in Roy-Bargmann stepdown analysis where the goal is to assess the contributions of the various DVs to a significant effect (Bock 1971; Bock and Haggard 1968). One asks whether, after adjusting for differences on higher-priority DVs serving as covariates, there is any significant mean difference among groups on a lower-priority DV. That is, does a lower-priority DV provide additional separation of groups beyond that of the DVs already used? In this sense, ANCOVA is used as a tool in interpreting MANOVA results. Results of stepdown analysis are reported in addition to individual ANOVAs.

However, MANOVA is a substantially more complicated analysis than ANOVA because there are several important issues to consider. MANOVA has all of the complications of ANOVA (e.g., homogeneity of variance; equality of sample sizes within groups; absence of ►outliers; power, cf. Woodward et al. 1990; normality of sampling distributions, independence of errors) and several more besides (homogeneity of variance-covariance matrices; multivariate normality, cf. Mardia 1971 and Seo et al. 1995; linearity, absence of ►multicollinearity and singularity; and choice among statistical criteria, cf. Olson 1979). These are not impossible to understand or test prior to analysis, but they are vital to an honest analysis.

Comprehensive statistical software packages typically include programs for MANOVA. The major SPSS module is GLM, however the older MANOVA module remains available through syntax and includes Roy-Bargmann stepdown analysis as an option. NCSS and SYSTAT have specific MANOVA modules, whereas SAS provides analysis of MANOVA through its GLM module. Analysis is also available through BMDP4V, STATA, and Statistica.

For more information about MANOVA, see Chaps. 7 and 8 of Tabachnick and Fidell (2007).

Multivariate Data Analysis: An Overview

Joseph F. Hair
Professor of Marketing
Kennesaw State University, Kennesaw, GA, USA

Most business problems involve many variables. Managers look at multiple performance measures and related metrics

when making decisions. Consumers evaluate many characteristics of products or services in deciding which to purchase. Multiple factors influence the stocks a broker recommends. Restaurant patrons consider many factors in deciding where to dine. As the world becomes more complex, more factors influence the decisions managers and customers make. Thus, increasingly business researchers, as well as managers and customers, must rely on more sophisticated approaches to analyzing and understanding data.

Analysis of data has previously involved mostly univariate and bivariate approaches. Univariate analysis involves statistically testing a single variable, while bivariate analysis involves two variables. When problems involve three or more variables they are inherently multidimensional and require the use of multivariate data analysis. For example, managers trying to better understand their employees might examine job satisfaction, job commitment, work type (part-time vs. full-time), shift worked (day or night), age and so on. Similarly, consumers comparing supermarkets might look at the freshness and variety of produce, store location, hours of operation, cleanliness, prices, courtesy and helpfulness of employees, and so forth. Managers and business researchers need multivariate statistical techniques to fully understand such complex problems.

Multivariate data analysis refers to all statistical methods that simultaneously analyze multiple measurements on each individual respondent or object under investigation. Thus, any simultaneous analysis of more than two variables can be considered multivariate analysis. Multivariate data analysis is therefore an extension of univariate (analysis of a single variable) and bivariate analysis (cross-classification, correlation, and simple regression used to examine two variables).

Figure 1 displays a useful classification of statistical techniques. Multivariate as well as univariate and bivariate techniques are included to help you better understand the similarities and differences. As you can see at the top, we divide the techniques into dependence and interdependence depending on the number of dependent variables. If there is one or more dependent variables a technique is referred to as a dependence method. That is, we have both dependent and independent variables in our analysis. In contrast, when we do not have a dependent variable we refer to the technique as an interdependence method. That is, all variables are analyzed together and our goal is to form groups or give meaning to a set of variables or respondents.

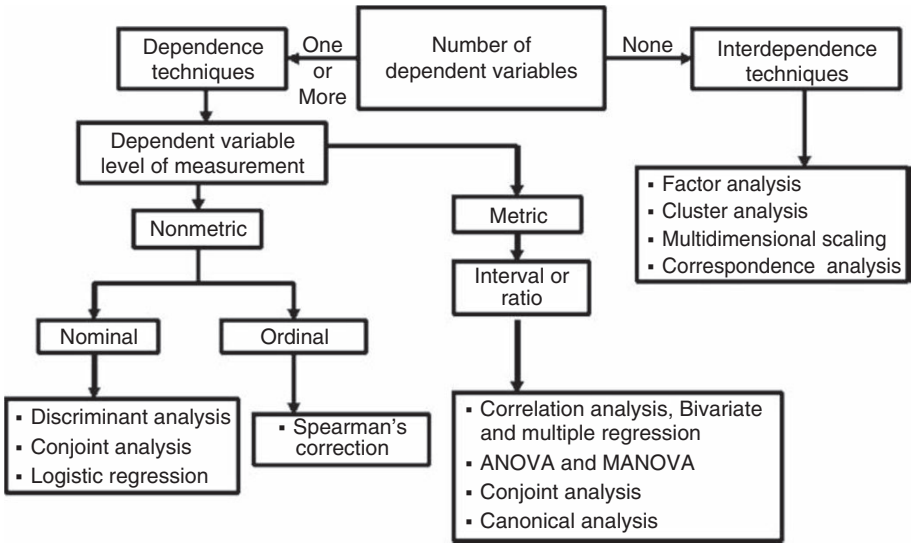
The classification can help us understand the differences in the various statistical techniques. If a research problem involves association or prediction using both dependent and independent variables, one of the dependence techniques on the left side of the diagram is appropriate. The choice of a particular statistical technique depends on whether the dependent variable is metric or nonmetric, and how many dependent variables are involved. With a nonmetric, ordinally measured dependent we would use the Spearman correlation. With a nonmetric, nominal dependent variable we use discriminant analysis (see ►Discriminant Analysis: An Overview, and ►Discriminant Analysis: Issues and Problems), conjoint analysis or ►logistic regression. On the other hand, if our dependent variable is metric, we can use correlation, regression, ANOVA or MANOVA, canonical correlation, and conjoint analysis (the statistical technique of conjoint analysis can be formulated to handle both metric and nonmetric variables). The various statistical techniques are defined in Fig. 2. For more information on multivariate statistical techniques see Hair et al. (2010).

Concluding Observations

Today multivariate data analysis is being used by most medium and large sized businesses, and even some small businesses. Also, most business researchers rely on multivariate analysis to better understand their data. Thus, in today's business environment it's just as important to understand the relationship between variables, which often requires multivariate analysis, as it is to gather the information in the first place. The importance of multivariate statistical methods that help us to understand relationships has increased dramatically in recent years. What can we expect in the future as applications of multivariate data analysis expand: (1) data will continue to increase exponentially, (2) data quality will improve as will data cleaning techniques and data maintenance, (3) data analysis tools will be more powerful and easier to use, and (4) there will be many more career opportunities involving examining and interpreting data using multivariate data analysis.

About the Author

Professor Joe Hair is a member of the American Marketing Association, Academy of Marketing Science, and Society for Marketing Advances. He has authored 55 books, monographs, and cases, and over 80 articles in scholarly journals. He is a co-author (with William C. Black, Barry Babin and Rolph Anderson) of the well known applications-oriented introduction to multivariate analysis text *Multivariate Data Analysis* (Prentice Hall, 7th edition, 2010). He serves on the editorial review boards of several journals and was the 2009 Academy of Marketing Science/Harold Berkman Lifetime Service Award recipient, the KSU Coles College Foundation Distinguished Professor in 2009, the Marketing Management Association Innovative Marketer



Multivariate Data Analysis: An Overview. Fig. 1 Classification of statistical techniques

ANOVA – ANOVA stands for analysis of variance. It is used to examine statistical differences between the means of two or more groups. The dependent variable is metric and the independent variable(s) is nonmetric. One-way ANOVA has a single non-metric independent variable and two-way ANOVA can have two or more non-metric independent variables. ANOVA is bivariate while MANOVA is the multivariate extension of ANOVA.

Bivariate Regression – this is a type of regression that has a single metric dependent variable and a single metric independent variable.

Cluster Analysis – this type of analysis enables researchers to place objects (e.g., customers, brands, products) into groups so that objects within the groups are similar to each other. At the same time, objects in any particular group are different from objects in all other groups.

Correlation – correlation examines the association between two metric variables. The strength of the association is measured by the correlation coefficient. **Canonical correlation** analyzes the relationship between multiple dependent and multiple independent variables, most often using metric measured variables.

Conjoint Analysis – this technique enables researchers to determine the preferences individuals have for various products and services, and which product features are valued the most.

Discriminant Analysis – enables the researcher to predict group membership using two or more metric dependent variables. The group membership variable is a non-metric dependent variable.

Factor Analysis – this technique is used to summarize the information from a large number of variables into a much smaller number of variables or factors. This technique is used to combine variables whereas cluster analysis is used to identify groups with similar characteristics.

Logistic Regression – logistic regression is a special type of regression that involves a non-metric dependent variable and several metric independent variables.

Multiple Regression – this type of regression has a single metric dependent variable and several metric independent variables.

MANOVA – same technique as ANOVA but it can examine group differences across two or more metric dependent variables at the same time.

Perceptual Mapping – this approach uses information from other statistical techniques (e.g., multidimensional scaling) to map customer perceptions of products, brands, companies, and so forth.

The multivariate normal distribution is a generalization of the familiar univariate normal or Gaussian distribution (Hogg et al. 2005; Miller and Miller 1999) to $p \geq 2$ dimensions. Just as with its univariate counterpart, the importance of the multivariate normal distribution emanates from a number of its useful properties, and especially from the fact that, according to the central limit theorem (Anderson 2003; Johnson and Wichern 2007) under certain regularity conditions, sum of random variables generated from various (likely unknown) distributions tends to behave as if its underlying distribution were multivariate normal.

The need for generalization to the multivariate distribution naturally arises if we simultaneously investigate more than one quantity of interest. In that case, single observation (result of an experiment) is not value of a single variable, but the set of p values of $p \geq 2$ random variables. Therefore, we deal with $p \times 1$ random vector $\mathbf{X}$ and each single observation becomes $p \times 1$ vector $\mathbf{x}$ of single realizations of p random variables under examination. All these variables have their particular expected values that jointly constitute $p \times 1$ mean vector $\boldsymbol{\mu}$, which is expected value of random vector $\mathbf{X}$. Since analysis of collective behaviour of several quantities must take into account their mutual *correlations,* in multivariate analysis we also define $p \times p$ *variance-covariance matrix*

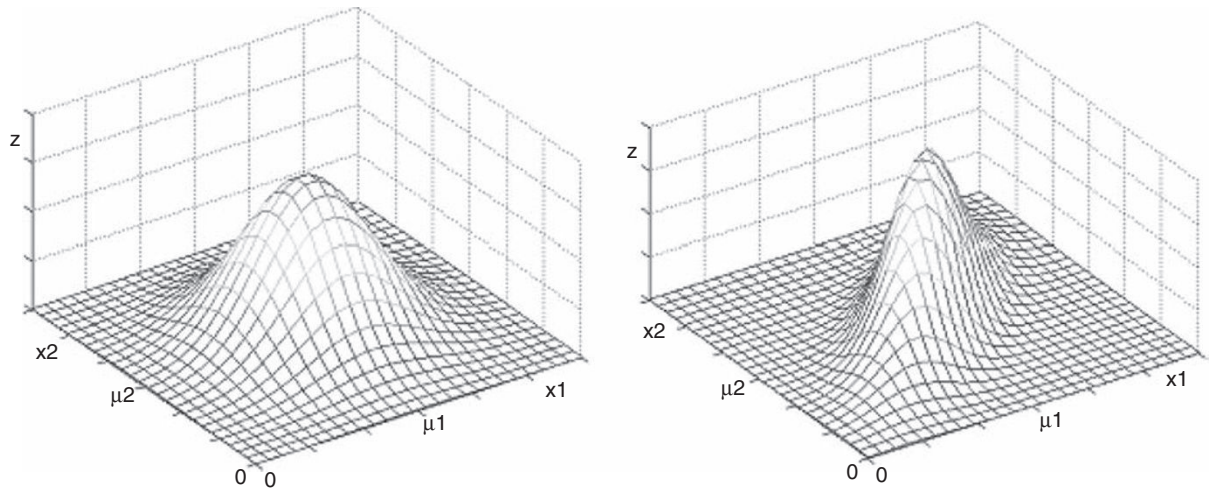
$$\boldsymbol{\Sigma} = \mathrm{cov}(\mathbf{X}) = E\left[(\mathbf{X}-\boldsymbol{\mu})(\mathbf{X}-\boldsymbol{\mu})^T\right] = \begin{bmatrix} \sigma_{11} & \sigma_{12} & \dots & \sigma_{1p} \\ \sigma_{21} & \sigma_{22} & \dots & \sigma_{2p} \\ \vdots & \vdots & \ddots & \vdots \\ \sigma_{p1} & \sigma_{p2} & \dots & \sigma_{pp} \end{bmatrix}, \quad (1)$$

where σ_{ij} are covariances between ith and jth component of $\mathbf{X}$ and σ_{ii} are variances of ith variable (more commonly denoted σ_i^2). This matrix is symmetric because $\sigma_{ij} = \sigma_{ji}$ and it is assumed to be *positive definite.*

Conceptually, the development of multivariate normal distribution starts from the univariate *probability* density function of a normal random variable X with the mean μ and variance σ^2. Common notation is $X \sim N(\mu, \sigma^2)$ and *probability density function* (pdf) of X is

$$f(x) = \frac{1}{\sqrt{2\pi\sigma^2}} e^{-\frac{(x-\mu)^2}{2\sigma^2}} = \frac{1}{\sqrt{2\pi\sigma^2}} e^{-\frac{1}{2}\left(\frac{x-\mu}{\sigma}\right)^2} = \frac{1}{\sqrt{2\pi\sigma^2}} e^{-\frac{1}{2}z^2}; -\infty < x < +\infty. \quad (2)$$

Variable Z is so-called *standard normal variable* or *z-score* and it represents the square of the distance from a single observation (measurement) x to the population



Multivariate Normal Distributions. Fig. 1 Bivariate normal distribution with: *left* - $\sigma_1 = \sigma_2, \rho = 0$; *right* - $\sigma_1 = \sigma_2, \rho = 0,75$

mean μ, expressed in standard deviation units. It is this distance that directly generalizes to $p \geq 2$ dimensions, because in the univariate case we can write

$$\left(\frac{x-\mu}{\sigma}\right)^2 = (x-\mu)(\sigma^2)^{-1}(x-\mu), \tag{3}$$

and in the multivariate case, by analogy, we have the *Mahalanobis distance* (Johnson and Wichern 2007) expressed as

$$(\mathbf{x}-\boldsymbol{\mu})^T\boldsymbol{\Sigma}^{-1}(\mathbf{x}-\boldsymbol{\mu}). \tag{4}$$

The multivariate normal probability density function is obtained (Anderson 2003; Hogg et al. 2005; Johnson and Wichern 2007) by replacing (3) by (4) in the density function (2) and substituting the normalizing constant by $(2\pi)^{-p/2}|\Sigma|^{-1/2}$, so that the p-dimensional normal probability density for the random vector $\mathbf{X} = [\mathbf{X}_1, \mathbf{X}_2, \ldots, \mathbf{X}_p]^T$ is

$$f(\mathbf{x}) = \frac{1}{(2\pi)^{p/2}|\Sigma|^{1/2}} e^{-(\mathbf{x}-\boldsymbol{\mu})^T\boldsymbol{\Sigma}^{-1}(\mathbf{x}-\boldsymbol{\mu})/2} \tag{5}$$

where $x_i \in (-\infty, \infty)$ and $i = 1, 2, \ldots, p$. Again analogously to the univariate case, we write $\mathbf{X} \sim N_p(\boldsymbol{\mu}, \boldsymbol{\Sigma})$.

As an example, consider bivariate $(p = 2)$ distribution in terms of the individual parameters $\mu_1, \mu_2, \sigma_1^2 = \sigma_{11}, \sigma_2^2 = \sigma_{22}$ and $\sigma_{12} = \sigma_{21}$. If we also introduce *correlation coefficient* $\rho = \rho_{12} = \text{corr}(X_1, X_2) = \sigma_{12}^2/(\sigma_1 \cdot \sigma_2)$, density (5) becomes

$$f(x_1, x_2) = \frac{1}{2\pi\sigma_1\sigma_2\sqrt{1-\rho^2}} \exp\left\{-\frac{1}{2(1-\rho^2)}\left[\left(\frac{x_1-\mu_1}{\sigma_1}\right)^2 + \left(\frac{x_2-\mu_2}{\sigma_2}\right)^2 - 2\rho\frac{x_1-\mu_1}{\sigma_1}\frac{x_2-\mu_2}{\sigma_2}\right]\right\}. \tag{6}$$

Formula (6) clearly indicates certain important general properties of multivariate normal distributions. First of all, if random variables X_1 and X_2 are uncorrelated, i.e., $\rho = 0$, it immediately follows that their joint density (6) can be factored as the product of two univariate normal densities of the form of (2). Since $f(x_1, x_2)$ factors as $f(x_1, x_2) = f(x_1) \cdot f(x_2)$, it follows that if X_1 and X_2 are uncorrelated, they are also *statistically independent*. This is a direct consequence of the general $(p \geq 2)$ multivariate normal property that uncorrelated variables are independent and have *marginal distributions* univariate normal. However, converse is not necessarily true for both of these statements and requires caution. Independent normal variables certainly are uncorrelated (this is true for any distribution anyway), but marginal distributions may be univariate normal without the joint distribution being multivariate normal. Similarly, marginally normal variables can be uncorrelated without being independent (Anderson 2003; Miller and Miller 1999).

Several other general properties of multivariate normal distribution are easier to conceive by studying the bivariate normal surface defined by (6) and illustrated in Fig. 1. Obviously, the bivariate (as well as multivariate) probability density function has a maximum at (μ_1, μ_2). Next, any intersection of this surface and a plane parallel to the z-axis has the shape of an univariate normal distribution, indicating that marginal distributions are univariate normal.

Finally, any intersection of this surface and a plane parallel to the x_1x_2 plane is an ellipse called *contour of constant probability density*. In the special case when variables are uncorrelated (independent) and $\sigma_1 = \sigma_2$ (Fig. 1 - left), contours of constant probability density are circles

and it is customary to refer to the corresponding joint density as a *circular normal density*. When variables are uncorrelated, but $\sigma_1 \neq \sigma_2$, contours are ellipses whose semi-axes are parallel to the x_1, x_2 axes of the coordinate system. In the presence of correlation, probability density concentrates along the line (Fig. 1 - right) determined by the coefficient of correlation and variances of variables, so the contours of constant probability density are ellipses rotated in a plane parallel to x_1x_2 plane (Anderson 2003; Miller and Miller 1999). All these properties are valid in p-dimensional spaces ($p > 2$) as well.

Here is the list of most important properties of the multivariate normal distribution (Anderson 2003; Johnson and Wichern 2007; Rao 2002).

1. Let $\mathbf{X}$ be a random vector $\mathbf{X} \sim N_p(\boldsymbol{\mu}, \boldsymbol{\Sigma})$ and $\mathbf{a}$ an arbitrary $p \times 1$ vector. Then the linear combination $\mathbf{a}^T\mathbf{X} = a_1X_1 + a_2X_2 + \ldots + a_pX_p$ is distributed as $N(\mathbf{a}^T\boldsymbol{\mu}, \mathbf{a}^T\boldsymbol{\Sigma}\mathbf{a})$. In words, any linear combination of jointly normal random variables is normally distributed. Converse is also true: if $\mathbf{a}^T\mathbf{X}$ is $\sim N(\mathbf{a}^T\boldsymbol{\mu}, \mathbf{a}^T\boldsymbol{\Sigma}\mathbf{a})$ for every $\mathbf{a}$, then $\mathbf{X} \sim N_p(\boldsymbol{\mu}, \boldsymbol{\Sigma})$.
2. Generalization of property 1: Let $\mathbf{X}$ be a random vector $\mathbf{X} \sim N_p(\boldsymbol{\mu}, \boldsymbol{\Sigma})$ and let us form q linear combinations $\mathbf{AX}$, where $\mathbf{A}$ is an arbitrary $q \times p$ matrix. Then it is true that $\mathbf{AX} \sim N_q(\mathbf{A}\boldsymbol{\mu}, \mathbf{A}\boldsymbol{\Sigma}\mathbf{A}^T)$. Similarly, for any vector of constants $\mathbf{d}$ we have $\mathbf{X} + \mathbf{d} \sim N_p(\boldsymbol{\mu} + \mathbf{d}, \boldsymbol{\Sigma})$.
3. All subsets of variables constituting $\mathbf{X} \sim N_p(\boldsymbol{\mu}, \boldsymbol{\Sigma})$ are (multivariate) normally distributed.
4. Multivariate normal $q_1 \times 1$ and $q_2 \times 1$ vectors $\mathbf{X}_1$ and $\mathbf{X}_2$ are independent if and only if they are uncorrelated, i.e., $\mathrm{cov}(\mathbf{X}_1, \mathbf{X}_2) = 0$ (a $q_1 \times q_2$ matrix of zeros).
5. If multivariate normal $q_1 \times 1$ and $q_2 \times 1$ vectors $\mathbf{X}_1$ and $\mathbf{X}_2$ are independent and distributed as $N_{q1}(\boldsymbol{\mu}_1, \boldsymbol{\Sigma}_{11})$ and $N_{q2}(\boldsymbol{\mu}_2, \boldsymbol{\Sigma}_{22})$, respectively, then $(q_1 + q_2) \times 1$ vector $[\mathbf{X}_1^T\ \mathbf{X}_2^T]^T$ has multivariate normal distribution

$$\begin{bmatrix} \mathbf{X}_1 \\ \mathbf{X}_2 \end{bmatrix} \sim N_{q_1+q_2}\left(\begin{bmatrix} \boldsymbol{\mu}_1 \\ \boldsymbol{\mu}_2 \end{bmatrix}, \begin{bmatrix} \boldsymbol{\Sigma}_{11} & 0 \\ 0 & \boldsymbol{\Sigma}_{22} \end{bmatrix} \right).$$

6. Let $\mathbf{X}_1, \mathbf{X}_2, \ldots, \mathbf{X}_n$ be mutually independent random vectors that are all multivariate normally distributed, each having its particular mean, but all having the same covariance matrix $\boldsymbol{\Sigma}$, i.e., $\mathbf{X}_j \sim N_p(\boldsymbol{\mu}_j, \boldsymbol{\Sigma})$. Linear combination of these vectors $\mathbf{V}_1 = c_1\mathbf{X}_1 + c_2\mathbf{X}_2 + \ldots + c_n\mathbf{X}_n$ is distributed as $N_p\left(\sum_{j=1}^{n} c_j\boldsymbol{\mu}_j, \left(\sum_{j=1}^{n} c_j^2\right)\boldsymbol{\Sigma}\right)$. Moreover, similarly to property 5, $\mathbf{V}_1$ and some other linear combination $\mathbf{V}_2 = b_1\mathbf{X}_1 + b_2\mathbf{X}_2 + \ldots + b_n\mathbf{X}_n$ are jointly multivariate normally distributed with covariance matrix

$$\begin{bmatrix} \left(\sum_{j=1}^{n} c_j^2\right)\boldsymbol{\Sigma} & (\mathbf{b}^T\mathbf{c})\boldsymbol{\Sigma} \\ (\mathbf{b}^T\mathbf{c})\boldsymbol{\Sigma} & \left(\sum_{j=1}^{n} b_j^2\right)\boldsymbol{\Sigma} \end{bmatrix}.$$

Thus, if $\mathbf{b}^T\mathbf{c} = 0$, i.e., vectors $\mathbf{b}$ and $\mathbf{c}$ are orthogonal, it follows that $\mathbf{V}_1$ and $\mathbf{V}_2$ are independent and vice versa.
7. All conditional distributions are multivariate normal. Formally, let $\mathbf{X}_1$ and $\mathbf{X}_2$ be any two subsets of a multivariate normal vector $\mathbf{X} \sim N_p(\boldsymbol{\mu}, \boldsymbol{\Sigma})$ with $\boldsymbol{\mu} = \begin{bmatrix} \boldsymbol{\mu}_1 \\ \boldsymbol{\mu}_2 \end{bmatrix}$, $\boldsymbol{\Sigma} = \begin{bmatrix} \boldsymbol{\Sigma}_{11} & \boldsymbol{\Sigma}_{12} \\ \boldsymbol{\Sigma}_{21} & \boldsymbol{\Sigma}_{22} \end{bmatrix}$, and $|\boldsymbol{\Sigma}_{22}| > 0$. The conditional distribution of $\mathbf{X}_1$, given a fixed $\mathbf{X}_2 = \mathbf{x}_2$, is multivariate normal with

$$\mathrm{mean}(\mathbf{X}_1|\mathbf{x}_2) = \boldsymbol{\mu}_1 + \boldsymbol{\Sigma}_{12}\boldsymbol{\Sigma}_{22}^{-1}(\mathbf{x}_2 - \boldsymbol{\mu}_2) \text{ and } \mathrm{cov}(\mathbf{X}_1|\mathbf{x}_2) = \boldsymbol{\Sigma}_{11} - \boldsymbol{\Sigma}_{12}\boldsymbol{\Sigma}_{22}^{-1}\boldsymbol{\Sigma}_{21}.$$

8. Generalized distance $(\mathbf{x} - \boldsymbol{\mu})^T\boldsymbol{\Sigma}^{-1}(\mathbf{x} - \boldsymbol{\mu})$ of observations $\mathbf{x}$ of a vector $\mathbf{X} \sim N_p(\boldsymbol{\mu}, \boldsymbol{\Sigma})$ from the mean $\boldsymbol{\mu}$ has a chi squared distribution with p *degrees of freedom* denoted χ_p^2.
9. With $\mathbf{X}_1, \mathbf{X}_2, \ldots, \mathbf{X}_n$ as a set of n observations from a (multivariate) normal population with mean $\boldsymbol{\mu}$ and covariance $\boldsymbol{\Sigma}$, we have the following results:
   (a) $\overline{\mathbf{X}}$ is distributed as $N_p(\boldsymbol{\mu}, (1/n)\boldsymbol{\Sigma})$
   (b) $(n-1)\mathbf{S}$ has a *Wishart distribution;* with $n-1$ degrees of freedom
   (c) $\overline{\mathbf{X}}$ and $\mathbf{S}$ are independent.

Multivariate Outliers

Isabel M. Rodrigues[1], Graciela Boente[2]
[1]Assistant Professor
Technical University of Lisbon (TULisbon), Lisboa, Portugal
[2]Professor, Facultad de Ciencias Exactas and Naturales Universidad de Buenos Aires and CONICET, Buenos Aires, Argentina

In the statistical analysis of data one is often confronted with observations that "appear to be inconsistent with the remainder of that set of data" (Barnett and Lewis 1994). Although such observations (the ▶outliers) have been the subject of numerous investigations, there is no general accepted formal definition of outlyingness. Nevertheless, the outliers describe abnormal data behavior, i.e., data that are deviating from the natural data variability (see, e.g., Peña and Prieto 2001, Filzmoser 2004, and Filzmoser et al. 2008 for a discussion).

Sometimes outliers can grossly distort the statistical analysis, while at other times their influence may not be as noticeable. Statisticians have accordingly developed numerous algorithms for the detection and treatment of outliers, but most of these methods were developed for univariate data sets. They are based on the estimation of location and scale, or on quantiles of the data. Since in a univariate sample outliers may be identified as an exceptionally large or small value, a simple plot of the data, such as scatterplot, stem-and-leaf plot, and QQ-plot can often reveal which points are outliers.

In contrast, for multivariate data sets the problem of outliers identification gives challenges that do not occur with univariate data since there is no simple concept of ordering the data. Furthermore, the multivariate case introduces a different kind of outlier, a point that is not extreme component wise but departs from the prevailing pattern of correlation structure. This departs causes that the observations appear as univariate outliers in some direction not easily identifiable. In this context, to detect an observation as possible outlier not only the distance from the centroid of the data is important but also the data shape. Also, as Gnanadesikan and Kettenring (1972) pointed out the visual detection of multivariate outliers is virtually impossible because the outliers do not "stick out on the end."

Since most standard multivariate analysis techniques rely on the assumption of normality, in 1963, Wilks proposed identifying sets of outliers of size j from $\{1, 2, \ldots, n\}$, in normal multivariate data, by checking the minimum values of the ratios $|A_{(I)}|/|A|$, where $|A_{(I)}|$ is the internal scatter of a modified sample in which the set of observations I of size j has been deleted and $|A|$ is the internal scatter of the complete sample. For $j = 1$ this method is equivalent to the classical way to declare a multivariate observation as a possible outlier by using the squared Mahalanobis' distance defined as

$$MD_i^2(\mathbf{x}_i, \mathbf{t}, \mathbf{V}) = ((\mathbf{x}_i - \mathbf{t})^T \mathbf{V}^{-1} (\mathbf{x}_i - \mathbf{t}))^{1/2}$$

where $\mathbf{t}$ is the estimated multivariate location and $\mathbf{V}$ the estimated scatter matrix. Usually $\mathbf{t}$ is the multivariate arithmetic mean, the centroid, and $\mathbf{V}$ the sample covariance matrix. Mahalanobis' distance identifies observations that lie far away from the center of the data cloud, giving less weight to variables with large variances or to groups of highly correlated variables. For a p-multivariate normally distributed data $MD_i^2(\mathbf{x}_i, \mathbf{t}, \mathbf{V})$ converge to χ_p^2, a chi-square distribution with p degree of freedom. Points with large $MD_i^2 \equiv MD_i^2(\mathbf{x}_i, \mathbf{t}, \mathbf{V})$, compared with some χ_p^2 quantile, are then considered outliers. Hence, to evaluate multivariate normality one may plot the ordered $MD_{(i)}^2$ against the expected order statistics of the ▶chi-square distribution with sample quantiles $\chi^2_{p[(i-1/2)/2]} = q_i$ where q_i $(i = 1, \ldots, n)$ is the $100(i - 1/2)/n$ sample quantile of χ_p^2. The plotted points $(MD_{(i)}, q_i)$ should be close to a line, so the points far from the line are potential outliers. Formal tests for multivariate outliers are considered by Barnett and Lewis (1994).

Clearly, the Mahalanobis distance relies on classical location and scatter estimators. The presence of outliers may distort arbitrarily the values of these estimators and render meaningless the results. This is particularly acute when there are several outliers forming a cluster, because

they will move the arithmetic mean toward them and inflate the classical tolerance ellipsoid in their direction. So this approach suffers from the *masking* and *swamping* effects by which multiple outliers do not have a large MD_i^2. A solution to this problem is well known in ►robust statistics: **t** and **V** have to be estimated in a robust manner, where the expression "robust"means resistance against the influence of outlying observations. Thus, the "robustified" ordered Mahalanobis distances, $RMD_{(i)}^2$ may be plotted to locate extreme outliers. This is the approach considered by Becker and Gather (2001), Filzmoser (2004), and Hardin and Rocke (2005) who studied outlier identification rules adapted to the sample size using different location and scatter robust estimators.

For a review on some of the robust estimators for location and scatter introduced in the literature see Maronna et al. (2006). The minimum covariance determinant (MCD) estimator – the procedure is due to Rousseeuw (1984) – is probably most frequently used in practice, partly because a computationally fast algorithm has been developped (Rousseeuw and Van Driessen 1999). The MCD estimator also benefits from the availability of software implementation in different languages, including R, S-Plus, Fortran, Matlab, and SAS. For these reasons the MCD estimator had gained much popularity, not only for outliers identification but also as an ingredient of many robust multivariate techniques.

Other currently popular multivariate outlier detection methods fall under projection pursuit techniques, originally proposed by Kruskal (1969). Projection pursuit searches for "interesting" linear projections of multivariate data sets, where a projection is deemed interesting if it minimizes or maximizes a projection index (typically a scale estimator). Therefore, the goal of projection pursuit methods is to find suitable projections of the data in which the outliers are readily apparent and may thus be downweighted to yield a estimator, which in turn can be used to identify the outliers. Since they do not assume the data to originate from a particular distribution but only search for useful projections, projection pursuit procedures are not affected by non-normality and can be widely applied in diverse data situations. The penalty for such freedom comes in the form of increased computational burden, since it is not clear which projections should be examined. An exact method would require to test over all possible directions.

The most well-known outlier identification method based upon the projection pursuit concept is the Stahel–Donoho (Stahel 1981; Donoho 1982) estimator. This was the first introduced high-breakdown and affine equivariant estimator of multivariate location and scatter that became better known after Maronna and Yohai (1995) published an analysis of it. It is based on a measure of the outlyingness of data points, which is obtained by projecting the observation on univariate directions. The Stahel–Donoho estimator then computes a weighted mean and covariance matrix, with weights inverse proportional to the outlyingness. This outlyingness measure is based upon the projection pursuit idea that if a point is a multivariate outlier, there must be some one-dimensional projection of the data in which this point is a univariate outlier. Using a particular observation as a reference point, the Stahel–Donoho algorithm determines which directions have optimal values for a pair of robust univariate location/scale estimators and then uses these estimators to assign weights to the other points. One way of reducing the computational cost of the Stahel–Donoho estimator is to reduce the number of projections that need to be examined.

In this direction, Peña and Prieto (2001) proposed a method, the Kurtosis1, which involves projecting the data onto a set of $2p$ directions. These directions are chosen to maximize and minimize the kurtosis coefficient of the data along them. A small number of outliers would cause heavy tails and lead to a larger kurtosis coefficient, while a larger number of outliers would start introducing bimodality and decrease the kurtosis coefficient. Viewing the data along projections that have maximum and minimum kurtosis values would therefore seem to display the outliers in a more recognizable representation.

For a much more detailed overview about outliers see Barnett and Lewis (1994) and also Rousseeuw et al. (2006) for a review on robust statistical methods and outlier detection.

Multivariate Rank Procedures : Perspectives and Prospectives

Pranab K. Sen
Cary C. Boshamer Professor of Biostatistics and Professor of Statistics and Operations Research
University of North Carolina, Chapel Hill, NC, USA

Developments ►in multivariate statistical analysis have genesis in the parametrics surrounding the *multivariate normal* distribution (see ►Multivariate Normal Distributions) in the continuous case while the *product multinomial law* dominates in discrete multivariate analysis. Characterizations of multi-normal distributions have provided a wealth of rigid mathematical tools leading to a very systematic evolution of mathematical theory laying down the foundation of multivariate statistical methods. *Internal multivariate* analyses comprising of *principal component models, canonical correlation* and *factor analysis* are all based on appropriate *invariance structures* that exploit the underlying linearity of the interrelation of different characteristics, without depending much on underlying normality, and these tools are very useful in many areas of applied research, such as sociology, psychology, economics, and agricultural sciences. In the recent past, there has been a phenomenal growth of multivariate analysis in medical studies, clinical trials and ►bioinformatics, among others. The role of multinormality is being scrutinized increasingly in these contexts.

External multivariate analyses pertaining to ►*multivariate analysis of variance* (MANOVA) and covariance (MANOCOVA), *classification and discrimination,* among others, have their roots in the basic assumption of multinormal distribution, providing some optimal, or at least desirable, properties of statistical inference procedures. Such optimal statistical procedures generally exist only when the multinormality assumption holds. Yet, in real life applications, the postulation of multinormality may not be tenable in a majority of cases. Whereas in the univariate case, there are some other distributions, some belonging to the so-called *exponential family of densities* and some not, for which exact statistical inference can be drawn, often being confined to suitable subclass of statistical procedures. In the multivariate case, alternatives to multinormal distributions are relatively few and lack generality. As such, almost five decades ago, it was strongly felt that statistical procedures should be developed to bypass the stringent assumption of multinormality; this is the genesis of *multivariate nonparametrics*.

Whereas the classical normal theory likelihood based multivariate analysis exploited *affine invariance*, leading to some optimality properties, it has some shortcomings too. Affine invariance makes sense only when the different characteristics or variates are linearly combinable in a meaningful way. Further, such parametric procedures are quite vulnerable to even small departures from the assumed multinormality. Thus, they are generally *nonrobust* even in a local sense. Moreover, in many applications, different characteristics are recorded on different units and often on a relative scale (viz., ranking of n individuals on some multivariate traits) where linearly combinability may not be compatible. Rather, it is more important to have coordinatewise invariance under arbitrary strictly monotone transformations – a feature that favors ranks over actual measurements. Multivariate rank procedures have this basic advantage of invariance under coordinatewise arbitrary strictly monotone transformations, not necessarily linear. Of course, this way the emphasis on affine invariance is sacrificed, albeit, there are affine-invariant rank procedures too (see Oja 2010).

The basic difference between univariate and multivariate rank procedures is that for suitable *hypothesis of invariance*, in the univariate case, such procedures are genuinely distribution-free, whereas in the multivariate case,

even the hypothesis of invariance holds, these tests are usually *conditionally distribution-free*. This feature, known as the *rank-permutation principle*, was initially developed by Chatterjee and Sen (1964) and in a more general framework, compiled and reported in Puri and Sen (1971), the first text in multivariate nonparametrics. During the past four decades, a phenomenal growth of research literature in multivariate nonparametrics has taken place; specific entries in the *Encyclopedia of Statistical Science* and *Encyclopedia of Biostatistics* (both published from Wiley-Interscience, New York) provide detailed accounts of these developments.

In the recent past, *high-dimensional low sample size* (HDLSS) problems have cropped up in diverse fields of application. In this setup, the dimension is generally far larger than the number of sample observations, and hence, standard parametric procedures are untenable; nonparametrics fare much better. This is a new frontier of multivariate nonparametrics and there is a tremendous scope of prospective research with deep impact on fruitful applications. ►Data mining (or knowledge discovery and data mining) and statistical learning algorithms also rest on multivariate nonparametrics to a greater extent. Bioinformatics and environmetrics problems also involve such nonstandard multivariate nonparametric procedures. In a micro-array data model, an application of multivariate rank methods has been thoroughly explored in Sen (2008).

About the Author

Dr. Pranab Kumar Sen is a Cary C. Boshamer Professor of Biostatistics, University of North Carolina (1982–) and a lifelong Adjunct Professor, Indian Statistical Institute, Calcutta (1993–). He was born on November 7, 1937 in Calcutta, India. He had his school and college education (B.Sc. (1955), M.Sc. (1957) and Ph.D. (1962), all in Statistics) from Calcutta University. Professor Sen is Fellow of the Institute of Mathematical Statistics (1968), Fellow of the American Statistical Association (1969), and Elected Member of the International Statistical Institute (1973). Professor Sen has (co-)authored over 615 publications in Statistics, Probability Theory, Stochastic Processes, and Biostatistics in leading journals in these areas, and (co-)authored or (co-) edited 23 books and monographs in Statistics, Probability Theory and Biostatistics. He has (co-)supervised the Doctoral Dissertation of 82 students from University of North Carolina (1969–2009), many of whom have achieved distinction both nationally and internationally. In 1988 he was awarded the Boltzman Award in Mathematical Sciences from Charles University, Prague, and in 1998, the Commemoration Medal by the Czech Union of Mathematicians and Physicists, Prague. In 2002, he was awarded the Senior Noether Award from the American Statistical Association for his significant contributions to Nonparametrics, teaching as well as research. In 2010, Professor Sen has received the Wilks Medal, American Statistical Association. He was the Founding (joint) Editor of two international journals: *Sequential Analysis* (1982) and *Statistics and Decisions* (1983). Currently, he is the Chief Editor of *Sankhya* (Series A and B).

"Professor Sen's pioneering contributions have touched nearly every area of statistics. He is the first person who, in joint collaboration with Professor S. K. Chatterjee, developed multivariate rank tests as well as time-sequential nonparametric methods. He is also the first person who carried out in-depth research in sequential nonparametrics culminating in his now famous Wiley book *Sequential Nonparametrics: Invariance Principles and Statistical Inference* and SIAM monograph." (Malay Ghosh and Michael J. Schell, A Conversation with Pranab Kumar Sen, *Statistical Science*, Volume 23, Number 4 (2008), 548–564.

Multivariate Reduced-Rank Regression

Alan J. Izenman
Senior Research Professor of Statistics, Director of the Center for Statistical and Information Science
Temple University, Philadelphia, PA, USA

Multivariate reduced-rank regression is a way of constraining the multivariate linear regression model so that the rank of the regression coefficient matrix has less than full

rank. Without the constraint, multivariate linear regression has no true multivariate content.

To see this, suppose we have a random r-vector $\mathbf{X} = (X_1, \ldots, X_r)^\tau$ of predictor (or input) variables with mean vector $\boldsymbol{\mu}_X$ and covariance matrix $\boldsymbol{\Sigma}_{XX}$, and a random s-vector $\mathbf{Y} = (Y_1, \ldots, Y_s)^\tau$ of response (or output) variables with mean vector $\boldsymbol{\mu}_Y$ and covariance matrix $\boldsymbol{\Sigma}_{YY}$. Suppose that the $(r+s)$-vector $\mathbf{Z} = (\mathbf{X}^\tau, \mathbf{Y}^\tau)^\tau$ has a joint distribution with mean vector and covariance matrix,

$$\boldsymbol{\mu}_Z = \begin{pmatrix} \boldsymbol{\mu}_X \\ \boldsymbol{\mu}_Y \end{pmatrix}, \qquad \boldsymbol{\Sigma}_{ZZ} = \begin{pmatrix} \boldsymbol{\Sigma}_{XX} & \boldsymbol{\Sigma}_{XY} \\ \boldsymbol{\Sigma}_{YX} & \boldsymbol{\Sigma}_{YY} \end{pmatrix}, \tag{1}$$

respectively, where we assume that $\boldsymbol{\Sigma}_{XX}$ and $\boldsymbol{\Sigma}_{YY}$ are both nonsingular. Now, consider the classical multivariate linear regression model,

$$\underset{s\times 1}{\mathbf{Y}} = \underset{s\times 1}{\boldsymbol{\mu}} + \underset{s\times r}{\boldsymbol{\Theta}}\ \underset{r\times 1}{\mathbf{X}} + \underset{s\times 1}{\mathcal{E}}, \tag{2}$$

where $\mathbf{Y}$ depends linearly on $\mathbf{X}$, $\boldsymbol{\mu}$ is the overall mean vector, $\boldsymbol{\Theta}$ is the multivariate regression coefficient matrix, and $\mathcal{E}$ is the error term. In this model, $\boldsymbol{\mu}$ and $\boldsymbol{\Theta}$ are unknown and are to be estimated. The least-squares estimator of $(\boldsymbol{\mu}, \boldsymbol{\Theta})$ is given by

$$(\boldsymbol{\mu}^*, \boldsymbol{\Theta}^*) = arg \min_{\boldsymbol{\mu},\boldsymbol{\Theta}} \mathrm{E}\{(\mathbf{Y} - \boldsymbol{\mu} - \boldsymbol{\Theta}\mathbf{X})(\mathbf{Y} - \boldsymbol{\mu} - \boldsymbol{\Theta}\mathbf{X})^\tau\}, \tag{3}$$

where

$$\boldsymbol{\mu}^* = \boldsymbol{\mu}_Y - \boldsymbol{\Theta}^*\boldsymbol{\mu}_X, \quad \boldsymbol{\Theta}^* = \boldsymbol{\Sigma}_{YX}\boldsymbol{\Sigma}_{XX}^{-1}. \tag{4}$$

In (3), the expectation is taken over the joint distribution of $(X^\tau, Y^\tau)^\tau$. The minimum achieved is $\boldsymbol{\Sigma}_{YY} - \boldsymbol{\Sigma}_{YX}\boldsymbol{\Sigma}_{XX}^{-1}\boldsymbol{\Sigma}_{XY}$. The $(s \times r)$-matrix $\boldsymbol{\Theta}^*$ is called the (full-rank) regression coefficient matrix. This solution is identical to that obtained by performing a sequence of s ordinary least-squares multiple regressions. For the jth such multiple regression, Y_j is regressed on the r-vector $\mathbf{X}$, where $j = 1, 2, \ldots, s$. Suppose the minimizing regression coefficient vectors are the r-vectors $\boldsymbol{\beta}_j^*$, $j = 1, 2, \ldots, s$. Arranging the coefficient vectors as the columns, $(\boldsymbol{\beta}_1^*, \ldots, \boldsymbol{\beta}_r^*)$, of an $(r \times s)$-matrix, and then transposing the result, it follows from (4) that

$$\boldsymbol{\Theta}^* = (\boldsymbol{\beta}_1^*, \ldots, \boldsymbol{\beta}_r^*)^\tau. \tag{5}$$

Thus, multivariate linear regression is equivalent to just carrying out a sequence of multiple regressions. This is why multivariate regression is often confused with multiple regression.

Now, rewrite the multivariate linear model as

$$\underset{s\times 1}{\mathbf{Y}} = \underset{s\times 1}{\boldsymbol{\mu}} + \underset{s\times r}{\mathbf{C}}\ \underset{r\times 1}{\mathbf{X}} + \underset{s\times 1}{\mathcal{E}}, \tag{6}$$

where the rank constraint is

$$\mathrm{rank}(\mathbf{C}) = t \le \min(r, s). \tag{7}$$

Equations (6) and (7) form the multivariate reduced-rank regression model. When the rank condition (7) holds, there exist two (nonunique) full-rank matrices $\mathbf{A}$ and $\mathbf{B}$, where $\mathbf{A}$ is an $(s \times t)$-matrix and $\mathbf{B}$ is a $(t \times r)$-matrix, such that

$$\underset{s\times r}{\mathbf{C}} = \underset{s\times t}{\mathbf{A}}\ \underset{t\times r}{\mathbf{B}}. \tag{8}$$

The multivariate reduced-rank regression model can now be written as

$$\underset{s\times 1}{\mathbf{Y}} = \underset{s\times 1}{\boldsymbol{\mu}} + \underset{s\times t}{\mathbf{A}}\ \underset{t\times r}{\mathbf{B}}\ \underset{r\times 1}{\mathbf{X}} + \underset{s\times 1}{\mathcal{E}}. \tag{9}$$

The rank condition has been embedded into the regression model. The goal is to estimate $\boldsymbol{\mu}$, $\mathbf{A}$, and $\mathbf{B}$ (and, hence, $\mathbf{C}$).

Let $\boldsymbol{\Gamma}$ be a positive-definite symmetric $(s \times s)$-matrix of weights. The weighted least-squares estimates of $(\boldsymbol{\mu}, A, B)$ are

$$(\boldsymbol{\mu}^*, \mathbf{A}^*, \mathbf{B}^*) = arg \min_{\boldsymbol{\mu},\mathbf{A},\mathbf{B}} \mathrm{E}\{(\mathbf{Y} - \boldsymbol{\mu} - \mathbf{AB}\mathbf{X})^\tau \boldsymbol{\Gamma} (\mathbf{Y} - \boldsymbol{\mu} - \mathbf{AB}\mathbf{X})\} \tag{10}$$

where

$$\boldsymbol{\mu}^* = \boldsymbol{\mu}_Y - \mathbf{AB}\boldsymbol{\mu}_X \tag{11}$$

$$\mathbf{A}^* = \boldsymbol{\Gamma}^{-1/2}\mathbf{V} \tag{12}$$

$$\mathbf{B}^* = \mathbf{V}^\tau \boldsymbol{\Gamma}^{1/2} \boldsymbol{\Sigma}_{YX} \boldsymbol{\Sigma}_{XX}^{-1}, \tag{13}$$

and $\mathbf{V} = (\mathbf{v}_1, \ldots, \mathbf{v}_t)$ is an $(s \times t)$-matrix, where the jth column, $\mathbf{v}_j$, is the eigenvector corresponding to the jth largest eigenvalue, λ_j, of the $(s \times s)$ symmetric matrix,

$$\boldsymbol{\Gamma}^{1/2} \boldsymbol{\Sigma}_{YX} \boldsymbol{\Sigma}_{XX}^{-1} \boldsymbol{\Sigma}_{XY} \boldsymbol{\Gamma}^{1/2}. \tag{14}$$

The multivariate reduced-rank regression coefficient matrix $\mathbf{C}$ with rank t is, therefore, given by

$$\mathbf{C}^* = \boldsymbol{\Gamma}^{-1/2} \left(\sum_{j=1}^{t} \mathbf{v}_j \mathbf{v}_j^\tau \right) \boldsymbol{\Gamma}^{1/2} \boldsymbol{\Sigma}_{YX} \boldsymbol{\Sigma}_{XX}^{-1}. \tag{15}$$

The minimum achieved is $tr\{\boldsymbol{\Sigma}_{YY}\boldsymbol{\Gamma}\} - \sum_{j=1}^{t} \lambda_j$.

The main reason that multivariate reduced-rank regression is so important is that it contains as special cases the classical statistical techniques of ▶principal component analysis, canonical variate and correlation analysis (see ▶Discriminant Analysis: An Overview, and ▶Discriminant Analysis: Issues and Problems), linear discriminant analysis, exploratory factor analysis, multiple correspondence analysis, and other linear methods of analyzing multivariate data. It is also closely related to artificial neural network models and to cointegration in the econometric literature.

For example, the special cases of principal component analysis, canonical variate and correlation analysis, and linear discriminant analysis are given by the following choices: For *principal component analysis*, set $\mathbf{X} \equiv \mathbf{Y}$

and $\mathbf{\Gamma} = \mathbf{I}_s$; for *canonical variate and correlation analysis*, set $\mathbf{\Gamma} = \mathbf{\Sigma}_{YY}^{-1}$; for *linear discriminant analysis*, use the canonical-variate analysis choice of $\mathbf{\Gamma}$ and set $\mathbf{Y}$ to be a vector of binary variables whose component values (0 or 1) indicate the group or class to which an observation belongs. Details of these and other special cases can be found in Izenman (2008). If the elements of $\mathbf{\Sigma}_{ZZ}$ in (1) are unknown, as will happen in most practical problems, they have to be estimated using sample data on $\mathbf{Z}$.

The relationships between multivariate reduced-rank regression and the classical linear dimensionality reduction techniques become more interesting when the meta-parameter t is unknown and has to be estimated. The value of t is called the *effective dimensionality* of the multivariate regression (Izenman 1980). Estimating t is equivalent to the classical problems of determining the number of principal components to retain, the number of canonical variate to retain, or the number of linear discriminant functions necessary for classification purposes. Graphical methods for estimating t include the scree plot, the rank trace plot, and heatmap plots. Formal hypothesis tests have also been developed for estimating t.

When the number of variables is greater than the number of observations, some adjustments to the results have to be made to ensure that $\mathbf{\Sigma}_{XX}$ and $\mathbf{\Sigma}_{YY}$ can be inverted. One simple way of doing this is to replace $\mathbf{\Sigma}_{XX}$ by $\mathbf{\Sigma}_{XX} + \delta\mathbf{I}_r$ and to replace $\mathbf{\Sigma}_{YY}$ by $\mathbf{\Sigma}_{YY} + \kappa\mathbf{I}_s$ as appropriate, where $\delta > 0$ and $\kappa > 0$. Other methods, including regularization, banding, tapering, and thresholding, have been studied for estimating large covariance matrices and can be used here as appropriate.

The multivariate reduced-rank regression model can also be developed for the case of nonstochastic (or fixed) predictor variables.

The multivariate reduced-rank regression model has its origins in Anderson (1951), Rao (1964, 1965), and Brillinger (1969), and its name was coined by Izenman (1972, 1975). For the asymptotic distribution of the estimated reduced-rank regression coefficient matrix, see Anderson (1999), who gives results for both the random-$\mathbf{X}$ and fixed-$\mathbf{X}$ cases. Additional references are the monographs by van der Leeden (1990) and Reinsel and Velu (1998).

About the Author

Professor Izenman was Director of the Statistics and Probability Program at the National Science Foundation (1992–1994). He has been an Associate Editor of the *Journal of the American Statistical Association*. He is Associate Editor of the journals *Law, Probability, and Risk* and *Statistical Analysis and Data Mining*. He is a Fellow of the American Statistical Association. He was Vice-President, ASA Philadelphia Chapter (1987–1988).

Multivariate Statistical Analysis

Nanny Wermuth
Professor of Statistics
Chalmers Technical University/University of Gothenburg, Gothenburg, Sweden

Classical multivariate statistical methods concern models, distributions and inference based on the Gaussian distribution. These are the topics in the first textbook for mathematical statisticians by T. W. Anderson that was published in 1958 and that appeared as a slightly expanded 3rd edition in 2003. Matrix theory and notation is used

there extensively to efficiently derive properties of the multivariate Gaussian or the Wishart distribution, of principal components, of canonical correlation and discriminant analysis (see ►Discriminant Analysis: An Overview, and ►Discriminant Analysis: Issues and Problems) and of the general multivariate linear model in which a Gaussian response vector variable Y_a has linear least-squares regression on all components of an explanatory vector variable Y_b.

In contrast, many methods for analyzing sets of observed variables have been developed first within special substantive fields and some or all of the models in a given class were justified in terms of probabilistic and statistical theory much later. Among them are factor analysis (see ►Factor Analysis and Latent Variable Modelling), path analysis, ►structural equation models, and models for which partial-least squares estimation have been proposed. Other multivariate techniques such as cluster analysis (see ►Cluster Analysis: An Introduction) and ►multidimensional scaling have been often used, but the result of such an analysis cannot be formulated as a hypothesis to be tested in a new study and satisfactory theoretical justifications are still lacking.

Factor analysis was proposed by psychologist C. Spearman (1904), (1926) and, at the time, thought of as a tool for measuring human intelligence. Such a model has one or several latent variables. These are hidden or unobserved and are to explain the observed correlations among a set of observed variables, called items in that context. The difficult task is to decide how many and which of a possibly large set of items to include into a model. But, given a set of latent variables, a classical factor analysis model specifies for a joint Gaussian distribution mutual independence of the observed variables given the latent variables. This can be recognized to be one special type of a graphical Markov model; see Cox and Wermuth (1996), Edwards (2000), Lauritzen (1996), Whittaker (1990).

Path analysis was developed by geneticist S. Wright (1923), (1934) for systems of linear dependence of variables with zero mean and unit variance. He used what we now call directed acyclic graphs to represent hypotheses of how the variables he was studying could have been generated. He compared correlations implied for missing edges in the graph with corresponding observed correlations to test the goodness of fit of such a hypothesis.

By now it is known, under which condition for these models in standardized Gaussian variables, maximum-likelihood estimates of correlations coincide with Wright's estimates via path coefficients. The condition on the graph is simple: there should be no three-node-two-edge subgraph of the following kind $\circ\!\!\longrightarrow\!\circ\longleftarrow\!\!\circ$. Then, the directed acyclic graph is said to be decomposable and captures the same independences as the concentration graph obtained by replacing each arrow by an undirected edge. In such Gaussian concentration graph models, estimated variances are matched to the observed variances so that estimation of correlations and variances is equivalent to estimation of covariances and variances.

Wright's method of computing implied path coefficients by "tracing paths" has been generalized via a so-called separation criterion. This criterion, given by Geiger, Verma and Pearl (1990), permits to read off a directed acyclic graph all independence statements that are implied by the graph. The criterion takes into account that not only ignoring (marginalizing over) variables might destroy an independence, but also conditioning on common responses may render two formerly independent variables to be dependent. In addition, the separation criterion holds for any distribution generated over the graph.

The separation criterion for directed acyclic graphs has been translated into conditions for the presence of edge-inducing paths in the graph; see Marchetti and Wermuth (2009). Such an edge-inducing path is also association-inducing in the corresponding model, given some mild conditions on the graph and on the distributions generated over it; see Wermuth (2010). In the special case of only marginalizing over linearly related variables, these induced dependences coincide with the path-tracing results given by Wright provided the directed acyclic graph model is decomposable and the variables are standardized to have zero means and unit variances. This applies not only to Gaussian distributions but also to special distributions of symmetric binary variables; see Wermuth et al. (2009).

Typically however, directed acyclic graph models are defined for unstandardized random variables of any type. Then, most dependences are no longer appropriately represented by linear regression coefficients or correlations, but maximum-likelihood estimates of all measures of dependence can still be obtained by separately maximizing each univariate conditional distribution, provided only that its parameters are variation-independent from parameters of distributions in the past.

Structural equation models, developed in econometrics, can be viewed as another extension of Wright's path analyses. The result obtained by T. Haavelmo (1943) gave an important impetus. For his insight that separate linear least-squares estimation may be inappropriate for equations having strongly correlated residuals, Haavelmo received a Nobel prize in 1989. It led to a class of models defined by linear equations with correlated residuals and to responses called endogenous. Other variables conditioned on and considered to be predetermined were named

exogenous. Vigorous discussions of estimation methods for structural equations occurred during the first few Berkeley symposia on mathematical statistics and probability from 1945 to 1965.

Path analysis and structural equation models were introduced to sociological research via the work by O.D. Duncan (1966, 1975). Applications of structural equation models in psychological and psychometric research resulted from cooperations between A. Goldberger and K. Jöreskog; see Goldberger (1971, 1972) and Jöreskog (1973, 1981). The methods became widely used once a corresponding computer program for estimation and tests was made available; see also Kline (2010).

In 1962, A. Zellner published his results on seemingly unrelated regressions. He points out that two simple regression equations are not separate if the two responses are correlated and that two dependent endogenous variables need to be considered jointly and require simultaneous estimation methods. These models are now recognized as special cases of both linear structural equations and of multivariate regression chains, a subclass of graphical Markov models; see Cox and Wermuth (1993), Drton (2009), Marchetti and Lupparelli (2010).

But it was not until 40 years later, that a maximum-likelihood solution for the Gaussian distribution in four variables, split into a response vector Y_a and vector variable Y_b, was given and an example of a poorly fitting data set with very few observations for which the likelihood equations have two real roots; see Drton and Richardson (2004). For well-fitting data and reasonably large sample sizes, this is unlikely to happen; see Sundberg (2010). For such situations, a close approximation to the maximum-likelihood estimate has been given in closed form for the seemingly unrelated regression model, exploiting that it is a reduced model to the covering model that has closed-form maximum-likelihood estimates, the general linear model of Y_a given Y_b; see Wermuth et al. (2006), Cox and Wermuth (1990).

For several discrete random variables of equal standing, i.e., without splits into response and explanatory variables, maximum-likelihood estimation was developed under different conditional independence constraints in a path-breaking paper by M. Birch (1963). This led to the formulation of general log-linear models, which were studied intensively among others by Haberman (1974), Bishop et al. (1975), Sundberg (1975) and by L. Goodman, as summarized in a book of his main papers on this topic, published in 1978. His work was motivated mainly by research questions from the social and medical sciences.

For several Gaussian variables of equal standing, two different approaches to reducing the number of parameters in a model, were proposed at about the same time. T. W. Anderson put structure on the covariances, the moment parameters of a joint Gaussian distribution and called the resulting models, hypotheses linear in covariances; see Anderson (1973), while A. P. Dempster put structure on the canonical parameters with zero constraints on concentrations, the off-diagonal elements of the inverse of a covariance matrix, and called the resulting models covariance selection models; see Dempster (1972).

Nowadays, log-linear models and covariance selection models are viewed as special cases of concentration graph models and zero constraints on the covariance matrix of a Gaussian distribution as special cases of covariance graph models. Covariance and concentration graph models are graphical Markov models with undirected graphs capturing independences. A missing edge means marginal independence in the former and conditional independence given all remaining variables in the latter; see also Wermuth and Lauritzen (1990), Wermuth and Cox (1998), (2004), Wermuth (2010).

The largest known class of Gaussian models that is in common to structural equation models and to graphical Markov models are the recursive linear equations with correlated residuals. These include linear summary graph models of Wermuth (2010), linear maximal ancestral graph of Richardson and Spirtes (2002), linear multivariate regression chains, and linear directed acyclic graph models. Deficiencies of some formulations start to be discovered by using algebraic methods. Identification is still an issue to be considered for recursive linear equations with correlated residuals, since so far only necessary or sufficient conditions are known but not both. Similarly, maximum-likelihood estimation still needs further exploration; see Drton et al. (2009).

For several economic time series, it became possible to judge whether such fluctuating series develop nevertheless in parallel, that is whether they represent cointegrating variables because they have a common stochastic trend. Maximum-likelihood analysis for cointegrating variables, formulated by Johansen (1988, 2009), has led to many important applications and insights; see also Hendry and Nielsen (2007).

Algorithms and corresponding programs are essential for any widespread use of multivariate statistical methods and for successful analyses. In particular, iterative proportional fitting, formulated by Bishop (1964) for log-linear models, and studied further by Darroch and Ratcliff (1972), was adapted to concentration graph models for CG (conditional Gaussian)-distributions (Lauritzen and Wermuth 1989) of mixed discrete and continuous variables by Frydenberg and Edwards (1989).

The EM (expectation-maximization)-algorithm of Dempster et al. (1977) was adapted to Gaussian directed

acyclic graph models with latent variables by Kiiveri (1987) and to discrete concentration graph models with missing observation by Lauritzen (1995).

With the TM-algorithm of Edwards and Lauritzen (2001), studied further by Sundberg (2002), maximum-likelihood estimation became feasible for all chain graph models called blocked concentration chains in the case these are made up of CG (conditional Gaussian)-regressions (Lauritzen and Wermuth 1989).

For multivariate regression chains of discrete random variables, maximum-likelihood estimation has now been related to the multivariate logistic link function by Marchetti and Lupparelli (2010), where these link functions provide a common framework and corresponding algorithm for ▶generalized linear models, which include among others linear, logistic and probit regressions as special cases; see McCullagh and Nelder (1989), Glonek and McCullagh (1995).

Even in linear models, estimation may become difficult when some of the explanatory variables are almost linear functions of others, that is if there is a problem of ▶multicollinearity. This appears to be often the case in applications in chemistry and in the environmental sciences. Thus, in connection with consulting work for chemists, Hoerl and Kennard (1970) proposed the use of ridge-regression (see ▶Ridge and Surrogate Ridge Regressions) instead of linear least-squares regression. This means for regressions of vector variable Y on X, to add to X^TX some positive constant k along the diagonal before matrix inversion to give as estimator $\tilde{\beta} = (kI + X^TX)^{-1}X^TY$.

Both ridge-regression and partial-least-squares, (see ▶Partial Least Squares Regression Versus Other Methods) proposed as an estimation method in the presence of latent variables by Wold (1980), have been recognized by Björkström and Sundberg (1999) to be shrinkage estimators and as such special cases of Tykhonov (1963) regularization.

More recently, a number of methods have been suggested which combine adaptive skrinkage methods with variable selection. A unifying approach which includes the least-squares estimator, shrinkage estimators and various combinations of variable selection and shrinkage has recently been given via a least squares approximation by Wang and Leng (2007). Estimation results depend necessarily on the chosen formulations and the criteria for shrinking dependences and for selecting variables.

Many more specialized algorithms and programs have been made available within the open access programming environment R, also those aiming to analyze large numbers of variables for only few observed individuals. It remains to be seen, whether important scientific insights will be gained by their use.

About the Author

Dr Nanny Wermuth is Professor of Statistics, at the joint Department of Mathematical Sciences of Chalmers Technical University and the University of Gothenburg. She is a Past President, Institute of Mathematical Statistics (2008–2009) and Past President of the International Biometric Society (2000–2001). In 1992 she was awarded a Max Planck-Research Prize, jointly with Sir David Cox. She chaired the Life Science Committee of the International Statistical Institute (2001–2005) and was an Associate editor of the *Journal of Multivariate Analysis* (1998–2001) and *Bernoulli* (2007–2010). Professor Wermuth is an Elected member of the German Academy of Sciences and of the International Statistical Institute (1982), an elected Fellow of the American Statistical Association (1989), and of the Institute of Mathematical Statistics (2001). She is a co-author (with David R. Cox) of the text *Multivariate dependencies: models, analysis and interpretation* (Chapman and Hall, 1996).

Multivariate Statistical Distributions

Donald R. Jensen
Professor Emeritus
Virginia Polytechnic Institute and State University,
Blacksburg, VA, USA

Origins and Uses

Multivariate distributions (MDs) are defined on finite-dimensional spaces. Origins trace to early studies of ►*multivariate normal distributions* as models for dependent chance observations (Adrian 1808; Bravais 1846; Dickson 1886; Edgeworth 1892; Galton 1889; Gauss 1823; Helmert 1868; Laplace 1811; Pearson 1896; Plana 1813; Schols 1875; Spearman 1904; Student 1908); for two and three dimensions in Bravais (1846) and Schols (1875); and for finite dimensions in Edgeworth (1892) and Gauss (1823), advancing such now–familiar concepts as regression and partial correlation. Let $\boldsymbol{Y} = [Y_1, \ldots, Y_5]$ designate chance observations; in pharmacology as systolic (Y_1) and diastolic (Y_2) pressures, pulse rate (Y_3), and gross (Y_4) and fine (Y_5) motor skills. Strengths of materials may register moduli of elasticity (Y_1) and of rupture (Y_2), specific gravity (Y_3), coefficient of linear expansion (Y_4), and melting point (Y_5). A complete probabilistic description of each vector observation entails the joint distribution of $[Y_1, \ldots, Y_5]$. A sample of n such k–vectors, arranged as rows, yields a random matrix $\boldsymbol{Y} = [Y_{ij}]$ of order $(n \times k)$, its distribution supporting much of ►*multivariate statistical analysis*.

Beyond modeling chance outcomes, MDs describe probabilistic features of data–analytic operations, to include statistical inference, decision theory (see ►Decision Theory: An Introduction, and ►Decision Theory: An Overview), and other evidentiary analyses. In inference the frequentist seeks joint distributions (1) of multiparameter estimates, and (2) of statistics for testing multiple hypotheses, both parametric and nonparametric. Such distributions derive from observational models. Similarly, multiparameter Bayesian methods require MDs in modeling prior, contemporary, and posterior distributions for the parameters. In addition, MDs serve to capture dependencies owing to repeated measurements on experimental subjects. MDs derive from other distributions through transformations, projections, conditioning, convolutions, extreme values, mixing, compounding, truncating, and censoring. Specifically, experiments modeled conditionally in a random environment yield unconditional distributions as mixtures; see Everitt and Hand (1981), Lindsay (1995), McLachlan and Basford (1988), and Titterington et al. (1985). Random processes, to include such concepts as stationarity, are characterized through MDs as their finite–dimensional projections. Beyond probability, MD–theory occasionally supports probabilistic proofs for purely mathematical theorems. In short, MDs arise throughout statistics, applied probability, and beyond, and their properties are essential to understanding those fields.

In what follows $\mathbb{R}^k$, $\mathbb{R}^k_+$, $\mathbb{F}_{n\times k}$, $\mathbb{S}_k$, and $\mathbb{S}^+_k$ respectively designate Euclidean k–space, its positive orthant, the real $(n \times k)$ matrices, the real symmetric $(k \times k)$ matrices, and their positive definite varieties. Special arrays are $\boldsymbol{I}_k$, the $(k \times k)$ identity, and the diagonal matrix $\mathrm{Diag}(a_1, \ldots, a_k)$. The transpose, inverse, trace, and determinant of $\boldsymbol{A} \in \mathbb{F}_{k\times k}$ are $\boldsymbol{A}'$, $\boldsymbol{A}^{-1}$, $\mathrm{tr}(\boldsymbol{A})$, and $|\boldsymbol{A}|$, with $\boldsymbol{a}' = [a_1, \ldots, a_k]$ as the transpose of $\boldsymbol{a} \in \mathbb{R}^k$. For $\boldsymbol{Y} \in \mathbb{R}^k$ random, its expected vector, dispersion matrix, and law of distribution are $E(\boldsymbol{Y}) \in \mathbb{R}^k$, $V(\boldsymbol{Y}) \in \mathbb{S}^+_k$, and $\mathcal{L}(\boldsymbol{Y})$. Abbreviations include *pdf*, *pmf*, *cdf*, and *chf*, for probability density, probability mass, cumulative distribution, and ►characteristic functions, respectively.

Some Properties

MDs merit scrutiny at several levels. At one extreme are weak assumptions on existence of low-order moments, as in Gauss–Markov theory. At the other extremity are rigidly parametric models, having MDs of specified functional forms to be surveyed subsequently. In between are

Multivariate Statistical Distributions. Table 1 Examples of spherical distributions on $\mathbb{R}^n$ having density $f(\boldsymbol{x})$ or characteristic function $\xi(\boldsymbol{t})$; see Chmielewski (1981)

Density or *chf*	Comments	
Normal	$f(\boldsymbol{x}) = c_1 \exp(-\boldsymbol{x}'\boldsymbol{x}/2)$	$N_n(\boldsymbol{0}, \boldsymbol{I}_n)$
Pearson Type II	$f(\boldsymbol{x}) = c_2(1-\boldsymbol{x}'\boldsymbol{x})^{\gamma-1}$	$\gamma > 1$
Pearson Type VII	$f(\boldsymbol{x}) = c_3(1+\boldsymbol{x}'\boldsymbol{x})^{-\gamma}$	$\gamma > n/2$
Student t	$f(\boldsymbol{x}) = c_4(1+\nu^{-1}\boldsymbol{x}'\boldsymbol{x})^{-(\nu+n)/2}$	ν a positive integer
Cauchy	$f(\boldsymbol{x}) = c_5(1+\boldsymbol{x}'\boldsymbol{x})^{-(n+1)/2}$	Student t $\nu = 1$
Scale mixtures	$f(\boldsymbol{x}) = c_6 \int_0^\infty t^{-n/2} \exp(-\boldsymbol{x}'\boldsymbol{x}/2t) dG(t)$	$G(t)$ a *cdf*
Stable laws	$\xi(\boldsymbol{t}) = c_7 \exp[\gamma(\boldsymbol{t}'\boldsymbol{t})^{\alpha/2}]$	$0 < \alpha < 2; \gamma > 0$

classes of MDs exhibiting such common structural features as symmetry or unimodality, giving rise to *semiparametric* models of note. Of particular relevance are derived distributions that are unique to all members of an underlying class.

Specifically, distributions on $\mathbb{F}_{n\times k}$ in the class $\{L_{n,k}(\boldsymbol{\Theta}, \boldsymbol{\Gamma}, \boldsymbol{\Sigma}); \phi \in \Phi\}$ have *pdf*s as given in Table 3. Here $\boldsymbol{\Theta} \in \mathbb{F}_{n\times k}$ comprise location parameters; $\boldsymbol{\Gamma} \in \mathbb{S}_n^+$ and $\boldsymbol{\Sigma} \in \mathbb{S}_k^+$ are scale parameters; $\phi(\cdot)$ is a function on $\mathbb{S}_k^+$; and $\boldsymbol{\Sigma}^{-\frac{1}{2}}$ is a factor of $\boldsymbol{\Sigma}^{-1}$. These distributions are invariant for $\boldsymbol{\Gamma} = \boldsymbol{I}_n$ in that $\mathcal{L}(\boldsymbol{Y} - \boldsymbol{\Theta}) = \mathcal{L}(\boldsymbol{Q}(\boldsymbol{Y} - \boldsymbol{\Theta}))$ for every real orthogonal matrix $\boldsymbol{Q}(n \times n)$. A subclass, taking $\phi(\boldsymbol{A}) = \psi(\mathrm{tr}(\boldsymbol{A}))$, with ψ defined on $[0,\infty)$, is $S_{n,k}(\boldsymbol{\Theta}, \boldsymbol{\Gamma}, \boldsymbol{\Sigma})$ as in Table 3. Here independence among rows of $\boldsymbol{Y} = [\boldsymbol{y}_1, \ldots, \boldsymbol{y}_n]'$ and multinormality are linked: If $\mathcal{L}(\boldsymbol{Y}) \in S_{n,k}(\boldsymbol{\Theta}, \boldsymbol{I}_n, \boldsymbol{\Sigma})$, then $\{\boldsymbol{y}_1, \ldots, \boldsymbol{y}_n\}$ are mutually independent if and only if $\boldsymbol{Y}$ is matrix normal, namely $N_{n,k}(\boldsymbol{\Theta}, \boldsymbol{I}_n, \boldsymbol{\Sigma})$ on $\mathbb{F}_{n\times k}$; see James (1954). A further subclass on $\mathbb{R}^n$, with $k = 1$ and $\boldsymbol{\Sigma}(1\times 1) = 1$, are the *elliptical distributions* on $\mathbb{R}^n$, namely, $\{\mathcal{S}_n(\boldsymbol{\theta}, \boldsymbol{\Gamma}, \psi); \psi \in \Psi\}$, with location-scale parameters $(\boldsymbol{\theta}, \boldsymbol{\Gamma})$ and the typical *pdf* $f(\boldsymbol{y}) = |\boldsymbol{\Gamma}|^{-\frac{1}{2}} \psi((\boldsymbol{y} - \boldsymbol{\theta})'\boldsymbol{\Gamma}^{-1}(\boldsymbol{y} - \boldsymbol{\theta}))$. The foregoing all contain multivariate normal and heavy–tailed Cauchy models as special cases, and all have served as observational models *in lieu of* multivariate normality. In particular, $\{\mathcal{S}_n(\boldsymbol{\theta}, \boldsymbol{I}_n, \psi); \psi \in \Psi\}$ often serve as semiparametric surrogates for $N_n(\boldsymbol{\theta}, \boldsymbol{I}_n)$ in univariate samples, and $\{L_{n,k}(\boldsymbol{\Theta}, \boldsymbol{\Gamma}, \boldsymbol{\Sigma}); \phi \in \Phi\}$ in the analysis of multivariate data. Examples from $\{\mathcal{S}_n(\boldsymbol{\theta}, \boldsymbol{I}_n, \psi); \psi \in \Psi\}$ are listed in Table 1, cross-referenced as in Chmielewski (1981) to well-known distributions on $\mathbb{R}^1$.

Inferences built on these models often remain exact as for normal models, certifying their use as semiparametric surrogates. This follows from the invariance of stipulated derived distributions as in Jensen and Good (1981). Further details, for their use as observational models on $\mathbb{R}^k$ and $\mathbb{F}_{n\times k}$, for catalogs of related and derived distributions, and for the robustness of various inferential procedures, are found in Cambanis et al. (1981), Chmielewski (1981), Devlin et al. (1976), Fang and Anderson (1990), Fang et al. (1990), Fang and Zhang (1990), James (1954), and Kariya and Sinha (1989). Regarding $\{L_{n,k}(\boldsymbol{\Theta}, \boldsymbol{\Gamma}, \boldsymbol{\Sigma}); \phi \in \Phi\}$ and its extensions, see Dawid (1977), Dempster (1969), and Jensen and Good (1981). These facts bear heavily on the robustness and validity of normal-theory procedures for use with nonnormal data, including distributions having heavy tails. The cited distributions all exhibit symmetries, including symmetries under reflections. Considerable recent work addresses skewed MDs, often resulting from truncation; see Arnold and Beaver (2000), for example.

Properties of distributions on $\mathbb{R}^1$ often extend nonuniquely to the case of MDs. Concepts of unimodality on $\mathbb{R}^k$ are developed in Dharmadhikari and Joag-Dev (1988), some enabling a sharpening of joint Chebyshev bounds. Stochastic ordering on $\mathbb{R}^1$ likewise admits a multiplicity of extensions. These in turn support useful probability inequalities on $\mathbb{R}^k$ as in Tong (1980), many pertaining to distributions cited here. Let $\mu(\cdot)$ and $\nu(\cdot)$ be probability measures on $\mathbb{R}^k$, and $\mathcal{C}_k$ the compact convex sets in $\mathbb{R}^k$ symmetric under reflection about $\boldsymbol{0} \in \mathbb{R}^k$. The concentration ordering (Birnbaum 1948) on $\mathbb{R}^1$ is extended in Sherman (1904): $\mu(\cdot)$ is said to be *more peaked about* $\boldsymbol{0} \in \mathbb{R}^k$ than $\nu(\cdot)$ if and only if $\mu(A) \geq \nu(A)$ for every $A \in \mathcal{C}_k$. Specifically, let $P_\Sigma(\cdot; \psi)$ and $P_\Omega(\cdot; \psi)$ be probability measures for $\mathcal{S}_n(\boldsymbol{0}, \boldsymbol{\Sigma}, \psi)$ and $\mathcal{S}_n(\boldsymbol{0}, \boldsymbol{\Omega}, \psi)$. Then a necessary and sufficient condition that $P_\Sigma(\cdot; \psi)$ should be more peaked about $\boldsymbol{0}$ than $P_\Omega(\cdot; \psi)$, is that $(\boldsymbol{\Omega} - \boldsymbol{\Sigma}) \in \mathbb{S}_n^+$, sufficiency in Fefferman et al. (1972), necessity in Jensen (1984). Similar orderings apply when both $(\boldsymbol{\Sigma}, \psi)$ are allowed to vary (Jensen 1984), extending directly to include distributions in $\{S_{n,k}(\boldsymbol{0}, \boldsymbol{\Gamma}, \boldsymbol{\Sigma}, \psi); \psi \in \Psi\}$. Numerous further notions of stochastic orderings for MDs are treated in Shaked and Shanthikumar (2007).

Interest in MDs often centers on their dependencies. A burgeoning literature surrounds ▶*copulas*, expressing a joint distribution function in terms of its marginals, together with a finite–dimensional parameter quantifying the degree of dependence; see Nelsen (1998) for example. Further concepts of dependence, including notions rooted in the geometry of $\mathbb{R}^k$, are developed in Joe (1997).

The Basic Tools

Let $(\Omega, \mathfrak{B}, P)$ be a probability space, Ω an event set, $\mathfrak{B}$ a field of subsets of Ω, and P a probability measure. Given a set $\mathfrak{X}_0$, an $\mathfrak{X}_0$–valued random element is a measurable mapping $\boldsymbol{X}(\omega)$ from Ω to $\mathfrak{X}_0$, multivariate when $\mathfrak{X}_0$ is finite-dimensional, as $\mathbb{R}^k$, its *cdf* then given by $F(x_1, \ldots, x_k) = P(\omega : X_1(\omega) \le x_1, \ldots, X_k(\omega) \le x_k)$. To each *cdf* corresponds a P_X on $(\mathbb{R}^k, \mathfrak{B}_k, P_X)$ and conversely, with $\mathfrak{B}_k$ as a field of subsets of $\mathbb{R}^k$. Moreover, $\{P_X = a_1P_1 + a_2P_2 + a_3P_3; a_i \ge 0, a_1 + a_2 + a_3 = 1\}$ decomposes as a mixture: P_1 assigns positive probability to the mass points of P_X; P_2 is absolutely continuous with respect to Lebesgue (volume) measure on $(\mathbb{R}^k, \mathfrak{B}_X, \cdot)$; and P_3 is purely singular. Corresponding to $\{P_1, P_2, P_3\}$ are *cdf*s $\{F_1, F_2, F_3\}$: F_1 has a mass function (*pmf*) $p(x_1, \ldots, x_k) = P(X_1 = x_1, \ldots, X_k = x_k)$, giving jumps of F_1 at its mass points; F_2 has a *pdf* $f_2(x_1, \ldots, x_k) = \frac{\partial^k}{\partial x_1 \cdots \partial x_k} F_2(x_1, \ldots, x_k)$ for almost all $\{x_1, \ldots, x_k\}$. The marginal *cdf* of $\boldsymbol{X}_1' = [X_1, \ldots, X_r]$ is $F_{m1}(x_1, \ldots, x_r) = F(x_1, \ldots, x_r, \infty, \ldots, \infty)$. With $\boldsymbol{X}_2' = [X_{r+1}, \ldots, X_k]$ and $\boldsymbol{x}_2' = [x_{r+1}, \ldots, x_k]$, the conditional *pmf* for $\mathcal{L}(\boldsymbol{X}_1 \mid \boldsymbol{x}_2)$, given that $\{\boldsymbol{X}_2 = \boldsymbol{x}_2\}$, is $p_{1\cdot 2}(x_1, \ldots, x_r) = \frac{p(x_1, \ldots, x_k)}{p_2(x_{r+1}, \ldots, x_k)}$ with $p_2(x_{r+1}, \ldots, x_k)$ as the marginal *pmf* for $\boldsymbol{X}_2$. A similar expression holds for P_2 in terms of the joint and marginal *pdf*s $f(x_1, \ldots, x_k)$ and $f_2(x_{r+1}, \ldots, x_k)$. As noted, F_1 is discrete and F_2 absolutely continuous, pure types to warrant their separate cataloging in the literature. On the other hand, P_3 is singular on a set in $\mathbb{R}^k$ having Lebesgue measure zero, often illustrated as a linear subspace. In contrast, P_3 is known to originate in practice through pairs $(\boldsymbol{X}, \boldsymbol{Y})$ as in Olkin and Tate (1961), such that $\boldsymbol{X}$ is multinomial and $\mathcal{L}(\boldsymbol{Y} \mid \boldsymbol{X} = \boldsymbol{x})$ is multivariate normal. Related studies are reported in a succession of articles including the recent (Bedrick et al. 2000).

The study of MDs draws heavily on the calculus of $\mathbb{R}^k$. Distributions not expressible in closed form may admit series expansions, asymptotic expansions of Cornish-Fisher and Edgeworth types, or large-sample approximations via central limit theory. Accuracy of the latter is gauged through Berry–Esséen bounds on rates of convergence, as developed extensively in Bhattacharya and Ranga Rao (1976) under moments of order greater than 2. Moreover, the integral transform pairs of Fourier, Laplace, and Mellin, including *chf*s on $\mathbb{R}^k$, are basic. Elementary operations in the space of transforms carry back to the space of distributions through inversion. Affine data transformations are intrinsic to the use of *chf*s of MDs, as treated extensively in Lukacs and Laha (1964). On the other hand, Mellin transforms couple nicely with such nonlinear operations as powers, products, and quotients of random variables, as treated in Epstein (1948) and Subrahmaniam (1970) and subsequently. In addition, functions generating joint moments, cumulants, factorial moments, and probabilities are used routinely. Projection methods determine distributions on $\mathbb{R}^k$ completely, via the one-dimensional distributions of every linear function. To continue, a property is said *to characterize* a distribution if unique to that distribution. A general treatise is Kagan et al. (1973), including reference to some MDs reviewed here.

We next undertake a limited survey of continuous and discrete MDs encountered with varying frequencies in practice. Developments are cited for random vectors and matrices. Continuing to focus on semiparametric models, we identify those distributions derived and unique to underlying classes of models, facts not widely accessible otherwise. The principal reference for continuous MDs is the encyclopedic (Kotz et al. 2000), coupled with monographs on multivariate normal (Tong 1990) and Student t (Kotz and Nadarajah 2004) distributions. For discrete MDs, encyclopedic accounts are archived in Johnson et al. (1997) and Patil and Joshi (1968).

Continuous Distributions

Central to classical **multivariate statistical analysis** are $\{N_{n,k}(\boldsymbol{\Theta}, \boldsymbol{I}_n, \boldsymbol{\Sigma}); n > k\}$ for $\mathcal{L}(\boldsymbol{Y})$, and the essential derived distribution $\mathcal{L}(\boldsymbol{W}) = W_k(n, \boldsymbol{\Sigma}, \boldsymbol{\Lambda})$, with $\boldsymbol{W} = \boldsymbol{Y}'\boldsymbol{Y}$, as noncentral Wishart having n degrees of freedom, scale matrix $\boldsymbol{\Sigma}$, and noncentrality matrix $\boldsymbol{\Lambda} = \boldsymbol{\Theta}'\boldsymbol{\Theta}$, with central *pdf* as in Table 3.

Student tDistributions

Vector distributions. There are two basic types. Let $[Y_1, \ldots, Y_k]$ be multivariate normal with means $[\mu_1, \ldots, \mu_k]$, unit variances, and correlation matrix $\boldsymbol{R}(k \times k)$. A *Type I t distribution* is that of $\{T_j = Y_j/S; 1 \le j \le k\}$ such that $\mathcal{L}(\nu S^2) = \chi^2(\nu)$ independently of $[Y_1, \ldots, Y_k]$. Its central *pdf* is listed in Table 2. To continue, suppose that $\boldsymbol{S} = [S_{ij}]$ and $\mathcal{L}(\nu \boldsymbol{S}) = W_k(\nu, \boldsymbol{R})$, independently of $[Y_1, \ldots, Y_k]$. A *Type II t distribution* is that of $\{T_j = Y_j/S_{jj}; 1 \le j \le k\}$. Both types are central if and only if $\{\mu_1 = \cdots = \mu_k = 0\}$. These distributions arise in multiple comparisons, in the construction of rectangular confidence sets for means, in the Bayesian analysis of multivariate normal data, and in various multistage procedures. For further details see Kotz et al. (2000) and Tong (1990).

More generally, if $\mathcal{L}(X_1, \ldots, X_k, Z_1, \ldots, Z_\nu) = \mathcal{S}_n(\boldsymbol{\theta}, \boldsymbol{\Gamma})$ with $\boldsymbol{\theta}' = [\mu_1, \ldots, \mu_k, 0, \ldots, 0]$ and $\boldsymbol{\Gamma} = \mathrm{Diag}(\boldsymbol{R}, \boldsymbol{I}_\nu)$, then with $\nu S^2 = \left(Z_1^2 + \ldots + Z_\nu^2\right)$, the central distribution of $\{T_j = X_j/S; 1 \le j \le k\}$ is Type I multivariate t for all distributions in $\{\mathcal{S}_n(\boldsymbol{\theta}, \boldsymbol{\Gamma}, \psi); \psi \in \Psi\}$ as structured. Multiple comparisons using $\{T_1, \ldots, T_k\}$ under normality thus are

Inv. Dirichlet	$\kappa_9\Pi_1^k\lvert\boldsymbol{V}_j\rvert^{(\nu_j-k-1)/2}\lvert\boldsymbol{I}_k+\Sigma_1^k\boldsymbol{V}_j\rvert^{(\nu_T-k-1)/2}$	$f(\boldsymbol{V}_1,\ldots,\boldsymbol{V}_k)$

exact in level for linear models having spherical errors (Jensen 1979). Similarly, if $\mathcal{L}(\boldsymbol{Y})=S_{n,k}(\boldsymbol{\Theta},\boldsymbol{I}_n,\boldsymbol{\Sigma})$ with parameters $\boldsymbol{\Theta}=[\boldsymbol{\theta},\ldots,\boldsymbol{\theta}]'$, $\boldsymbol{\theta}\in\mathbb{R}^k$; if $X_j=n^{1/2}\bar{Y}_j$ with $\{\bar{Y}_j=(Y_{1j}+\cdots+Y_{nj})/n;1\le j\le k\}$; and if $\boldsymbol{S}$ is the sample dispersion matrix; then the central distribution of $\left\{T_j=X_j/S_{jj}^{\frac{1}{2}};1\le j\le k\right\}$ is Type II multivariate t for every $\mathcal{L}(\boldsymbol{Y})$ in $\{S_{n,k}(\boldsymbol{0},\boldsymbol{I}_n,\boldsymbol{\Sigma},\psi);\psi\in\Psi\}$. Noncentral distributions generally depend on the particular distribution $\mathcal{S}_n(\boldsymbol{\theta},\boldsymbol{\Gamma})$ or $S_{n,k}(\boldsymbol{\Theta},\boldsymbol{I}_n,\boldsymbol{\Sigma})$.

Matric T distributions. Let $\boldsymbol{Y}$ and $\boldsymbol{W}$ be independent, $\mathcal{L}(\boldsymbol{Y})=N_{r,k}(\boldsymbol{0},\boldsymbol{I}_r,\boldsymbol{\Sigma})$ and $\mathcal{L}(\boldsymbol{W})=W_k(\nu,\boldsymbol{\Sigma})$ such that $\nu\ge k$, and let $\boldsymbol{T}=\boldsymbol{Y}\boldsymbol{W}^{-\frac{1}{2}}$ using any factorization $\boldsymbol{W}^{-\frac{1}{2}}$ of $\boldsymbol{W}^{-1}$. Then $\mathcal{L}(\boldsymbol{T})$ is *matric t* with *pdf* as in Table 3. Alternatively, consider $\boldsymbol{X}'=[\boldsymbol{Y}',\boldsymbol{Z}']$ with distribution $S_{n,k}(\boldsymbol{0},\boldsymbol{I}_n,\boldsymbol{\Sigma})$ such that $n=r+\nu$ and $\nu\ge k$, and again let $\boldsymbol{T}=\boldsymbol{Y}\boldsymbol{W}^{-\frac{1}{2}}$ but now with $\boldsymbol{W}=\boldsymbol{Z}'\boldsymbol{Z}$. These variables arise from distributions $S_{n,k}(\boldsymbol{0},\boldsymbol{I}_n,\boldsymbol{\Sigma})$ in the same manner as for $N_{n,k}(\boldsymbol{0},\boldsymbol{I}_n,\boldsymbol{\Sigma})$. Then $\boldsymbol{T}$ has a matric t distribution for every distribution $\mathcal{L}(\boldsymbol{Y})$ in $\{S_{n,k}(\boldsymbol{0},\boldsymbol{I}_n,\boldsymbol{\Sigma},\psi);\psi\in\Psi\}$. This property transfers directly to $\mathcal{L}(\boldsymbol{ATB})$ as in Dickey (1967) with $\boldsymbol{A}$ and $\boldsymbol{B}$ nonsingular.

Gamma Distributions

Vector Distributions. Extract $\mathrm{Diag}(W_{11},\ldots,W_{kk})$ from $\boldsymbol{W}=[W_{ij}]$. Their joint distributions arise in the analysis of nonorthogonal designs, in time-series, in multiple comparisons, in the analysis of multidimensional contingency tables, in extensions of Friedman's χ^2 test in two-way data based on ranks, and elsewhere. There is a gamma distribution on $\mathbb{R}_+^k$ for diagonals of the matrix Gamma (Lukacs and Laha 1964) of Table 3; k–variate χ^2 when $\boldsymbol{W}$ is Wishart; see Kibble (1941) for $k=2$; and a k–variate exponential distribution for the case $n=2$. Rayleigh distributions $\mathcal{L}\left(W_{11}^{\frac{1}{2}},W_{22}^{\frac{1}{2}},\ldots,W_{kk}^{\frac{1}{2}}\right)$ on $\mathbb{R}_+^k$ support the detection of signals from noise (Miller 1975); more general such distributions are known (Jensen 1970a); as are more general χ^2 distributions on $\mathbb{R}^k$ having differing marginal degrees of freedom (Jensen 1970b). Densities here are typically intractable, often admitting multiple series expansions in special functions. Details are given in Kotz et al. (2000). As $n\to\infty$, the χ^2 and Rayleigh distributions on $\mathbb{R}_+^k$ are multinormal in the limit, for central and noncentral cases alike, whereas for fixed n, the limits as noncentrality parameters

grow again are multivariate normal (Jensen 1969). Alternative approximations, through normalizing Wilson-Hilferty transformations, are given in Jensen (1976) and Jensen and Solomon (1994).

Matric distributions. Let $\mathcal{L}(\boldsymbol{Y}) \in L_{n,k}(\boldsymbol{0}, \boldsymbol{I}_n, \boldsymbol{\Sigma}, \phi)$ with $n \geq k$; the *pdf* of $\boldsymbol{W} = \boldsymbol{Y}'\boldsymbol{Y}$ is given in Table 3 under Gamma (Hsu 1940) as in that reference. The *pdf* under Gamma (Lukacs and Laha 1964), with $\lambda > 0$, reduces to that of a scaled Wishart matrix when 2λ is an integer. The noncentral Wishart *pdf* with $\boldsymbol{\Lambda} \neq \boldsymbol{0}$ admits series expansions in special polynomials. Moreover, as $n \to \infty$, for fixed $\boldsymbol{\Lambda}$ its limit distribution is multinormal, and for fixed n, its ▶asymptotic normality attains as the noncentrality parameters grow in a specified manner (Jensen 1976). Wishart matrices arise in matrix normal samples, e.g., as scaled sample dispersion matrices, and otherwise throughout multivariate distribution theory. Parallel remarks apply for Gamma (Hsu 1940) of Table 3 when the underlying observational model belongs to $\{L_{n,k}(\boldsymbol{\Theta}, \boldsymbol{I}_n, \boldsymbol{\Sigma}, \phi); \phi \in \Phi\}$.

Dirichlet Distributions

If X and Y are independent gamma variates having a common scale, then $U = X/(X + Y)$ and $V = X/Y$ have *beta* and *inverted beta* distributions, respectively, the scaled Snedecor-Fisher F specializing from the latter. This section treats vector and matrix versions of these.

Vector distributions. Let $\{Z_0, \ldots, Z_k\}$ be independent gamma variates with common scale and the shape parameters $\{\alpha_0, \ldots, \alpha_k\}$, and let $T = (Z_0 + \cdots + Z_k)$. Then the joint distribution of $\{U_j = Z_j/T; 1 \leq j \leq k\}$ is the k-dimensional *Dirichlet distribution* $D(\alpha_0, \ldots, \alpha_k)$ with *pdf* as given in Table 2. An important special case is that $\{\alpha_j = \nu_j/2; 0 \leq j \leq k\}$ with $\{\nu_0, \ldots, \nu_k\}$ as positive integers and with $\{Z_0, \ldots, Z_k\}$ as independent χ^2 variates. However, in this case neither χ^2 nor independence is required. For if $\boldsymbol{y} = \left[\boldsymbol{y}_0', \boldsymbol{y}_1', \ldots, \boldsymbol{y}_k'\right]' \in \mathbb{R}^n$ with $\{\boldsymbol{y}_j \in \mathbb{R}^{\nu_j}; 0 \leq j \leq k\}$ and $n = \nu_0 + \cdots + \nu_k$ such that $\mathcal{L}(\boldsymbol{y}) = \mathcal{S}_n(\boldsymbol{0}, \boldsymbol{I}_n)$, then $\left\{U_j = \boldsymbol{y}_j'\boldsymbol{y}_j/T; 1 \leq j \leq k\right\}$, but now with $T = \boldsymbol{y}_0'\boldsymbol{y}_0 + \boldsymbol{y}_1'\boldsymbol{y}_1 + \cdots + \boldsymbol{y}_k'\boldsymbol{y}_k$, has the distribution $D(\nu_0/2, \nu_1/2, \ldots, \nu_k/2)$ for all such $\mathcal{L}(\boldsymbol{y}) \in \{\mathcal{S}_n(\boldsymbol{0}, \boldsymbol{I}_n, \psi); \psi \in \Psi\}$.

The *inverted* Dirichlet is that of $\{V_j = Z_j/Z_0; 1 \leq j \leq k\}$, with $\{Z_0, \ldots, Z_k\}$ as before, having *pdf* as listed in Table 2. The scaled $\{V_j = \nu_0 Z_j/\nu_j Z_0; 1 \leq j \leq k\}$ then have a *multivariate F distribution* whenever $\{\alpha_j = \nu_j/2; 0 \leq j \leq k\}$ with $\{\nu_0, \ldots, \nu_k\}$ as positive integers. This arises in the ▶analysis of variance in conjunction with ratios of independent mean squares to a common denominator (Finney 1941). As before, neither χ^2 nor independence is required in the latter; take $\left\{V_j = \nu_0 \boldsymbol{y}_j'\boldsymbol{y}_j/\nu_j \boldsymbol{y}_0'\boldsymbol{y}_0; 1 \leq j \leq k\right\}$ with $\mathcal{L}(\boldsymbol{y}) \in \{\mathcal{S}_n(\boldsymbol{0}, \boldsymbol{I}_n, \psi); \psi \in \Psi\}$ as for Dirichlet distributions.

Matric distributions. Take $\{\boldsymbol{S}_0, \ldots, \boldsymbol{S}_k\}$ in $\mathbb{S}_k^+$ as independent Wishart matrices with $\{\mathcal{L}(\boldsymbol{S}_j) = W_k(\nu_j, \boldsymbol{\Sigma}); \nu_j \geq k; 0 \leq j \leq k\}$. Let $\boldsymbol{T} = \boldsymbol{S}_0 + \cdots + \boldsymbol{S}_k$ and $\left\{\boldsymbol{W}_j = \boldsymbol{T}^{-\frac{1}{2}}\boldsymbol{S}_j\boldsymbol{T}^{-\frac{1}{2}}; 1 \leq j \leq k\right\}$. A matric Dirichlet distribution (Olkin and Rubin 1964), taking the lower triangular square root, has *pdf* as listed in Table 3, such that $\boldsymbol{W}_j$ and $\left(\boldsymbol{I}_k - \Sigma_1^k \boldsymbol{W}_j\right)$ are positive definite, and $\nu_T = \nu_0 + \cdots + \nu_k$. Neither independence nor the Wishart character is required. If instead $\boldsymbol{Y} = \left[\boldsymbol{Y}_0', \boldsymbol{Y}_1', \ldots, \boldsymbol{Y}_k'\right] \in \mathbb{F}_{n \times k}$, $n = \nu_0 + \cdots + \nu_k$, $\nu_j \geq k$, and $\left\{\boldsymbol{S}_j = \boldsymbol{Y}_j'\boldsymbol{Y}_j; j = 0, 1, \ldots, k\right\}$, then for $\mathcal{L}(\boldsymbol{Y}) = S_{n,k}(\boldsymbol{0}, \boldsymbol{I}_n, \boldsymbol{\Sigma})$, invariance properties assure that $f(\boldsymbol{W}_1, \ldots, \boldsymbol{W}_k)$ is identical to that given in Table 3, for every distribution $\mathcal{L}(\boldsymbol{Y})$ in $\{S_{n,k}(\boldsymbol{0}, \boldsymbol{I}_n, \boldsymbol{\Sigma}, \psi); \psi \in \Psi\}$.

An *inverted* matric Dirichlet distribution (Olkin and Rubin 1964) takes $\{\boldsymbol{S}_0, \boldsymbol{S}_1, \ldots, \boldsymbol{S}_k\}$ as before, and defines $\left\{\boldsymbol{V}_j = \boldsymbol{S}_0^{-\frac{1}{2}}\boldsymbol{S}_j\boldsymbol{S}_0^{-\frac{1}{2}}; 1 \leq j \leq k\right\}$ using the symmetric root of $\boldsymbol{S}_0$. Its *pdf* $f(\boldsymbol{V}_1, \ldots, \boldsymbol{V}_k)$ is known allowing $\boldsymbol{S}_0$ to be noncentral. The central *pdf* is given in Table 3. The special case $k = 1$ is sometimes called a *Type II multivariate beta distribution.* Again neither independence nor the Wishart character is required. To see this, again take $\left\{\boldsymbol{S}_j = \boldsymbol{Y}_j'\boldsymbol{Y}_j; 0 \leq j \leq k\right\}$ as for matric Dirichlet distributions, and conclude that $f(\boldsymbol{V}_1, \ldots, \boldsymbol{V}_k)$, as in Table 3, is identical for every $\mathcal{L}(\boldsymbol{Y})$ in $\{S_{n,k}(\boldsymbol{0}, \boldsymbol{I}_n, \boldsymbol{\Sigma}, \psi); \psi \in \Psi\}$.

Distributions of Latent Roots

Topics in multivariate statistics, to include reduction by invariance, tests for hypotheses regarding dispersion parameters, and the study of energy levels in physical systems, all entail the latent roots of random matrices. Suppose that $\mathcal{L}(\boldsymbol{W}) = W_k(\nu, \boldsymbol{\Sigma})$, and consider the ordered roots $\{w_1 > \ldots > w_k > 0\}$ of $|\ \boldsymbol{W} - w\boldsymbol{\Sigma}\ | = 0$. Their joint *pdf* is listed in Table 2. On occasion ratios of these roots are required, including simultaneous inferences for dispersion parameters, for which invariance in distribution holds. For if $\boldsymbol{W} = \boldsymbol{Y}'\boldsymbol{Y}$, then the joint distributions of ratios of the roots of $|\ \boldsymbol{W} - w\boldsymbol{\Sigma}\ | = 0$ are identical for all $\mathcal{L}(\boldsymbol{Y}) \in \{S_{n,k}(\boldsymbol{0}, \boldsymbol{I}_n, \boldsymbol{\Sigma}, \psi); \psi \in \Psi\}$ such that $n \geq k$.

To continue, consider $\boldsymbol{S}_0$ and $\boldsymbol{S}_1$ as independent Wishart matrices having $W_k(\nu_0, \boldsymbol{\Sigma})$ and $W_k(\nu_1, \boldsymbol{\Sigma}, \boldsymbol{\Lambda})$, respectively. Then central ($\boldsymbol{\Lambda} = \boldsymbol{0}$) and noncentral joint distributions of the roots of $|\ \boldsymbol{S}_1 - \ell\boldsymbol{S}_0\ | = 0$ are known, as given in Table 2 for the case $\boldsymbol{\Lambda} = \boldsymbol{0}$. An invariance result holds for the central case. For if $\boldsymbol{Y} = \left[\boldsymbol{Y}_0', \boldsymbol{Y}_1'\right]'$ with $n = \nu_0 + \nu_1$ such that $\nu_0 \geq k$ and $\nu_1 \geq k$, $\boldsymbol{S}_0 = \boldsymbol{Y}_0'\boldsymbol{Y}_0$ and $\boldsymbol{S}_1 = \boldsymbol{Y}_1'\boldsymbol{Y}_1$, then by invariance the latent root *pdf* $f(\ell_1, \ldots, \ell_k)$ is the same for all $\mathcal{L}(\boldsymbol{Y})$ in $\{L_{n,k}(\boldsymbol{0}, \boldsymbol{I}_n, \boldsymbol{\Sigma}, \phi) : \phi \in \Phi\}$, as given in Table 3.

Other Distributions

Numerous other continuous multivariate distributions are known; a compendium is offered in Kotz et al. (2000). Multivariate versions of *Burr distributions* arise through gamma mixtures of independent Weibull distributions. Various *multivariate exponential distributions* are known; some properties and examples are found on specializing multivariate Weibull distributions. Various *multivariate stable distributions*, symmetric and asymmetric, are characterized through the structure of their *chf*s, as are types of symmetric MDs surveyed earlier. *Multivariate extreme-value distributions* are treated in Kotz et al. (2000), with emphasis on the bivariate case. The *Beta-Stacy distributions* yield a *multivariate Weibull distribution* as a special case. *Multivariate Pareto distributions* have their origins in econometrics. *Multivariate logistic distributions* model binary data in the analysis of quantal responses. Properties of *chf*s support a bivariate distribution having normal and gamma marginals (Kibble 1941).

Discrete Distributions

A guided tour is given with special reference to Johnson et al. (1997) and Patil and Joshi (1968). Inequalities for selected multivariate discrete distributions are offered in Jogdeo and Patil (1975).

Binomial, Multinomial, and Related

The outcome of a random experiment is classified as having or not having each of s attributes $\{A_1, \ldots, A_s\}$. If $\{X_1, \ldots, X_s\}$ are the numbers having these attributes in n independent trials, then theirs is a *multivariate binomial distribution* with parameters

$$\{\pi_i = \Pr(A_i), \pi_{ij} = \Pr(A_iA_j), \ldots, \pi_{12\cdot s} = \Pr(A_1A_2 \ldots A_s); \iota \in [1, 2, \ldots s]; i \neq j \neq k \neq \ldots\}$$

where ι takes successive values $\{i, j, k, \ldots\}$. The ►*binomial* ►distribution $B(n, \pi)$ obtains at $s = 1$. For bivariate binomial distributions see Hamdan (1972), Hamdan and Al-Bayyati (1971), and Hamdan and Jensen (1976). The limit as $n \to \infty$ and $\pi \to 0$ such that $n\pi \to \lambda$ is Poisson, the distribution of "rare events". More generally, as $n \to \infty$ and $\pi_i \to 0$, such that $\{n\theta_i \to \lambda_i, n\theta_{ij} \to \lambda_{ij}, \ldots, n\pi_{12\cdot s} \to \lambda_{12\cdot s}\}$, where $\{\theta_i, \theta_{ij}, \ldots\}$ are specified functions of $\{\pi_i, \pi_{ij}, \ldots\}$, then the limit of the multivariate binomial distribution is *multivariate Poisson*.

Suppose that independent trials are continued until exactly k trials exhibit none of the s attributes. The joint distribution of the numbers $\{Y_1, \ldots, Y_s\}$ of occurrences of $\{A_1, \ldots, A_s\}$ during these trials is a *multivariate Pascal distribution*.

To continue, let $\{A_0, \ldots, A_s\}$ be exclusive and exhaustive outcomes having probabilities $\{\pi_0, \ldots, \pi_s\}$, with $\{0 < \pi_i < 1; \pi_0 + \cdots + \pi_s = 1\}$. The numbers $\{X_1, \ldots, X_s\}$ of occurrences of $\{A_1, \ldots, A_s\}$ in n independent trials have the ►*multinomial distribution* with parameters $(n, \pi_1, \ldots, \pi_s)$. If independent trials are repeated until A_0 occurs exactly k times, the numbers of occurrences of $\{A_1, \ldots, A_s\}$ during these trials have a *negative multinomial distribution* with parameters $(k, \pi_1, \ldots, \pi_s)$.

In a multiway contingency table an outcome is classified according each of k criteria having the exclusive and exhaustive classes $\{A_{io}, A_{i1}, \ldots A_{is_i}; i = 1, \ldots, k\}$. If in n independent trials $\{X_{i1}, \ldots, X_{is_i}; i = 1, \ldots, k\}$ are the numbers occurring in $\{A_{i1}, \ldots, A_{is_i}; i = 1, \ldots, k\}$, then their joint distribution is called a *multivariate multinomial distribution* (also multivector multinomial). These are the joint distributions of marginal sums of the contingency table, to include the k–variate binomial distribution when $\{s_1 = s_2 = \cdots = s_k = 1\}$.

Hypergeometric and Related

A collection of N items consists of $s + 1$ types: N_0 of type A_0, N_1 of type A_1, …, N_s of type A_s, with $N = N_0 + \cdots + N_s$. Random samples are taken from this collection. If n items are drawn without replacement, the joint distribution of the numbers of items of types $\{A_1, \ldots, A_s\}$ is a *multivariate hypergeometric distribution* with parameters $(n, N, N_1, \ldots, N_s)$. With replacement, their distribution is multinomial with parameters $(n, N_1/N, \ldots, N_s/N)$.

If successive items are drawn without replacement until exactly k items of type A_0 are drawn, then the numbers of types $\{A_1, \ldots, A_s\}$ thus drawn have a *multivariate inverse hypergeometric distribution* with parameters $(k, N, N_1, \ldots, N_s)$.

To continue, sampling proceeds in two stages. First, m items are drawn without replacement, giving $\{x_1, \ldots, x_s\}$ items of types $\{A_1, \ldots, A_s\}$. Without replacing the first sample, n additional items are drawn without replacement at the second stage, giving $\{Y_1, \ldots, Y_s\}$ items of types $\{A_1, \ldots, A_s\}$. The conditional distribution of $(Y_1, \ldots, Y_s)$, given that $\{X_1 = x_1, \ldots, X_s = x_s\}$, is a *multivariate negative hypergeometric distribution.*

Multivariate Series Distributions

Further classes of discrete multivariate distributions are identified by types of their *pmf*s. Some arise through truncation and limits. If $[X_1, \ldots, X_s]$ has the s–variate negative multinomial distribution with parameters $(k, \pi_1, \ldots, \pi_s)$, then the conditional distribution of $[X_1, \ldots, X_s]$, given that $[X_1, \ldots, X_s] \neq [0, \ldots, 0]$, converges as $k \to 0$ to the s–variate *logarithmic series distribution* with parameters $(\theta_1, \ldots, \theta_s)$ where $\{\theta_i = 1 - \pi_i; i = 1, \ldots, s\}$. See Patil and Joshi (1968) for details. A modified multivariate logarithmic series distribution arises as a mixture, on n, of the multinomial distribution with parameters $(n, \pi_1, \ldots, \pi_s)$, where the mixing distribution is a logarithmic series distribution (Patil and Joshi 1968).

A class of distributions with parameters $(\theta_1, \ldots, \theta_s) \in \Theta$, derived from convergent power series, has *pmf*s of the form $p(x_1, \ldots, x_s) = \frac{a(x_1, \ldots, x_s)\theta_1^{x_1} \cdots \theta_s^{x_s}}{f(\theta_1, \ldots, \theta_s)}$ for $\{x_i = 0, 1, 2, \ldots; i = 1, \ldots, s\}$. The class of such distributions, called *multivariate power series distributions,* contains the s–variate multinomial distribution with parameters $(n, \pi_1, \ldots, \pi_s)$; the s-variate logarithmic series distribution with parameters $(\theta_1, \ldots, \theta_s)$; the s-variate negative multinomial distribution with parameters $(k, \pi_1, \ldots, \pi_s)$; and others. See Patil and Joshi (1968) for further properties. Other discrete multivariate distributions are described next.

Other Distributions

A typical *Borel-Tanner* distribution refers to the number of customers served before a queue vanishes for the first time. If service in a single-server queue begins with r customers of type I and s of type II with different arrival rates and service needs for each type, then the joint distribution of the numbers served is the *bivariate Borel-Tanner* distribution as in Shenton and Consul (1973).

In practice *compound distributions* often arise from an experiment undertaken in a random environment; the compounding distribution then describes variation of parameters of the model over environments. Numerous bivariate and multivariate discrete distributions have been obtained through compounding, typically motivated by the structure of the problem at hand. Numerous examples are cataloged in references Johnson et al. (1997) and Patil

and Joshi (1968); examples are listed in Table 4 from those and other sources.

About the Author

Donald Jensen received his Ph.D. from Iowa State University in 1962, and joined Virginia Polytechnic Institute and State University in 1965, attaining the rank of Professor in 1973. He has published over 140 journal articles in distribution theory, multivariate analysis, linear inference, robustness, outlier detection and influence diagnostics, regression design, and quality control. Dr. Jensen served as Associate editor of *The American Statistician* for a decade (1971–1980), and has been a reviewer for Mathematical Reviews for the last 30 years. He is an elected member of the International Statistical Institute. Professor Jensen received an early five-year Research Career Development Award from the US National Institutes of Health.

Multivariate Statistical Process Control

Robert L. Mason[1], John C. Young[2]
[1]Southwest Research Institute, San Antonio, TX, USA
[2]Lake Charles, LA, USA

Statistical process control (SPC) includes the use of statistical techniques and tools, such as ▶control charts, to

monitor change in a process. These are typically applied separately to each process variable of interest. Statistical process control procedures help provide an answer to the question: "Is the process in control?" When an out-of-control event is identified as a signal in a control chart, procedures often are available for locating the specific process variables that are the cause of the problem.

In multivariate statistical process control (MVSPC), multivariate statistical control procedures are used to simultaneously monitor many process variables that are interrelated and form a correlated set that move together (see Mason and Young 2002). The relationships that exist between and among the variables of the multivariate process are used in developing the procedure. Assume that the observation vectors obtained from a process are independent random variables that can be described by a multivariate normal distribution (see ►Multivariate Normal Distributions) with a mean vector and a covariance matrix. Any change in the mean vector and/or the covariance matrix of this distribution is considered an out-of-control situation and should be detectible with an appropriate multivariate control chart.

Implementation of a multivariate control procedure is usually divided into two parts: Phase I and Phase II. Phase I includes the planning, development, and construction phase. In this phase, the practitioner studies the process in great detail. Preliminary data are collected under good operational conditions and examined for statistical control and other potential problems. The major problems include statistical ►outliers, variable collinearities, and autocorrelated observations, i.e., time-dependent observations. After statistical control of the preliminary data is established, the data is used as the process history and referred to as the historical data set (HDS). If the parameters of the process are unknown, parameter estimates of the mean vector and covariance matrix are obtained from the data of the HDS for use in monitoring the process.

Phase II is the monitoring stage. In this phase, new observations are examined in order to determine if the process has deviated from the in-control situation specified by the HDS. Note that, in MVSPC, deviations from the HDS can occur through a mean vector change, a covariance matrix change, or both a mean vector and covariance matrix change in the process. In certain situations a change in one parameter can also induce a change in the other parameter.

Process control is usually determined by examining a control statistic based on the observed value of an individual observation and/or a statistic related to a rational subgroup (i.e., sample) of the observations such as the sample mean. Easy monitoring is accomplished by charting the value of the multivariate control statistic on a univariate chart. Depending on the charted value of this statistic, one can determine if control is being maintained or if the process has moved to an out-of-control situation.

For detecting both large and small shifts in the mean vector, there are three popular multivariate control chart methods. An implicit assumption when using these charts is that the underlying population covariance matrix is constant over the time period of interest. Various forms of ►Hotelling's T^2 statistic are generally chosen when the detection of large mean shifts is of interest (e.g., see Mason and Young 2002). For detecting small shifts in the process mean, the multivariate exponential weighted moving average (MEWMA) statistic (e.g., see Lowry et al. 1992) or the multivariate cumulative sum (MCUSUM) statistic (e.g., Woodall and Ncube 1985) can be utilized. These statistics each have advantages and disadvantages, and they can be used together or separately.

All of the above procedures were developed under the assumption that the data are independent and follow a multivariate normal distribution. Autocorrelated data can present a serious problem for both the MCUSUM and MEWMA statistics, but seems to have lesser influence on the behavior of the T^2 statistic. A main reason for the influence of autocorrelation on the MEWMA and MCUSUM statistics is that both of them are dependent on a subset of past-observed observation vectors, whereas the T^2 statistic depends only on the present observation.

A related problem in MVSPC is monitoring shifts in the covariance matrix for a multivariate normal process when the mean vector is assumed to be stable. A useful review of procedures for monitoring multivariate process variability is contained in Yeh et al. (2006). The methods for detecting large shifts in the covariance matrix include charts based on the determinant of the sample covariance matrix (Djauhari 2005), while the methods for detecting small shifts include charts based on a likelihood-ratio EWMA statistic (Yeh et al. 2004) and on related EWMA-type statistics (Yeh et al. 2003). A recent charting method that is applicable in monitoring the change in covariance matrix for a multivariate normal process is based on a form of Wilks' ratio statistic (Wilks 1963). It consists of taking the ratio of the determinants of two estimators of the process covariance matrix (Mason et al. 2009). One estimator is obtained using the HDS and the other estimator is computed using an augmented data set consisting of the newest observed sample and the HDS. The Wilks' chart statistic is particularly helpful when the number of variables is large relative to the sample size.

Current attention in the MVSPC literature is focused on procedures that simultaneously monitor both the mean vector and the covariance matrix in a multivariate process (e.g., see Reynolds and Cho 2006 or Chen et al. 2005). These charts are based on EWMA procedures and can be very useful in detecting small-to-moderate changes in a process. Several papers also exist that present useful overviews of MVSPC (e.g., see Woodall and Montgomery 1999 and Bersimis et al. 2007). These papers are valuable for their insights on the subject and their extensive reference lists.

About the Authors

Dr. Robert L. Mason is an Institute Analyst at Southwest Research Institute in San Antonio, Texas. He was President of the American Statistical Association in 2003, Vice-President in 1992–1994, and a Member of its Board of Directors in 1987–1989. He is a Fellow of both the American Statistical Association and the American Society for Quality, and an Elected Member of the International Statistical Institute. He has been awarded the Founder's Award and the Don Owen Award from the American Statistical Association and the W.J. Youden Award (twice) from the American Society for Quality. He is on the Editorial Board of the *Journal of Quality Technology*, and is an Associate Editor of *Communications in Statistics*. He has published over 130 research papers and coauthored 6 textbooks including *Statistical Design and Analysis of Experiments with Applications to Engineering and Science* (Wiley, 1989; 2nd ed. 2003). He also is the coauthor (with John C. Young) of *Multivariate Statistical Process Control with Industrial Applications* (ASA-SIAM; 2002).

Prior to his retirement in 2007, Dr. John C. Young was Professor of Statistics for 40 years at McNeese State University in Lake Charles, Louisiana. He has published approximately 100 papers in the statistical, medical, chemical, and environmental literature, and is coauthor of numerous book chapters and three textbooks.

Multivariate Statistical Simulation

Mark E. Johnson
Professor
University of Central Florida, Orlando, FL, USA

Multivariate statistical simulation comprises the computer generation of multivariate probability distributions for use in statistical investigations. These investigations may be robustness studies, calibrations of small sample behavior of estimators or confidence intervals, power studies, or other Monte Carlo studies. The distributions to be generated may be continuous, discrete or a combination of both types. Assuming that the n-dimensional distributions have independent components, the problem of variate generation is reduced to simulating from univariate distributions for which, fortunately, there is a vast literature (Devroye 1986; L'Eculer 2010; and international standard ISO 28640, for

example). Thus, the real challenge of multivariate statistical simulation is in addressing the dependence structure of the multivariate distributions.

For a few situations, the dependence structure is readily accommodated from a generation standpoint. Consider the usual n-dimensional multivariate normal distribution (see ▶Multivariate Normal Distributions) with mean vector $\underline{\mu}$ and covariance matrix Σ. For a positive definite covariance matrix, there exists a lower triangular (Cholesky) decomposition $LL' = \Sigma$. Assuming a source of independent univariate normal variates to occupy the vector $\underline{X}$, the random vector $\underline{Y} = L\,\underline{X} + \underline{\mu}$ has the desired multivariate normal distribution. Having been able to generate multivariate normal random vectors, componentwise transformations provide the capability to generate the full Johnson translation system (1949a), of which the log-normal distribution may be the most familiar. In using the multivariate Johnson system, it is possible to specify the covariance matrix of the transformed distribution. Some researchers transform the multivariate normal distribution without noting the severe impact on the covariance matrix of the transformed distribution. This oversight makes it difficult to interpret the results of simulation studies involving the Johnson translation system (see Johnson 1987 for further elaboration).

In expanding to distributions beyond the Johnson translation system, it is natural to consider generalizations of the normal distribution at the core of this system. The exponential power distribution with density function $f(x)$ proportional to $\exp(-|x|^{\tau})$ is a natural starting point since it includes the double exponential distribution ($\tau = 1$), the normal distribution ($\tau = 2$) and the uniform distribution in the limit ($\tau \to \infty$) and is easy to simulate (Johnson 1979). A further generalization of the exponential power distribution amenable to variance reduction simulation designs was developed by Johnson, Beckman and Tietjen (1980) who noted that the normal distribution arises as the product of ZU where Z is distributed as the square root of a chi-squared(3) distribution and is independent of U which is uniform on the interval $(-1, 1)$. Their generalization occurs by considering arbitrary degrees of freedom and powers other than 0.5. Since by Khintchine's unimodality theorem, any unimodal distribution can be represented as such a product there are many possibilities that could be pursued for other constructions ultimately for use in multivariate simulation contexts.

Multivariate distribution *families* are appealing for simulation purposes. A useful extension of the Johnson translation system has been developed by Jones and Pewsey (2009). The family is defined implicitly via the equation

$$Z = \sinh[\delta \sinh^{-1}(X_{\varepsilon,\delta}) - \varepsilon]$$

where Z has the standard normal distribution, $X_{\delta,\varepsilon}$ has a sinh-arcsinh distribution, ε is a skewness parameter and δ relates to the tail weight of the distribution. This family of distributions is attractive for use in Monte Carlo studies, since it includes the normal distribution as a special intermediate (non-limiting) case and covers a variety of skewness and tailweight combinations. Extensions of the Jones-Pewsey family to the multivariate case can follow the approach originally taken by Johnson (1949b), with adaptations by Johnson et al. (1982) to better control impacts of the covariance structure and component distributions.

Variate generation for multivariate distributions is readily accomplished (at least, in principle) for a specific multivariate distribution provided certain conditional distributions are identified. Suppose $\underline{X}$ is a random vector to be generated. A direct algorithm is to first generate X_1 as the marginal distribution of the first component of $\underline{X}$, say x_1. Second, generate from the conditional distribution of X_2 given $X_1 = x_1$ to obtain x_2. Third, generate from the conditional distribution X_3 given, $X_1 = x_1$ and $X_2 = x_2$ and then continue until all n components have been generated. This conditional distribution approach converts the multivariate generation problem into a series of univariate generation problems. For cases in which the conditional distributions are very complicated or not particularly recognizable, there may be alternative formulae for generation, typically involving a transformation to $n+1$ or more independent random variables. Examples include a multivariate Cauchy distribution and the multivariate Burr-Pareto-logistic distributions (see Johnson 1987).

The general challenge in multivariate statistical simulation is to incorporate the dependence structure as it exists in a particular distribution. As noted earlier, the multivariate normal distribution is particularly convenient since dependence is introduced to independent normal components through appropriate linear transformations. Further transformations to the components of the multivariate normal distribution give rise to skewed, light tailed or heavy tailed marginal distributions while retaining some semblance of the dependence structure. An important approach to grappling with the dependence structure is to recognize that marginal distributions are not terribly relevant in that the components can be transformed to the uniform distribution via $U_i = F_i(X_i)$, where F_i is the distribution function of X_i. In other words, in comparing multivariate distributions, the focus can be on the transformed distribution having uniform marginal's. This multivariate distribution is known as a "copula." Examining the

►copulas associated with the Burr, Pareto and logistic distributions led Cook and Johnson to recognize the essential similarity of these three multivariate distributions. A very useful introduction to copulas is Nelsen (2006) while Genest and MacKay (1986) deserve credit for bringing copulas to the attention of the statistical community.

This entry does not cover all possible distributions or families of distributions that could be considered for use in multivariate simulation studies. Additional possibilities (most notably elliptically contoured distributions) are reviewed in Johnson (1987).

Multivariate Techniques: Robustness

Mia Hubert[1], Peter J. Rousseeuw[2]
[1]Associate Professor
Katholieke Universiteit Leuven, Leuven, Belgium
[2]Senior Researcher
Renaissance Technologies, New York, NY, USA

The usual multivariate analysis techniques include location and scatter estimation, ►principal component analysis, factor analysis (see ►Factor Analysis and Latent Variable Modelling), discriminant analysis (see ►Discriminant Analysis: An Overview, and ►Discriminant Analysis: Issues and Problems), ►canonical correlation analysis, multiple regression and cluster analysis (see ►Cluster Analysis: An Introduction). These methods all try to describe and discover structure in the data, and thus rely on the correlation structure between the variables. Classical procedures typically assume normality (i.e. gaussianity) and consequently use the sample mean and sample covariance matrix to estimate the true underlying model parameters.

Below are three examples of multivariate settings used to analyze a data set with n objects and p variables, forming an $n \times p$ data matrix $\boldsymbol{X} = (\boldsymbol{x}_1, \ldots, \boldsymbol{x}_n)'$ with $\boldsymbol{x}_i = (x_{i1}, \ldots, x_{ip})'$ the ith observation.

1. ►Hotelling's T^2 statistic for inference about the center of the (normal) underlying distribution is based on the sample mean $\bar{\boldsymbol{x}} = \sum_{i=1}^{n} \boldsymbol{x}_i$ and the sample covariance matrix $\boldsymbol{S}_x = \frac{1}{n-1} \sum_{i=1}^{n} (\boldsymbol{x}_i - \bar{\boldsymbol{x}})(\boldsymbol{x}_i - \bar{\boldsymbol{x}})'$.
2. Classical principal component analysis (PCA) uses the eigenvectors and eigenvalues of $\boldsymbol{S}_x$ to construct a smaller set of uncorrelated variables.
3. In the multiple regression setting, also a response variable $\boldsymbol{y} = (y_1, \ldots, y_n)'$ is measured. The goal of linear regression is to estimate the parameter $\boldsymbol{\theta} = (\beta_0, \boldsymbol{\beta})' = (\beta_0, \beta_1, \ldots, \beta_p)'$ relating the response variable and the predictor variables in the model

$$y_i = \beta_0 + \beta_1 x_{i1} + \cdots + \beta_p x_{ip} + \varepsilon_i.$$

The least squares slope estimator can be written as $\hat{\boldsymbol{\beta}}_{LS} = \boldsymbol{S}_x^{-1} \boldsymbol{s}_{xy}$ with $\boldsymbol{s}_{xy} = \frac{1}{n-1} \sum_{i=1}^{n} (y_i - \bar{y})(\boldsymbol{x}_i - \bar{\boldsymbol{x}})$ the cross-covariance vector. The intercept is given by $\hat{\beta}_0 = \bar{y} - \hat{\boldsymbol{\beta}}_{LS}' \bar{\boldsymbol{x}}$.

These classical estimators often possess optimal properties under the Gaussian model assumptions, but they can be strongly affected by even a few ►outliers. Outliers are data points that deviate from the pattern suggested by

the majority of the data. Outliers are more likely to occur in datasets with many observations and/or variables, and often they do not show up by simple visual inspection. When the data contain nasty outliers, typically two things happen:

- The multivariate estimates differ substantially from the "right" answer, defined here as the estimates we would have obtained without the outliers.
- The resulting fitted model does not allow to detect the outliers by means of their residuals, Mahalanobis distances, or the widely used "leave-one-out" diagnostics.

The first consequence is fairly well-known (although the size of the effect is often underestimated). Unfortunately the second consequence is less well-known, and when stated many people find it hard to believe or paradoxical. Common intuition says that outliers must "stick out" from the classical fitted model, and indeed some of them do so. But the most harmful types of outliers, especially if there are several of them, may affect the estimated model so much "in their direction" that they are now well-fitted by it.

Once this effect is understood, one sees that the following two problems are essentially equivalent:

- Robust estimation: find a "robust" fit, which is similar to the fit we would have found without the outliers.
- Outlier detection: find all the outliers that matter.

Indeed, a solution to the first problem allows us, as a by-product, to identify the outliers by their deviation from the robust fit. Conversely, a solution to the second problem would allow us to remove or downweight the outliers followed by a classical fit, which yields a robust estimate.

It turns out that the more fruitful approach is to solve the first problem and to use its result to answer the second. This is because from a combinatorial viewpoint it is more feasible to search for *sufficiently many* "good" data points than to find *all* the "bad" data points.

Many robust multivariate estimators have been constructed by replacing the empirical mean and covariance matrix with a robust alternative. Currently the most popular estimator for this purpose is the *Minimum Covariance Determinant* (MCD) estimator (Rousseeuw 1984). The MCD method looks for the h observations (out of n) whose classical covariance matrix has the lowest possible determinant. The raw MCD estimate of location is then the average of these h points, whereas the raw MCD estimate of scatter is a multiple of their covariance matrix. Based on these raw estimates one typically carries out a reweighting step, yielding the reweighted MCD estimates (Rousseeuw and Van Driessen 1999).

The MCD location and scatter estimates are affine equivariant, which means that they behave properly under affine transformations of the data. Computation of the MCD is non-trivial, but can be performed efficiently by means of the FAST-MCD algorithm (Rousseeuw and Van Driessen 1999) which is available in standard SAS, S-Plus, and R.

A useful measure of robustness is the *finite-sample breakdown value* (Donoho and Huber 1983; Hampel et al. 1986). The breakdown value is the smallest amount of contamination that can have an arbitrarily large effect on the estimator. The MCD estimates of multivariate location and scatter have breakdown value $\approx (n-h)/n$. The MCD has its highest possible breakdown value of 50% when $h = [(n+p+1)/2]$. Note that no affine equivariant estimator can have a breakdown value above 50%.

Another measure of robustness is the *influence function* (Hampel et al. 1986), which measures the effect on an estimator of adding a small mass of data in a specific place. The MCD has a bounded influence function, which means that a small contamination at any position can only have a small effect on the estimator (Croux and Haesbroeck 1999).

In regression, a popular estimator with high breakdown value is the *Least Trimmed Squares* (LTS) estimator (Rousseeuw 1984; Rousseeuw and Van Driessen 2006). The LTS is the fit that minimizes the sum of the h smallest squared residuals (out of n). Other frequently used robust estimators include S-estimators (Rousseeuw and Yohai 1984) and MM-estimators (Yohai 1987), which can achieve a higher finite-sample efficiency than the LTS.

Robust multivariate estimators have been used to robustify the Hotelling T^2 statistic (Willems et al. 2002), PCA (Croux and Haesbroeck 2000; Salibian-Barrera et al. 2006), multiple regression with one or several response variables (Rousseeuw et al. 2004; Agulló et al. 2008), discriminant analysis (Hawkins and McLachlan 1997; Hubert and Van Driessen 2004; Croux and Dehon 2001), factor analysis (Pison et al. 2003), canonical correlation (Croux and Dehon 2002), and cluster analysis (Hardin and Rocke 2004).

Another important group of robust multivariate methods are based on projection pursuit (PP) techniques. They are especially useful when the dimension p of the data is larger than the sample size n, in which case the MCD is no longer well-defined. Robust PP methods project the data on many univariate directions and apply robust estimators of location and scale (such as the median and the median absolute deviation) to each projection. Examples include the Stahel-Donoho estimator of location and scatter (Maronna and Yohai 1995) and generalizations (Zuo et al. 2004), robust

PCA (Li and Chen 1985; Croux and Ruiz-Gazen 2005; Hubert et al. 2002; Boente et al. 2006), discriminant analysis (Pires 2003), canonical correlation (Branco et al. 2005), and outlier detection in skewed data (Brys et al. 2005; Hubert and Van der Veeken 2008). The hybrid ROBPCA method (Hubert et al. 2005; Debruyne and Hubert 2009) combines PP techniques with the MCD and has led to the construction of robust principal component regression (Hubert and Verboven 2003), partial least squares (Hubert and Vanden Branden 2003), and classification for high-dimensional data (Vanden Branden and Hubert 2005).

A more extensive description of robust multivariate methods and their applications can be found in (Hubert et al. 2008; Hubert and Debruyne 2010).

About the Author

Dr. Peter Rousseeuw was Professor and Head (since 1992) of the Division of Applied Mathematics, Universiteit Antwerpen, Belgium. Currently he is a Senior Researcher at Renaissance Technologies in New York. He has (co-)authored over 160 papers, two edited volumes and three books, including *Robust Regression and Outlier Detection* (with A.M. Leroy, Wiley-Interscience, 1987). In 2003 ISI-Thompson included him in their list of Highly Cited Mathematicians. His paper *Least Median of Squares Regression* (1984), Journal of the American Statistical Association, 79, 871–880) which proposed new robust methods for regression and covariance, has been reprinted in *Breakthroughs in Statistics III* (the three-volume collection consists of the 60 most influential publications in statistics from 1850 to 1990), Kotz and Johnson 1997, Springer-Verlag, New York. He is an Elected Member, International Statistical Institute (1991) and an Elected Fellow of Institute of Mathematical Statistics (elected 1993) and American Statistical Association (elected 1994). He was Associate Editor, *Journal of the American Statistical Association* (1988–1993), and *Computational Statistics and Data Analysis* (1988–1998). He has supervised 20 Ph.D. students.

National Account Statistics

Barbara M. Fraumeni
Associate Executive Director, Chair of the Ph.D. Program in Public Policy, and Professor of Public Policy
University of Southern Maine, Portland, ME, USA

National accounts are the system by which the current level of economic activity is measured, the summary statistic being Gross Domestic Product (GDP). Government officials, policy makers, businessmen, and investors often react to GDP real growth rates and levels as GDP is a primary indicator of the health of the economy. Safeguards are taken in the United States, and probably in many other countries, to ensure that no one has advance knowledge of these numbers before the official release to protect against someone capitalizing from inside knowledge.

National accounts are the economist's version of business accounts. Both national and business accountants follow specific rules and methodologies. The most common set of rules for national accounts is summarized for national accounts in the *System of National Accounts* (SNA); the current published version is dated 2008. (Many countries have not yet changed their national accounts to reflect changes between SNA 1993 and SNA 2008.) The SNA was developed by Sir Richard Stone and is maintained by a group of international organizations. The United States national accounts (National Income and Product Accounts or NIPAs) were developed by Simon Kuznets and use a different system than the SNA. However, the NIPAs are currently largely compatible with the SNA. National accounts and business accounts are similar in that they both use a double-entry system and have a number of account components which relate to a snapshot, i.e., an assets and liabilities balance sheet for a particular date, or a flow account, i.e., a production account or a profit or loss statement for the year. However, national accounts and business accounts use significantly different rules and methodologies.

GDP is a measure of the goods and services currently produced by labor and property located within a specific geographic region. GDP can be measured in three different ways using an expenditure, income or value-added approach. The expenditures approach estimates GDP as:

$$\text{GDP} = \text{Consumption} + \text{Investment} + \text{Government Expenditures} + \text{Exports} - \text{Imports},$$

where in this formula consumption and investment exclude consumption and investment by government, which are included in the Government Expenditures total. Imports are subtracted to ensure that only production within a specific geographic region are included in GDP. The income approach estimates GDP as the sum of income received and costs incurred in production. The value-added approach estimates GDP as:

$$\text{GDP} = \text{Total Sales} - \text{Total Intermediate Inputs}.$$

An intermediate input is a good or service purchased for resale, i.e., by a retailer from a wholesaler, or a good or service purchased for use in producing another good or service (hence the name intermediate "input"), i.e., flour used to produce a loaf of bread. If the price paid for a product by a retailer, i.e., carrots brought by a grocery store from a farm, were included in GDP as well as the price paid for the product by an individual consumer, i.e., carrots bought by an individual consumer from a grocery store, then there would be double-counting in GDP equal to the price paid by the retailer, i.e., the grocery store. At each stage of production normally some inputs are added, such as transportation, packaging, and labor costs. These costs as reflected in the final price to a consumer, investor, or government are included in GDP. Note that GDP, regardless of which approach is used, does not include capital gains as these do not result from current production.

There are three major categories of output in the SNA: Market, produced for your own use, and other non-market output. Market produced for your own use includes food produced and consumed on a farm. Other non-market output consists of goods and or services produced by non-profit institutions or governments that are supplied free, or at prices that are not economically significant. Although market output is generally the easiest to estimate, problems arise in the estimation of all three types of output.

Miodrag Lovric (ed.), *International Encyclopedia of Statistical Science*, DOI 10.1007/978-3-642-04898-2,

In all cases, collection of data is critical to the estimation of GDP. Missing data points are estimated using interpolation or extrapolation with indicators, such as computer programmer for software production, supplementary data sources, and/or best judgment. Other components of GDP are imputed notably because there is no market information. The imputation for services from owner-occupied housing is normally the largest imputation. Rent payments for houses of similar sizes and quality in similar locations are often used to impute these services when possible. Services from intangibles, such as research and development (R & D), represent a particularly challenging measurement problem.

GDP is presented in the prices of the day, frequently called nominal or current dollars, or in units which allow for comparisons over time, called volume in SNA terminology, real in NIPA terminology, or by many others constant dollars or quantity. Creating volume or real GDP is one of the major challenges facing national accountants. Volume or real measures are created by holding prices constant, allowing for changes in the number and the quality of goods and services over time. Volume or real measures are estimated directly or by deflating nominal measures with prices indexes. Typically indexes are used such as the Paasche, Laspeyres, Fisher or Thornqvist index. Fixed price (volume or quantity) indexes commonly are a Paasche or Laspeyres index; chained prices (volume or quantity) indexes frequently are a Fisher or Thornqvist index. Quality changes in goods and services can be particularly difficult to measure, such as quality changes in computers. During the second half of the nineties in the United States, prices of computers were declining at the same time as performance and sales of computers was increasing. If price and volume (or quantity) indexes had not been adjusted for quality changes and chain indexes were not used, GDP would have been misestimated. Aggregate indexes, such as GDP, will change if the composition of goods and services produced changes even if there are no quality changes because indexes typically involve nominal dollar weights.

This short description describes the primary macroeconomic aggregate of national accounts: GDP, but there are many other economic statistics contained in national accounts. To give a sense of the large volume of information available in national accounts, note that there are nine accounts in the SNA and seven accounts in the NIPAs. The SNA accounts include those for production, distribution of income, redistribution of income, use of income, capital, financial, other changes in asset values, balance sheet, and goods and services. The NIPA accounts include those for domestic income and product, private enterprise income, personal income and outlay, government receipts and expenditures, foreign transactions current, domestic capital, and foreign transactions capital. For further information on national accounts, it is recommended that you refer to the references, particularly those by Lequiller and Blades, and Landefeld et al., and the two short documents by the Bureau of Economic Analysis.

About the Author

Dr. Barbara Fraumeni is Professor of Public Policy, Public Policy Ph.D. Chair, Associate Dean for Research and Associate Dean for Academic and Student Affairs, at Muskie School of Public Service, University of Southern Maine. She was Chief Economist of the U.S. Bureau of Economic Analysis (1999–2005). She was awarded the Gold Medal, highest award given by the U.S. Department of Commerce, for creating an R&D Satellite Account that treats R&D as investment and can be used to assess its contribution to economic growth and competitiveness, during her tenure as Chief Economist at the Bureau of Economic Analysis (November 8, 2006). She also received the 2006 American Economic Association's Committee on the Status of Women in the Economics Profession (CSWEP) Carolyn Shaw Bell Award for furthering the status of women in the economics professions through example, mentoring, and achievements. Currently, she is Chair, Committee on the Status of Women in the Economics Profession, American Economic Association (2008–2011). She also serves on the National Academy of Sciences/Committee on National Statistics Panel on Productivity in Higher Education, the United Nations Economic Commission for Europe/Organisation for Economic Cooperation and Development/Eurostat Task Force on Measuring Sustainable Development, as a Senior Fellow of the China Center for Human Capital and Labor Market Research of the Central University of Finance and Economics, and as a Research Fellow of the National Bureau of Economic Research. Her areas of expertise include measurement issues and national income accounting.

Network Models in Probability and Statistics

Stephen E. Fienberg[1], Andrew C. Thomas[2]
[1]Professor
Carnegie Mellon University, Pittsburgh, PA, USA
[2]Visiting Assistant Professor
Carnegie Mellon University, Pittsburgh, PA, USA

A network is a representation for a collection of individuals or other units connected in a pairwise fashion by relationships, such as friendship. Networks are typically displayed visually as "graphs," so that individuals correspond to the "nodes" of a graph, with the existence of a relationship indicated by an edge between pairs of nodes. Relationships can be univariate or multivariate, and the connections between individuals can be either directed (from one to the other) or undirected. In terms of statistical science, a network model is one that accounts for the structure of the network ties in terms of the probability that each network tie exists, whether conditional on all other ties, or as considered part of the distribution of the ensemble of ties.

A network with N nodes has $\binom{N}{2}$ unordered pairs of nodes, and hence $2\binom{N}{2}$ possible directed edges. If the labels on edges reflect the nodes they link, as (i,j), Y_{ij} represents the existence of an edge from individual i to j, and $\{\mathbf{Y}\} = \{Y_{12}, Y_{13}, \ldots Y_{(N-1)N}\}$ represents the ties in the graph.

Conditionally Independent Edges and Dyads

For a binary graph with conditionally independent edges, each edge outcome Y_{ij} can be expressed as a Bernoulli binary random variable with probability of existence p_{ij}. The simplest of this class of network models is the Erdős–Rényi–Gilbert random graph model (Erdős and Rényi 1959, 1960; Gilbert 1959) (sometimes referred to as the Erdős-Rényi model, or "the" random graph), in which any given edge exists with probability p. This model extends immediately to directed graphs, where any arc has the same existence probability p as any other. There is a large, and still growing, probabilistic literature on random graph models and their generalizations, that is well summarized in Durrett (2006) and Chung and Lu (2006).

The Erdős–Rényi–Gilbert class of model assumes that there is no differentiation between nodes, and that the two arcs within a dyad are independent of each other. The p_1 model of Holland and Leinhardt (1981) proposes that three factors affect the outcome of a dyad: the "gregariousness" α of an individual, how likely they are to have outgoing ties; the "popularity" β of an individual; how likely they are to have incoming ties; and "reciprocity" ρ, the tendency to which the two arcs in a dyad are identical, taking into account their existing characteristics. Given a parameter for the overall density θ, the form of the joint likelihood is

$$P(X = x) = \exp\left(\rho m + \theta x_{++} + \sum_i \alpha_i x_{i+} + \sum_j \beta_j x_{+j}\right) K(\rho, \theta, \alpha, \beta). \quad (1)$$

where $K(\rho, \theta, \alpha, \beta)$ is a normalizing constant to insure that the total probabilities add to 1. Additionally, Holland and Leinhardt (1981) present an iterative proportional fitting method for maximum likelihood estimation for this model, and discuss the complexities involved in assessing goodness-of-fit.

A natural extension of the p_1 model is the case of tightly linked "blocks" of nodes, within which the α and β parameters are equated, suggesting an equivalence

between members of the same block. The inference for and discovery of "communities" in networks has become especially popular in recent network literature in a variety of different applications; see Newman (2004) for an example.

Ensemble Models and Topological Motivations

Rather than focusing on the dyads as independent units, there are classes of models that consider topological features of interest in the network as the main measure of the model. The best known of these is the Exponential Random Graph Model, or ERGM (Frank and Strauss 1986), also known as p^* (Anderson et al. 1999), which extends directly from the p_1 model, by adding statistical summaries of topological relevance. For example, the number of three-cycles or triangles in a graph is equal to

$$T = \sum_{i,j,k} X_{ij}X_{jk}X_{ki};$$

this can then be added into the likelihood of Eq. (1), as in

$$P(X = x) = \exp\left(\tau T + \rho m + \theta x_{++} + \sum_i \alpha_i x_{i+} + \sum_j \beta_j x_{+j}\right) K(\tau, \rho, \theta, \alpha, \beta), \quad (2)$$

where $K(\tau, \rho, \theta, \alpha, \beta)$ is a new normalizing constant. Due to the computational intractability of this normalizing constant, much of the recent literature on ERGMs uses Markov chain Monte Carlo methods (see ►Markov Chain Monte Carlo) for maximum likelihood estimation of the model parameters. Additionally, these models often have degenerate or near-degenerate solutions, as explained in Rinaldo et al. (2009).

Evolutionary Models and Methods

Two popular models for binary networks come from a network model based charcterized by stepwise changes. The first is the "small world" model Watts and Strogatz (1998), which suggests that many networks in nature exhibit high local clustering – the tendency of a node's neighbours to be connected, a sign of an "ordered" system – with short characteristic path lengths, typical of a more "chaotic" system. The second is the "scale-free" model of Barabási and Albert (1999), in which nodes enter sequentially into a existing system, making connections with previously added nodes. The probability of selecting a node for a new link is proportional to its degree at that time, so that "rich" nodes are more likely to receive new links, a notion that goes back almost a century to the work of Yule (1925). The recent literature on this class of evolutionary models emerged from ideas in statistical physics and has been subject to criticism for its loose assessment of the "scale-free" property Li et al. (2006).

Considerable current interest focuses on continuous-time dynamic models of networks, for example, that describe the changes in edge properties. For example, Wasserman (1980) described Markov models for edge states in which the probability of a friendship being made or broken during a particular time interval is proportional to properties of the individuals and of reciprocity in general. Snijders (2004) among others has extended these ideas.

Further Reading

For in-depth reviews of the probabilistic literature on random graph models, see Durrett (2006) and Chung and Lu (2006). Kolaczyk (2009) provides a detailed examination of a number of different network models and their applications, and Goldenberg et al. (2010) provides a broad statistical review with an extensive bibliography.

Network sampling refers to the observation of a sampled network from some population or family F of possible networks. In particular, F can be a family of subnets obtainable from a fixed graph or network G. In this case, G is usually referred to as the population graph or the population network.

A graph G with vertex set V and edge set E is identified by a binary function $y = \{(u, v, y_{uv}) : (u, v) \in V^2\}$ that for each ordered pair of vertices in V returns a value y_{uv} indicating whether or not $(u, v) \in E$. If $V = \{1, \ldots, N\}$ and the vertices are ordered according to their labeling, y can be displayed as the adjacency matrix (y_{uv}) of G. A more general network G, a valued graph with univariate or multivariate variables defined on the vertex pairs, can be represented by a univariate or multivariate function y on V^2.

A family F of subnets obtainable from a fixed population network specified by a function y can be generated by a vertex sample S selected according to a specified probabilistic sampling design. Let $E(S)$ be the subset of V^2 generated by S, and let $y(S)$ be the restriction of y to $E(S)$. The family F of observable subnets consists of the subnets represented by $y(S)$ for different outcomes of S. In particular, a subnet induced by S consists of y_{uv} for $(u, v) \in S^2$, and a subnet generated from and towards S consists of y_{uv} for all (u, v) with $u \in S$ or $v \in S$.

The subnets represented by $y(S)$ are random due to the randomness of the sampling design of S. Any inference on y based on $y(S)$ is referred to as design based inference. The population network represented by y is usually too complicated to describe in detail, and it might be conveniently summarized by some summary statistics or by some probabilistic model assumptions focusing on important features between the variables involved in y. If the probabilistic sampling design of S is combined with probabilistic model assumptions about y, the observed subnet $y(S)$ is random due to the randomness of both design and model. In this case, model based inference refers to inference on features of the model of y, while model assisted inference is sometimes used as a term for inference on the outcome of y.

As a simple example, consider an undirected population graph on $V = \{1, \ldots, N\}$ given by the adjacency matrix $y = (y_{uv})$ with $y_{vv} = 0$ and $y_{uv} = y_{vu}$ for $u \neq v$. The number of edges R and the number of isolated vertices N_0 should be estimated by using the information from a subgraph induced by a Bernoulli (p)-sample S of vertices. Here vertices in V are independently selected with a common probability p, which for instance could be chosen as $0.1 + N^{-1/2}$ in order to get a small probability for a sample that is too small. Let n_k be the number of vertices of degree k in the sample graph for $k = 0, 1, \ldots$ Then the number of edges in the sample graph is given by $r = (1/2)\Sigma_k k n_k$, and R can be estimated by r/p^2. It can be shown that N_0 has an unbiased estimator given by the alternating series $(1/p)\Sigma_k n_k(-q/p)^k$ where $q = 1 - p$. This estimator has very low precision, and it is desirable to replace it with a model based alternative. Assume that the population graph is a Bernoulli (α)-graph so that y_{uv} for $u < v$ are independent Bernoulli (α)-variables. It follows that R and N_0 have expected values $N(N-1)\alpha/2$ and $N(1-\alpha)^{N-1}$, respectively. Now α can be estimated by the edge density $2r/n(n-1)$ of the sample graph, and it follows that R and N_0 could be predicted to be close to their estimated expected values $N(N-1)r/n(n-1)$ and $N[1 - 2r/n(n-1)]^{N-1}$, respectively.

For a more statistical example, consider a population network with a multivariate y having means and variances that should be estimated by using the information from a subnet generated by a vertex sample S selected according to a specified probabilistic design. Obviously any model assumptions that explain the multivariate structure between the variables in y should be beneficial in order

to find predictors of the estimated expected values of the means and variances of the variables in y.

Further information about the literature on survey sampling in networks can be found in the following references.

About the Author

Professor Frank is one of the pioneers in network sampling, He has published papers on network methodology, snowball sampling, Markov graphs, clustering, and information theory. Jointly with Professor David Strauss he introduced Markov graphs in 1986 and explained how sufficient network statistics can be deduced from explicit assumptions about the dependencies in a network.

Introduction

Neural networks emulate aspects of real neural systems to attempt to achieve some of the remarkable capabilities of real neural systems, or to help understand the working of neural systems. There are many types of neural networks, some concerned with data prediction and classification (which are of interest here), and others with detailed understanding of the operation of real neural systems. What they all share is modelling (on a digital computer) some simplification of the extremely complicated and sophisticated structure of real neural systems: in essence parallel operation of relatively simple but highly interconnected processing elements (model neurons).

Neural networks that are of interest to statisticians use highly simplified model neurons, and interconnections between neurons (synapses). The earliest such networks were based on the seminal work of McCulloch and Pitts (1943) who characterized neurons as threshold logic devices. These were used by Rosenblatt and Minsky to build systems which they called Perceptrons. Such systems are inherently limited (as was shown by Minsky and Papert [1969]), and it was not until the 1980s that modern ideas of using of Neural Networks for statistical purposes came to the fore. (A more detailed history may be found in Haykin [2009], Chap. 1.)

Neural networks consist of a model M, with a set of parameters P. M is one of a generic set of models such as those below. An important concept in neural networks is that the parameters *adapt* as a result of the data applied to the network. The initial issues are choosing the right model M, then choosing an initial set of parameters, and an effective way to adapt the parameters P (a learning rule). In addition, it is necessary to check that the resultant parameter values actually solve the problem. Often a number of models and initial parameter values are used, and then the final results assessed. Neural network adaptation techniques allow them to approximate regression techniques. Because the networks include non-linear elements they can go beyond linear regression. A detailed discussion of the nature of the relationship between neural networks and statistical techniques may be found in Bishop (1995).

Types of Neural Network

Neural networks may be supervised or unsupervised. Supervised neural networks (sometimes characterised as *having a teacher*) are provided with sets of inputs and their corresponding outputs (*training data*) and internally adapt their parameters to attempt *learn* how to map (new) inputs into outputs in a way consistent with the training data. Unsupervised neural networks also receive data which they use to alter their internal structure, but in this case, there are no corresponding outputs: the network needs to approximate some aspects of the internal structure of the training data. Normally, the training data is divided into data used for training, and data used to test the resultant network. Supervised neural networks are used for prediction (function approximation) and classification, and unsupervised networks are normally used for data dimensionality reduction, and classification purposes.

Supervised Neural Networks

Most supervised networks are *feedforward*: that is, the external input is connected to some neurons, and these are then connected to others in turn in such a way that there are no loops. These are in general easier to train than recurrent neural networks, but can have no sensitivity to the history of their inputs. The simplest such network is the simple Delta-unit network (SimpleΔ), and consists of a set of input units and an output unit: however such networks are limited in what they can learn.

In the SimpleΔ network, the output unit calculates a weighted sum of the N inputs X_i, (plus a bias term, written here as $w_0 X_0$, with X_0 always 1).

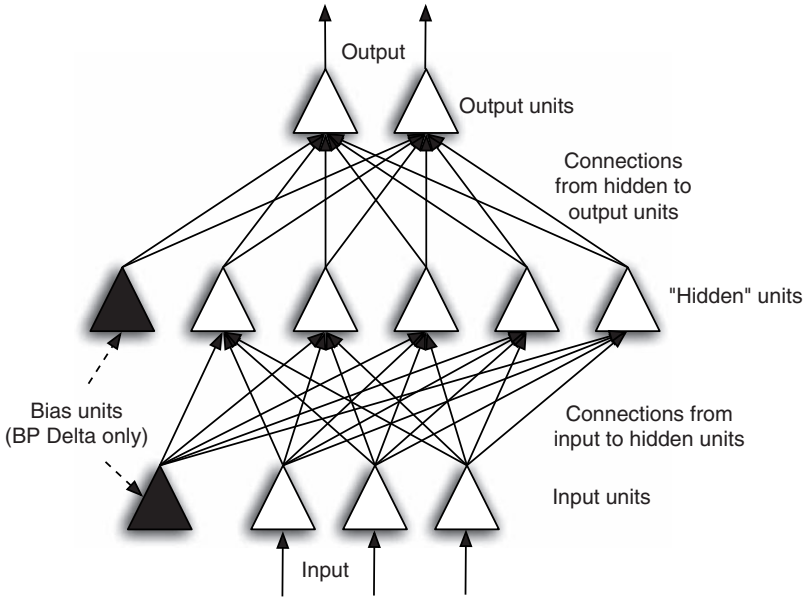
$$A = \Sigma_{(i=0)}^{N} (w_i X_i) \tag{1}$$

where A is the activation of the output unit, and the w_i are the weights between the input units and the output unit. Often this activation is then compressed, for example using a logistic function to produce the output Y so that $Y = 1/(1+\exp(-KA))$. If D is the desired output for a given input vector $\bar{X} = (X_0, X_1, \ldots, X_N)$ then it can be shown that adjusting the weights using

$$\delta w_i = k(D - Y)\frac{dY}{dA}X_i \tag{2}$$

will result in making D closer to Y for small positive k. However, the range of functions (or classifications) that can be represented by such a network is restricted to linearly seperable functions. To enable a more general class of problems to be solved requires that (for example) increasing a value for an input x_i can sometimes increase and sometimes decrease Y, and this requires additional model neurons: these are called *hidden neurons* as they are neither input nor output neurons. They are usually arranged in layers.

The two commonest forms of feedforward supervised neural networks are back-propagated Delta rule networks (BPΔ) and radial basis function (RBF) networks: they (largely) share a common architecture, illustrated in Fig. 1. The primary difference between BPΔ and RBF networks is the nature of the hidden layer units. In BPΔ networks, these calculate a weighted sum of their inputs, then non-linearly squash this output: typically, a logistic function is used for squashing. In this case, if Y is the output,



Neural Networks. Fig. 1 Feedforward neural network. Input arrives at the (three) input units, and is transferred through the connections from input to hidden units to the hidden units. For back-propagated delta-rule networks, there is one other input to each hidden unit, a bias input from a unit (in *black*) whose output is always 1. The output from the hidden units passes through connections to the output units, (again, for back-propogated delta-rule networks there is an extra bias input). The output units provide the output. Note that this is a *fully connected layered feedforward* net because all units in each layer are connected to all units in the next layer

$$Y = 1/\left(1 + \exp(-K\,\Sigma_{(i=0)}^{N}(w_i X_i))\right) \quad (3)$$

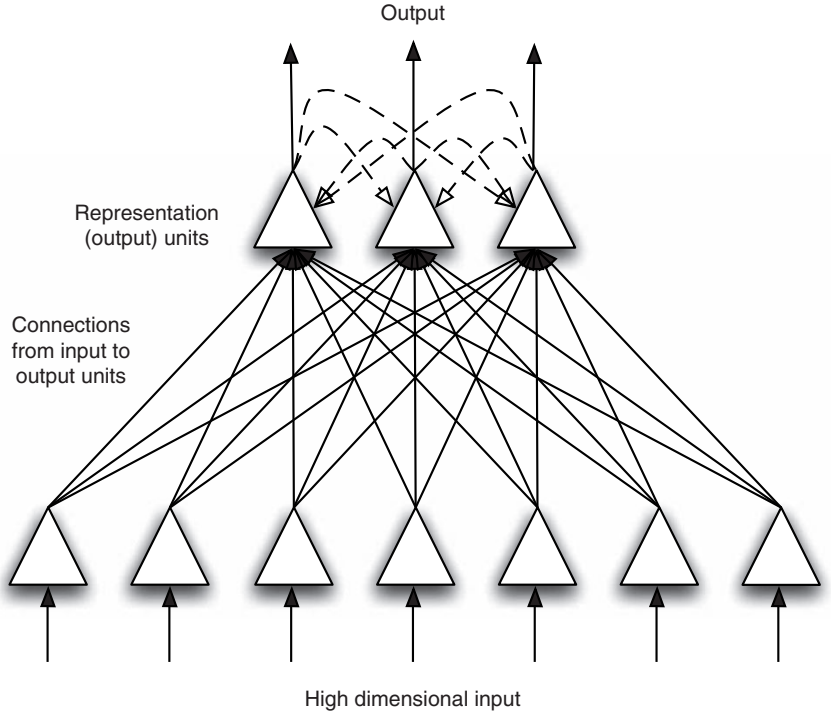
where $w_i X_i$ is weighted input, N is the number of units in the previous layer (including the bias unit), and K is a positive number which determines the steepness of the logistic function. The network adapts by altering all of the w_i. Here M is the network architecture (number of layers and of hidden units in each layer), and P is the w_i. The network shown in Fig. 1 has a single hidden layer with five hidden units: there may be multiple hidden layers, with different numbers of units in each.

In RBF networks, the hidden units compute a high dimensional Gaussian of their input. Thus they have a single maximum, and the region of the input space to which they respond is localized, unlike the BPΔ hidden units. The Gaussian may have different standard deviations (SDs) in different dimensions. Typically, a relatively large number of hidden units is used, and the Gaussian centers and SDs are fixed. (There may be an initial stage in which these centers and SDs are adjusted so that the hidden units together cover the whole of the region of the input space populated by the actual inputs.) In training, only the connections between the hidden units and the output units are adapted, usually using a simple Delta-rule technique. Thus M is the RBF units (and usually their centers and standard deviations), and P is the weights from the RBFs to the output units. Only a single layer of hidden units is used.

For the BPΔ network, the weights are adjusted by propagating the errors back through the feedforward architecture (see Haykin [2009] for details). This uses simple locally calculated gradient descent, although steepest descent is also possible, though the change in weight then requires non-local values for its computation. Because the relationship between the weights and the overall error may be very complex, the BPΔ network can become trapped in local minima (which is why normal practice is to start from different locations in weight space). For the RBF network, the weights to the output units are adjusted using Eq. (2). The RBF network may also be sensitive to the placing and radii of the RBF units: often the centers are initialized to some of the training data, and the radii calculated from initial training data. However, because the weights are only a single layer, gradient descent algorithms are guaranteed to find a global minimum of the error.

Unsupervised Neural Networks

Unsupervised neural networks adapt the connections between neurons as a result of the input to the network.



Neural Networks. Fig. 2 Simple self-organized neural network. Input arrives at the (seven) input units, and is transferred through the connections from these to the representation or output units. These units may be interconnected (*dotted lines*), or they may interact in an algorithmically defined way

Typically, these consist of a single layer of input units providing adjustable weighted inputs to a layer of representation (and also output) units, as shown in Fig. 2.

Generally, the weighted connections from the input to the representation units are adjusted so that the unit that received the greatest activation ("won") will be more likely to win in the future: clearly this leaves open the possibility that some units may never win, or that some units may win too often, so that there may also be adjustment of the sensitivity of output units as well. A more sophisticated self-organized network was designed by Kohonen (1989), and it places a geometry on the representation units so that one can talk of different output units being nearer or further from each other: the learning algorithm used also attempts to ensure that the whole output space is used. This allows the data in the original high-dimensional input space to be projected down to a much lower-dimensional output space: this can be very useful when attempting to understand the structure of, or to classify high dimensional datasets.

Other Architectures

Some network architectures also allow adaptation of the architecture: these often have phases of adding neurons, followed by phases of removing them. The aim is to produce a simple M which can then provide a simple model of the data being analysed. Though not a new idea (Frean 1990; Hassibi et al. 1993), this area has seen recent interest (Franco et al. 2010). Recurrent neural networks (networks with feedback loops) are also used for prediction and classification where the network needs to be sensitive to previous inputs. Training in such networks can present convergence issues: the algorithms used in the BPΔ and RBF networks require the absence of loops. Details of some training techniques may be found in Haykin (2009).

Neyman-Pearson Lemma

Czesław Stępniak
Professor
Maria Curie-Skłodowska University, Lublin, Poland
University of Rzeszów, Rzeszów, Poland

Neyman–Pearson lemma (also called fundamental lemma) presented in 1933 is the basic tool in testing statistical hypotheses. Its essence consists of the following mathematical problem.

Given a measure μ on a measurable space $(\mathcal{X}, \mathcal{A})$ and given nonnegative measurable real functions f_0 and f_1 on $(\mathcal{X}, \mathcal{A})$ satisfying the condition $\int_{\mathcal{X}} f_i(x)d\mu(x) = 1$, for $i = 1, 2$, consider the family $\mathcal{S} = \mathcal{S}(\alpha)$ of all $\mathcal{A}$-measurable subsets S of $\mathcal{X}$ such that

$$\int_S f_0(x)d\mu(x) \le \alpha, \text{ where } \alpha \text{ is a given positive constant, non greater than 1.} \quad (1)$$

Find all sets in $\mathcal{S}(\alpha)$ maximizing the integral $\int_S f_1(x)d\mu(x)$.

Neyman-Pearson lemma states that the family of the sets S in $\mathcal{S}(\alpha)$ of the form $\{x \in \mathcal{X} : f_1(x) > kf_0(x)\}$ for some nonnegative constant k is not empty and it includes the desired solution. Moreover, any solution may be presented in this form almost surely w.r.t μ.

A version of this lemma for *randomized tests* is more useful. As known a randomized test is represented by a real function $\phi = \phi(x)$ on $\mathcal{X}$ taking values in the interval $[0, 1]$ which plays the role of a fuzzy set in $\mathcal{X}$. In consequence, the

condition (1) and the integral $\int_{\mathcal{S}} f_1(x)d\mu(x)$ are replaced by $\int_{\mathcal{X}} \phi(x)f_0(x)d\mu(x) \le \alpha$, and $\int_{\mathcal{X}} \phi(x)f_1(x)d\mu(x)$, respectively. In this case the Neyman–Pearson has the following statistical interpretation.

Suppose a random variable X has a density f_X, being one of the functions f_0 or f_1. Then one of the equivalent *most powerful* (MP) tests for the hypothesis $H : f_X = f_0$ under the alternative $K : f_X = f_1$ at the significance level α may be presented in the form

$$\phi(x) = \begin{cases} 1, & \text{if } f_1(x) > kf_1(x) \\ \gamma, & \text{if } f_1(x) = kf_1(x), \\ 0, & \text{if } f_1(x) < kf_1(x) \end{cases} \tag{2}$$

where nonnegative k and γ belonging to the interval $[0,1]$ are determined by the condition

$$\int_{\mathcal{X}} \phi(x)f_0(x)d\mu(x) = \alpha, \tag{3}$$

unless there exists a test ϕ of size less than α with power 1.

The Neyman–Pearson lemma was also generalized for testing a hypothesis of type $H : f_X \in \{f_1, \ldots, f_m\}$ against a simple alternative $K : f_X = f_{m+1}$..

Example Random value X takes values $-1, 0, 1, 2, 3, 4, 5$ according to one of the distributions given in the table.

x	–1	0	1	2	3	4	5
$P_0(X = x)$	0.08	0.15	0.2	0.1	0.45	0.01	0.01
$P_1(X = x)$	0.33	0.1	0.1	0.1	0.05	0.02	0.3

Construct the MP test for the hypothesis H: $P = P_0$ against the alternative K: $P = P_1$ at the significance level $\alpha = 0.05$.

First we compute the likelihood rations $q(x) = \frac{P_1(X=x)}{P_0(X=x)}$ and range them in the descending order. Let $r(x)$ denote the rank of $q(x)$ while x_i – the value x corresponding to the rank i. Further steps may be observed in the table

x	$q(x)$	$r(x)$	i	x_i	$f_i = P_0(X = x_i)$	$s_i = \sum_{j \le i} f_j$
–1	4.13	2	1	5	0.01	0.01
0	0.67	5	2	–1	0.08	0.09
1	0.5	6	3	4	0.01	0.1
2	1.0	4	4	2	0.1	0.2
3	0.11	7	5	0	0.15	0.35
4	2	3	6	1	0.2	0.55
5	30	1	7	3	0.45	1.0

Now we only need to apply the conditions (2) and (3) in discrete form. The last column in the table shows that the MP nonrandomized test for the hypothesis H against K at the significance level 0.05 rejects H, if and only if $X = 5$. Moreover its power is equal to 0.3. The corresponding MP randomized test is defined *by*

$$\phi(x) = \begin{cases} 1, & \text{if} \quad X = 5 \\ 0.5, & \text{if} \quad X = -1 \\ 0, & \text{otherwise.} \end{cases}$$

Its power is equal to 0.47.

Nonlinear Mixed Effects Models

Marie Davidian
William Neal Reynolds Professor, Director,
Center for Quantitative Sciences in Biomedicine, North Carolina State University, Raleigh, NC, USA

The *nonlinear mixed effects model* (or *hierarchical nonlinear model*) is a standard framework for analysis of data in the form of continuous repeated measurements over time on each individual from a sample of individuals drawn from a population of interest. It is particularly relevant when the goal is to make inference on the average behavior and variability in the population of individuals of features underlying the individual profiles, where the profiles are well-represented by a function nonlinear in parameters that characterize the features under study.

A key area where this model is appropriate is in pharmacokinetic analysis, where repeated blood samples are collected from each of several subjects at intermittent time points following a dose or doses of a drug, from which continuous drug concentration measurements are ascertained. The objective is to characterize the underlying pharmacological processes within the body that lead to observed concentrations and how these processes vary across subjects in the population. To describe the processes formally, it is routine to represent the body of an individual subject by a simple compartment model, which yields an expression for concentration at any time post-dose as a function nonlinear in parameters that quantify absorption, distribution, and elimination of the drug for the subject. For example, representation of the body by a single "blood compartment," with oral dose D given at time $t = 0$, leads to the standard model for concentration at time t, $C(t)$, given by

$$C(t) = \frac{Dk_a}{V(k_a - Cl/V)}\left\{\exp(-k_a t) - \exp\left(-\frac{Cl}{V}t\right)\right\}, \quad (1)$$

where k_a is the fractional rate of absorption of the drug from the gut into the bloodstream; V is roughly the volume required to account for all drug in the body; and Cl is the clearance rate, the volume of blood from which drug is eliminated per unit time. In (1), the goal is to learn about the parameters (k_a, V, Cl) that summarize pharmacokinetic processes for a given subject and their mean or median values and the extent of variation of them in the population of subjects. This information is critical for designing dosage regimens to maintain drug concentrations in a desired range; if population variation in (k_a, V, Cl) is substantial, designing a regimen that will work well for most individuals may be difficult. If some of the variation is systematically associated with subject characteristics like weight or age, regimens tailored to subpopulations of subjects sharing certain characteristics may be developed. See Giltinan (2006) for an excellent review of this area.

Additional applications where the inferential goals are similar and for which the nonlinear mixed effects model is a suitable framework include growth analysis in agriculture and forestry and analysis of viral dynamics, among others. In general, relevant applications are such that a model for response–time profile at the individual level, derived from theoretical or empirical considerations, like (1), and depending on parameters characterizing directly underlying features of interest, is available and is central to the data-analytic objectives.

For each individual i in a sample of N individuals from a population of interest, $i = 1, \ldots, N$, let Y_{ij} denote a continuous, univariate response (e.g., drug concentration) at time t_{ij}, $j = 1, \ldots, n_i$. Let $\boldsymbol{U}_i$ denote a vector of covariates specifying conditions under which i is observed; for example, in (1), $\boldsymbol{U}_i = D_i$ = oral dose given to individual i at time 0; in the case of multiple doses, $\boldsymbol{U}_i$ would summarize the times and corresponding doses given. The $\boldsymbol{U}_i$ are needed to describe the response–time relationship at the level of individual i, as in (1), and hence are often referred to as "within-individual" covariates. Assume further that a vector of characteristics that do not change over the observation period on i are recorded, such as age, ethnicity, weight, and so on; summarize these in a vector $\boldsymbol{A}_i$, often called "among-individual" covariates because they characterize how individuals may differ but are not required to describe individual response–time relationships. The available data are then $(\boldsymbol{Y}_i, \boldsymbol{U}_i, \boldsymbol{A}_i)$, $i = 1, \ldots, N$, where $\boldsymbol{Y}_i = (Y_{i1}, \ldots, Y_{in_i})'$, which, combining the within- and among-individual covariates as $\boldsymbol{X}_i = \left(\boldsymbol{U}_i', \boldsymbol{A}_i'\right)'$, may be written more succinctly as $(\boldsymbol{Y}_i, \boldsymbol{X}_i)$, $i = 1, \ldots, N$.

The model may be conceived as a two stage hierarchy. At the first stage, a model for data at the level of a given individual i is specified. Let $m(t, \boldsymbol{U}, \boldsymbol{\theta})$ be a function of time, within-individual conditions of measurement, and a vector of parameters $\boldsymbol{\theta}$ characterizing features underlying the response-time profile; e.g., $m(t, \boldsymbol{U}, \boldsymbol{\theta})$ is $C(t)$, $\boldsymbol{U} = D$, and $\boldsymbol{\theta} = (k_a, V, Cl)'$ in (1). Key to the development is that individual i is assumed to have individual-specific such parameters $\boldsymbol{\theta}_i$ governing his/her trajectory $m(t, \boldsymbol{U}_i, \boldsymbol{\theta}_i)$; in (1), $\boldsymbol{\theta}_i = (k_{ai}, V_i, Cl_i)' = (\theta_{i1}, \theta_{i2}, \theta_{i3})'$. Writing $\boldsymbol{m}_i(\boldsymbol{U}_i, \boldsymbol{\theta}_i) = \{m(t_{i1}, \boldsymbol{U}_i, \boldsymbol{\theta}_i), \ldots, m(t_{in_i}, \boldsymbol{U}_i, \boldsymbol{\theta}_i)\}'$, it is assumed that

$$E(\boldsymbol{Y}_i \mid \boldsymbol{U}_i, \boldsymbol{\theta}_i) = \boldsymbol{m}_i(\boldsymbol{U}_i, \boldsymbol{\theta}_i), \quad \text{so that} \quad E(Y_{ij} \mid \boldsymbol{U}_i, \boldsymbol{\theta}_i) = m(t_{ij}, \boldsymbol{U}_i, \boldsymbol{\theta}_i). \tag{2}$$

A model for $\mathrm{Cov}(\boldsymbol{Y}_i \mid \boldsymbol{U}_i, \boldsymbol{\theta}_i)$ is also specified. The diagonal elements embody assumptions regarding measurement error, sampling variation, and the fact that error-free realizations of the response–time process may not fall directly on the trajectory $m(t, \boldsymbol{U}_i, \boldsymbol{\theta}_i)$ because, for example, it is a simplified representation of a complex biological phenomenon (e.g., as (1) is a gross simplification of the underlying physiology). The off-diagonal elements are dictated by assumptions on possible autocorrelation among the Y_{ij}, $j = 1, \ldots, n_i$, given $(\boldsymbol{U}_i, \boldsymbol{\theta}_i)$. Due to the intermittent nature of the times of measurement $t_{i1}, \ldots, t_{in_i}$, autocorrelation between any pair of measurements is often assumed negligible; however, this need not always be the case. Combining these, it is assumed that

$$\mathrm{Cov}(\boldsymbol{Y}_i \mid \boldsymbol{U}_i, \boldsymbol{\theta}_i) = V_i(\boldsymbol{U}_i, \boldsymbol{\theta}_i, \boldsymbol{\alpha}), \tag{3}$$

where $\boldsymbol{\alpha}$ is the collection of parameters used to describe within-subject variance and correlation. See Davidian (2009) for discussion of considerations involved in specifying model for $\mathrm{Cov}(\boldsymbol{Y}_i \mid \boldsymbol{U}_i, \boldsymbol{\theta}_i)$. The most common model, sometimes adopted by default without adequate consideration of its rather strong assumptions, is $V_i(\boldsymbol{U}_i, \boldsymbol{\theta}_i, \boldsymbol{\alpha}) = \sigma^2 I_{n_i}$, where $\boldsymbol{\alpha} = \sigma^2$; I_n is a $(n \times n)$ identity matrix; and σ^2 represents a constant variance due to, say, measurement error and variation in realizations, that is the same across all subjects.

Along with (2) and (3), the first stage individual level model is ordinarily completed by an assumption on the distribution of $\boldsymbol{Y}_i$ given $(\boldsymbol{U}_i, \boldsymbol{\theta}_i)$. A standard such assumption is that this distribution is normal with mean (2) and covariance matrix (3); this may be reasonable for some types of responses on a transformed scale, in which case Y_{ij} may be taken to be a transformation of the original response in the foregoing discussion.

At the second stage, a model for the population describes possible systematic relationships between individual-specific parameters $\boldsymbol{\theta}_i$ and individual characteristics $\boldsymbol{A}_i$ in the population as well as the "inherent" variation among the $\boldsymbol{\theta}_i$ once a such relationships are taken into account. A general population model is written as

$$\boldsymbol{\theta}_i = \boldsymbol{d}(\boldsymbol{A}_i, \boldsymbol{\beta}, \boldsymbol{b}_i), \tag{4}$$

where $\boldsymbol{d}$ is a r-dimensional function that describes the relationship between $\boldsymbol{\theta}_i$ and $\boldsymbol{A}_i$ in terms of a parameter $\boldsymbol{\beta}$ $(p \times 1)$ and random effects $\boldsymbol{b}_i$ $(q \times 1)$ accounting for the additional inherent variation. The $\boldsymbol{b}_i$ are typically taken to be independent across i, and the $\boldsymbol{b}_i$ are often assumed independent of the $\boldsymbol{A}_i$, $i = 1, \ldots, N$, with $E(\boldsymbol{b}_i) = 0$ and $\mathrm{Cov}(\boldsymbol{b}_i) = G$ for unstructured covariance matrix G; moreover, it is routine to assume that the $\boldsymbol{b}_i$ are normally distributed with these moments. As an example, in the context of (1), supposing $\boldsymbol{A}_i = (w_i, \delta_i)'$, with w_i weight and δ_i an indicator of creatinine clearance, where $\delta_i = 1$ if >50 mL/min, consider $k_{ai} = \theta_{i1} = d_1(\boldsymbol{A}_i, \boldsymbol{\beta}, \boldsymbol{b}_i) = \exp(\beta_1 + b_{i1})$, $V_i = \theta_{i2} = d_2(\boldsymbol{A}_i, \boldsymbol{\beta}, \boldsymbol{b}_i) = \exp(\beta_2 + b_{i2})$, and $Cl_i = \theta_{i3} = d_3(\boldsymbol{A}_i, \boldsymbol{\beta}, \boldsymbol{b}_i) = \exp(\beta_3 + \beta_4 w_i + \beta_5 \delta_i + b_{i3})$, where $\boldsymbol{b}_i = (b_{i1}, b_{i2}, b_{i3})'$ $(q = 3)$, and $\boldsymbol{\beta} = (\beta_1, \ldots, \beta_5)'$ $(p = 5)$. This model enforces positivity of k_{ai}, V_i, and Cl_i; moreover, if the $\boldsymbol{b}_i$ are normal, then the distributions of their components, and thus those of the $\boldsymbol{\theta}_i$, are lognormal (and hence skewed), which is common in this application. Alternatively, an analogous specification would be to reparameterize (1), taking $\boldsymbol{\theta}_i = \left(k_{ai}^*, V_i^*, Cl_i^*\right)'$, where $k_{ai}^* = \log(k_{ai})$, $V_i^* = \log(V_i)$, and $Cl_i^* = \log(Cl_i)$, and to write $k_{ai}^* = \beta_1 + b_{i1}$, $V_i^* = \beta_2 + b_{i2}$, and $Cl_i^* = \beta_3 + \beta_4 w_i + \beta_5 \delta_i + b_{i3}$. Here, the population model (4) may be written in the linear form $\boldsymbol{\theta}_i = A_i \boldsymbol{\beta} + B_i \boldsymbol{b}_i$, where A_i and B_i are "design matrices" specifying dependence on $\boldsymbol{A}_i$ and whether or not all elements of $\boldsymbol{\theta}_i$ have associated random effects, respectively; see Davidian (2009). A linear population model is the default specification in many papers and software packages.

The nonlinear mixed effects model may be summarized as is conventional by writing the stage 1, individual level model as in (2) and (3), substituting the population model (4), so that conditioning is with respect to $\boldsymbol{X}_i$ and the random effects $\boldsymbol{b}_i$, as follows:

Stage 1: Individual-Level Model

$$E(\boldsymbol{Y}_i \mid \boldsymbol{X}_i, \boldsymbol{b}_i) = \boldsymbol{m}_i(\boldsymbol{U}_i, \boldsymbol{\theta}_i) = \boldsymbol{m}_i(\boldsymbol{X}_i, \boldsymbol{\beta}, \boldsymbol{b}_i),$$

$$\mathrm{Cov}(\boldsymbol{Y}_i \mid \boldsymbol{X}_i, \boldsymbol{b}_i) = V_i(\boldsymbol{U}_i, \boldsymbol{\theta}_i, \boldsymbol{\alpha}) = V_i(\boldsymbol{X}_i, \boldsymbol{\beta}, \boldsymbol{b}_i, \boldsymbol{\alpha}) \tag{5}$$

Stage 2: Population Model

$$\boldsymbol{\theta}_i = \boldsymbol{d}(\boldsymbol{A}_i, \boldsymbol{\beta}, \boldsymbol{b}_i), \qquad \boldsymbol{b}_i \sim (0, G). \tag{6}$$

Standard assumptions are that the distribution of $\boldsymbol{Y}_i$ given $(\boldsymbol{X}_i, \boldsymbol{b}_i)$ is normal with moments (5); that $\boldsymbol{b}_i \sim N(0, G)$, independently of $\boldsymbol{A}_i$ (and $\boldsymbol{U}_i$, and hence $\boldsymbol{X}_i$); and that $\boldsymbol{b}_i$ are independent across i.

The usual objective is inference on $\boldsymbol{\beta}$ and G, corresponding to average behavior of and extent of variation in features underlying individual profiles in the population. The obvious approach to inference in (5), (6) is maximum likelihood. Letting $\boldsymbol{\gamma} = (\boldsymbol{\beta}', \boldsymbol{\alpha}')'$, and writing the conditional density of $\boldsymbol{Y}_i$ given $\boldsymbol{X}_i$ as $f_i(\boldsymbol{y}_i \mid \boldsymbol{x}_i; \boldsymbol{\gamma}, G)$, by independence across i, the loglikelihood for (γ, G) based on the

observed data $(\boldsymbol{Y}_i, \boldsymbol{X}_i)$, $i = 1, \ldots, N$, is

$$\ell(\boldsymbol{\gamma}, G) = \log\left\{\prod_{i=1}^{N} f_i(\boldsymbol{y}_i \,|\, \boldsymbol{x}_i;\, \boldsymbol{\gamma}, G)\right\} = \log\left\{\prod_{i=1}^{N} \int f_i(\boldsymbol{y}_i \,|\, \boldsymbol{x}_i, \boldsymbol{b}_i;\, \boldsymbol{\gamma}) f(\boldsymbol{b}_i;\, G)\, d\boldsymbol{b}_i\right\}, \quad (7)$$

where $f_i(\boldsymbol{y}_i \,|\, \boldsymbol{x}_i, \boldsymbol{b}_i;\, \boldsymbol{\gamma})$ is the conditional density of $\boldsymbol{Y}_i$ given $(\boldsymbol{X}_i, \boldsymbol{b}_i)$ assumed in stage 1; and $f(\boldsymbol{b}_i;\, G)$ is the density of the $\boldsymbol{b}_i$ assumed in stage 2, e.g., the $N(0, G)$ density. From the right side of (7), $\ell(\boldsymbol{\gamma}, G)$ involves N almost certainly analytically intractable q-dimensional integrals, so maximization of $\ell(\boldsymbol{\gamma}, G)$ in $(\boldsymbol{\gamma}, G)$ requires a way of numerically evaluating or analytically approximating these integrals.

A natural approach when $f(\boldsymbol{b}_i;\, G)$ is a normal density is Gaussian quadrature, which approximates the integral by a weighted average of the integrand over a q-dimensional grid. Although accuracy increases with the number of grid points, the larger is q, the greater the computational burden, but reducing the number of grid points in each dimension can compromise accuracy. A variant, adaptive Gaussian quadrature, can reduce the number of grid points needed (Pinheiro and Bates 2005); regardless, because evaluation of the N integrals must be carried out at each internal iteration of the optimization algorithm for maximizing (7), computation can be challenging unless q is small (e.g., $\leq$ 3). The SAS procedure `nlmixed` (SAS Institute 2009) offers options for maximization of (7) using Gaussian or adaptive Gaussian quadrature to "do" the integrals.

Alternative methods accordingly seek to avoid the integrations via analytical approximations to $f_i(\boldsymbol{y}_i \,|\, \boldsymbol{x}_i;\, \boldsymbol{\gamma}, G)$ in (7). The two main approaches, which assume $f_i(\boldsymbol{y}_i \,|\, \boldsymbol{x}_i, \boldsymbol{b}_i;\, \boldsymbol{\gamma})$ and $f(\boldsymbol{b}_i;\, G)$ are normal, follow from writing (5), (6) equivalently as $\boldsymbol{Y}_i = \boldsymbol{m}_i(\boldsymbol{X}_i, \boldsymbol{\beta}, \boldsymbol{b}_i) + V^{1/2}(\boldsymbol{X}_i, \boldsymbol{\beta}, \boldsymbol{b}_i, \boldsymbol{\alpha})\, \boldsymbol{\epsilon}_i$, where $\boldsymbol{\epsilon}_i$ is $N(0, I_{n_i})$ conditional on $(\boldsymbol{X}_i, \boldsymbol{b}_i)$. Taking a linear Taylor series about $\boldsymbol{b}_i = \boldsymbol{b}_i^*$ "close" to $\boldsymbol{b}_i$ and disregarding negligible terms leads to

$$\boldsymbol{Y}_i \approx \boldsymbol{m}_i\left(\boldsymbol{X}_i, \boldsymbol{\beta}, \boldsymbol{b}_i^*\right) - Z_i\left(\boldsymbol{X}_i, \boldsymbol{\beta}, \boldsymbol{b}_i^*\right) \boldsymbol{b}_i^* + Z_i\left(\boldsymbol{X}_i, \boldsymbol{\beta}, \boldsymbol{b}_i^*\right) \boldsymbol{b}_i + V_i^{1/2}\left(\boldsymbol{X}_i, \boldsymbol{\beta}, \boldsymbol{b}_i^*, \boldsymbol{\alpha}\right) \boldsymbol{\epsilon}_i, \quad (8)$$

where $Z_i\left(\boldsymbol{X}_i, \boldsymbol{\beta}, \boldsymbol{b}_i^*\right) = \partial / \partial \boldsymbol{b}_i \{\boldsymbol{m}_i(\boldsymbol{X}_i, \boldsymbol{\beta}, \boldsymbol{b}_i)\}|_{\boldsymbol{b}_i = \boldsymbol{b}_i^*}$. Taking $\boldsymbol{b}_i^* = 0$, the mean of $\boldsymbol{b}_i$, (8) implies that the distribution of $\boldsymbol{Y}_i$ given $\boldsymbol{X}_i$ is approximately normal with

$$E(\boldsymbol{Y}_i \,|\, \boldsymbol{X}_i) \approx \boldsymbol{m}_i(\boldsymbol{X}_i, \boldsymbol{\beta}, 0), \quad \mathrm{Cov}(\boldsymbol{Y}_i \,|\, \boldsymbol{X}_i) \approx Z_i(\boldsymbol{X}_i, \boldsymbol{\beta}, 0)\, G\, Z_i'(\boldsymbol{X}_i, \boldsymbol{\beta}, 0) + V_i(\boldsymbol{X}_i, \boldsymbol{\beta}, 0, \boldsymbol{\alpha}). \quad (9)$$

This suggests replacing $f_i(\boldsymbol{y}_i \,|\, \boldsymbol{x}_i;\, \boldsymbol{\gamma}, G)$ in (7) by the corresponding normal density and maximizing the resulting likelihood, first proposed by Beal and Sheiner (1982) in the pharmacokinetics literature. This and related methods based on (9) with $\boldsymbol{b}_i^* = 0$ are referred to as "first order" methods and are available in SAS `proc nlmixed`, the SAS macro `nlinmix` (Littell et al. 2006), and in the pharmacokinetics package `NONMEM` (2006).

The "first order" methods may yield too crude an approximation to the true $E(\boldsymbol{Y}_i \,|\, \boldsymbol{X}_i)$ and $\mathrm{Cov}(\boldsymbol{Y}_i \,|\, \boldsymbol{X}_i)$, resulting in inconsistent inferences on $\boldsymbol{\beta}$ and G. The more "refined" "first order conditional" approximation takes $\boldsymbol{b}_i^*$ in (8) to be the mode $\widehat{\boldsymbol{b}}_i$ of the posterior density $f_i(\boldsymbol{b}_i \,|\, \boldsymbol{y}_i, \boldsymbol{x}_i;\, \boldsymbol{\gamma}, G)$ implied by (5), (6), and takes the distribution of $\boldsymbol{Y}_i$ given $\boldsymbol{X}_i$ to be approximately normal with

$$E(\boldsymbol{Y}_i \,|\, \boldsymbol{X}_i) \approx \boldsymbol{m}_i(\boldsymbol{X}_i, \boldsymbol{\beta}, \widehat{\boldsymbol{b}}_i) - Z_i(\boldsymbol{X}_i, \boldsymbol{\beta}, \widehat{\boldsymbol{b}}_i)\widehat{\boldsymbol{b}}_i,$$
$$\mathrm{Cov}(\boldsymbol{Y}_i \,|\, \boldsymbol{X}_i) \approx Z_i(\boldsymbol{X}_i, \boldsymbol{\beta}, \widehat{\boldsymbol{b}}_i)\, G\, Z_i'(\boldsymbol{X}_i, \boldsymbol{\beta}, \widehat{\boldsymbol{b}}_i) + V_i(\boldsymbol{X}_i, \boldsymbol{\beta}, \widehat{\boldsymbol{b}}_i, \boldsymbol{\alpha}). \quad (10)$$

Approaches based on (10) iterate between update of the $\widehat{\boldsymbol{b}}_i$ holding the current estimates of $(\boldsymbol{\gamma}, G)$ fixed and maximization in $(\boldsymbol{\gamma}, G)$ of the approximate loglikelihood implied by (10) for fixed $\widehat{\boldsymbol{b}}_i$ and are available in the SAS macro `nlinmix`, `NONMEM`, and the `R` package `nlme` (R Development Core Team 2009).

Another tactic, relevant only when the n_i are sufficiently large to permit individual-specific fitting of the stage 1 model is to use the resulting $\widehat{\boldsymbol{\theta}}_i$ as "data" to fit the stage 2 model; see Davidian and Giltinan (1995, Sect. 5.3) and Davidian (2009). It is also possible to place (5), (6) within a Bayesian framework, adding at third, "hyperprior" stage to the hierarchy with an assumed prior density for $(\boldsymbol{\gamma}, G)$. As shown by Wakefield et al. (1994) and Davidian and Giltinan (1995, Chap. 8), Bayesian inference may be implemented via ▶Markov chain Monte Carlo (MCMC) and carried out using software such as `WinBUGS` (Lunn et al. 2000).

Of necessity, this brief review covers only the basic formulation of the model and selected implementation strategies and software. Alternative strategies, model extensions, and further details are given in the aforementioned references and in the vast literature on this topic; see Davidian (2009) for a bibliography.

About the Author

Dr. Marie Davidian is William Neal Reynolds Professor of Statistics and Director of the Center for Quantitative Sciences in Biomedicine at North Carolina State University (NCSU), and Adjunct Professor of Biostatistics and Bioinformatics at Duke University. She is Fellow, American

Statistical Association (1998), Fellow, Institute of Mathematical Statistics (2006), and Fellow, American Association for the Advancement of Science (2006). Dr. Davidian was awarded the American Statistical Association Award for Outstanding Statistical Application (1993), and the Janet L. Norwood Award for Outstanding Achievement by a Woman in the Statistical Sciences, University of Alabama at Birmingham (2007). In 2009, she received the George W. Snedecor Award, Committee of Presidents of Statistical Societies "for her fundamental contributions to the theory and methodology of longitudinal data, especially nonlinear mixed effects models; significant contributions to the analysis of clinical trials and observational studies; and her leadership as president of ENAR (Eastern North American Region/International Biometric Society) and as a member of the International Biometric Society council." She was Associate editor of the following journals: *Journal of the American Statistical Association* (1995–2001), *Biometrics* (1997–2000), and *Statistica Sinica* (2003–2005). She was also Coordinating Editor of *Biometrics* (2000–2002). Currently, she is Executive Editor, *Biometrics* (2006–2011). Professor Davidian has (co-)authored about 85 refereed papers and several books, including *Nonlinear Models for Repeated Measurement Data* (with Giltinan, D.M., London, Chapman & Hall, 1995), and *Applied Longitudinal Data Analysis* (with Fitzmaurice, G., Verbeke, G., Molenberghs, G., New York, Springer, 2009). She has supervised more than 20 Ph.D. students.

Technological Educational Institute of Athens, Athens, Greece

Introduction

When an experiment is performed n times, within the experimental region $X \subseteq \mathcal{R}^k$, known as design space, the outcome or response variable, Y, can be considered either as discrete variable or continuous variable. That means the set of all possible response outcomes Ψ, known as response space, can follow one of the two cases:

Case 1: Ψ is finite, i.e., $\Psi = \{0, 1, 2, \ldots, \lambda\}$ with cardinal number $\nu = \lambda + 1$. The most common case, $\nu = 2$, corresponds to binary response problems where $Y \in \Psi = \{0, 1\}$. When $n > 2$ we are referring to polytomous experiments. In some cases, like Poisson experiments, the set Ψ is countable infinite.
Case 2: Ψ has the power of the continuum, i.e., cardinality c, as Ψ can be any interval in $\mathcal{R}$.

In Case 1 and for binary problems the outcome $Y_i = 0$ or 1, $i = 1, 2, \ldots, n$ is linked with the covariate $x \in X$ and the parameter vector θ, from the parameter space $\Theta \subseteq \mathcal{R}^p$, through a probability model T as

$$p(x) = p(Y_i = 1|x) = T(x; \theta) = 1 - P(Y_i = 0|x) \quad (1)$$

Example 1 In bioassay the typical situation is to consider logit, probit, or exponential models as T, i.e.,

$$T_L(x, \theta) = \log\{p(x)(1 - p(x))\},$$
$$T_P(x, \theta) = \Phi^{-1}\{p(x)\},\ T_E(x, \theta) = \exp(-\theta x)$$

respectively, with "log," "exp," and "Φ" having their trivial meaning.

McCullagh and Nelder (1989) discussed extensively such cases and ▶generalized linear models.

Now, the latter (Case 2) situation is faced with the general regression model: A real-valued, continuous, twice differentiable function, from $X \times \Theta$, is considered to define the (assumed correct) deterministic portion $f(x, \theta)$. The error is applied as a stochastic portion additively in the form

$$Y_i = f(x_i, \theta) + e_i, \quad i = 1, 2, \ldots, n, \quad \theta \in \Theta \subseteq \mathcal{R}^p, \quad x \in X \subseteq \mathcal{R}^k. \tag{2}$$

Example 2 Typical, one variable nonlinear problems, let $x = u$, which might provide response curves with no significant difference between them, for particular values of the parameters, are

MODEL	NAME
$f_G(u, \vartheta) = \vartheta_0 \exp\{\vartheta_1 e^{\vartheta_2 u}\}$	Gompertz model
$f_J(u, \vartheta) = \vartheta_0 + \vartheta_1\{\exp(\vartheta_2 u^{\vartheta_3})\}$	Janoscheck model
$f_L(u, \vartheta) = \vartheta_0 / \{1 + \vartheta_1 \exp(\vartheta_2 u)\}$	Logistic model
$f_B(u, \vartheta) = \{\vartheta_0 + \vartheta_1 \exp(\vartheta_2 u)\}^3$	Bertalanffy model
$f_T(u, \vartheta) = \vartheta_0 + \vartheta_1 \tanh(\vartheta_2(u + \vartheta_3))$	Tanh model
$f_3(u, \vartheta) = \frac{1}{2}\vartheta_0\left\{1 + \frac{2}{\pi}\arctan(\vartheta_1(u - \vartheta_2))\right\}$	3 - Tanh model
$f_4(u, \vartheta) = \vartheta_0 + \frac{2}{\pi}\vartheta_1 \arctan(\vartheta_2(u - \vartheta_3))$	4 - Tanh model

When a real function f exists such that $f(x_i, \theta) = g(x_i)^T\theta$, then the problem is reduced to the linear regression problem. The nonlinear optimal design can be defined through two different problems:

Problem 1: The underlying model describing the physical phenomenon is nonlinear, as in (1), (2). The target then is either to fit (with ▶Least Squares) the model or to estimate $\theta \in \Theta$ as well as possible.

Problem 2: A nonlinear function, known as general nonlinear aspect, of the unknown parameter θ, $\varphi(\theta)$ say, is asked to be estimated as well as possible, even when the underlying model is assumed linear.

Robust estimation of a general nonlinear aspect $\varphi(\theta)$, as in Problem 2 above based on one-step-M-estimators with a bounded asymptotic bias was discussed by Kitsos and Muller (1995).

In both problems, interest is focused on the assumption about the errors. In this article it is assumed that e_i are iid from the normal distribution $N(0, \sigma^2)$.

In principle, $\sigma^2 = \sigma^2(x; \theta)$ in nonlinear situation and $\sigma^2 = \sigma^2(x)$ in linear.

The target is to discuss for the nonlinear design problem:

- When a design is optimal, i.e., possible optimality criteria that can be imposed, see Ford et al. (1989) as well as Pukelseim (1993), among others, for such approach.
- How we can fit the nonlinear model, see the early work of Bard (1974) and Seber and Wild (1989) for such approach.

On the Existence of the Least Square Estimators

After collection of the data the question arises as to whether it is possible to get estimates in all problems, that is those of binary response and regression.

For the model (2), we introduce the quantity

$$S_n(\theta) = \sum (y_i - f(u_i, \theta))^2 = \|y - f(u, \theta)\|_2 \tag{3}$$

where $\|.\|_2$ is the 1_2-norm. An estimate $\hat{\theta}$ will be called the *least squares estimate* (LSE) if

$$S_n(\hat{\theta}) = \min\{S_n(\theta);\ \theta \in \Theta\}. \tag{4}$$

Jennrich (1969), in his pioneering work, imposing some assumptions, proved that the model (2) has an LSE, $\hat{\theta}$, as a measurable function $\Psi \to \Theta$, where Ψ is the space of values of $Y's$. Under the usual normality assumption for the errors, it is known that this LSE coincides with the maximum likelihood estimators (MLE).

For the binary response problem the likelihood function L can be evaluated as

$$L \propto \Pi\{T(u_i, \theta)\}^{y_i}\{1 - T(u_i, \theta)\}^{1-y_i} \tag{5}$$

and maximum likelihood estimators can be obtained. Roughly speaking that occurs when the intersection of the sets of values taken by the explanatory variables corresponding to 1s and to 0s is not the null set. This happens to be a necessary and sufficient condition for the logit and probit models.

Now, having ensured that the likelihood equation can provide MLE and denoting by ℓ the log-likelihood we define the matrix

$$S(\hat{\theta}, \xi_n, y) = -\left(\frac{\partial^2 \ell}{\partial\theta_i \partial\theta_j}\right) \tag{6}$$

where ξ_n is the design measure on n observations. The matrix

$$S(\hat{\theta}, \xi_n, y) = -\left(\frac{\partial^2 \ell}{\partial\theta_i \partial\theta_j} \quad \Big| \theta = \hat{\theta}\right) \tag{7}$$

will be called the "sample information matrix."

Example 3 Maximum likelihood estimates for the logistic can be obtained through the "normal equations":

$$\sum T_i = \sum y_i \text{ and } \sum u_i T_i = \sum y_i u_i$$

with $T_i = T(u_i; \theta)$ as in T_L model, Example 1 above.

The problem in nonlinear model fit is the construction of confidence intervals, as first Beale (1960) discussed, see also Seber and Wild (1989).

Linearization of the Model

The idea of the (design) matrix X being known is essential in dealing with linear models. In nonlinear models we can not define a matrix X in the same fashion. This can be done only approximately through the partial derivatives of θ, with θ taking its "true" value, θ_t. We define the nxp matrix

$$X = (x_{ij}) = \left.\frac{\partial f(u_i, \theta)}{\partial \theta_j}\right|_{\theta=\theta_t}. \tag{8}$$

Then the matrix $X = X(\theta)$ is formed as a function of θ. Function $f(u, \theta)$ can be linearized through a Taylor series expansion in the neighborhood of θ_t (the *true* parameter) as

$$f(u, \theta) = f(u, \theta_t) + \sum(\theta_j - \theta_{tj})(\partial f(u, \theta))/(\partial \theta_j)\big|_{\theta=\theta_t}. \tag{9}$$

Following the pattern of ▶linear regression models in the nonlinear regression case (See ▶Nonlinear Regression), an approximation to the covariance matrix, of the estimates of the parameters, can be defined as

$$C \cong [X^T(\theta_t)X(\theta_t)]^{-1}\sigma^2. \tag{10}$$

Moreover, for all nonlinear problems a useful approximation to the covariance matrix is

$$C^{-1} \cong nM(\theta_t, \varepsilon). \tag{11}$$

With $M(.,.)$ being the "average per observation information matrix."

The index t declares that the parameter takes its *true* value, which of course is asked to be estimated! Here is exactly the difficulty in nonlinear problems. For this one could seek minimum bias experiments. But the linearization of the model, not only creates problems in confidence intervals (as we have now "banana shape" intervals), but as well as on fitting the model, depending on the curvature of the model.

The linearization idea can be applied to the logit model in the following example.

Example 4 Given that $[1 + \exp(-\theta_1(u - \theta_2))]^{-1} \cong 1/2 + 1/6\,\theta_1(u - \theta_2)$, when $|\theta_1(u - \theta_2)| \leq 3$, then the normal equations of Example 3 are approximately

$$n/2 + (\theta_1/6)\sum(u_i - \theta_2) = \sum y_i$$
$$(1/2)\sum u_i + (\theta_1/6)\sum u_i(u_i - \theta_2) = \sum u_i y_i.$$

Optimality Criteria

For both models (1) and (2) we shall denote by $\eta = E(Y)$. Then it is

$$\eta = E(Y) = \begin{cases} g(x, \theta) & \text{models (2.2)} \\ T(x, \theta) & \text{models (2.1).} \end{cases} \tag{12}$$

Let $\nabla\eta$ denote the vector of partial derivatives of η with respect to $\theta \in \Theta \subseteq \mathcal{R}^p$. Then for the exponential family of models Fisher's information matrix is defined to be

$$I(\theta, x) = \sigma^{-2}(\nabla\eta)(\nabla\eta)^T. \tag{13}$$

The concept of the average-per-observation information matrix plays an important role to the nonlinear problems scenario for the definition of the optimality criteria, as well as for the fit of the model (when defining the appropriate approximate confidence intervals). It is defined for ξ, the design measure, Pukelsheim (1993) to be

$$M(\theta, \xi) = \begin{cases} n^{-1}\Sigma I(\theta, x_i), & \text{discrete case} \\ \int_X I(\theta, x)\xi(dx), & \text{continuous case.} \end{cases} \tag{14}$$

On the basis of the experiment the average-per-observation information matrix $M = M(\theta, \xi)$ is obtained which depends, in principle, on θ.

As the nonlinear experimental design problem suffers "on θ dependence", i.e., $M = M(\theta, \xi)$, there is not a unique theoretical framework for every model (1) or (2).

Example 5 For the logit or probit model the $D(\theta)$-optimal design concentrated at two points, i.e., $\xi_1 = \xi_2 = 1/2$ and the optimal design points are

$$x_1 = (x_0 - \theta_1)/\theta_2, \quad x_2 = (-x_0 - \theta_1)/\theta_2.$$

The D-optimal points corresponds to $x_0 = 1.54$ for the logistic and $x_0 = 1.14$ for the probit. If the design space $X = [\alpha, \beta] \subseteq \mathcal{R}$ is symmetric about $-\theta_1/\theta_2$ and $(\pm x_0 - \theta_1)/\theta_2 \notin X$ then $x_1 = \alpha, x_2 = \beta$.

Example 6 In chemical kinetics different models have been developed to describe a chemical process. To develop the sequential design the initial local optimum design is needed, for the particular model. Therefore, Kitsos (1995) provides all the appropriate support points. For the family of generalized linear models the support points have been provided by Sitter and Torsney (1995).

Nonlinear Regression

Andrej Pázman
Professor, Faculty of Mathematics, Physics and Informatics, Comenius University, Bratislava, Slovakia

An important task of statistics is to find the relationship that exists between different variables. In *regression problems* typically one random variable Y, often called the *response variable*, is of particular interest. The other dependent variables $x_1, \ldots, x_k$, also called *explanatory variables or regressors*, are usually non-random and are principally used to predict or explain the behavior of Y. More exactly, the aim is to find the dependence of the mean $E_x(Y)$ on the vector $x = (x_1, \ldots, x_k)^T$ in a form

$$E_x(Y) = \eta(x, \theta),$$

where $\eta(.,.)$ is a "sufficiently smooth" known function, and $\theta = (\theta_1, \ldots, \theta_p)^T$ is the vector of *parameters*, which are to be estimated from the observed data. The remaining part of Y, $\varepsilon_x = Y - \eta(x, \theta)$, is the error variable, it cannot be observed directly, and does not depend on θ, neither stochastically. When $\eta(.,.)$ is linear on θ, the regression is called *linear*, if not, the *regression is nonlinear*. The data related to N observations are given by the *design of the experiment* $\left(x^{(1)}, \ldots, x^{(N)}\right)$, where each $x^{(i)} = \left(x_1^{(i)}, \ldots, x_k^{(i)}\right)^T$ is a choice of the values of the regressors, and by the vector of observations of the response variable, $y = (y_1, \ldots, y_N)^T$. The corresponding model of the experiment can be then written in a vector form

$$y = \eta(\theta) + \varepsilon, \tag{1}$$

where $\eta(\theta) = \left(\eta\left(x^{(1)}, \theta\right), \ldots, \eta\left(x^{(N)}, \theta\right)\right)^T$ and $\varepsilon = (\varepsilon_1, \ldots, \varepsilon_N)^T$. The possible values of θ are restricted by the assumption $\theta \in \Theta$ where Θ is the *parameter space*. We have $E(\varepsilon) = 0$ and assume $Var(\varepsilon) = \sigma^2 I$, where σ^2 is the unknown variance of Y. A more general set-up with $Var(\varepsilon) = \sigma^2 W$, with W known and not depending on θ, can be reduced to (1) by a linear transformation of y, hence implicitly we are considering it as well.

Typically many models in physics and chemistry and models for engineering problems are nonlinear regression models with parameters having a physical meaning. The form of the function $\eta(.,.)$ is then prescribed by a physical law, but ►nonlinear models are used also in cases when the model is aimed just for data fitting, and the nonlinear modeling requires the estimation of a smaller number of parameters than the fit of the data by a linear regression (cf. Ratkowsky 1983). One advantage of the nonlinear regression with least squares estimation is that a broad range of relationships can be fitted. One disadvantage is that the detection of ►outliers is much more difficult than in linear models. Sophisticated examples of nonlinear regression are obtained when $\eta(x, \theta)$ as a function of x is a solution of some differential equations, for example in compartmental models describing the exchange of some products in a chemical reaction, or the circulation of substances between different parts of a human body (cf. Seber and Wild 1989).

Estimation of θ. Typically one uses in a regression model the least squares estimator (LSE): $\hat{\theta} = \arg\min_{\theta\in\Theta} \|y - \eta(\theta)\|^2$. In linear models, with $\eta(\theta) = F\theta$, the computation is direct, namely $\hat{\theta} = \left(F^T F\right)^{-1} F^T y$, while in nonlinear models iterative methods are required. Different numerical methods of minimization are available, but the most used is the Gauss–Newton method (cf. Seber and Wild 1989), in which the improvement at the nth step is given by $\theta^{(n+1)} = \theta^{(n)} + \lambda^{(n)} v^{(n)}$ with $v^{(n)} = \left[M\left(\theta^{(n)}\right)\right]^{-1} F^T\left(\theta^{(n)}\right)\left(y - \eta\left(\theta^{(n)}\right)\right)$, where $M(\theta) = F^T(\theta) F(\theta)$, $F(\theta) = \frac{\partial \eta(\theta)}{\partial \theta^T}$, and with some $\lambda^{(n)} \in (0,1]$. Numerical problems can arise here as only local minima are computed, and a clever choice of the starting $\theta^{(1)}$ is necessary. Problems with an eventual ill-conditioned $M\left(\theta^{(n)}\right)$ are usually solved by a regularization called the Levenberg–Marquardt method.

Statistical inference based on the ▶asymptotic normality of $\hat{\theta}$. Under the assumption that i) Θ is compact, ii) $\eta\left(x^{(i)}, \theta\right)$ and its first and second order derivatives with respect to θ are continuous, iii) their values do not vary "too quickly" for an increasing $i \in \{1, 2, \ldots\}$, and iv) $\lim_{N\to\infty} \frac{1}{N} \lim \left\|\eta(\theta) - \eta\left(\bar{\theta}\right)\right\|^2 = 0$ implies $\theta = \bar{\theta}$, we find that the estimators $\hat{\theta}$ and $s^2 = \frac{1}{N-p}\left\|y - \eta\left(\hat{\theta}\right)\right\|^2$ converge with $N \to \infty$ strongly to $\bar{\theta}$, the true value of θ, and to σ^2 respectively (strong consistency). Moreover, if $\bar{\theta}$ is in the interior of Θ, and if $M^*\left(\bar{\theta}\right) = \lim_{N\to\infty} \frac{1}{N} F^T\left(\bar{\theta}\right) F\left(\bar{\theta}\right)$ is nonsingular, then $\sqrt{N}\left[\hat{\theta} - \bar{\theta}\right]$ converges in distribution to a random vector distributed normally with zero mean and variance $\sigma^2\left[M^*\left(\bar{\theta}\right)\right]^{-1}$. All this makes the nonlinear model asymptotically very similar to a linear model with normal errors, hence all standard methods of inference known from linear models are at hand (approximately, for large N): the estimator $\hat{\theta}$ is asymptotically unbiased, with $Var\left(\hat{\theta}\right) \doteq s^2\left[M\left(\hat{\theta}\right)\right]^{-1}$, and the approximate confidence ellipsoid for θ is

$$\left\{\theta \in \Theta : \left[\theta - \hat{\theta}\right]^T M\left(\hat{\theta}\right)\left[\theta - \hat{\theta}\right] < p s^2 \mathcal{F}_{p,N-p}\right\},$$

where $\mathcal{F}_{p,N-p}$ is a quantile of the F-distribution, etc. This is usually exploited in statistical packages for least squares estimation. Methods of *optimal design of experiments* (see ▶Optimum Experimental Design) also make much use of this similarity to a linear model. Higher order asymptotic results are at hand as well (cf. Gallant 1987), for example, in obtaining a ▶bias correction.

Inference problems for small-sample properties of $\hat{\theta}$. For a not too large N and under normal errors a better confidence region for θ than the confidence ellipsoid is the likelihood region

$$\left\{\theta \in \Theta : \|y - \eta(\theta)\|^2 - \left\|y - \eta\left(\hat{\theta}\right)\right\|^2 < p s^2 \mathcal{F}_{p,N-p}\right\}$$

(cf. Bates and Watts 1988 for examples), which is related to the asymptotic properties of the likelihood ratio test. Attempts to make further small sample corrections of these regions lead to the introduction of the *intrinsic and parameter measures of nonlinearity* (cf. Bates and Watts 1988), which are in fact geometric measures of curvatures either of the *expectation surface* of the model

$$\{\eta(\theta) : \theta \in \Theta\}$$

in the Euclidean geometry of the sample space, or of the parameter space in the Riemannian geometry, induced by the metric tensor given by $M(\theta)$ (the *Fisher information matrix for* $\sigma = 1$). Models with a large intrinsic measure of nonlinearity tend to give false or unstable LSE $\hat{\theta}$, while models with a large parameter measure of nonlinearity tend to give $\hat{\theta}$ having a large bias and, in general, a distribution of LSE which is far from a normal distribution. Explicit formulae for these measures are

$$\max_{v\in\mathbb{R}^p, v\neq 0} \sigma \frac{\left\|Z(\theta)\left[\sum_{i,j} v_i \frac{\partial^2 \eta(\theta)}{\partial\theta_i \partial\theta_j} v_i\right]\right\|}{v^T M(\theta) v}$$

with either $Z(\theta) = P(\theta) = F(\theta)\left[M(\theta)\right]^{-1} F^T(\theta)$ for the parametric nonlinearity, or $Z(\theta) = I - P(\theta)$ for the intrinsic nonlinearity. Computation is simplified using the QR decomposition of $F(\theta)$ (cf. Bates and Watts [1988] and Ratkowsky [1983] for an algorithm). In general, the geometry is very useful for understanding the nonlinear regression model (cf. Bates and Watts 1988; Pázman 1993), and extending the result to more general situations such as regression models with parameter constraints (Pázman 2002).

The influence of the parameter nonlinearity of the model is fully reflected by the probability distribution of $\hat{\theta}$, given $\bar{\theta}$ (cf. Pázman 1993), namely

$$\frac{\det\left[Q\left(\hat{\theta}, \bar{\theta}\right)\right]}{(2\pi)^{p/2}\sigma^p \det^{1/2}\left[M\left(\hat{\theta}\right)\right]} \exp\left\{-\frac{1}{2\sigma^2}\left\|P\left(\hat{\theta}\right)\left[\eta\left(\hat{\theta}\right) - \eta\left(\bar{\theta}\right)\right]\right\|^2\right\},$$

with $Q_{ij}\left(\hat{\theta}, \bar{\theta}\right) = M_{ij}\left(\hat{\theta}\right) + \left[\eta\left(\hat{\theta}\right) - \eta\left(\bar{\theta}\right)\right]^T\left[I - P\left(\hat{\theta}\right)\right] \frac{\partial^2 \eta(\theta)}{\partial\theta_i \partial\theta_j}$, which is correct under the assumption that the errors are normal, and that the intrinsic curvature is not so large to cause failure of the LSE.

Notice that some basic features of nonlinear regression models can be extended to more general models where the notion of the error variable is not used because the variance of Y depends on its mean. The best known are the ▶generalized linear models, where another parameter instead of $E_x(Y)$ is a linear function of the unknown parameters and the maximum likelihood estimator is used instead of the LSE.

About the Author

Professor Andrej Pázman is a leading personality in Slovak mathematical statistics. He is a member of the Learned Society of the Slovak Academy of Sciences, a member of Royal Statistical Society in UK, of the Institute of Mathematical Statistics in the USA, of the International Statistical Institute, and an honorary member of the Union of Slovak Mathematicians and Physicists. He was awarded the Gold Medal of the Faculty of Mathematics and Physics of Comenius University, both, the Silver and the Gold Juraj Hronec Medals of the Slovak Academy of Sciences for Contributions to Mathematical Sciences, and also the Premium of the Slovak Literary Found, and the WU Best Paper Award of the city of Vienna. Nonlinear Time Series Analysis

Howell Tong
Professor Emeritus, Saw Swee Hock Professor of Statistics
London School of Economics and Political Science, London, UK
National University of Singapore, Singapore, Singapore

Introduction

A function f from R^p to R is said to be *linear* if for vectors $x, y \in R^p$ and any real scalar α, $f(\alpha x + y) = \alpha f(x) + f(y)$. Any function f that is not linear is said to be *nonlinear*.

In the analysis of stationary time series, the spectral density function, if it exists, is nonlinear under the above definition. However, for reasons to be made clear later, a statistical analysis that is based on it or its equivalents is ordinarily considered a linear analysis. Often, a time series is observed at discrete time intervals. For a discrete-time stationary time series $\{X_t : t = \ldots, -1, 0, 1, \ldots\}$ with finite variance, $corr(X_t, X_{t+s})$ is a function of s only, say $\rho(s)$, and is called the auto-correlatoin function. The spectral density function is the Fourier transform of $\rho(s)$ if $\sum_{s=-\infty}^{\infty} |\rho(s)| < \infty$. Now, Yule (1927) introduced the celebrated autoregressive model in time series. Typically the model takes the form

$$X_t = \alpha_0 + \alpha_1 X_{t-1} + \cdots + \alpha_p X_{t-p} + \varepsilon_t, \qquad (1)$$

where the α's are parameters and $\{\varepsilon_t\}$ is a sequence of independent and identically distributed random variables with zero mean and finite variance, or a white noise for short. It is commonly denoted as an $AR(p)$ model. Clearly X_t is a linear function of $X_{t-1}, \ldots, X_{t-p}, \varepsilon_t$. Under the assumption of normality, the distribution of the time series is completely specified by its constant mean, constant variance and $\rho(s)$'s. Perhaps for the close connection with the analysis of linear models (of which the autoregressive model is one), an analysis based on the autocorrelation function or equivalently the spectral density function is loosely referred to as a linear analysis of the time series. By the same token, an analysis based on higher order moments or their Fourier transforms is loosely called a nonlinear analysis. Broadly speaking, tools based on the Fourier transforms of moments constitute what is called the frequency-domain approach, while those based on the moments constitute the time-domain approach, which often includes building a time series model of the form (1) or its generalizations.

Similar discussion as the above can be extended to cover $\{X(t) : t \in R\}$

Can We Do Without Nonlinearity?

A general answer is in the negative simply because the dynamical laws governing Nature or human activities are seldom linear. In the real world, we can see the footprints of nonlinearity everywhere we look. Below are a few examples.

(a) *Phase Transition*
The melting of ice of a glacier will alter fundamentally the amount of water flowing in a river near the glacier. Phase transition (from solid to liquid in the above example) is an important signature of nonlinearity. Animals behave differently (e.g., hunting effort) during time of short food supply versus time of abundant food supply.

(b) *Saturation*
In economics, diminishing return is a well-known phenomenon: doubling your effort does not necessarily double your reward.

(c) *Synchronization*
The celebrated Dutch scientist, Christiaan Huygens, observed that clocks placed on the same piece of soft timber were synchronized! Biological systems can also exhibit synchoronization. It has been noted that girls sharing the same dormitory have a higher chance of synchronizing their menstruation. Even female keepers of baboons have been known to have a similar experience.

(d) *Chaos*
When we toss a coin to randomize our choice, we are exploiting nonlinearity, for the dynamical system underlying the tossing is a set of (typically three) nonlinear ordinary differential equations, the solution of which is generally very sensitive to the initial spinning unless we "cheat." The system is said to generate chaos in a technical sense. When statisticians generate pseudo-random numbers, they are also generating chaos. One of the most commonly used pseudo-random generator is the linear congruential generator, which is a piecewise linear (i.e., nonlinear) function that does precisely this. It might surprise you that you are actually using nonlinear devices almost daily because encrypting passwords is closely related to pseudo-random number generation.

In the following sections, we focus on the time-domain approach because at the current state of development, this approach tends to admit simpler interpretations in practical applications.

What Is a Nonlinear Time Series Model?

A short answer is that it is not a linear time series model. This raises the need to define a linear model. A fairly commonly adopted definition is as follows. A stationary time series model is called a linear time series model if it is equivalent (for example in the mean-square sense) to

$$X_t = \sum_{s=-\infty}^{\infty} \beta_s \varepsilon_{t-s}, \tag{2}$$

where $\{\varepsilon_t\}$ is a white noise and the summation is assumed to exist in some sense. An alternative definition due to Hannan (1973) is one that requires that the minimizer of $E|X_t - h(X_{t-1}, X_{t-2}, \ldots)|^2$ with respect to h over the space of all measurable functions is the linear function. Here the mean square is assumed to exist.

Are Linear Time Series Models Fit for Purpose?

Examples abound of the inability of linear time series models to capture essential features of the underlying dynamics.

Yule (1927) introduced the autoregressive model to model the annual sunspot numbers with a view to capturing the observed 11-year sunspot cycle but noted the inadequacy of his model. He noted the asymmetry of the cycle and attempted to model it with an $AR(4)$ model only to discover that it gave statistically a worse fit than a simpler AR(2) model.

Moran (1953) fitted an $AR(2)$ model to the annual lynx data corresponding to the MacKenzie River region in Canada, with a view to capturing the observed 10-year cycle. He was quick to point out that the fitted residuals were heteroscedastic.

Whittle (1954) analyzed a seiche record from Wellington Bay in New Zealand. He noted that, besides the fundamental frequency of oscillations and a frequency due to the reflection of an island at the bay, there were sub-harmonics bearing an interesting arithmetic relation with the above frequencies. Now, sub-harmonics are one of the signatures of nonlinear oscillations, long known to the physicists and engineers.

Examples of Nonlinear Time Series Models

First, we describe parametric models. Due to space limitation, we describe the two most commonly used models. For other models, we refer to Tong (1990). We shall describe (i) the threshold model and (ii) the (generalized) autoregressive conditional heteroscedasticity model, or in short the TAR model and the (G)ARCH model respectively. The former was introduced by Tong in 1977 and developed systematically in Tong and Lim (1980) and Tong

(1983, 1990), and the latter by Engles (1982), later generalized by Bollerslev (1986).

There are several different but equivalent ways to express a TAR model. Here is a simple form. Let $\{Z_t\}$ denote an indicator time series that takes positive integer values, say $\{1, 2, \ldots, K\}$. Let $\{\eta_t\}$ denote a white noise with zero mean and unit variance, $\alpha_0^{(j)}, \alpha_i^{(j)}, \beta^{(j)}$ be real constants for $j = 1, 2, \ldots, K$. Then a time series $\{X_t : t = 0, \pm 1, \pm 2, \ldots\}$ is said to follow a *threshold autoregressive model* if it satisfies, when $Z_t = j$, $j = 1, \ldots, K$,

$$X_t = \alpha_0^{(j)} + \sum_{i=1}^{p} \alpha_i^{(j)} X_{t-i} + \beta^{(j)} \eta_t. \tag{3}$$

For the case in which $Z_t = j$ if and only if $X_{t-d} \in R_j$ for some positive integer d and for some partition of R, i.e., $R = \bigcup_{i=1}^{K} R_i$ say, the TAR model is called a *self-exciting threshold autoregressive model*, or SETAR model for short. In this case, given $X_{t-s}, s > 0$, the conditional mean of X_t is piecewise linear, and the conditional variance of X_t piecewise constant.

For the case in which $Z_t = j$ if and only if $Y_{t-d} \in R_j$ for some covariate time series $\{Y_t\}$, some positive integer d and some partition of R, i.e. $R = \cup_{i=1}^{K} R_i$ say, then we have a TAR model driven by (or excited by) $\{Y_t\}$. Note that the covariate time series $\{Y_t\}$, and thus the indicator time series $\{Z_t\}$, can be observable or hidden. If the indicator time series, whether observable or hidden, forms a Markov chain (see ▶Markov Chains), then we call $\{X_t\}$ a Markov-chain driven TAR; this model was first introduced by Tong (Tong and Lim 1980, p. 285; Tong 1982; p. 62). In the econometric literature, the sub-class with a hidden Markov chain is commonly called a *Markov switching model*.

The TAR model, especially the SETAR model, has many practical applications in diverse areas/disciplines, including earth sciences, ecology, economics, engineering, environmental science, finance, hydraulics, medical science, water resources and many others.

The nonlinear parametric model that is mostly and widely used in econometrics and finance is the (G)ARCH model. The ARCH model is given by

$$X_t = \eta_t \sigma_t, \tag{4}$$

where $\{\eta_t\}$ is as defined previously but sometimes assumed to be Gaussian, and $\sigma_t^2 = \alpha_0 + \sum_{i=1}^{p} \alpha_i X_{t-i}^2$, $\alpha_0 > 0, \alpha_i \geq 0, i = 1, \ldots, p$. Note that the ARCH model differs from the SETAR model in its σ_t being a continuous function instead of a piecewise constant function as in the latter. The GARCH model generalizes σ_t^2 to $\sigma_t^2 = \alpha_0 + \sum_{i=1}^{p} \alpha_i X_{t-i}^2 + \sum_{i=1}^{q} \beta_i \sigma_{t-i}^2$, where the β_is are usually also assumed to be non-negative, although the non-negativity assumption may be relaxed; see Cryer and Chan (2008, Chap. 12).

One of the limitations of any parametric modelling approach is the subjectivity of selecting a family of possible parametric models. We can sometimes mitigate the situation if a certain parametric family is suggested by subject matter considerations. In the absence of the above, mitigation is weaker even if we are assured that the family is dense in some sufficiently large space of models. It is then tempting to allow the data to suggest the form of F where we are contemplating a model of say

$$X_t = F(X_{t-1}, \ldots, X_{t-p}, \varepsilon_t), \tag{5}$$

F being unknown. This is one of the strengths of the nonparametric modelling approach, which is a vast and rapidly expanding area. A word of caution is the so-called curse of dimensionality, meaning that when $p > 3$ the estimated F is unlikely to be reliable unless we have a huge sample size. One way to ameliorate the situation is to replace $X_{t-1}, \ldots, X_{t-p}$ by $\xi_{t-1}, \ldots, \xi_{t-q}$ with q much smaller than p, e.g. $q = 1$ or 2. The ξ's are typically suitably chosen but unknown linear functions of X's, sometimes called indices. This is called the semi-parametric modelling approach, which is also a rapidly expanding field. For comprehensive accounts of the above developments, see, e.g., Fan and Yao (2005) and Gao (2007). Another way is to impose some simplifying structure on (5) such as zero interaction as in Chen and Tsay (1993), who gave

$$X_t = F(X_{t-1}) + \cdots + F(X_{t-p}) + \varepsilon_t. \tag{6}$$

About the Author

Past President of the Hong Kong Statistical Society (1983–1984), Professor Howell Tong, was Founding Chair of Statistics, Chinese University of Hong Kong (1982–1985), Chair of Statistics at the University of Kent at Canterbury, (1986–1998), and Chair of Statistics at the London School of Economics (1999–September 2009). Between 1997 and 2004, he was also Chair of Statistics and Pro-Vice Chancellor and Founding Dean of the Graduate School, University of Hong Kong. He was elected a Fellow of the Institute of Mathematical Statistics (1993) and is a Foreign member of the Norwegian Academy of Science and Letters (2000). Among many awards, Professor Tong won the State Natural Science Prize, China, in 2000 and received the Guy medal in Silver (Royal Statistical Society, UK) in 2007, in recognition of his many important contributions to time series analysis.

Nonparametric Density Estimation

Ricardo Cao
Professor
Universidade da Coruña, A Coruña, Spain

The density function of a continuous random variable, X, is the derivative of its distribution function $f(x) = dF(x)/dx$, and can be represented as

$$f(x) = \lim_{h\to 0} \frac{F(x+h) - F(x-h)}{2h} = \lim_{h\to 0} \frac{1}{2h} \int_{x-h}^{x+h} dF(u) = \lim_{h\to 0} \frac{E\left[1\left(|X-x| \le h\right)\right]}{2h}. \quad (1)$$

Nonparametric density estimation can be performed via estimation of the last term in (1). Given a random sample $(X_1, \ldots, X_n)$, this ratio can be estimated replacing the unknown expectation by its empirical analog, suggesting the naive estimator

$$\hat{f}(x) = \frac{1}{2h} \int_{x-h}^{x+h} dF_n(u) = \frac{1}{n} \sum_{i=1}^{n} \frac{1\left(|X_i - x| \le h\right)}{2h}. \quad (2)$$

This estimator was proposed first by Rosenblatt (1956). It is the relative frequency, per unit of length, of the observations within the interval $[x-h, x+h]$. For a fixed sample size, it does not make sense to define the estimator by the limit, when $h \to 0$, of the previous quantity. In fact this limit is zero since, for h small enough, the numerator in (2) equals zero. However, as $n \to \infty$, one may think of the value h (often called smoothing parameter or bandwidth) as a sequence, h_n, tending to zero.

The naive estimator in (2) can be also written as

$$\hat{f}(x) = \frac{1}{nh} \sum_{i=1}^{n} K\left(\frac{x - X_i}{h}\right), \quad (3)$$

with $K(u) = 1\left(|u| \le 1\right)/2$. The function K is called the kernel. In fact the kernel used in (2) is the uniform density function. Other kernel functions used in practice are the triangular density, the Gaussian or the Epanechnikov kernel. Kernel functions are generally required to hold that $\int_{\mathbb{R}} uK(u)\,du = 0$, $\int_{\mathbb{R}} K(u)\,du = 1$ and $\int_{\mathbb{R}} u^2 K(u)\,du < \infty$. This kernel estimator was proposed by Rosenblatt (1956) and Parzen (1962).

Using the structure of (3) as a sum of iid random variables, its bias and variance can be easily computed. In general, the estimator is biased and, for small values of h, the bias and the variance are approximately $E\left(\hat{f}(x) - f(x)\right) \simeq \frac{h^2}{2} f''(x) \int t^2 K(t)\,dt$ and $Var\left(\hat{f}(x)\right) \simeq \frac{f(x)}{nh} \int K(t)^2\,dt$. Thus, it seems reasonable to require, for consistency, that $h \to 0$ and $nh \to \infty$ as $n \to \infty$. The behavior of these two terms is opposite: while the bias increases with the smoothing parameter, the variance decreases as the bandwidth gets large. Hence, it is intuitive that the choice of the smoothing parameter is very important in practice, since it regulates the balance between the bias (systematic error) and the variance (stochastic error) of the estimator. Undoubtedly any practical choice for h has to be a compromise between both terms.

A well-known nonparametric density estimator is the histogram. It is a predecessor of the kernel estimator in (3). The nearest neighbours method consists in using the distance between a given point and its kth nearest sample value to compute a nonparametric density estimator. This method adapts the "amount of smoothing" to the point where the density is estimated. The spline method can be

thought as estimating some piecewise polynomial approximation of the underlying density. The method of orthogonal series can be viewed as estimating some approximation of the true density function, namely, a finite linear combination of terms of a basis of the functional space where the density is assumed to belong. The list of books devoted to nonparametric density estimation includes Silverman (1986), Devroye and Györfi (1985) and Wand and Jones (1995).

An important issue in nonparametric density estimation is the problem of selection of the smoothing parameter. The most popular error measures for bandwidth selection are the integrated squared error criterion $ISE = \int \left(\hat{f}_h(x) - f(x)\right)^2 dx$, and the mean integrated squared error, given by $MISE = E(ISE)$.

Under regularity conditions on f, an asymptotic representation for $MISE$ can be obtained: $MISE(h) = AMISE(h) + o(h^4) + O(n^{-1})$, where

$$AMISE(h) = \frac{h^4}{4} \int f''(x)^2 dx \int t^2 K(t) dt + \frac{1}{nh} \int K(t)^2 dt.$$

Minimization of $AMISE(h)$ in h gives the asymptotically optimal bandwidth

$$h_{AMISE} = \left(\frac{\int K(t)^2 dt}{n \int f''(x)^2 dx \int t^2 K(t) dt} \right)^{1/5}.$$

However, the value h_{AMISE} is not observable since it depends on the curvature of the underlying density. In practice, most of the bandwidth selectors are defined as minimizers of the error measures *ISE*, *MISE* or *AMISE*.

Among the dozens of proposals for bandwidth selection in this context we mention the least squares cross validation, proposed by Rudemo (1982) and Bowman (1984), the biased cross-validation method, (see Scott and Terrell 1987), the plug-in methods (see Sheather and Jones 1991), the smoothed cross-validation, proposed by Hall et al. (1992), and the bootstrap bandwidth selectors (see Cao 1993).

Nonparametric density estimation methods can be also extended to multivariate settings (see the book by Scott 1992). Similar ideas have been successfully used for the estimation of other curves as the regression function, the distribution function, the conditional distribution and density and the hazard rate, among many other.

[2]Professor
K.U. Leuven, Leuven, Belgium

Meanings of the Word "Nonparametric"

The terminology *nonparametric* was introduced by Wolfowitz in 1942 to encompass a group of statistical techniques for situations where one does not specify the

functional form of the distributions of the random variables that one is dealing with. In its earlier form, this comprised mainly methods working with rank statistics, and was also coined "*distribution free*" methods. Most often these methods are applied to perform hypothesis tests. For an example of such a hypothesis test, see the entry by Jurečková (same volume). Other examples include the ►Kolmogorov–Smirnov test, the runs test, ►sign test, ►Wilcoxon-signed-rank test, the Mann–Whitney U-test (see ►Wilcoxon–Mann–Whitney Test) and ►Fisher Exact Test. For an overview and details, see Hollander and Wolfe (1999). This type of nonparametric method has the advantage that it can be applied to ordinal and rank data; the data may be frequencies or counts, and do not have to be measured on a continuous scale.

In more recent times, nonparametric statistics has evolved to settings where a model for the data is not specified a priori, but is in some form determined from the data. This will be explained in more detail below. In such nonparametric models there are parameters to estimate, even many parameters in most cases, hence the name-giving might be somewhat misleading. Main examples of such estimation methods are kernel estimators, splines and wavelet estimators. These techniques are also known as "*smoothing methods*."

Nonparametric Regression Estimation

In parametric regression models we relate the mean of a response variable Y, conditional on covariates X via a parametric function. For example, in ►linear regression models, we assume that $Y = \beta_0 + X\beta_1 + \varepsilon$, where β_0 and β_1 are unknown parameter vectors and ε is often assumed to be a normal random variable with zero mean and an unknown variance σ^2. In nonparametric regression we do not specify the functional form for the conditional mean of Y and write the model as $Y = f(X) + \varepsilon$, where X may be random, or take fixed values. The terminology smoothing arises from the commonly made assumption for most methods (however, see the "►Wavelet Estimation" section below) that the unspecified function f is smooth.

Nonparametric estimation starts with choosing a basis which defines a space of functions. The function f is then approximated within this space by $\tilde{f}(x) = \sum_{j=1}^{J} \beta_j \psi_j(x)$. The basis functions may also depend on further parameters, specifying for example the location. These may be estimated or specified in advance. Fourier series are one example. Nonparametric estimation of f then proceeds with estimating the unknown parameters. Spaces of functions are often infinite dimensional, hence the number of basis functions to be used, J in the above sum, is a tuning parameter. The more basis functions taken, the better the approximation will be, in general. However, estimating more parameters comes at a cost of increased variance and increased computational effort.

The smoothing methods are used in a similar way for the estimation of density functions. While histograms give rough approximations, the nonparametric density estimators are smooth curves. Likewise, splines, wavelets or kernels may be used. For the latter method, see for example Wand and Jones (1995).

Spline Estimation

The choice of the basis characterizes the estimated function. Often taken choices are *spline* functions. A jth degree polynomial spline is a curve that consists of piecewise jth degree polynomial parts that are continuously joined together at *knots*. The smoothness of the resulting function depends on whether also the higher derivatives of the spline are continuous. When each observation x_i, $i = 1, \ldots, n$ is taken as a knot, this results in a *smoothing spline* (see ►Smoothing Splines). When a set of knots $\kappa_1, \ldots, \kappa_K$ is chosen, with $K < n$, the sample size, the function is a *regression spline*. In cases that $K < n$, estimation of the unknown spline coefficients β_j can be done via ►least squares in case of (approximate) normal errors ε. For smoothing splines, one introduces a penalty term that is related to the derivatives of f. Also for regression splines, penalties on the coefficients may be stated, to reduce the influence of the choice of the knots. This results in *penalized regression splines*. An expanded description of spline regression methods can be found in the entry by Opsomer and Breidt (same volume). Some main references are Eubank (1988), Wahba (1990), Green and Silverman (1994) and Ruppert et al. (2003).

Wavelet Estimation

Thanks to a fast decomposition algorithm (Mallat 1989), wavelet bases have gained considerable success as a representation for data to be smoothed. Wavelet basis functions are short waveforms located at a specific point in time or space and with a specific scale. This locality in time and frequency provides a tool for a multiscale and sparse representation of data. Especially piecewise smooth data, with isolated singularities, are typical objects for which wavelets are well suited. Indeed, the singularities can be captured by a relatively limited number of local wavelet basis functions, with appropriate scales, while the smooth intervals in between the singularities produce many but small contributions in a wavelet decomposition.

While other methods may have difficulties in catching singularities, in a wavelet decomposition they pose no bottleneck, provided that at the position of a singularity the wavelet representation is locally more refined than in

between the singularities. The location of the singularities is done automatically, even in the presence of noise, by the fact that the coefficients corresponding to the basis functions at those positions are large, as they carry the contributions that constitute the singularity. Singularities are thus well captured by selecting the largest coefficients, rather than a predetermined subset. Putting the smallest coefficients to zero therefore removes most of the noise without affecting the noise-free data too much. The usage of this thresholding or any sophisticated variant, which is always a nonlinear processing, is always the main reason for using a wavelet decomposition and it is always linked to the intermittend nature of the data, i.e., the presence of isolated singularities in otherwise smooth behavior. The use of thresholds relies on the sparsity property of a wavelet resprepresentation. The multiscale property, on the other hand, is mostly used for additional across-scale processing, for instance to remove false positives after thresholding (for smoother intervals between singularities) or to correct for false negatives by looking across scales (for sharper reconstruction of singularities). Also scale dependent processing is necessary in the case of correlated noise on the observations (Donoho and Johnstone 1995).

The selection of appropriate thresholds has been a major domain of research. Limiting or even reducing to zero the number of false positives is the objective of an important class of thresholds, including the universal threshold (Donoho and Johnstone 1994) or False Discovery Rate thresholds (Benjamini and Hochberg 1995). Another class of thresholds focusses on the expected, integrated squared loss, i.e., risk, of the result. Stein's Unbiased Risk Estimator and modifications (such as cross-validation) provide practical methods for finding minimum risk thresholds. A third, and wide class of threshold assessment methods is based on Bayesian – mostly empirical Bayes – models, such as EBayesthresh (Johnstone and Silverman 2004, 2005). The prior model for noise-free coefficients reflects the idea of sparsity, mostly through a zero-inflated or otherwise mixture model with heavy tails (where heavy here includes everything heavier than the normal distribution).

Kernel and Local Polynomial Estimation

Kernel estimation of a regression function starts from the idea that the function is locally well approximated by a low order polynomial curve. The Nadaraya–Watson estimator locally approximates the curve f at value x by a constant regression function. Observations X_i close to x get a large weight, and observations further away receive less or zero weight. The kernel function K determines the weighting and is assumed to be a density function. The estimator takes the following form, $\widehat{f}_h(x) = \sum_{i=1}^n K_h(x - X_i) Y_i \big/ \sum_{i=1}^n K_h(x - X_i)$, where h is called the bandwidth. This is a tuning parameter, small values of h imply that only close neighbors get a large weight, this might result in a rather wiggly fit. Large values of h will result in much smoother fitted curves. Several studies have focussed on appropriate bandwidth choices, for example via cross-validation or plug-in methods based on asymptotic properties of the estimator. Variants on this estimator are the Priestley–Chao and Gasser–Müller estimator. Local polynomial estimators are similar in spirit. Instead of taking a local constant approximation of the function f around x, a local polynomial approximation is obtained. More information on kernel regression methods can be found in the entry by Opsomer and Breidt (same volume). For more details, see Fan and Gijbels (1996).

Nonparametric Estimation Based on Incomplete Observations

Abdurahim Abdushukurov
Professor and Head, Vice Rector
National University of Uzbekistan, Tashkent, Uzbekistan

Incomplete observations occur in survival analysis, especially in clinical trials and engineering when we partially observe death in biological organisms or failure in mechanical systems.

From statistical literature one can learn that incomplete observations arise in two ways: by censoring and truncation. Note that truncation is sampling an incomplete population, while censoring occurs when we are able to sample the complete population, but the individual values of observations below and/or above given values are not specified. Therefore, censoring should not be confused with truncation. In this article we deal only with right-censoring model, which is easily described from the methodological point of view.

Let $X_1, X_2, \ldots$ be a sequence of independent and identically distributed random variables (i.i.d.r.v.-s) (the lifetimes) with common distribution function (d.f.) F. Let X_j be censored on the right by Y_j, so that observations available for us at the nth stage consist of the sample $S^{(n)} = \{(Z_j, \delta_j), 1 \le j \le n\}$, where $Z_j = min(X_j, Y_j)$ and $\delta_j = I(X_j \le Y_j)$ with $I(A)$ meaning the indicator of the event A. Suppose that Y_j are again i.i.d.r.v.-s, the so-called censoring times with common d.f. G, independent of lifetimes X_j.

The main problem consists of nonparametrically estimating F with nuisance G based on censored sample $S^{(n)}$, where r.v.-s of interest X_j-s are observed only when δ_j=1. Kaplan and Meier (1958) were the first to suggest the product-limit (PL) estimator F_n^{PL} defined as

$$F_n^{PL}(t) = \begin{cases} 1 - \prod_{\{j: Z_{(j)} \le t\}} \left[1 - \frac{\delta_{(j)}}{n-j+1}\right], & t \le Z_{(n)}, \\ 1, & t > Z_{(n)}, \delta_{(n)} = 1, \\ \textit{undefined}, & t > Z_{(n)}, \delta_{(n)} = 0, \end{cases}$$

where $Z_{(1)} \le \ldots \le Z_{(n)}$ are the ▶order statistics of Z_j and $\delta_{(1)}, \ldots, \delta_{(n)}$ are the corresponding δ_j. In statistical literature there are different versions of this estimator. However, those do not coincide if the largest Z_j is a censoring time. Gill (1980) redefined the F_n^{PL} setting $F_n^{PL}(t) = F_n^{PL}(Z_{(n)})$ when $t > Z_{(n)}$. Further, we use Gill's modification of the PL-estimator. At present, there is an enormous literature on properties of the PL-estimator (see, e.g., Abdushukurov [2009], Akritas [2000], Csörgő [1996], Gill [1980, 1994]) and most of the work on estimating incomplete observations are concentrated on the PL-estimator. However, F_n^{PL} is not a unique estimator of F.

The second, closely related with the F_n^{PL}, nonparametrical estimator of F is the exponential hazard estimator

$$F_n^E(t) = 1 - exp\left\{-\sum_{j=1}^{n} \frac{\delta_{(j)} I(Z_{(j)} \le t)}{n-j+1}\right\}, -\infty < t < \infty.$$

F_n^E plays an important role in investigating the limiting properties of the estimator F_n^{PL}.

Abdushukurov (1998, 1999) proposed another estimator for F of power type:

$$F_n(t) = 1 - (1 - H_n(t))^{R_n(t)} = \begin{cases} 0, & t < Z_{(1)}, \\ 1 - \left(\frac{n-j}{n}\right)^{R_n(t)}, & Z_{(j)} \le t < Z_{(j+1)}, 1 \le j \le n-1, \\ 1, & t \ge Z_{(n)}, \end{cases}$$

where

$$H_n(t) = \frac{1}{n} \sum_{j=1}^{n} I(Z_j \le t)$$

is an empirical estimator of d.f. $H(t) = P(Z_j \le t) = 1 - (1 - F(t))(1 - G(t))$ and

$$R_n(t) = \frac{-log\left(1 - F_n^E(t)\right)}{\sum_{j=1}^{n} \frac{I(Z_{(j)} \le t)}{n-j+1}}$$

As we see, estimator F_n is defined on whole line. Let

$$a_n(t) = \sum_{j=1}^{n} \frac{I(Z_{(j)} \le t)}{(n-j)(n-j+1)}.$$

Note that $\sup\{a_n(t), t \le T\} \le [n(1 - H_n(T))]^{-1} = \mathbb{O}\left(\frac{1}{n}\right)$ with probability 1, where $T < Z_{(n)}$.

The following inequalities show that all three estimators are closely related (Abdushukurov (1998, 2009)): *For $t < Z_{(n)}$ with probability 1*

$(I)\ 0 < -log\left(1 - F_n^{PL}(t)\right) + log\left(1 - F_n^E(t)\right) < a_n(t);$
$(II)\ 0 \le F_n^{PL}(t) - F_n^E(t) < \frac{1}{2} a_n(t);$
$(III) < -log(1 - F_n(t)) + log\left(1 - F_n^E(t)\right) < a_n(t);$
$(IV)\ \left|-log\left(1 - F_n^{PL}(t)\right) + log(1 - F_n(t))\right| < a_n(t);$
$(V)\ \left|F_n^{PL}(t) - F_n(t)\right| < a_n(t);$
$(VI)\ \left|F_n^E(t) - F_n(t)\right| < a_n(t).$

Thus, one can expect the stochastic equivalences of these estimators in the sense of their weak convergence to the same Gaussian process (Abdushukurov 1998). Let d.f.-s F and G be continuous and $T < T_H = \inf\{t : H(t) = 1\}$. Then one can define the sequence of Wiener processes $\{\mathbb{W}_n(x), 0 \le x < \infty\}_{n=1}^{\infty}$ such that when $n \to \infty$

$$\sup_{t \le T} \left| n^{\frac{1}{2}} \left(F_n^*(t) - F(t)\right) - (1 - F(t))\mathbb{W}_n(d(t))\right| \xrightarrow{P} 0,$$

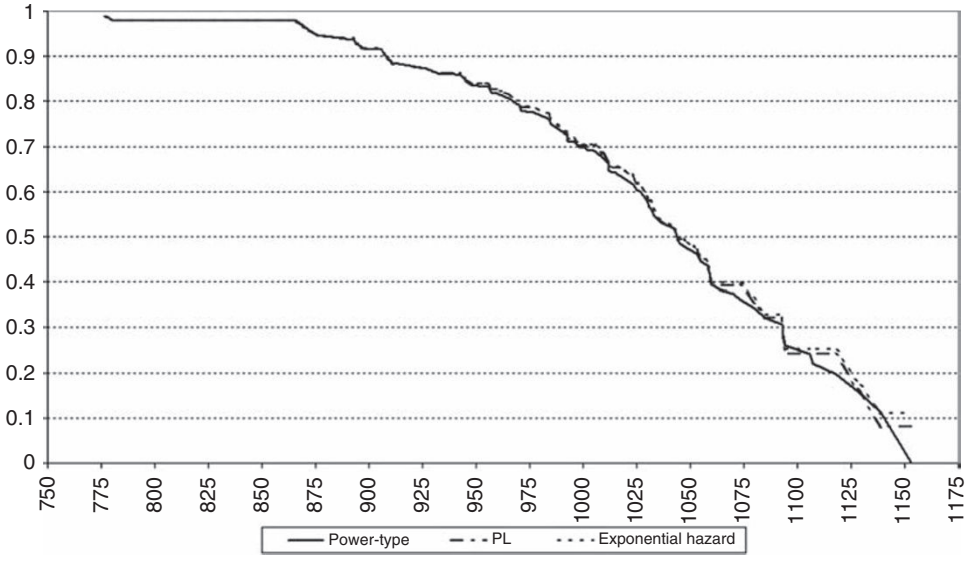
where F_n^* stands for one of estimators F_n^{PL}, F_n^E, F_n and

$$d(t) = \int_{-\infty}^{t} [(1-F)^2(1-G)]^{-1} dF.$$

Here we state the weak convergence result in the form of weak approximation by the sequence of appropriate copies of the limiting Gaussian process. This implies that $n^{\frac{1}{2}}\left(F_n^* - F\right)$ converges weakly in the Skorochod's space $\mathbb{D}(-\infty, T]$ to the mean-zero Gaussian process with covariance function $\sigma(t;s) = (1 - F(t))(1 - F(s))d(min(t,s))$, $t, s \le T$. Thus, we see that all three estimators are equivalent in the asymptotic sense. But as we see in Abdushukurov (1998, 2009) the estimator F_n has some peculiarities and even better properties than F_n^{PL} and F_n^E do for all $n \ge 1$. Let us consider the following exponential representation for any right continuous d.f. (Gill 1980):

$$1 - F(t) = exp\left\{-\int_{-\infty}^{t} \frac{dF(u)}{1 - F(u-)}\right\} \prod_{s \le t} (1 - \Delta\Lambda(s)),$$

where $\Delta\Lambda(s) = (F(s) - F(s-))/(1 - F(s-))$ and $F(s-) = lim_{u \uparrow s} F(u)$. Then we see that F_n^{PL} is a natural estimator for $\prod_{s \le t}(1 - \Delta\Lambda(s))$, that is a discrete d.f. On the other side, F_n^E and F_n are natural estimators for continuous d.f. $F(t) = 1 - exp\left\{-\int_{-\infty}^{t}(1-F)^{-1}dF\right\} = 1 - (1 - H(t))^{R(t)}$, where $R(t) = -log(1 - F(t))/[-log(1 - H(t))]$ - relative risk function. Obviously, the relative risk estimators $F_n(t)$ and $G_n(t) =$



Nonparametric Estimation Based on Incomplete Observations. Fig. 1 Plots of estimators $1 - F_n$, $1 - F_n^{PL}$ and $1 - F_n^E$ of survival function $1 - F$ using Channing House data

$1-(1-H_n(t))^{1-R_n(t)}$ of $F(t)$ and $G(t)$ satisfy the empirical analogy of equality $(1-F(t))(1-G(t)) = 1-H(t)$, $-\infty < t < \infty$, that is $(1-F_n(t))(1-G_n(t)) = 1-H_n(t)$, $-\infty < t < \infty$. But for exponential hazard estimators $F_n^E(t)$ and $G_n^E(t) = 1 - exp\left\{-\sum_{j=1}^{n}(1-\delta_{(j)})I(Z_{(j)} \le t)/(n-j+1)\right\}$ of $F(t)$ and $G(t)$, we have

$$\left(1-F_n^E(t)\right)\left(1-G_n^E(t)\right) = exp\left\{-\sum_{j=1}^{n}\frac{I(Z_{(j)} \le t)}{n-j+1}\right\} \ne 1-H_n(t).$$

Moreover, for $t \ge Z_{(n)}, F_n(t) = 1$, but $F_n^E(t) < 1$. Therefore, F_n is a correct estimator of continuous d.f. F than F_n^{PL} and F_n^E. In the Fig. 1, we demonstrate plots of estimators $1-F_n$, $1-F_n^{PL}$, and $1-F_n^E$ of survival function $1-F$ using well-known Channing House data of size n=97.

Brief History of Nonparametric Statistics

A statistical procedure is called nonparametric if it is valid under less restrictive assumptions than those required by the classical, or parametric, procedures. The difference between parametric and nonparametric statistics is best illustrated in the context of estimating the population distribution function on the basis of a ►simple random sample from the population. The parametric approach assumes that the population distribution belongs to a particular parametric family of distributions, such as the normal, and estimates the distribution by estimating the unknown parameters. In contrast, the nonparametric approach uses the empirical distribution function. In fact, parametric statistics makes frequent use of a particular branch of nonparametric statistics which consists of diagnostic procedures, including graphics and goodness-of-fit tests, aimed at confirming the approximate validity of the employed assumption.

In its earliest form, the field of nonparametric procedures comprised mainly of *distribution free* test procedures for relatively simple designs. Examples are the ►sign test and signed-rank test for the one-sample location problem and paired data design, the Mann–Whitney–Wilcoxon (MWW) rank sum test for the two-sample problem (see ►Wilcoxon–Mann–Whitney Test), the Kruskal–Wallis test for k-sample problem, the Friedman test for a complete randomized block design, the Wald–Wolfowitz runs test for randomness, Kendall's and Spearman's rank correlation coefficients and tests for independence, and Fisher's exact test for association in 2×2 contingency tables. The popularity of these tests lies in the fact that

they can be applied to ordinal and rank data, have good robustness properties, while some of them, notably the MWW rank sum test and the Kruskal–Wallis test, retain high efficiency relative to corresponding classical procedures under normality. Moreover, the idea of inverting tests to obtain estimators gave rise to the popular Hodges–Lehmann (see ▶Hodges-Lehmann Estimators) and Theil–Sen estimators. Detailed accounts of this branch of nonparametric statistics can be found in Hajek and Sidak (1967), Lehmann (1975), Hettmansperger (1984), Hollander and Wolfe (1999), and Gibbons and Chakraborti (2010).

Following this early activity on distribution-free test procedures and corresponding estimators, nonparametric statistics expanded to include *nonparametric regression* which focuses on estimating an unknown regression function using *smoothing methods* such as kernel, splines and wavelets. See Eubank (1988), Hart (1997), Wahba (1990), Green and Silverman (1994), Fan and Gijbels (1996), Härdle et al. (1998). This remains a very active research area with emphasis now placed in overcoming complications caused by the presence of a large number of covariates. This has led to a number of innovative *semi-parametric* models, variable selection methods, and dimension reduction methods; see Hastie and Tibshirani (1990), Cook and Li (2002), Fan and Li (2001), Fan and Lv (2008) for some representative contributions in these areas.

Another recent direction of nonparametric statistics deals with efforts to extend the Kruskal–Wallis test to more complicated factorial designs. The main obstacle towards a successful extension lies in the fact that in such designs the observations are not iid under the more specialized null hypotheses, such as the hypotheses of no main effects and no interaction, which are of interest in such designs. Two main developments have been the aligned rank tests (cf. Puri and Sen 1971; Mansouri 1999), and distance based methods (cf. Hettmansperger and McKean 1998); see also the recent approach of Gao and Alvo (2005). These procedures, however, are not based on the overall ranks of the observations, and have been developed for homoscedastic models. A different approach to constructing rank tests for factorial designs is the so-called rank transform (RT) method. It consists of substituting ranks instead of the observations in the classical F statistics. This approach was motivated by the fact that asymptotically equivalent versions of the MWW rank sum test or the Kruskal–Wallis test statistics can be obtained by substituting ranks instead of the observations in the pooled variance two sample t test statistic or the one-way ANOVA F statistic, respectively. The validity of the RT in these cases sparked an interest in exploring it further. While the RT procedure was shown to be valid in certain balanced additive designs, Akritas (1990) showed that in general it fails. The main argument for establishing this failure lies in the fact that the hypotheses of no main effects and no interaction are not invariant under monotone transformations and thus cannot be tested by statistics (such as rank statistics) which are invariant under such transformations. In addition, the aforementioned paper pointed to the fact that, in general, ranks are heteroscedastic even if the original observations are homoscedastic. These observations motivated Akritas and Arnold (1994) to introduce nonparametric versions of the linear models for factorial designs and to construct Wald-type weighted rank test statistics for testing nonparametric versions of the common hypotheses of no main effects and no interactions. This approach has been extended to analysis of covariance designs and to high dimensional settings. The rest of this article gives an account of these developments.

Factorial Designs

Consider for simplicity the crossed two-factor design, and let Y_{ijk} denote the kth observation in cell formed from the ith level of the row factor and the jth level of the column factor. The fully nonparametric version of this design specifies only that

$$Y_{ijk} \sim F_{ij}, \tag{1}$$

where F_{ij} is some cumulative distribution function. The model (1) allows discrete and continuous quantitative response variables, and does not assume homoscedasticity. Akritas and Arnold (1994) defined nonparametric hypotheses in terms of the following decomposition

$$F_{ij}(y) = M(y) + A_i(y) + B_j(y) + \Gamma_{ij}(y),\ i = 1, \ldots, a,\ j = 1, \ldots, b, \tag{2}$$

where $M = \overline{F}_{\cdot\cdot}$, $A_i = \overline{F}_{i\cdot} - M$ and $B_j = \overline{F}_{\cdot j} - M$ are the nonparametric main effects for the row and column factors, and $\Gamma_{ij} = F_{ij} - A_i - B_j$ are nonparametric versions of the interaction effects. The nonparametric hypotheses of no main row or column effects, and no interaction specify that the corresponding nonparametric effects are zero: $H_0(A) : A_i = 0$, for all i, $H_0(B) : B_j = 0$, for all j, and $H_0(\Gamma) : \Gamma_{ij} = 0$, for all i and j. Letting $\mu_{ij} = \int y dF_{ij}(y)$ denote the mean of Y_{ijk} it easily follows that

$$\alpha_i = \int y dA_i(y),\ \beta_j = \int y dB_j(y),\ \text{and}\ \gamma_{ij} = \int y d\Gamma_{ij}(y)$$

constitute the unique decomposition of μ_{ij} as $\mu_{ij} = \mu + \alpha_i + \beta_j + \gamma_{ij}$ so that $\sum \alpha_i = \sum \beta_j = \sum_i \gamma_{ij} = \sum_j \gamma_{ij} = 0$. It follows that the nonparametric versions of the null hypotheses are

stronger than their parametric counterparts (i.e., imply but are not implied by them). It turns out that these stronger versions of the common hypotheses are invariant under monotone transformations and thus can be tested by rank statistics.

For designs with independent observations, Akritas et al. (1997) (abbreviated by AAB97 from now on) constructed a class of Wald-type rank test statistics which adjusts for the heteroscedasticity in the ranks (Akritas 1990). A scored rank version of this statistic was developed in Brunner and Puri (2002). A Box-type approximation which enhances the small sample type I error performance was also proposed in AAB97; for more details on the Box-type approximation procedure see Brunner et al. (1997). The Wald-type statistics in AAB97 were further extended to repeated measures designs in Akritas and Brunner (1997a), to censored independent data in Akritas and Brunner (1997b), and to censored dependent data in O'Gorman and Akritas (2001).

Akritas and Arnold (1994) introduced the nonparametric hypotheses only in the context of the full (or saturated) model, using equal weights in the constraints that define the effects. This practice was followed in the aforementioned subsequent literature on nonparametric hypotheses. An extension of the class of nonparametric hypotheses to non-saturated designs, and to arbitrary weights in defining the effects, is given in Akritas, Stavropoulos and Caroni (2009). Wald statistics, however, are not convenient for non-saturated designs. This is mainly because estimators of the effects, on which Wald statistics are based, are not always available in closed form. This is particularly prevalent with non-orthogonal designs. Moreover, software development, and consequently statistical practice, has favored heavily the likelihood ratio F tests over the Wald-type tests. Akritas (1990) constructed the first rank version of a weighted F statistic but remarked that, because F statistics do not have a closed form expression, a general asymptotic theory of such statistics would require different asymptotic methods. By adopting Wald-type statistics instead of weighted F statistics, AAB97 circumvented this problem, but the methodology is confined to saturated designs. Akritas et al. (2009) derive an asymptotic theory that covers rank versions of weighted F statistics for any hypothesis in any factorial design. In particular, the theory and the statistics apply not only for testing that some effects are zero against general alternatives (adjusted, or type III in SAS, sum of squares) but also for the so-called sequential analysis (type I sum of squares in SAS). Thus, the aforementioned paper extends the application of the robust rank methodology to the entire spectrum of ANOVA applications for factorial designs.

Analysis of Covariance Designs

Consider for simplicity the one-way analysis of covariance design. Thus, we observe (Y_{ij}, X_{ij}), for $i = 1, \ldots, k$ and $j = 1, \ldots, n_i$, where i enumerates the factor or treatment levels, the covariates X_{ij} are either observed constants or observed random variables, and Y_{ij} is the observed response random variable. The fully nonparametric model of Akritas et al. (2000) assumes only that, given $X_{ij} = x$,

$$Y_{ij} \sim F_{ix},$$

where F_{ix} is a distribution function that depends only on i, x in an unspecified way. The decomposition

$$F_{ix}(y) = M(y) + A_i(y) + D_x(y) + C_{ix}(y),$$

which is extends the decomposition (2) to allowing for a continuous index, helps define effects in this nonparametric context.

Akritas et al. (2000) and Akritas and Van Keilegon (2001) develop test procedures for the hypothesis for no covariate adjusted factor effects $H_0(A) : A_i(y) = 0$, for all i and all y. This procedure was extended to censored data in Du et al. (2003), while Tsangari and Akritas (2003) extended the procedure to ANCOVA designs with up to three covariates. Tsangari and Akritas (2004) considered ANCOVA designs with dependent data.

Testing for the covariate effect, as well as the factor-covariate interaction effect, falls in the category of testing against *high-dimensional alternatives*; see Wang and Akritas (2006). The techniques for doing so are similar to those for analyzing high-dimensional factorial designs, which is discussed next.

High Dimensional Factorial Designs

Advances in data gathering technologies have produced massive data sets giving rise to designs with a large number of factor levels and few replications. Such high dimensional designs have motivated the development of high-dimensional analysis of variance or HANOVA – a term introduced by Fan and Lin (1998). Having a large number of factor levels but possibly few replications calls for a very different asymptotic theory than that involved in the developments outlined in Section ►"Factorial Designs". For example, the asymptotic theory of the F statistic is now obtained by studying the difference $F - 1$.

Dealing with heteroscedasticity when there are only a few replications per cell is particularly challenging. Several approaches for doing so are explored in Akritas and Papadatos (2004), where an up to date literature review is presented. Rank statistics for testing the nonparametric hypotheses (2), and their versions for higher-way layouts, with independent data are presented in Wang and

Akritas (2004, 2009). Bathke and Harrar (2008) considered a version of the nonparametric hypotheses for multivariate designs and constructed corresponding rank test procedures.

The conceptual connection between a factorial design having factors have many levels and ANCOVA designs (the covariate can be thought of as a factor with many levels) was exploited in Wang and Akritas (2006), and in Wang et al. (2008) to develop tests for the covariate effect.

When the factor with many levels is time, the data, known as curves or functional data, are often dependent. The aforementioned procedures have been extended to testing for various aspects of functional dependent data in Wang and Akritas (2010), and in Wang et al. (2010).

Finally, nonparametric models for mixed and random effects designs are presented in Gaugler (2008). The main contribution of the nonparametric modeling in mixed effects designs is the relaxation of the so-called *symmetry assumption*. This is the assumption of independence of the main random effect and the interaction effect. It is shown that violations of this assumption (which likely occur in the majority of real data applications) has devastating effects on the significance level of the traditional *F* test.

About the Author

Michael Akritas is Professor of Statistics, Penn State University. He has served as Director of the Statistical Consulting Center for Astronomy (1994–2000), as Guest Editor for *Sociological Methods and Research*, and for *Statistics & Probability Letters*, and as Associate Editor for *Statistics & Probability Letters*, *Journal of Environmental Statistics*, *Journal of Nonparametric Statistics*, and the *Journal of the American Statistical Association*. He is currently Co-Editor of the *Journal of Nonparametric Statistics*. He is Elected Fellow of the American Statistical Association (2001), and Fellow of the Institute of Mathematical Statistics (2001).

Nonparametric Predictive Inference

Frank P. A. Coolen
Professor
Durham University, Durham, UK

Overview

Nonparametric predictive inference (NPI) is a statistical method based on Hill's assumption $A_{(n)}$ Hill (1968), which gives a direct conditional probability for a future observable random quantity, conditional on observed values of related random quantities (Augustin and Coolen 2004; Coolen 2006). Suppose that $X_1, \ldots, X_n, X_{n+1}$ are continuous and exchangeable random quantities. Let the ordered observed values of $X_1, \ldots, X_n$ be denoted by $x_{(1)} < x_{(2)} < \ldots < x_{(n)} < \infty$, and let $x_{(0)} = -\infty$ and $x_{(n+1)} = \infty$ for ease of notation. For a future observation X_{n+1}, based on n observations, $A_{(n)}$ (Hill 1968) is

$$P(X_{n+1} \in (x_{(j-1)}, x_{(j)})) = \frac{1}{n+1} \quad \text{for } j = 1, 2, \ldots, n+1$$

$A_{(n)}$ does not assume anything else, and is a post-data assumption related to exchangeability. Hill discusses $A_{(n)}$ in detail. Inferences based on $A_{(n)}$ are predictive and nonparametric, and can be considered suitable if there is hardly any knowledge about the random quantity of interest, other than the n observations, or if one does not want to use such information, e.g., to study effects of additional assumptions underlying other statistical methods. $A_{(n)}$ is not sufficient to derive precise probabilities for many events of interest, but it provides optimal bounds for probabilities for all events of interest involving X_{n+1}. These bounds are lower and upper probabilities in the theories of imprecise probability (Walley 1991) and interval probability (Weichselberger 2001), and as such they have strong consistency properties (Augustin and Coolen 2004). NPI is a framework of statistical theory and methods that use these $A_{(n)}$-based lower and upper probabilities, and also considers several variations of $A_{(n)}$ which are suitable for different inferences. For example, NPI has been presented for Bernoulli data, multinomial data and lifetime data with right-censored observations. NPI enables inferences for $m \geq 1$ future observations, with their interdependence explicitly taken into account, and based on sequential assumptions $A_{(n)}, \ldots, A_{(n+m-1)}$. NPI provides a solution to some explicit goals formulated for objective (Bayesian) inference, which cannot be obtained when using precise probabilities (Coolen 2006). NPI is also exactly calibrated (Lawless and Fredette 2005), which is a strong consistency property, and it never leads to results that are in conflict with inferences based on empirical probabilities.

NPI for Bernoulli random quantities (Coolen 1998) is based on a latent variable representation of Bernoulli data as real-valued outcomes of an experiment in which there is a completely unknown threshold value, such that outcomes to one side of the threshold are successes and to the other side failures. The use of $A_{(n)}$ together with lower and upper probabilities enable inference without a prior distribution on the unobservable threshold value as is needed in ▶Bayesian statistics where this threshold value is typically represented by a parameter. Suppose that there is a sequence of $n + m$ exchangeable Bernoulli trials, each with "success" and "failure" as possible outcomes, and data consisting of s successes in n trials. Let Y_1^n denote the random number of successes in trials 1 to n, then a sufficient representation of the data for NPI is $Y_1^n = s$, due to the

assumed exchangeability of all trials. Let Y_{n+1}^{n+m} denote the random number of successes in trials $n+1$ to $n+m$. Let $R_t = \{r_1, \ldots, r_t\}$, with $1 \le t \le m+1$ and $0 \le r_1 < r_2 < \ldots < r_t \le m$, and, for ease of notation, define $\binom{s+r_0}{s} = 0$. Then the NPI upper probability for the event $Y_{n+1}^{n+m} \in R_t$, given data $Y_1^n = s$, for $s \in \{0, \ldots, n\}$, is

$$\overline{P}\left(Y_{n+1}^{n+m} \in R_t \,\middle|\, Y_1^n = s\right) = \binom{n+m}{n}^{-1} \sum_{j=1}^{t} \left[\binom{s+r_j}{s} - \binom{s+r_{j-1}}{s}\right] \binom{n-s+m-r_j}{n-s}$$

The corresponding NPI lower probability is derived via the conjugacy property

$$\underline{P}\left(Y_{n+1}^{n+m} \in R_t \,\middle|\, Y_1^n = s\right) = 1 - \overline{P}\left(Y_{n+1}^{n+m} \in R_t^c \,\middle|\, Y_1^n = s\right)$$

where $R_t^c = \{0, 1, \ldots, m\} \backslash R_t$.

For multinomial data, a latent variable representation via segments of a probability wheel has been presented, together with a corresponding adaptation of $A_{(n)}$ (Coolen and Augustin 2009). For data including right-censored observations, as often occur in lifetime data analysis, NPI is based on a variation of $A_{(n)}$ which effectively uses a similar exchangeability assumption for the future lifetime of a right-censored unit at its moment of censoring (Coolen and Augustin 2004). This method provides an attractive predictive alternative to the well-known Kaplan–Meier estimate (see ▶Kaplan-Meier Estimator) for such data.

Applications

Many applications of NPI have been presented in the literature. These include solutions to problems in Statistics, Reliability and Operational Research. For example, NPI methods for multiple comparisons of groups of real-valued data are attractive for situations where such comparisons are naturally formulated in terms of comparison of future observations from the different groups (Coolen 2001). NPI provides a frequentist solution to such problems which does not depend on counterfactuals, which play a role in hypothesis testing and are often criticized by opponents of frequentist statistics. An important advantage of the use of lower and upper probabilities is that one does not need to add assumptions to data which one feels are not justified. A nice example occurs in precedence testing, where experiments to compare different groups may be terminated early in order to save costs or time (Coolen-Schrijner et al. 2009). In such cases, the NPI lower and upper probabilities are the sharpest bounds corresponding to all possible orderings of the not-fully observed data. NPI provides an attractive framework for decision support in a wide range of problems where the focus is naturally on a future observation. For example, NPI methods for replacement decisions of technical units are powerful and fully adaptive to process data (Coolen-Schrijner and Coolen 2004).

NPI has been applied for comparisons of multiple groups of proportions data (Coolen and Coolen-Schrijner 2007), where the number m of future observations per group plays an interesting role in the inferences. Effectively, if m increases the inferences tend to become more imprecise, while imprecision tends to decrease if the number of observations in the data set increases. NPI for Bernoulli data has also been implemented for system reliability, with particularly attractive algorithms for optimal redundancy allocation (Coolen-Schrijner et al. 2008; MacPhee et al. 2009). NPI for multinomial data enables inference if the number of outcome categories is not known, and explicitly distinguishes between defined and undefined categories for which no observations are available yet (Coolen 2007). Typically, if outcome categories have not occurred yet, the NPI lower probability of the next observation falling in such a category is zero, but the corresponding NPI upper probability is positive and depends on whether or not the category is explicitly defined, on the total number of categories or whether this number is unknown, and on the number of categories observed so far. Such NPI upper probabilities can be used to support cautious decisions, which are often deemed attractive in reliability and ▶risk analysis.

Challenges

Development of NPI is gathering momentum, inferential problems for which NPI solutions have recently been presented or are being developed include aspects of medical diagnosis with the use of ROC curves, robust classification, inference on competing risks, quality control and ▶acceptance sampling. Main research challenges for NPI include its generalization for multidimensional data, which is similarly challenging for NPI as for general nonparametric methods due to the lack of a unique natural ordering of the data. NPI theory and methods that enable information from covariates to be taken into account also provide interesting and challenging research opportunities. A research monograph introducing NPI theory, methods and applications is currently in development, further information is available from www.npi-statistics.com.

About the Author

Frank P.A. Coolen is Professor of Statistics at the Department of Mathematical Sciences, Durham University (UK). He served as editor of the Section on Reliability – Mathematical and Statistical Methods for the Wiley *Encyclopedia of Quantitative Risk Analysis and Assessment* (2008). He currently serves on the editorial

boards of *Journal of Statistical Planning and Inference*, *Journal of Statistical Theory and Practice*, *Journal of Risk and Reliability*, and *Quality and Reliability Engineering International*. His main research is on foundations and methods of Statistics and Reliability, in particular he has been developing Nonparametric Predictive Inference (NPI) over the last decade. Together with collaborators and students, Frank has published about 150 journal and conference papers, a majority of these on NPI or other statistical methods that use lower and upper probabilities.

Nonparametric Rank Tests

Thomas P. Hettmansperger
Professor Emeritus of Statistics
Penn State University, State College, PA, USA

There are three major reasons for considering nonparametric rank tests. They do not require a parametric distribution assumption, such as normality, for the observations in order to determine the p-value of the test (nonparametric or distribution-free property). When the observations come from a population with tails that are heavier than those of a normal population, nonparametric rank tests can be much more powerful and efficient than t and F tests. Finally, they are more robust to ►outliers and data contamination than traditional t and F tests. These three properties (nonparametric, efficient, and robust) have been well documented; see, for example, Hettmansperger and McKean (1998), Hollander and Wolfe (1999), Higgins (2004), Lehmann (2006), and Sprent and Smeeton (2007). Nonparametric methods are implemented in all standard statistical computing packages.

The most widely used nonparametric rank test is the *Mann–Whitney–Wilcoxon rank sum test* (abbreviated MWW) (This test is also commonly called Wilcoxon–Mann–Whitney test and abbreviated as WMW.) (*see* ►Wilcoxon–Mann–Whitney Test). Suppose we have two samples of independent and identically distributed observations, denoted by $X_1, \ldots, X_m$ and $Y_1, \ldots, Y_n$, from two populations represented by continuous cumulative distribution functions $F(x)$ and $G(y)$, respectively. Often, we assume that the population distributions differ only in their locations (typically the mean or median). Then $G(y) = F(y - \Delta)$ where Δ represents the difference in locations. We are interested in testing the null hypothesis $H_0 : \Delta = 0$ versus an alternative hypothesis such as $H_A : \Delta > 0$. This hypothesis indicates that the Y distribution is shifted to the right of the X distribution. The traditional test would be the one-sided two-sample t test.

Example 1 Researchers held the hypothesis that silver content (measured by the percentage of silver in a coin)

decreased from early mintings of Byzantine coins to later mintings in the mid twelfth century. Data (ordered) is contained in Hendy and Charles (1970) and consists in early minting values: 5.9, 6.2, 6.4, 6.6, 6.8, 6.9, 7.0, 7.2, 7.7 and later minting values: 5.1, 5.3, 5.5, 5.6, 5.8, 5.8, 6.2. Based on this data we wish to test $H_0 : \Delta = 0$ versus $H_A : \Delta > 0$ where Δ represents the difference in locations of the early and late mintings. Let X denote the late minting and Y denote the early minting.

The MWW statistic is computed as follows: combine the X and Y data, assign ranks to the combined data. In case of ties assign the average rank. Then the MWW statistic, denoted by W, is the sum of ranks of the Y data. When the null hypothesis is true, the expected value of W is $n(n+m+1)/2$ and we will reject $H_0 : \Delta = 0$ in favor of $H_A : \Delta > 0$ when W is observed sufficiently far above $n(n+m+1)/2$. Sufficiently far is determined by the p-value of the test: p-value $= P(W > \text{obs}W)$ where obs$W$ is the observed value of W from the data.

Example 1, continued Late minting X data has $m = 7$ observations with ranks 1, 2, 3, 4, 5.5, 5.5, 8.5 and the early minting Y data has $n = 9$ with ranks 7, 8.5, 10, 11, 12, 13, 14, 15, 16. The sum of ranks of the early data is $W = 106.5$, the expected value under the null hypothesis is 76.5, and the p-value is 0.001. This indicates that the observed value of $W = 106.5$ is far above the expected value of 76.6, and hence we reject the null hypothesis and conclude that the later minting contained significantly less silver content than the early minting.

Calculating the p-value: The most convenient method is to approximate the p-value using a normal approximation for the null sampling distribution of W. This requires the standard deviation of W under the null hypothesis and is given by $\sqrt{mn(m+n+1)/12}$. Then $[W - n(m+n+1)/2]/\sqrt{mn(m+n+1)/12}$ can be referred to a standard normal table. Accuracy of the approximation can generally be increased by using a ►continuity correction. For the example above, obs$W = 106.5$, $n(m+n+1)/2 = 76.5$, $\sqrt{mn(m+n+1)/12} = 9.45$, and the standardized value of 3.17 determines the p-value = 0.001.

There are tables of the exact distribution of W for restricted values of m and n. Finally, since, under the null hypothesis, all permutations of the combined data are equally likely, a computer can be used to approximate the p-value by sampling the permutations and assigning the first m observations in a permutation to the X sample. In this case the p-value is approximately equal to the number of sampled permutations such that W is greater than or equal to obs$W$ divided by the number of sampled permutations. Note this null permutation distribution of W does not require specification of the underlying population distributions and this determines the nonparametric property of the MWW rank test.

Since we use only the ranks of the data, outliers will have a minimal effect on the value of W. An extreme outlier will only be assigned the maximum or minimum rank of m+n or 1. This is the source of the robustness of W.

In addition to the MWW test above, there is an associated point estimate of the difference in locations Δ. It is given by the median of the mn pairwise differences $Y_j - X_i$ for $i = 1, 2, \ldots, m$ and $j = 1, 2, \ldots, n$. For the coins data the estimate of Δ is 7.5. Note that this estimate is not generally equal to the difference in sample medians. If we record the range of Δ values for which the MWW test fails to reject the null hypothesis at significance level approximately 0.05, then we have an approximate 95% confidence interval for Δ. For the example, we find a 95.6% confidence interval to be (4.5,11.0). See the references for detailed discussions of the construction of confidence intervals.

In case we wish to carry out an hypothesis test in a one sample setting, we can use the ►Wilcoxon-signed-rank test. Here we have a random sample $X_1, \ldots, X_n$ from a population with continuous distribution function $F(x)$. Let θ denote the median of the population and suppose that $F(x)$ is symmetric about θ. For testing $H_0 : \theta = 0$ versus $H_A : \theta > 0$ let S be the sum of ranks of the positive observations when ranked among the absolute values of the data. The statistic S compares the right side of the sample to the left side much the way the MWW statistic compares the Y-sample to the X-sample. Under the null hypothesis we have the mean and standard deviation of S as $n(n+1)/4$ and $\sqrt{n(n+1)(2n+1)/24}$, respectively. Using the fact that S has an approximate normal sampling distribution, the p-value of the test can be approximated by standardizing S and referring the standardized statistic to a standard normal table. The corresponding estimate of θ is the median of the pairwise averages $(X_i + X_j)/2$ for $i \le j$. Further, a nonparametric confidence interval is available; see the references for details. Traditional methods are based on the one sample t-statistic.

The MWW rank sum test can be extended to the one-way layout for testing the null hypothesis $H_0 : F_1(x) = \ldots = F_c(x)$. In this case we have samples from c populations. The test is constructed by combining all the data and ranking it. The *Kruskal–Wallis statistic* is then based on the c average ranks for the c samples. The formula is:

$$KW = \frac{12}{N(N+1)} \sum_{i=1}^{c} n_i \left[\bar{R}_i - (N+1)/2 \right]^2,$$

where N is the total sample size. Under the null hypothesis KW has an approximate chisquared distribution with $c-1$ degrees of freedom. Hence, it is easy to approximate the p-value of this test. The MWW methods can then be used for multiple comparisons and the estimation of location differences. The Kruskal-Wallis test enjoys the same nonparametric, efficiency, and robustness properties as the MWW.

In summary, nonparametric rank tests for the one, two, and c-sample designs are readily available. Relative to the traditional t and F tests they are robust and efficient. They provide a very attractive alternative to the traditional tests and are easily implemented using standard statistical software. Rank tests and estimates are available for more complex designs such as multi-way analysis of variance and regression. See the references for details.

About the Author

Professor Hettmansperger was Head of the Statistics Department (1988–1990). He is a Fellow of the American Statistical Association, Institute of Mathematical Statistics, and an elected member of the International Statistical Institute. He was the 1986 recipient of the C. I. Noll Award for Teaching in the Eberly College of Science. In 2004 he received the Noether Senior Scholar Award from the American Statistical Association for his outstanding work and contribution to nonparametric statistics.

Nonparametric Regression Based on Ranks

Jana Jurečková
Professor
Charles University in Prague, Prague, Czech Republic

Consider the linear regression model (see ►Linear Regression Models)

$$Y_i = \beta_0 + \mathbf{x}_i^\top \boldsymbol{\beta} + e_i, \quad i = 1, \ldots, N$$

where $\beta_0 \in \mathbb{R}_1$, $\boldsymbol{\beta} \in \mathbb{R}_p$ are unknown parameters and $e_1, \ldots, e_N$ are independent errors, identically distributed according to a continuous d.f. F and $\mathbf{x}_i \in \mathbb{R}_p$ are given regressors, $i = 1, \ldots, N$. We look for the rank test of the hypotheses

$$\mathbf{H}_0^{(1)} : \boldsymbol{\beta} = \mathbf{0} \text{ versus } \mathbf{K}^{(1)} : \boldsymbol{\beta} \neq \mathbf{0}, \quad \beta_0 \text{ unspecified},$$

$$\mathbf{H}_0^{(2)} : \boldsymbol{\beta}^* = (\beta_0, \boldsymbol{\beta}^\top)^\top = \mathbf{0} \text{ versus } \mathbf{K}^{(2)} : \boldsymbol{\beta}^* \neq \mathbf{0}.$$

Another situation is that $\boldsymbol{\beta}$ is partitioned as $\boldsymbol{\beta} = \begin{pmatrix} \boldsymbol{\beta}_1 \\ \boldsymbol{\beta}_2 \end{pmatrix}$, where $\boldsymbol{\beta}_1 \in \mathbb{R}_{p_1}$, $\boldsymbol{\beta}_2 \in \mathbb{R}_{p_2}$, $p_1 + p_2 = p$, and we want to test the hypothesis

$$\mathbf{H}_1 : \boldsymbol{\beta}_2 = \mathbf{0} \text{ versus } \boldsymbol{\beta}_2 \neq \mathbf{0}, \quad \beta_0, \boldsymbol{\beta}_1 \text{ unspecified}.$$

Rank Tests for $\mathbf{H}_0^{(1)}$

Let $R_{N1}, \ldots, R_{NN}$ be the ranks of $Y_1, \ldots, Y_N$ and let $a_N(1), \ldots, a_N(N)$ be the scores generated by a nondecreasing, square-integrable score function $\varphi : (0,1) \mapsto \mathbb{R}_1$ so that $a_N(i) = \varphi\left(\frac{i}{N+1}\right)$, $i = 1, \ldots, N$. The rank tests are based on the linear rank statistics

$$S_{Nj} = \sum_{i=1}^{N} (x_{ij} - \bar{x}_{Nj}) a_N(R_{Ni}), \quad \bar{x}_{Nj} = \frac{1}{N} \sum_{i=1}^{N} x_{ij}, \quad j = 1, \ldots, N$$

and their vector

$$\mathbf{S}_N = \sum_{i=1}^{N} (\mathbf{x}_i - \bar{\mathbf{x}}_N) a_N(R_{Ni}) = (S_{N1}, \ldots, S_{Np})^\top.$$

The distribution function of observation Y_i under $\mathbf{H}_0^{(1)}$ is $F(y - \beta_0)$, $i = 1, \ldots, N$. Hence, the vector of ranks $(R_{N1}, \ldots, R_{NN})$ assumes all possible permutations of $(1, 2, \ldots, N)$ with the same probability $\frac{1}{N!}$. Moreover, $\mathbf{S}_N$ depends only on $\mathbf{x}_1, \ldots, \mathbf{x}_N$, on the scores

$a_N(1),\ldots,a_N(N)$ and on the ranks. Our test for $\mathbf{H}_0^{(1)}$ is based on the quadratic form

$$\mathcal{S}_N = A_N^{-2}\left(\mathbf{S}_N^\top \mathbf{Q}_N^{-1}\mathbf{S}_N\right), \tag{1}$$

where

$$A_N^2 = \frac{1}{N-1}\sum_{i=1}^N (a_N(i)-\bar{a}_N)^2, \quad \mathbf{Q}_N = \sum_{i=1}^N (\mathbf{x}_i-\bar{\mathbf{x}}_N)(\mathbf{x}_i-\bar{\mathbf{x}}_N)^\top$$

and $\mathbf{Q}_N^{-1}$ is replaced by the generalized inverse $\mathbf{Q}_N^-$ if $\mathbf{Q}_N$ is singular. We reject $\mathbf{H}_0^{(1)}$ if $\mathcal{S}_N > k_\alpha$ where k_α is a suitable critical value. The distribution of $\mathcal{S}_N$ and hence the critical values under the hypothesis $\mathbf{H}_0^{(1)}$ do not depend on the distribution function F of the errors. For small N, the critical value can be calculated numerically, but it would become laborious with increasing N. Otherwise we must use asymptotic critical values based on the large-sample approximation of the distribution of $\mathcal{S}_N$. The large sample distribution of $\mathcal{S}_N$ under $\mathbf{H}_0^{(1)}$ is χ^2 distribution with p degrees of freedom, under some conditions on the regressors and the scores.

We reject hypothesis $\mathbf{H}_0^{(1)}$ on the significance level α (usually $\alpha = 0.01$ or 0.05) if $\mathcal{S}_N > \chi_p^2(1-\alpha)$, where $\chi_p^2(1-\alpha)$ is the $(1-\alpha)$ quantile of the χ^2 distribution with p degrees of freedom.

Rank Tests for $\mathbf{H}_0^{(2)}$

For the sake of identifiability of parameter β_0, we should assume that the basic distribution of the errors is symmetric around 0. Let $R_{N1}^+,\ldots,R_{NN}^+$ be the ranks of $|Y_1|,\ldots,|Y_N|$. Choose a score-generating function $\varphi^*(u) = \varphi\left(\frac{u+1}{2}\right) : (0,1) \mapsto [0,\infty)$ and the scores $a_N^*(1),\ldots,a_N^*(N)$ generated by φ^*. Put $x_{i0} = 1$, $i = 1,\ldots,N$, and consider the signed-rank statistics

$$\mathbf{S}_N^+ = \left(S_{N,0}^+, S_{N,1}^+,\ldots,S_{N,p}^+\right)^\top,$$

$$S_{N,j}^+ = \sum_{i=1}^N x_{ij}\ \text{sign}\ Y_i\ a_N^*\left(R_{Ni}^+\right), \quad j = 0,1,\ldots,p.$$

The test criterion for $\mathbf{H}_0^{(1)}$ will be the quadratic form

$$\mathcal{S}_N^+ = A_N^{*-2}\left(\mathbf{S}_N^{+\prime}\left(\mathbf{Q}_N^*\right)^{-1}\mathbf{S}_N^+\right)$$

where $A_N^{*2} = \frac{1}{N}\sum_{i=1}^N\left[a_N^*(i)\right]^2$, $\mathbf{Q}_N^* = \sum_{i=1}^N \mathbf{x}_i^*\mathbf{x}_i^{*\top}$, and $\mathbf{x}_i^* = (x_{i0},x_{i1},\ldots,x_{ip})^\top$.

The distribution of $\mathbf{S}_N^+$ (and hence of $\mathcal{S}_N^+$) is generated by $N!2^N$ equally probable realizations of $(\text{sign}\ Y_1,\ldots,\text{sign}\ Y_N)$ and $\left(R_{N1}^+,\ldots,R_{NN}^+\right)$. The asymptotic distribution of $\mathcal{S}_N^+$ under $\mathbf{H}_0^{(2)}$ will be $\chi^2(p+1)$ under some conditions on the regressors and on the scores. Hence, we reject hypothesis $\mathbf{H}_0^{(2)}$ on the significance level α if $\mathcal{S}_N^+ > \chi_{p+1}^2(1-\alpha)$, where $\chi_{p+1}^2(1-\alpha)$ is the $(1-\alpha)$ quantile of the χ^2 distribution with $p+1$ degrees of freedom.

Tests of $\mathbf{H}_1$ Based on Regression Rank Scores

Consider the model

$$Y_i = \beta_0 + x_{ni}^\top\boldsymbol{\beta} + \mathbf{z}_{ni}^\top\boldsymbol{\delta} + e_i, \quad i = 1,\ldots,n$$

with unknown parameters $\beta_0 \in \mathbb{R}^1$, $\boldsymbol{\beta} \in \mathbb{R}^p$, $\boldsymbol{\delta} \in \mathbb{R}^q$, and the hypothesis

$$\mathbf{H}_1 : \ \boldsymbol{\delta} = \mathbf{0}, \quad \beta_0,\ \boldsymbol{\beta}\ \text{unspecified}.$$

For the sake of the identifiability of the parameters, we rewrite the model in the form

$$Y_i = \beta_0 + \mathbf{x}_{ni}^\top\boldsymbol{\beta} + (\mathbf{z}_{ni} - \widehat{\mathbf{z}}_{ni})^\top\boldsymbol{\delta} + e_i, \quad i = 1,\ldots,n \tag{2}$$

where $\widehat{\mathbf{Z}}_n$ is the projection of matrix $\mathbf{Z}_n$ with the rows $\mathbf{z}_{n1}^\top,\ldots,\mathbf{z}_{nn}^\top$ on the space spanned by the columns of matrix $\mathbf{X}_n$, i.e.,

$$\widehat{\mathbf{Z}}_n = \widehat{\mathbf{H}}_n\mathbf{Z}_n,\ \widehat{\mathbf{H}}_n = \mathbf{X}_n\left(\mathbf{X}_n^\top\mathbf{X}_n\right)^{-1}\mathbf{X}_n^\top.$$

The model under the hypothesis is just $Y_i = \beta_0 + x_{ni}^\top\boldsymbol{\beta} + e_i$, $i = 1,\ldots,n$. The alternative model is (2). The regression rank scores for the hypothetical model are defined as the vector $\widehat{\mathbf{a}}_n(\tau) = (\hat{a}_{n1}(\tau),\ldots,\hat{a}_{nn}(\tau))^\top$ of solutions of the parametric linear programming problem

$$\begin{aligned}
&\sum_{i=1}^n Y_i\,\hat{a}_{ni}(\tau) := \max \quad \text{subject to}\\
&\sum_{i=1}^n \hat{a}_{ni}(\tau) = (1-\tau)n, \ \sum_{i=1}^n x_{ij}\,\hat{a}_{ni}(\tau) = (1-\tau)\sum_{i=1}^n x_{ij},\\
&j = 1\ldots,p,\\
&\widehat{\mathbf{a}}_n(\tau) \in [0,1]^n, \quad 0 \le \tau \le 1.
\end{aligned} \tag{3}$$

The restrictions in (3) imply that $\widehat{\mathbf{a}}_n(\tau)$ is invariant to the transformations $Y_i \mapsto Y_i + b_0 + \mathbf{x}_i^\top\mathbf{b}$, $b_0 \in \mathbb{R}^1$, $\mathbf{b} \in \mathbb{R}^p$.

Gutenbrunner et al. (1993) constructed the tests of $\mathbf{H}_1$ under some conditions on the tails of F (not heavier than the tails of t-distribution with 5 d.f.) and on the $\mathbf{x}_i$. Take a nondecreasing score function $\varphi : (0,1) \mapsto \mathbb{R}^1$ and calculate the scores

$$\widehat{\mathbf{b}}_n = (\hat{b}_{n1},\ldots,\hat{b}_{nn})^\top,\ \hat{b}_{ni} = -\int_0^1 \varphi(t)\,d\hat{a}_{ni}(t),\ i = 1,\ldots,n$$

and the q-dimensional vector of *linear regression rank scores statistics*

$$\mathbf{S}_n = n^{-1/2}(\mathbf{Z}_n - \widehat{\mathbf{Z}}_n)^\top\widehat{\mathbf{b}}_n.$$

The test criterion for the hypothesis $\mathbf{H}_1$ is

$$\mathcal{T}_n^2 = (A(\varphi))^{-2}\, \mathbf{S}_n^\top\, \widetilde{\mathbf{D}}_n^{-1}\, \mathbf{S}_n \text{ where}$$
$$\widetilde{\mathbf{D}}_n = n^{-1}(\mathbf{Z}_n - \widehat{\mathbf{Z}}_n)^\top(\mathbf{Z}_n - \widehat{\mathbf{Z}}_n).$$

The asymptotic distribution of $\mathcal{T}_n^2$ under $\mathbf{H}_1$ is the χ^2 distribution with q degrees of freedom, under some conditions on $\mathbf{x}_{ni}$ and $\mathbf{z}_{ni}$, $i = 1, \ldots, n$. Hence, we reject $\mathbf{H}_1$ on the significance level α provided $\mathcal{T}_n^2 > \chi_q^2(1-\alpha)$.

The usual choices of the *score-generating function* φ in all above tests are

- Wilcoxon scores: $\varphi(u) = 2u - 1, \quad 0 \le u \le 1$
- van der Waerden (normal scores): $\varphi(u) = \Phi^{-1}(u)$, $0 < u < 1$, where Φ is the standard normal distribution function
- Median scores: $\varphi(u) = \frac{1}{2}\,\text{sign}\left(u - \frac{1}{2}\right), \quad 0 \le u \le 1$

The computation aspects for the regression rank scores, as dual to the regression quantiles, are discussed in monograph of Koenker (2005). The tests were extended to the linear autoregression times series by Hallin and Jurečková (1999); there are other related works cited.

The Statistical Model

The entry by Claeskens and Jansen (same volume) provides an overview of ►nonparametric estimation and describes the major classes of nonparametric regression methods in use today. In the current entry, we provide more details on two of these classes, kernel methods and spline methods. When applying these methods, the researcher is interested in estimating the relationship between one dependent variable, Y, and one or several covariates, $X_1, \ldots, X_q$. We discuss here the situation with one covariate, X (the case with multiple covariates is addressed in the references provided below). The relationship between X and Y can be expressed as the conditional expectation

$$\mathrm{E}(Y|X = x) = f(x).$$

Unlike in parametric regression, the shape of the function $f(\cdot)$ is not restricted to belong to a specific parametric family such as polynomials.

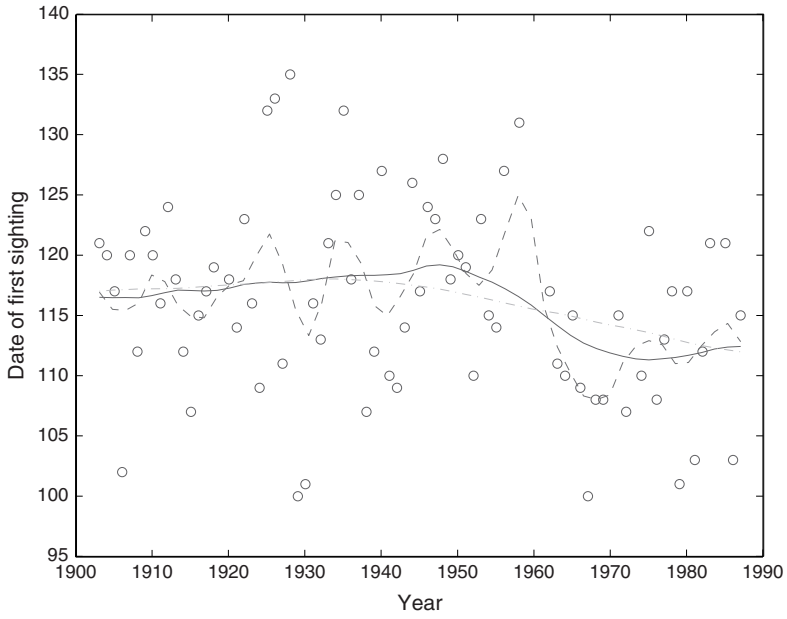
This representation for the mean function is the key difference between parametric and nonparametric regression, and the remaining aspects of the statistical model for (X, Y) are similar between both regression approaches. In particular, the random variable Y is often assumed to have a constant (conditional) variance, $\mathrm{Var}(Y|X) = \sigma^2$, with σ^2 unknown. The constant variance and other common regression model assumptions, such as independence, can be relaxed just as in parametric regression.

Kernel Methods

Suppose that we have a dataset available with observations $(x_1, y_1), \ldots, (x_n, y_n)$. A simple kernel-based estimator of $f(x)$ is the *Nadaraya–Watson kernel regression* estimator, defined as

$$\hat{f}_h(x) = \frac{\sum_{i=1}^n K_h(x_i - x) y_i}{\sum_{i=1}^n K_h(x_i - x)}, \tag{1}$$

with $K_h(\cdot) = K(\cdot/h)/h$ for some kernel function $K(\cdot)$ and bandwidth parameter $h > 0$. The function $K(\cdot)$ is usually a symmetric probability density and examples of commonly used kernel functions are the Gaussian kernel $K(t) = (\sqrt{2\pi})^{-1}\exp(-t^2/2)$ and the *Epanechnikov* kernel $K(t) = \max\left\{\frac{3}{4}(1-t^2), 0\right\}$.



Nonparametric Regression Using Kernel and Spline Methods. Fig. 1 Dates (Julian days) of first sightings of bank swallows in Cayuga Lake basin, with three kernel regressions using bandwidth values h calculated as the range of years multiplied by 0.05 (−−), 0.2 (–) and 0.4 (–·)

Generally, the researcher is not interested in estimating the value of $f(\cdot)$ at a single location x, but in estimating the curve over a range of values, say for all $x \in [a_x, b_x]$. In principle, kernel regression requires computing (1) for any value of interest. In practice, $\hat{f}_h(x)$ is calculated on a sufficiently fine grid of x-values and the curve is obtained by interpolation.

We used the subscript h in $\hat{f}_h(x)$ in (1) to emphasize the fact that the bandwidth h is the main determinant of the shape of the estimated regression, as demonstrated in Fig. 1. When h is small relative to the range of the data, the resulting fit can be highly variable and look "wiggly." When h is chosen to be larger, this results in a less variable, more smooth fit, but it makes the estimator less responsive to local features in the data and introduces the possibility of bias in the estimator. Selecting a value for the bandwidth in such a way that it balances the variance with the potential bias is therefore a crucial decision for researchers who want to apply nonparametric regression on their data. Data-driven bandwidth selection methods are available in the literature, including in the references provided below.

A class of kernel-based estimators that generalizes the Nadaraya–Watson estimator in (1) is referred to as *local polynomial regression* estimators. At each location x, the estimator $\hat{f}_h(x)$ is obtained as the estimated intercept, $\hat{\beta}_0$, in the weighted least squares fit of a polynomial of degree p,

$$\min_{\boldsymbol{\beta}} \sum_{i=1}^{n} \left(y_i - \beta_0 + \beta_1(x_i - x) + \cdots + \beta_p(x_i - x)^p\right) K_h(x_i - x).$$

This estimator can be written explicitly in matrix notation as

$$\hat{f}_h(x) = (1, 0, \ldots, 0)\left(\boldsymbol{X}_x^T \boldsymbol{W}_x \boldsymbol{X}_x\right)^{-1} \boldsymbol{X}_x^T \boldsymbol{W}_x \boldsymbol{Y}, \qquad (2)$$

where $\boldsymbol{Y} = (y_1, \ldots, y_n)^T$, $\boldsymbol{W}_x = \text{diag}\{K_h(x_1 - x), \ldots, K_h(x_n - x)\}$ and

$$\boldsymbol{X}_x = \begin{bmatrix} 1 & x_1 - x & \cdots & (x_1 - x)^p \\ \vdots & \vdots & & \vdots \\ 1 & x_n - x & \cdots & (x_n - x)^p \end{bmatrix}.$$

It should be noted that the Nadaraya–Watson estimator (1) is a special case of the local polynomial regression estimator with $p = 0$. In practice, the local linear ($p = 1$) and local quadratic estimators ($p = 2$) are frequently used.

An extensive literature on kernel regression and local polynomial regression exists, and their theoretical properties are well understood. Both kernel regression and local polynomial regression estimators are biased but consistent estimators of the unknown mean function, when that function is continuous and sufficiently smooth. For further information on these methods, we refer to reader to

the monographs by Wand and Jones (1995) and Fan and Gijbels (1996).

Spline Methods

In the previous section, the unknown mean function was assumed to be *locally* well approximated by a polynomial, which led to local polynomial regression. An alternative approach is to represent the fit as a *piecewise* polynomial, with the pieces connecting at points called *knots*. Once the knots are selected, such an estimator can be computed globally in a manner similar to that for a parametrically specified mean function, as will be explained below. A fitted mean function represented by a piecewise continuous curve only rarely provides a satisfactory fit, however, so that usually the function and at least its first derivative are constrained to be continuous everywhere, with only the second or higher derivatives allowed to be discontinuous at the knots. For historical reasons, these constrained piecewise polynomials are referred to as *splines*, leading to the name *spline regression* or *spline smoothing* for this type of nonparametric regression.

Consider the following simple type of polynomial spline of degree p:

$$\beta_0 + \beta_1 x + \cdots + \beta_p x^p + \sum_{k=1}^{K} \beta_{p+k}(x - \kappa_k)_+^p, \qquad (3)$$

where $p \geq 1$, $\kappa_1, \ldots, \kappa_K$ are the knots and $(\cdot)_+^p = \max\{(\cdot)^p, 0\}$. Clearly, (3) has continuous derivatives up to degree $(p-1)$, but the pth derivative can be discontinuous at the knots. Model (3) is constructed as a linear combination of *basis functions* $1, x, \ldots, x^p, (x-\kappa_1)_+^p, \ldots, (x-\kappa_K)_+^p$. This basis is referred to as the *truncated power basis*. A popular set of basis functions are the so-called *B-splines*. Unlike the truncated power splines, the B-splines have compact support and are numerically more stable, but they span the same function space. In what follows, we will write $\psi_j(x), j = 1, \ldots, J$ for a set of (generic) basis functions used in fitting regression splines, and replace (3) by $\beta_1\psi_1(x) + \cdots + \beta_J\psi_J(x)$.

For fixed knots, a regression spline is linear in the unknown parameters $\boldsymbol{\beta} = (\beta_1, \ldots, \beta_J)^T$ and can be fitted parametrically using least squares techniques. Under the homoskedastic model described in section "▶The Statistical Model", the *regression spline* estimator for $f(x)$ is obtained by solving

$$\hat{\boldsymbol{\beta}} = \arg\min_{\boldsymbol{\beta}} \sum_{i=1}^{n} \left(y_i - \sum_{j=1}^{J} \beta_j \psi_j(x_i) \right)^2 \qquad (4)$$

and setting $\hat{f}(x) = \sum_{j=1}^{J} \hat{\beta}_j \psi_j(x)$. Since deviations from the parametric shape can only occur at the knots, the amount of smoothing is determined by the degree of the basis and the location and number of knots. In practice, the degree is fixed (with $p = 1, 2$ or 3 as common choices) and the knot locations are usually chosen to be equally-spaced over the range of the data or placed at regularly spaced data quantiles. Hence, the number of knots K is the only remaining smoothing parameter for the spline regression estimator. As K (and therefore J) is chosen to be larger, increasingly flexible estimators for $f(\cdot)$ are produced. This reduces the potential bias due to approximating the unknown mean function by a spline function, but increases the variability of the estimators.

The *smoothing spline* estimator is an important extension of the regression spline estimator. The smoothing spline estimator for $f(\cdot)$ for a set of data generated by the statistical model described in section "▶The Statistical Model" is defined as the minimizer of

$$\sum_{i=1}^{n} (y_i - f(x_i))^2 + \lambda \int_{a_x}^{b_x} (f^{(p)}(t))^2 dt, \qquad (5)$$

over the set of all functions $f(\cdot)$ with continuous $(p-1)$th derivative and square integrable pth derivative, and $\lambda > 0$ is a constant determining the degree of smoothness of the estimator. Larger values of λ correspond to smoother fits. The choice $p = 2$ leads to the popular *cubic smoothing splines*. While not immediately obvious from the definition, the function minimizing (5) is exactly equal to a special type of regression spline with knots at each of the observation points $x_1, \ldots, x_n$ (assuming each of the locations x_i is unique). For further information on smoothing splines, see the entry by Wahba (same volume).

Traditional regression spline fitting as in (4) is usually done using a relatively small number of knots. By construction, smoothing splines use a large number of knots (typically, n knots), but the smoothness of the function is controlled by a penalty term and the smoothing parameter λ. The *penalized spline* estimator represents a compromise between these two approaches. It uses a moderate number of knots and puts a penalty on the coefficients of the basis functions. Specifically, a simple type of penalized spline estimator for $m(\cdot)$ is obtained by solving

$$\hat{\boldsymbol{\beta}} = \arg\min_{\boldsymbol{\beta}} \sum_{i=1}^{n} \left(y_i - \sum_{j=1}^{J} \beta_j \psi_j(x_i) \right)^2 + \lambda \sum_{j=1}^{J} \beta_j^2 \qquad (6)$$

and setting $\hat{f}_\lambda(x) = \sum_{j=1}^{J} \hat{\beta}_j \psi_j(x)$ as for regression splines. Penalized splines combine the advantage of a parametric fitting method, as for regression splines, with the flexible adjustment of the degree of smoothness as in smoothing splines. Both the basis function and the exact form

of the penalization of the coefficients can be varied to accommodate a large range of regression settings.

Spline-based regression methods are extensively described in the statistical literature. While the theoretical properties of (unpenalized) regression splines and smoothing splines are well established, results for penalized regression splines have only recently become available. The monographs by Wahba (1990), Eubank (1999) and Ruppert et al. (2003) are good sources of information on spline-based methods.

About the Authors

Jean Opsomer is Professor of Statistics at Colorado State University. Previously, he was Professor of Statistics and Director of the Center for Survey Statistics and Methodology at Iowa State University. He received his Ph.D. in Operations Research in 1995 from Cornell University. He is a Fellow of the American Statistical Association and an Elected Member of the International Statistical Institute. His research interests include survey statistics, nonparametric regression methods and environmental statistics.

Jay Breidt is Professor and Chair of Statistics at Colorado State University. He received his Ph.D. in 1991 from Colorado State University and was on the faculty at Iowa State University from 1991–2000. He is a Fellow of the American Statistical Association, an Elected Member of the International Statistical Institute, and a member of the Federal Economic Statistics Advisory Committee. His research interests include time series modeling, survey sampling, and environmental statistics.

Nonparametric Statistical Inference

Jean Dickinson Gibbons[1],
Subhabrata Chakraborti[2]
[1]Russell Professor Emerita of Statistics
The University of Alabama, Tuscaloosa, AL, USA
[2]Professor of Statistics
The University of Alabama, Tuscaloosa, AL, USA

Nonparametric statistical inference is a collective term given to inferences that are valid under less restrictive assumptions than with classical (parametric) statistical inference. The assumptions that can be relaxed include specifying the probability distribution of the population from which the sample was drawn and the level of measurement required of the sample data. For example, we may have to assume that the population is symmetric, which is much less restrictive than assuming the population is the normal distribution. The data may be ratings or ranks, i.e., measurements on an ordinal scale, instead of precise measurements on an interval or ratio scale. Or the data may be counts. In nonparametric inference, the null distribution of the statistic on which the inference is based does not depend on the probability distribution of the population from which the sample was drawn. In other words, the statistic has the same sampling distribution under the null hypothesis, irrespective of the form of the parent population. This statistic is therefore called distribution-free, and, in fact, the field of nonparametric statistics is sometimes called distribution-free statistics. Nonparametric methods are often based on ranks, scores, or counts. This allows us to make less restrictive assumptions and still carry out an inference such as calculate a P-value or find a confidence interval. Strictly speaking, the term nonparametric implies an inference that may or may not be concerned with the value of a parameter of the population. This allows more flexibility, in that the inference may be concerned only with the form of the population, as in goodness-of-fit tests, or with some other characteristic of the data distribution, as in tests for randomness, trend or autocorrelation, or it may be that the inference is concerned with the median of the distribution. It has become customary to include all such tests and estimation procedures under the umbrella of nonparametric statistical inference.

The earliest example of nonparametric statistical inference has been attributed to John Arbuthnot in the early 1700s when the sign test statistic was introduced with the analysis of birth data to show that males have a higher birth rate than females. The sign test statistic (see ►Sign Test) is

the number of plus signs among, say, n differences within a set of n paired sample observations that have no ties. The number of plus signs follows the ▶binomial distribution with parameter p representing the probability of a plus sign. This is true regardless of the form of the parent population of pairs, and hence the sign test statistic is distribution-free. The next example of nonparametric statistical inference was goodness-of-fit tests and contingency table analysis due to Karl Pearson in the early 1900s. Also in the early 1900s Charles Spearman, a psychologist, recommended substituting ranks in calculating the correlation coefficient; this statistic is called Spearman's rho, a measure of rank correlation. Sir Maurice Kendall's landmark book *Rank Correlation Methods* appeared in 1948; this treatise covers Spearman's rho and ▶Kendall's tau in great detail. The fifth edition of this book appeared in 1990, co-authored with Jean D. Gibbons. John Walsh published a three-volume handbook of nonparametric statistical methods in 1962, 1965 and 1968. I.R. Savage compiled a bibliography of nonparametric methods published in 1962.

Gottfried Noether published a slim volume titled *Elements of Nonparametric Statistics* in 1967; this book addressed some of the theoretical bases of nonparametric statistics. The first two comprehensive books suitable for classroom use as a course in nonparametric statistics were *Distribution-free Statistical Tests* by James V. Bradley in 1958 and *Nonparametric Statistical Inference* by Jean D. Gibbons in 1971. The latter book is now in its fifth edition, co-authored with Subhabrata Chakraborti. At the present time there are several other books on the subject. The American Statistical Association organized a separate Section on Nonparametric Statistics in the 1990s and now publishes a separate periodical called the *Journal of Nonparametric Statistics*.

The best known and most widely used nonparametric inference procedures are the ▶Wilcoxon-signed-rank test and confidence interval estimate for the median of one population or the median difference in a population of differences, the Wilcoxon rank sum test (or equivalently the Mann-Whitney test, see ▶Wilcoxon–Mann–Whitney Test) and confidence interval estimate for the difference of the medians of two populations, the Kruskal–Wallis test for equal treatment effects in a one-way ▶analysis-of-variance situation and multiple comparisons, the Friedman test for equal treatment effects in a two-way analysis-of-variance situation and multiple comparisons, the Spearman's rho and Kendall's tau coefficients of correlation for samples from bivariate populations. Nonparametric methods are also available for multivariate data as well as for regression settings although some of these procedures are not as well-known. Bootstrapping and ▶permutation tests, which are applicable under very weak assumptions, take advantage of modern computing power and have brought renewed focus and interest into nonparametric methodology.

The primary advantage of nonparametric procedures over classical (parametric) procedures is that they are inherently robust and valid under very weak assumptions. With classical statistical inference, any conclusions reached should be tempered by qualifying statements like, "If the population from which the sample was drawn is the normal distribution, then …." In practice, one seldom has any reliable information about the population. With a small sample size, one cannot even make an informed guess about the shape of the population. Nonparametric methods are easy to use and understand. Their properties can frequently be derived by combinatorial theory rather than calculus. Kendall's tau as a measure of relative concordance of pairs is much easier to interpret than the classical product-moment correlation coefficient. Data used in classical statistics are implicitly assumed to be measured on at least an interval scale. But many studies, particularly in social science research, collect data as opinions or ratings, as in Likert scale data. Such data cannot possibly be assumed to have come from a normal distribution.

Many nonparametric techniques have a classical or parametric counterpart. The classical techniques are derived under a specific set of assumptions (mainly about the distribution, such as normality) and are frequently the most powerful when those assumptions are fully satisfied. But if those assumptions are not met or cannot be verified (which is usually the case in practice), or are disregarded, or are not even known, the researcher can have little or no faith in any inferences drawn. In fact, the inference may be less reliable than a judicious opinion, or even a guess. In this context a typical question then is "How much is lost by using a nonparametric type of inference if the classical assumptions were indeed met?" Studies of the relative power of nonparametric tests have shown that under the classical assumptions, the nonparametric test is frequently almost as powerful as the corresponding classical test, and little power is lost while considerable confidence in the conclusions is gained. And of course the nonparametric methods are still applicable when many of the assumptions behind the classical methods are not satisfied or can not be fully justified.

About the Authors

Jean Dickinson Gibbons is the Thomas D. Russell Professor Emerita of Applied Statistics at the University of Alabama. She earned her Ph.D. in statistics from Virginia Tech in 1962. Professor Gibbons was the Chair of the Applied Statistics Program at the University of Alabama for 20 years. She was the first Chair of ASA Committee on Women in Statistic (1972–1974) and served three terms on

the ASA Board of Directors. She was elected a Fellow of the American Statistical Association at age 34 and was a Senior Fulbright-Hays Scholar at the Indian Statistical Institute in Calcutta. She has published numerous articles on nonparametric statistics, both theoretical and applied. She is author or co-author of many highly regarded textbooks, including the well-known text *Nonparametric Statistical Inference* (first published in 1970 and is now in its fifth and revised edition (with Professor Chakraborti). Professor Gibbons has been widely considered as one of the leading experts in nonparametric statistics and has enjoyed being a mentor and role model for many young women studying statistics.

"Statistics is my love," Gibbons said. "Its my vocation, as well as my avocation. I was so delighted when I discovered statistics and I think that it is a field that will always be of utmost importance." (Virgina Tech College of Science Magazine, Fall Issue 2009).

Subhabrata Chakraborti is Professor of Statistics and a Robert C. and Rosa P. Morrow Faculty Excellence Fellow at the University of Alabama. He earned his Master's and Ph.D. in statistics from the State University of New York at Buffalo in 1982 and 1984, respectively. He is a Fellow of the American Statistical Association, an elected member of the International Statistical Institute, member of the Institute of Mathematical Statistics and has been a Fulbright Senior Scholar. Professor Chakraborti has authored and co-authored over 75 publications in a variety of international journals. He is the co-author of the new editions of *Nonparametric Statistical Inference*, (2003 and 2010) with Jean D. Gibbons. Professor Chakraborti has been the winner of the Burlington Northern Faculty Achievement Award at the University of Alabama for excellence in teaching. He has been cited for his contributions in mentoring and collaborative work with students and colleagues from around the world. Dr. Chakraborti has served (1997–2002) as an Associate Editor of *Computational Statistics and Data Analysis* and is currently serving (1996–) as an Associate editor of *Communications in Statistics*.

Non-probability Sampling Survey Methods

H. Öztaş Ayhan
Professor and Head
Middle East Technical University, Ankara, Turkey

Non-probability sampling is generally used in experimental or trial research and does not represent the target population. Non-probability sampling uses subjective judgement and utilizes convenient selection of units from the

population. Non-probability sampling methods produce cost savings for personal interview surveys; the resulting samples often look rather similar to probability sample data (Fowler 2002). There are several non-probability selection methods that are used in practice. We will briefly overview these methods in the following sections.

Convenience (Haphazard) Sampling

The sample is composed of conveniently accessible persons who will contribute to the survey. Samples of volunteer subjects should be included here. It is used in many sciences that display little care about the representativeness of their specimens (Kish 1995).

Purposive (Judgement) Sampling

In purposive sampling, the participants are selected by the researcher subjectively. The selection is based on the judgement of the researcher. Respondents are not selected randomly but by using the judgement of the interviewers. Consequently, there is an unknown probability of inclusion for any selected sample unit.

Expert Choice

Expert choice is a form of purposive or judgment sampling, which is used by experts to pick "typical" or "representative" specimens, units, or portions. Experts often hold differing views on the best way to choose representative specimens or to decide which are the most representative units. Sometimes the researcher asks that, instead of a real population, a hypothetical universe be postulated as the parent of the sample (Kish 1995).

Snowball Sampling

A more specialized type of purposive sample is a *snowball sample*, in which respondents are asked to suggest more respondents. Snowball samples are non-probability samples, since it is impossible to know the probability with which any person in the larger population ends up in the sample (Weisberg 2005). When an incomplete list of a special population is available, enumerators evaluate these units. Later, the enumerator enquires about a possible nearby address that has the same characteristic as the respondent. Then, this address is also visited and enumerated as a sample unit. The accumulation of the additional addresses to the existing list resembles the expansion of a snowball, which is rolling downhill.

Quota Sampling

Quota sampling is a form of purposive sampling, where the enumerators are instructed to obtain specific quotas from which to build a sample roughly proportional to the population on a few demographic variables (Kalton 1983; Kish 1995). Quota sampling is a method of stratified sampling in which the selection within strata is non-random. The sample selection method employs controls (*independent* or *interrelated*) and fixed quotas as alternatives. The statisticians have criticized the method for its theoretical weakness, while market and opinion researchers have defended it for its cheapness and administrative convenience (Moser and Kalton 1979).

Mobile Population Sampling

Mobile population sampling is one of the very specific areas in which special non-probability sampling techniques are widely used. One of the main reasons for this is that it is not possible to obtain a list of the mobile target population, for probability sampling. The second important reason is the mobility of the population elements, which makes it difficult to access as a sample unit. The use of list sampling is not a possibility, while the use of specified area sampling is also difficult for some types of mobile units (e.g., birds, fishes, etc.) due to unrecognized boundary concept of the defined population areas. The mobile population sampling can be examined for several different types of populations. Basically, we can summarize these as *mobile animal populations* and *mobile human populations*.

Sampling from Mobile Animal Populations

The mobile animals can be examined as types of *wild animals, birds*, *insects*, or *fishes*. Sometimes it is possible to create protected boundaries for some of these animals. In this case, it will be possible to examine these animals by using a non-probability selection method. In other cases, there may be no defined boundary for their evaluation. In both cases, it may not be possible to use a probability sampling. Therefore one of the common methods for this enumeration is the use of *capture-tag-recapture method*. The animal has to be caught first, and measured, then labeled with a tag (*mechanical* or *electronic*) and then let go. The second stage is based on the possibility of catching the same labeled animal for another periodic measurement. The method continues until the desired round of planned measurements on the selected units are achieved. The total population is estimated from the proportion in the capture of individuals that have been previously captured and tagged (Kish 1995).

Sampling from Mobile Human Populations within Small Areas

Determining the number of people in a crowded street by ordinary methods would require the demarcation of

a number of small areas in the street and counting the number of people on each of these areas, known as *grid sampling*. Equally it is no use stationing observers at fixed points with instructions to count passers-by is another approach to enumerate the mobile human population, which the method is known as the use of *stationary observers*. These difficulties can be overcome by using *moving observers* instead of stationary observers. To obtain an estimate of the number of people in a street, the observer traverses the street in one direction, counting all the people he passes, in whichever direction they are moving, and deducing all the people who overtake him. Crowded streets were dealt with by teams of two or more observers, moving down the street in a transverse line, with each observer counting the people between him and the next observer (Yates 1960).

Sampling of Nomadic Tribes

Nomadic tribes usually live in unpopulated rural areas. Generally, they deal with animal husbandry and are travelling with their animals through a specified route over several months (Ayhan and Ekni 2003). Due to their mobility, it is not possible to observe and enumerate them by stationary observers. Therefore, moving observers are recommended to be used to enumerate this special population for censuses (see ►Census) as well as surveys.

Sampling of Homeless People

Most sample-based studies of the homeless are basically designed to measure characteristics of the currently homeless. The main challenge for designing such samples is that there typically is no fixed reference on which to base a sampling frame (Sumner et al. 2001). Due to several difficulties related to listing of homeless people within a perfect sampling frame, many homeless studies in the past were based on the non-probability samples. Recently, multistage probability samples have been used for alternative estimation.

Non-probability Sampling from Internet Users

Couper (2000) differentiates three types of non-probability Web surveys that are basically availability samples: *Web surveys as entertainment, self-selected Web surveys*, and *volunteer panels of internet users*. In addition, Ayhan (2005) had proposed a sample weighting adjustment methodology for the non-probability sample that is selected from voluntary participation Web surveys. The future of Web surveys is heading towards voluntary panels of internet surveys, which requires generalizations from the selected non-probability samples.

The use of non-probability sampling methods in practice has also been reviewed by Weisberg (2005), and the following points have been emphasized. First, the usual statistical advice is to avoid non-probability samples. Second, many surveys either explicitly use non-probability sampling or do so implicitly. Third, the balancing of survey errors and survey costs can sometimes justify non-probability sampling, regardless of the usual textbook injunctions against it.

About the Author

Dr. Öztaş Ayhan is a Professor and Head of the Department of Statistics at Middle East Technical University, Ankara, Turkey. He is also the Director of the Statistics Program of the Graduate School. During 1990–1992 period, he served as the Director of Technical Services Department of the State Institute of Statistics. In 1993, he has received the distinguished service medal of the State Institute of Statistics. Professor Ayhan has jointly written and also edited 12 books and research monographs in the fields of social and health statistics. He has published over 40 research articles in the fields of survey sampling and survey methodology. He is an Elected Member of the International Statistical Institute, since 1995. He has been the Country Representative for Turkey of the International Association of Survey Statisticians. From 1997 to 2001, he has also served as a Council Member of the International Association of Survey Statisticians. He has been the Vice President of the Turkish Statistical Association (2007–2009).

Nonresponse in Surveys

Jelke Bethlehem
Professor, Senior Survey Methodologist at Statistics Netherlands
University of Amsterdam, Amsterdam, Netherlands

Our complex society experiences an ever growing demand for statistical information relating to social, demographic, industrial, economic, financial, political, and cultural situation of the country. Such information enables policy makers and others to take informed decisions for a better future. Sometimes, statistical information can be retrieved from administrative sources. More often there is a lack of such sources. In this case, the sample survey is a powerful instrument to collect new statistical information.

A sample survey collects information on a small part of the population. In principle, this sample only provides information about the selected elements of the population. Nevertheless, if the sample is selected using a proper sampling design, it is also possible to make inference about the population as a whole.

Many things can go wrong when carrying out a survey. There are all kinds of phenomena that may have a negative impact on the quality of the survey outcomes. Nonresponse is one such problem.

Nonresponse is the phenomenon that elements in the selected sample do not provide the requested information, or that the provided information is unusable. Nonresponse comes in two forms. *Unit nonresponse* denotes the situation in which all requested information on a sampled population element is missing. If information is missing on some items in the ▶questionnaire only, it is called *item nonresponse*.

Due to non-response the amount of collected data is smaller than expected. This problem can be taken care of by selecting a larger sample. A more serious problem is that estimates of population characteristics may be biased. This situation occurs if, due to non-response, some groups in the population are over- or underrepresented, and these groups behave differently with respect to the characteristics to be investigated. Consequently, wrong conclusions may be drawn from the survey results. Therefore, it is vital to reduce the amount of nonresponse in the fieldwork of the survey as much as possible.

Nonresponse rates have been rising over the years, see Bethlehem (2009). Currently, these rates often exceed 50%. So no information is obtained from more than halve of the sampled elements. Some case studies have shown that nonresponse may result in serious biases. In practice, it is very difficult to asses the possible negative effects of nonresponse, due to lack of information on nonrespondents. And even if such effects can be detected, it is no simple matter to correct for them.

To be able to do something, it is very important to have auxiliary information. For example, if there is an auxiliary variable that has been measured in the sample, and for which population characteristics are known, then this variable can be used to check whether the available data show unbalancedness, i.e., they are not representative for the population.

There are several techniques available to correct for non-response bias. The usual treatment for unit nonresponse is adjustment weighting, and for item nonresponse imputation techniques (see ▶Imputation) can be applied.

The basic principle of *adjustment weighting* is that every observed element is assigned a specific weight. Estimates for population characteristics are obtained by processing the weighted values instead of the values themselves. The easiest and most straightforward method used to compute weights is post-stratification. The population is divided into strata after selection of the sample. If each stratum is homogeneous with respect to the target variable of the survey, then the observed elements resemble the unobserved elements. Therefore, estimates of stratum characteristics will not be very biased, so they can be used to construct population estimates.

To take as much advantage as possible of the available auxiliary information also more advanced weighting methods have been developed, like *linear weighting* (see

Bethlehem and Keller 1987) and *calibration estimation* (see Deville and Särndal 1992).

To carry out adjustment weighting auxiliary variables are needed and preferable auxiliary variables having a strong relationship with the target variables of the survey. In practical situations, the available information may be limited, and also the relationships may not be as strong as preferred. Therefore, sometimes adjustment may not be capable of completely removing the bias.

A fortunate development is that a tendency that more and more data from registers can be used. Such registers contains more useful auxiliary information, and therefore correction procedures based on these variables will be more effective.

Item non-response requires a different approach. A great deal of additional information is available for the elements involved. All available responses to other questions can be used to predict the answer to the missing questions. This computation of a "synthetic" answer to a question is called *imputation*. Predictions are usually based on models describing relationships between the variable with missing values and other variables for which the values are available.

Imputation techniques can be classified as random or deterministic, depending on whether residuals are set to zero or not. Deterministic techniques have the disadvantage that they distort the properties of the distribution of the values of the variable. These techniques tend to predict values in the middle part of the distribution. Therefore, standard errors computed from the imputed data set are generally too small. They create a too optimistic view of the precision of estimates. Random imputation methods do not have this nasty property. They much better able to preserve the original distribution. However, they introduce an extra source of variability.

Another point to take into consideration is the effect of imputation on relationship between variables. Several imputation techniques cause estimates of covariances and correlations to be biased. The estimates produce too low values. For more information, see e.g., Kalton and Kasprzyk (1986).

Research for new imputation techniques is in progress. An example is the multiple imputation technique proposed by Rubin (1979). This technique computes a set of imputed values for each missing value. This results in a number of imputed data sets. Inference is based on the distribution of estimates obtained by computing the estimate for each data set. This approach has attractive theoretical properties, but may not be so easy to implement in practical situations.

An overview of the state of the art in nonresponse research can be found in Groves et al. (2001).

About the Author

Dr. Jelke Bethlehem joined Statistics Netherlands in 1978, first as Research Worker and later as Senior Statistician. His main topics were the treatment of nonresponse in sample surveys, in which he obtained his Ph.D., and disclosure control of published survey data. From 1987 to 1996 he was head of the Statistical Informatics Department, which concentrated on the development of standard software for processing survey data. Currently, he is Senior Advisor of the Department of Statistical Methods of the Central Bureau of Statistics (CBS) Netherlands. He has been the principal investigator of a number of research projects in the area of survey methodology and nonresponse. Dr. Bethlehem is also part-time professor in Statistical Information Processing at the University of Amsterdam. He was Vice-President of the International Association of Survey Statisticians (IASS), from 2005 to 2007. Professor Bethlehem has published widely in a number of journals and books in survey methodology.

As in other types of surveys, we can distinguish between *unit nonresponse*, where the expected (invited) eligible units do not participate in the survey, and *item nonresponse*, where the units participate, but certain responses are missing to some questions.

In addition, due to the availability of paradata – i.e., data from the process of answering a Web survey ►questionnaire that are stored in the log files together with the responses (Couper 2005) – a variety of *additional nonresponse measures and patterns* may be detected in Web surveys (Bosnjak 2000). In particular, *partial nonresponse*, where respondents answer only part of the questionnaire and then drop out is an issue requiring further discussion.

Here we predominantly focus on unit and partial nonresponse, while leaving the item nonresponse aside because it is not so much a problem of participation in Web surveys, but is more a problem related to Web questionnaire design issues, which is not our focus here.

When discussing the amount of unit and partial nonresponse in Web surveys, it is important to distinguish between different types of Web surveys (Couper 2001). The level of nonresponse can be precisely assessed only for list-based Web surveys, that is, surveys where a list of sample members (either probability or non-probability) are invited individually, giving them a unique URL and/or username/password to answer the questionnaire. Only in this case is it possible to distinguish between crucial response outcomes and calculate required response rates. For example, the AAPOR (AAPOR 2009) lists the following disposition codes for Internet surveys of specifically named persons: complete and partially complete questionnaires, eligible but with nonresponse (either due to explicit or implicit refusals and break-offs, non-contacts, or some other reason), cases with unknown eligibility, and not eligible. This coding is rather difficult, especially if e-mail invitations to the survey are used. For those units that do not respond (do not even log on to the first questionnaire page) it can rarely be established whether they are eligible or whether they actually received the invitation (whether they were actually contacted). The cases with unknown eligibility and those where it cannot be determined if contact has been made occur much more frequently in Web surveys than in any other survey modes.

In contrast to the list-based Web surveys, there are also unrestricted self-selected Web surveys where participants become aware of the questionnaire via word of mouth, advertisements, or serendipity. In this case, any response rate is difficult or impossible to calculate due to the unknown target population (thus an unknown denominator).

Another special aspect of Web surveys are surveys where pre-recruited lists of Internet users or of the general population (usually panels) are invited to the survey. In this case, two types of responses are of interest here: one is cooperation in the pre-recruitment stage and inclusion in the sampling frame, the other is cooperation for a particular Web survey project.

Despite the different types of Web surveys and difficulties in distinguishing between some disposition codes, we can define the following response outcome rates for Web surveys:

- *Response rate* and *completion rate*: The response rate as a ratio of completed questionnaires to the number of eligible units (AAPOR 2009) can be calculated for list-based Web surveys. However, since we often do not have information about the eligibility of the units (unless we somehow estimate their share or simply assume that all invited units are eligible), a completion rate may be a better measure. It is defined as the number of completed questionnaires among all invitations sent. In addition, if a distinction between partial (questionnaire answered only partially, then a drop-out) and complete respondents is made, overall (referring to partial and complete respondents) and full (referring to complete respondents only) response and completion rates can be defined.
- *Absorption rate* and *failure rate* (Vehovar et al. 2002): The absorption rate can be defined for list-based Web surveys as the number of absorbed or delivered (email, mail, fax) invitations among all invitations sent (delivered and undelivered). Its opposite, the failure rate (sometimes also called the attrition rate), is defined as the number of undelivered invitations (known as non-contacts) among all invitations sent. These rates are indicators of the quality of the sampling frame. The absorption rate is similar to the contact rate, and is defined as the ratio of contacted units to the number of eligible units (AAPOR 2009). However, the absorption rate is a more robust measure when the exact number of eligible units cannot be established, which is often the case in Web surveys.

- *Cooperation rate*. The cooperation rate is defined as the ratio of interviews obtained to the number of units contacted (AAPOR 2009). For list-based Web surveys, an approximate measure of the cooperation rate can be calculated if we assume that all units with absorbed (e-mail, mail, fax) invitations are also contacted units. Again, we can distinguish between the overall and full cooperation rates, depending on complete and partial respondents.
- *Refusal rate*. For list-based Web surveys, the refusal rate, as a ratio of the units that explicitly refuse to participate to the number of eligible units (AAPOR 2009), can also be calculated. In this case, those who explicitly state that they do not want to participate and/or want to be excluded from the list are counted as explicit refusals, while eligibility is again usually only estimated.
- *Click-through rate*. This is a special measure that is specific to Web surveys and can be reported for any type of Web surveys, including unrestricted self-selected ones. Namely, it refers to respondents who click on the URL link and access the Web questionnaire. For example, when banner ads or some other publication of the URL is used, the click-through rate is defined as the percentage of those clicking on the banner ad/invitation and going to the questionnaire page among those exposed to the ad/invitation. For list-based Web surveys, the click-through rate is defined as the percentage of invited units who access the first questionnaire page. In general, we can define the click-through rate for all Web surveys where the number of respondents exposed to the invitation can be established (regardless of whether or not they were actually contacted, and regardless of whether or not they are eligible). In special cases, the cooperation click-through rate can be defined as the number of units accessing the Web questionnaire among all contacted, eligible, and available during data collection.
- *Drop-out* and *complete rate*. The drop-out rate (sometimes called the attrition rate) refers to respondents who started to answer the Web questionnaire, but abandoned it prematurely. It refers to the percentage of respondents who only partially complete the questionnaire among all respondents. The opposite – complete rate – is defined as the percentage of complete responses among all respondents. The manner in which partial respondents are distinguished from complete respondents depends on the particular survey. In general, partial respondents can be answering drop-outs, item nonresponding drop-outs with low item nonresponse rate for the displayed questions, and/or item nonrespondents with item nonresponse large enough not to include them among complete respondents.

The above rates for Web surveys can be very variable. The articles published in journals in 2009 included in the Web of Science database and reporting the results of some Web surveys, show the response rates vary from less than 20% to close to 100%. (The Web of Science database returns 1,718 unique records (articles) for 2009 when entering the following keywords: Web surveys, Web questionnaire, Internet survey, Internet questionnaire, online survey, and online questionnaire. After reading abstracts of a ▶simple random sample of 100 of these records, we estimate that 25% of these articles actually do not report on Web surveys. Among the remaining ones, for 48% of the articles not enough data was provided to estimate a response rate or they report on an unrestrictred, self-selected Web survey.) Unfortunately, no systematic study was recently done to give an overview of response rates. However, a meta-analysis of experimental studies comparing response rates of Web vs. some other survey mode (Lozar Manfreda et al. 2008) showed that Web surveys on average yield an 11% lower response rate than other survey modes, when comparable samples and procedures are used. This is alarming if we assume that the level of nonresponse is also an indicator of nonresponse bias. However, since this is not necessarily the case (Groves and Peytcheva 2008), further investigations into how Web respondents differ from nonrespondents are needed and some studies on this topic have already been done (for example Biffignandi and Pratesi 2000; Taylor et al. 2009; Sax et al. 2008).

In general, the *response rate* in Web surveys *depends on different factors*, such as the sociological and technological environment, survey design, and characteristics of the respondent (Vehovar et al. 2002).

The social environment indirectly affects participation in Web surveys through general economic development, telecommunication policy, educational system, technological tradition, etc. In addition, the general survey climate, perception of direct marketing, legitimacy of surveys and their sponsors, data protection scandals, and opinion leaders also influence participation. As regards Web surveys with email invitations, the increasing problem of spam and viruses negatively influence participation to a large degree (Fan and Yan 2009). Email invitations may either be considered spam, and as such ignored or not even delivered (in some email systems they are automatically intercepted by spam filters), or people do not want to click on the URL address in the invitation due to the fear of viruses. The critical issue regarding privacy on the Internet may also

negatively affect participation in Web surveys since Internet users are reluctant to reveal personal information if conditions of its use are not clearly specified.

The social environment interacts closely with the technological environment. General telecommunication and information infrastructure is especially critical for successful implementation of Web surveys. Considerable differences can be observed with respect to Internet penetration in various countries. By the year 2009, Internet penetration surpassed 70% of the active population only in some developed countries such as the US, Canada, some European countries (e.g., Faroe Islands, Switzerland, Luxemburg, Andorra, UK, Spain), or certain Asian countries (e.g., Japan, South Korea), and 80% only in a few countries (e.g., Greenland, Iceland, Norway, Finland, Netherlands, Sweden, Australia, New Zeeland). In general, while the developed world has reached a high penetration rate, in some of the largest countries (like China, Russia, and India) as well as in the remaining developing countries, penetration is still below 25% (Internet World Stats 2009). In addition to the problem of non-coverage, the quality of Internet infrastructure (speed of Internet connections) and cost for Internet connections additionally affects participation in Web surveys.

Regarding the respondents' characteristics, response rates to surveys usually vary across social-demographic categories, survey experience, interest in the survey topic, and other attitudes. In addition, for Web surveys, computer literacy and the respondent's orientation towards computer use also become extremely important. Actually, the intensity of computer and Internet usage is the most important predictor of cooperation in a Web survey, even when observed within the social-demographic categories defined by age, gender, education, and income (Batagelj and Vehovar 1998; Kwak and Radler 2002; Vehovar et al. 1999). Of course, when computer orientation is not controlled, it appears that the usual characteristics of Internet usage also determine the participation in Web surveys: respondents are younger, more educated, richer, and male (Bandilla et al. 2003; Batagelj and Vehovar 1998; Braungberger et al. 2007; McCabea et al. 2006). In addition, the respondent's technical equipment may also affect Web survey participation with technologically advanced users being more willing (or able) to participate.

Although the above influences on web survey participation are of extreme importance, researchers cannot do much to change them. On the other hand, the design of a Web survey is becoming a crucial factor by which survey researchers can influence the readiness of people to participate. Several studies have been done to develop implementation procedures that would result in high quality data from Web surveys. It has also been shown that response rates in Web surveys can be increased particularly by incentives (e.g., Göritz 2006), as well as by mixed-modes (e.g., Dillman et al. 2009; Greene et al. 2008; Kroth et al. 2009), and increased number of contacts with respondents.

In addition to *developing techniques for increasing response rates*, another stream of measures address the *post-survey adjustments*. These techniques not only compensate for nonresponse, but also the non-coverage, frame problems and non-probability nature of the sample. Besides standard weighting and imputation strategies, propensity score adjustment is frequently used in the context of Web surveys (e.g., Lee 2006; Lee and Valliant 2009; Schonlau et al. 2009).

As survey response rates have been declining over the years in general (de Leeuw and de Heer 2002; Grapentine 2008; Stoop 2005) and as Web surveys gain even lower response rates than other survey modes (Lozar Manfreda et al. 2008), the predictions for the future are rather negative. We can expect even less willingness to participate in Web surveys. Therefore, the development of measures to increase response rates (particularly incentives) seems to be crucial. In addition, the increased use of probability-based Internet panels (e.g., Knowledge Network in U.S.A., Centerdata panel in the Netherlands), as well as numerous non-probability access panels, seem to be gaining momentum. This will be emphasized even more due to lower costs of Web survey data collection in comparison to other survey modes. This forces survey organizations to consider this mode of data collection, regardless of the problem of non-coverage and higher levels of nonresponse.

About the Authors

Katja Lozar Manfreda, PhD, is an assistant professor of statistics and Head of the Department of Informatics and Methodology (since 2009), Faculty of Social Sciences, University of Ljubljana, Slovenia. She is the General Secretary of the RC33 committee on Logic and Methodology of the International Sociological Association. She has (co-)authored over 15 scientific papers and book chapters. Dr. Lozar Manfreda has received the AAPOR Warren J. Mitofski Innovators Award in 2009 for the WebSM site. She was a guest editor for a special issue of Journal of Official Statistics in 2006 and she has been a member of the editorial board of the Survey Research Methods since 2007.

Nejc Berzelak Nejc Berzelak is a teaching assistant of social science methodology and researcher, University of

Ljubljana, Slovenia. He is an editor of the WebSM portal, website devoted to web survey methodology.

Dr. Vasja Vehovar is a full professor of Statistics at the Faculty of Social Sciences, University of Ljubljana, Slovenia. From 1996 he has been the principal investigator of the national project Research on Internet in Slovenia (RIS), the leading source for information society research in Slovenia. He is also involved in various EU information society research projects. He is responsible for development of the WebSM portal devoted to web survey methodology and was the coordinator of the corresponding EU Framework project. In 2009, he has received the AAPOR Warren J. Mitofski Innovators Award for the WebSM website, together with Katja Lozar Manfreda. His research interests span from survey methodology to information society issues.

Nonsampling Errors in Surveys

Judith M. Tanur
Distinguished Teaching Professor Emerita
Stony Brook University, Stony Brook, NY, USA

The term "nonsampling errors" is usually employed to refer to all the problems that can occur in sample surveys with the exception of sampling error (which is the inherent variability of estimates from sample to sample (See the entry Sampling distributions). Mosteller (1978), in a classic article that is outdated in detail but still very much worth reading, uses the term more broadly so that it refers to experiments as well as surveys. In his usage it includes such things as the Hawthorne Effect and bad breaks in random assignment; the usage here will be confined to sample surveys.

Broadly, nonsampling error can be broken down into five categories as shown in Fig. 1: specification errors, coverage errors, nonresponse, response errors, and processing errors. In this article these types of errors will be discussed separately, but the reader should note that in reality the issues overlap and interact – for example, a question that tends to produce confusion in a mail survey may work perfectly well in person. In addition, a brief article such as this cannot address all possible nonsampling errors that are discussed in the literature. Please see the references at the end of the article for fuller treatments, some older and some newer; see also the article on Total Survey Error.

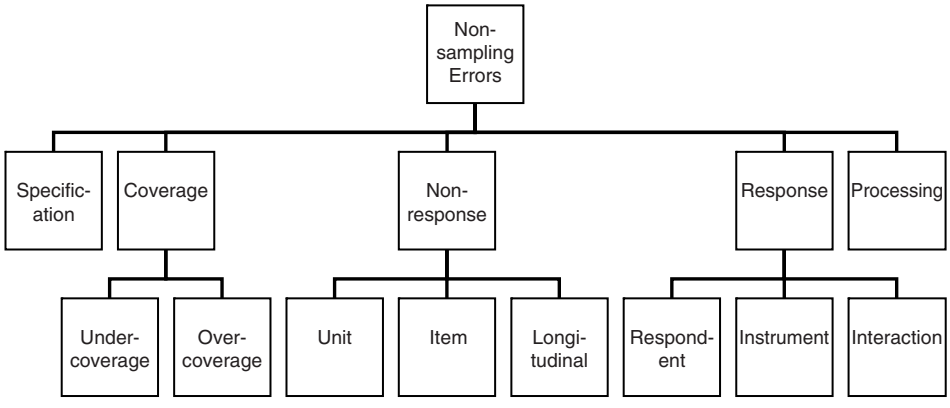
Specification Errors

Specification errors occur in the planning stage of a survey if researchers prepare an instrument that does not collect the data necessary to meet the objectives of the study. Leaving out a question the answer to which would be crucial to the analysis would be an example.

Coverage Errors

Undercoverage errors occur when members of the target population are missing from the frame from which the sample is drawn. Early in the twentieth century, for example, sample surveys in the United States had to be done via in-person interviewing or by mail because telephone penetration was sufficiently small as to make telephone numbers a frame that suffered from undercoverage in representing the US population. As telephone penetration grew to close to 100% towards the end of the twentieth century, telephone interviewing (especially random digit dialing using CATI, computer-assisted telephone interviewing) became the method of choice for many governmental and non-governmental surveys. Now as more and more households replace their landlines with cell phones, methods using random digit dialing sampling again suffer from undercoverage, and methods are being devised to reach the cell-phone only population. (This is especially difficult in the United States where there are legal prohibitions against using automated dialers to call cell phones.) A turn toward what has been dubbed "address-based sampling" is one current solution to these undercoverage problems – the method uses post-office address lists (which are usually quite complete) and then reaches households either via phone if they can be traced through reverse directories, via mail, or as a last resort because of the expense involved, in person.

Overcoverage errors occur when the frame includes individuals who are not members of the target population, as when those who will not vote in an election are interviewed about their voting intentions and their answers



Nonsampling Errors in Surveys. Fig. 1 Conceptualization of nonsampling errors

included in estimates of candidates' popularity with voters. Survey researchers have devised careful questioning and weighting procedures (most of them proprietary) to deal with this problem of overcoverage in pre-election surveys. The issues are less straightforward in other types of surveys.

Nonresponse Errors

If a unit from the population designated to be in the sample cannot be reached or refuses to participate in the survey, then what is called unit nonresponse occurs. To avoid unit nonresponse survey researchers make repeated call-backs and often offer incentives to participate. Nonresponse *error* occurs to the extent that nonresponders are different from responders and hence estimates of the quantities of interest in the survey are biased. Often a subsample of nonresponders is pursued with special efforts, both to reduce unit nonresponse and to estimate nonresponse error on the theory that hard-to-reach respondents are more similar to nonrespondents than are other respondents.

If a unit from the population responds to the survey but leaves out answers to some of the questions, those omissions are referred to as item nonresponse. When there is item nonresponse the editing process for a survey often "fills in" those blanks by a process known as ▶imputation. (Imputation is also sometimes used for unit nonresponse.)

When a survey is longitudinal, a so-called panel survey, in which respondents are questioned several times over a period of months or years, there is a special kind of nonresponse when a respondent who has given answers during previous rounds of the survey cannot be contacted or refuses to answer in the current round. Survey researchers who carry out longitudinal surveys put in place careful procedures to keep in touch with respondents to help avoid this kind of panel attrition.

Response Errors

When a respondent gives an answer to a survey question, but that answer is "wrong," a response error occurs.

Of course, respondents can simply lie, and one of the reasons for lying is to maintain one's self presentation. Hence there is a class of so-called sensitive questions that researchers often suspect respondents will be reluctant to answer truthfully – for example, questions about illegal acts or about sexual behavior. Methods for reducing respondents' tendency to respond untruthfully to sensitive questions include introducing the question with a statement that many people actually indulge in that behavior, through arranging for the respondent to answer privately (which always is the case in a mailed survey and which can be done in-person through a sealed ballot box or by having the respondent him/herself enter responses on the computer screen out of view of the interviewer). A randomized response protocol has been developed in which the respondent does a randomization (e.g., tosses a coin) and depending on the outcome (which is unknown to the interviewer) answers the sensitive question or an innocuous one (e.g., does your social security number end in an even digit?). Since both the probability distribution for the outcome of the randomization device and that for the answer to the innocuous question are known, an estimate of the proportion of respondents admitting to the sensitive behavior can be generated. Of course, complications arise with any attempt to relate those answers to other variables.

Sometimes respondents give an incorrect answer because of memory problems. Survey researchers have developed memory aids to help solve this problem – for example, a respondent can fill in a time line in order to remember events in his/her own history. In a longitudinal study, often the events reported in the first interview are not used as data but only to "bound" the respondent's memory in the subsequent interview. In the second and subsequent interviews, the respondent is reminded about the events s/he reported up to the time of the previous interview and asked what has happened since that time. A special kind of forgetting is called "telescoping," in which the respondent reports events that happened before the start of the reference period as having happened during the reference period. Huttenlocher et al. (1990) have shown that telescoping can be a natural result of how elapsed time is stored in memory.

Instrument Errors

The differing modes of survey presentation, whether an in-person interview (using either a paper ▶questionnaire or a computer), a mailed questionnaire, a survey on the web, or a telephone interview can make a difference in how the respondent understands and answers the questions. This is a broad field of study; a current reference is Biemer and Lyberg (2003). Don Dillman and his colleagues have made deep studies of the effects of the physical form of the questionnaire and of how to design both paper surveys and computer displays to avoid errors generated by the physical layout. See, for example, Dillman et al. (2009).

The problem of wording of questions and their effect on nonsampling error was for many years more of an art than a science. In recent years some progress has been made in systematizing this knowledge and providing theoretical underpinnings. The movement to study cognitive aspects of survey methodology (CASM) was given impetus by a

seminar described the Jabine et al. (1984). It is now standard practice to do cognitive interviewing as part of the questionnaire design and testing process and thus avoid some misunderstandings as sources of nonsampling error. Useful works contributing to this part of the understanding of nonsampling errors are Tanur (1992), Tourangeau et al. (2000) and Sudman et al. (1996).

Interaction

The earliest surveys, Converse (1987) reports, were carried out by a researcher on his/her own behalf – interviewing respondents to find out what s/he wanted to know. It was an individual effort and conversations were often quite informal, with the aim of getting the information needed from the respondent and without any particular effort to standardize the questions asked. But as surveys got larger and the number of interviewers grew correspondingly large, researchers began to insist on standardization. The ideal was to have every interviewer ask every respondent the same questions in the same order using the exact same words and the same intonation. In a landmark article Suchman and Jordan (1990) showed that such standardization could sometime not only irritate respondents to the extent that they would be reluctant to continue the interview, but could also lead to such gross misunderstandings that incorrect data were recorded, thus providing another source of nonsampling error. Michael Schober and Fred Conrad and their colleagues (e.g., Conrad and Schober 2000) have experimented with conversational interviewing to try to alleviate that problem. They find, in particular, that when the respondent's situation is complicated, conversational interviewing is more likely to result in accurate data than more standardized procedures. When the respondent's situation is simple there seems to be little gain in conversational interviewing.

The race of the interviewer and of the respondent and whether they match have long been suspected as sources of nonsampling error. By the early 1980s survey researchers believed that the race of the interviewer had an effect only when the topic was itself concerned racial matters. In recent pre-election polling in the United States there was fear that a so-called Bradley effect (or Wilder effect) might occur. Such a putative effect posits that white respondents are unwilling to say that they would vote against a Black candidate when interviewed, but were willing to vote against a Black candidate in the privacy of the voting booth. There seems to be little evidence that a Bradley effect occurred in the polling the preceded the election of Barak Obama in 2008.

Processing

As survey data are edited for consistency and for imputation, errors can be introduced. Vigilance and both computer and human checking are the only ways such errors can be caught and corrected.

About the Author

Judith M. Tanur is Distinguished Teaching Professor Emerita in the Sociology Department, Stony Brook University. She has authored or co-authored over 75 papers and written or edited nine books. She has served on the Board of Directors of the American Statistical Association and received its Founders' Award (1997). She is a Fellow of the American Statistical Association (1980), the American Association for the Advancement of Science (1983), the American Psychological Society (2007), and an Elected member of the International Statistical Association (1987). She was a co-winner of the Innovators Award from the American Association for Public Opinion Research in 2005 for the creation of the Interdisciplinary Workshop on Cognitive Aspects of Survey Methodology. Professor Tanur is known as a co-editor (with William Kruskal) of the *International Encyclopedia of Statistics*, Free Press, l978.

Non-uniform Random Variate Generations

Professor, DIRO
Université de Montréal, Montréal, QC, Canada

Introduction

As explained in the entry ►Uniform Random Number Generators, the simulation of random variables on a computer operates in two steps: In the first step, uniform random number generators produce imitations of i.i.d. $U(0,1)$ (uniform over (0,1)) random variables, and in the second step these numbers are transformed in an appropriate way to imitate random variables from other distributions than the uniform ones, and other types of random objects. Here we discuss the second step only, assuming that infinite sequences of (truly) i.i.d. $U(0,1)$ random variables are available from the first step. This assumption is not realized exactly in software implementations, but good-enough approximations are available (L'Ecuyer 2004).

For some distributions, simple exact transformations from the uniform to the target distribution are available, usually based on the inversion method. But for many types of distributions and processes, in particular those having shape parameters, and multivariate distributions, one relies on approximations that require a compromise between efficiency and approximation error. That is, the sampling is not always done exactly from the target distribution, but the discrepancy between the sampling and target distributions can often be made smaller with more work. This work is generally divided in two parts: A one-time setup cost to compute constants and tables that depend on the distribution parameters, and a marginal cost for each random variate generated from this distribution. The marginal speed and also the quality of the approximation can often be improved by a larger investment in the setup time, sometimes to precompute larger tables. This investment can be worthwhile when a large number of random variates has to be generated from the same distribution, with the same shape parameters. Robustness with respect to shape parameters is another issue: Some methods provide a good approximation only in a certain range of values of these parameters, so one must be careful not to use the generator outside that range.

Generally speaking, inversion should be the preferred method whenever it is feasible and not too inefficient, because of its compatibility with important variance-reduction techniques such as common random numbers, antithetic variates, randomized quasi-Monte Carlo, etc. (Law and Kelton 2000; L'Ecuyer 2009).

Inversion is not always convenient, in particular for complicated multivariate distributions, for which the density is sometimes known only up to a multiplicative constant. One important approximation method for that situation is Markov chain Monte Carlo (MCMC) (*see* ►Markov Chain Monte Carlo Methods), which constructs an artificial Markov chain (see ►Markov Chains) whose stationary distribution is the target distribution. A random variate that follows approximately the target distribution is obtained by returning the current state after running the Markov chain long enough; *see* the entry ►Monte Carlo Statistical Methods.

In the remainder, we briefly summarize some of the most basic techniques. Detailed coverages of non-uniform variate generation can be found in (Devroye (1986; 2006) and Hörmann et al. 2004).

Inversion

A general transformation that provides a univariate random variable X having the cumulative distribution function (cdf) F from a $U(0,1)$ random variable U is $X = F^{-1}(U)$, where $F^{-1} : [0,1] \to \mathbb{R}$ is the inverse distribution function, defined as

$$F^{-1}(u) \stackrel{\text{def}}{=} \inf\{x \in \mathbb{R} \mid F(x) \geq u\}.$$

This is the *inversion method*.

As an illustration, if X is a binomial random variable with parameters $(n,p) = (2,0.4)$, then we have $P[X = i] = p_i$ where $p_0 = (0.6)^2 = 0.36$, $p_1 = 2 \times 0.6 \times 0.4 = 0.48$, $p_2 = (0.4)^2 = 0.16$, and $p_i = 0$ elsewhere. Inversion then returns $X = 0$ if $U < 0.36$, $X = 1$ if $0.36 \leq U < 0.84$, and $X = 2$ if $U \geq 0.84$. Another simple way of generating X here is to generate two Bernoulli random variables X_1 and X_2 by inversion from two independent uniforms U_1 and U_2, i.e., $X_1 = \mathbb{I}[U_1 < p]$ and $X_2 = \mathbb{I}[U_2 < p]$, where $\mathbb{I}$ is the indicator function, and return $X = X_1 + X_2$. This method requires two uniforms and is not inversion for X.

For certain distributions, there is a closed-form formula for F^{-1}. For example, if X has a discrete uniform distribution over $\{0,\ldots,k-1\}$, we have $X = F^{-1}(U) = \lfloor kU \rfloor$. If X is geometric with parameter p, so $P[X = x] = p(1-p)^x$ for $x = 0,1,\ldots$, we have $X = F^{-1}(U) = \lceil \ln(1-U)/\ln(1-p) \rceil - 1 = \lfloor \ln(1-U)/\ln(1-p) \rfloor$ with probability 1. If X is exponential, with rate λ, then $X = F^{-1}(U) = -\ln(1-U)/\lambda$. To generate X with cdf F but truncated to an interval $(a,b]$, it suffices to generate U uniform over $(F(a),F(b)]$, and to return $F^{-1}(U)$.

For certain distributions there is no closed-form expression for F^{-1} but good numerical approximations are available. For distributions having a location and a scale parameter, we only need a good approximation of F^{-1} for the standardized form of the distribution, say with location at 0 and scale 1. We generate from the standardized distribution, then multiply by the scale parameter and add the location parameter. This applies in particular to the normal distribution, for which good numerical approximations of the standard inverse cdf Φ^{-1} are available. For example, the `probdist` package of SSJ (L'Ecuyer 2008) implements a slight modification of a rational Chebyshev approximation proposed in Blair et al. (1976), which is quite fast and provides essentially machine-precision accuracy when using 64-bit floating point numbers. For any $u \in (0,1)$ that can be represented by such a floating-point number (given as input), the approximation procedure returns $\Phi^{-1}(u)$ with relative error smaller than 10^{-15}.

In general, given an approximation $\tilde{F}^{-1}$ of F^{-1}, the absolute error on X for a given U is $|\tilde{F}^{-1}(U) - F^{-1}(U)|$. The corresponding error on U is $|F(\tilde{F}^{-1}(U)) - U|$. This second error can hardly be less than the error in the representation of U, and we are also limited by the machine precision on the representation of X. If one of these two limits is reached for each $U \in [0,1]$, for practical purposes we have an exact inversion method.

When shape parameters are involved (e.g., for the gamma and beta distributions), things are more complicated because a different approximation of F^{-1} must be constructed for each choice of shape parameters.

When we have an algorithm for computing F but not F^{-1}, and F is continuous, as a last resort we can always approximate $X = F^{-1}(U)$ by a numerical method that finds a root of the equation $U = F(X)$ for a given U. For instance, we can run the robust Brent-Dekker iterative root finding algorithm (Brent 1973, Chapter 4) until we have reached the required precision, as done by default in SSJ (L'Ecuyer 2008).

Faster inversion algorithms for fixed shape parameters can be constructed if we are ready to invest in setup time. These methods are called *automatic* when the code that approximates F^{-1} is produced automatically by a general one-time setup algorithm (Hörmann et al. 2004). The setup computes tables that contain the interpolation points and coefficients. With these tables in hand, random variate generation is very fast. For example, a general adaptive method that constructs an accurate Hermite interpolation method for F^{-1}, given a function that computes F, is developed in Hörmann and Leydold (2003). In Derflinger (2010), the authors propose an algorithm that constructs an approximation of F^{-1} to a given accuracy (specified by the user) for the case where only the density of X is available. This algorithm is an improvement over similar methods in Ahrens and Kohrt (1981). These methods assume that the distribution has bounded support, but they can be applied to most other distributions by truncating the tails far enough for the error to be negligible.

For discrete distributions, say over the values $x_1 < \cdots < x_k$, inversion finds $I = \min\{i \mid F(x_i) \geq U\}$ and return $X = x_I$. To do this, one may first tabulate the pairs $(x_i, F(x_i))$ for $i = 1,\ldots,k$, and then find I by sequential or binary search in the table (L'Ecuyer 2004). However, the fastest implementation when k is large is obtained by using an index (Chen and Asau 1974; Devroye 1986). The idea is to partition the interval $(0,1)$ into c subintervals of equal sizes, $[j/c,\ (j+1)/c)$ for $j = 0,\ldots,c-1$, and store the smallest and largest possible values of X for each subinterval, namely $L_j = F^{-1}(j/c)$ and $R_j = F^{-1}((j+1)/c)$. Once U is generated, we find the corresponding interval number $J = \lfloor cU \rfloor$, and search for I only in that interval, with linear or binary search. The fastest average time per call is usually obtained by taking a large c (so that k/c does not exceed a few units), and linear search in the subintervals (to minimize the overhead). The resulting algorithm is as fast (on average) as the alias method (Law and Kelton 2000; Walker 1974), which is often presented as the fastest algorithm but does not preserve inversion. If k is large or even infinite, for example for the Poisson distribution or the ▶binomial distribution with a large n, the pairs $(x_i, F(x_i))$ are precomputed and tabulated only in the areas where the probabilities are not too small, usually around the center of the distribution. Other values are computed dynamically only in the very rare cases where they are needed. Similar indexing techniques can also be used for piecewise-polynomial approximations of F^{-1} for continuous distributions.

Rejection Methods and Thinning

When inversion is too costly, the alternative is often a rejection method. It works as follows. Suppose we want to generate X from density f. It suffices to know f up to a multiplicative constant, i.e., to know κf, where κ might be unknown. If f is known, we take $\kappa = 1$. We pick a density

r such that $\kappa f(x) \le t(x) \stackrel{\text{def}}{=} ar(x)$ for all x for some constant a, and such that sampling random variates Y from r is easy. The function t is called a *hat function*. Integrating this inequality with respect to x on both sides, we find that $\kappa \le a$. To generate X with density f, we generate Y from the density r and $U \sim U(0,1)$ independent of Y, repeat this until $Ut(Y) \le \kappa f(Y)$, and return $X = Y$ (Devroye 1986; von Neumann 1951). The number of times we have to retry is a geometric random variable with mean $a/\kappa - 1 \ge 0$. We want a/κ to be as small as possible.

If κf is expensive to compute, computations can often be accelerated by using *squeeze functions* q_1 and q_2 that are less costly to evaluate and such that $q_1(x) \le \kappa f(x) \le q_2(x) \le t(x)$ for all x. After generating Y, we first check if $Ut(Y) \le q_1(Y)$. If so we accept Y immediately. Otherwise if $Ut(Y) \ge q_2(Y)$, we reject Y immediately. We verify the condition $Ut(Y) \le \kappa f(Y)$ explicitly only when none of the two previous inequalities is satisfied. One may also use multiple levels of embedded squeezing, with crude squeezing functions that are very quick to evaluate at the first level, then tighter but slightly more expensive ones at the second level, and so on.

In most practical situations, rejection is combined with a change of variable to transform the original density into a nicer one, for which a more efficient implementation of the rejection method can be constructed. The change of variable can be selected so that the transformed density is concave and a piecewise linear hat function is easy to construct. Typical examples of transformations can be $T(x) = \log x$ and $T(x) = -x^{-1/2}$, for instance (Devroye 1986; Hörmann et al. 2004). The rejection method also works for discrete distributions; we just replace the densities by the probability mass functions.

One special case of change of variable combined with rejection leads to the *ratio-of-uniforms* method. It is based on the observation that if X has density f over the real line, κ is a positive constant, and the pair (U, V) has the uniform distribution over the set

$$C = \left\{(u,v) \in \mathbb{R}^2 \text{ such that } 0 \le u \le \sqrt{\kappa f(v/u)}\right\},$$

then V/U has the same distribution as X (Devroye 1986; Kinderman and Monahan 1977). Thus, one can generate X by generating (U, V) uniformly over C, usually by a rejection method, and returning $X = V/U$.

A special form of rejection called *thinning* is frequently used to generate non-homogeneous ►point processes. For example, suppose we want to generate the jump times of a Poisson process (see ►Poisson Processes) whose time-varying rate is $\{\lambda(t), t \ge 0\}$, where $\lambda(t) \le \bar{\lambda}$ at all time t for some constant $\bar{\lambda}$. Then we can generate *pseudo-jumps* at constant rate $\bar{\lambda}$ by generating the times between successive jumps as i.i.d. exponentials with mean $1/\bar{\lambda}$. A pseudo-jump at time t is accepted (becomes a real jump) with probability $\lambda(t)/\bar{\lambda}$.

Multivariate Distributions

A d-dimensional *random vector* $\mathbf{X} = (X_1, \ldots, X_d)^t$ has distribution function F if $\mathbb{P}[X_1 \le x_1, \ldots, X_d \le x_d] = F(x_1, \ldots, x_d)$ for all $\mathbf{x} = (x_1, \ldots, x_d)^t \in \mathbb{R}^d$. The distribution function of a random vector does not have an inverse in general, so the inversion method does not apply directly to multivariate distributions. There are situations where one can generate X_1 directly by inversion from its marginal distribution, then generate X_2 by inversion from its marginal distribution conditional on X_1, then generate X_3 by inversion from its marginal distribution conditional on (X_1, X_2), and so on. But this is not always possible or convenient.

There are important classes of multivariate distributions for which simple and elegant methods are available. For example, suppose $\mathbf{X}$ has a *multinormal distribution* with mean vector $\boldsymbol{\mu}$ and covariance matrix $\boldsymbol{\Sigma}$. When $\boldsymbol{\mu} = \mathbf{0}$ and $\boldsymbol{\Sigma} = \mathbf{I}$ (the identity), we have a *standard multinormal* distribution. This one is easy to generate: the coordinates are independent standard normals, and they can be generated separately by inversion. For the general case, it suffices to decompose $\Sigma = \mathbf{A}\mathbf{A}^t$, generate $\mathbf{Z}$ standard multinormal, and return $\mathbf{X} = \boldsymbol{\mu} + \mathbf{A}\mathbf{Z}$. The most popular way to decompose $\boldsymbol{\Sigma}$ is the Cholesky decomposition, for which $\mathbf{A}$ is lower triangular, but there are in fact many other possibilities, including for example the eigendecomposition as in ►principal component analysis. The choice of decomposition can have a large impact on the variance reduction in the context of randomized quasi-Monte Carlo integration, by concentrating much of the variance on just a few underlying uniform random numbers (Glasserman 2004; L'Ecuyer 2009).

Multivariate normals are useful for various purposes. For example, to generate a random point on a sphere in d dimensions centered at zero, generate a standard multinormal vector $\mathbf{Z}$, then normalize its length to the desired radius. This is equivalent to generating a *random direction*. A more general class of multivariate distributions named *radially symmetric* are defined by putting $\mathbf{X} = R\mathbf{Z}/\|\mathbf{Z}\|$ where $\mathbf{Z}/\|\mathbf{Z}\|$ is a random direction and R has an arbitrary distribution over $(0, \infty)$. For example, if R has the Student distribution, then $\mathbf{X}$ is multivariate Student. A further generalization yields the *elliptic multivariate* random variable: $\mathbf{X} = \boldsymbol{\mu} + R\mathbf{A}\mathbf{Z}/\|\mathbf{Z}\|$ where $\mathbf{Z}$ is a multinormal in k dimensions and $\mathbf{A}$ is a $d \times k$ matrix. It is easy to generate $\mathbf{X}$ if we know how to generate R.

A very rich class of multivariate distributions are defined via *copula methods* (Hörmann and Derflinger 2002; Nelsen 1999). Start with an arbitrary d-dimensional cdf G with continuous marginals G_j, generate $\mathbf{Y} = (Y_1, \ldots, Y_d)^t$ from G, and let $\mathbf{U} = (U_1, \ldots, U_d) = (G_1(Y_1), \ldots, G_d(Y_d))^t$. At this point, the U_j have the uniform distribution over $(0,1)$, but they are not independent in general. The cdf of $\mathbf{U}$ is the *copula associated with* G and it specifies the dependence structure of the vector $\mathbf{U}$. In fact, any cdf over $(0,1)^d$ with uniform marginals can act as a copula. To generate a vector $\mathbf{X} = (X_1, \ldots, X_d)^t$ with arbitrary marginal cdf's F_j and a dependence structure specified by this copula, just put $X_j = F_j^{-1}(U_j)$ for each j. A popular choice for G is the multinormal cdf with standard normal marginals; then $\mathbf{Y}$ and $\mathbf{U}$ are easy to generate, and one can select the correlation matrix of $\mathbf{Y}$ to approximate a target correlation (or rank correlation) matrix for $\mathbf{X}$. This is known as the NORTA (normal to anything) method. It can usually match the correlations pretty well. But to approximate the whole dependence structure in general, a much richer variety of ▶copulas is required (Hörmann and Derflinger 2002; Nelsen 1999).

The rejection method extends rather straightforwardly to the multivariate case. For a known target d-dimensional density f, pick a d-dimensional density r such that $f(\mathbf{x}) \le ar(\mathbf{x})$ for all $\mathbf{x}$ and some constant a, and such that sampling random vectors $\mathbf{Y}$ from r is easy. To generate $\mathbf{X}$ with density f, generate $\mathbf{Y}$ from r and $U \sim U(0,1)$ independent of $\mathbf{Y}$, until $Uar(\mathbf{Y}) \le f(\mathbf{Y})$, and return $\mathbf{X} = \mathbf{Y}$.

Stochastic Processes

Various types of ▶stochastic processes can be simulated in a way that becomes obvious from their definition. The *Lévy processes* form an important class; they are continuous-time stochastic processes $\{Y(t), t \ge 0\}$ with $Y(0) = 0$ and whose increments over disjoint time intervals are independent, and for which the increment over a time interval of length t has a distribution that depends only on t (the mean and standard deviation must be proportional to t) (Asmussen and Glynn 2007; Bertoin 1996). Special instances include the (univariate or multivariate) *Brownian motion* (*see* ▶Brownian Motion and Diffusions), the stationary *Poisson process*, the *gamma process*, and the *inverse Gaussian process*, for example, whose increments have the (multi)normal, Poisson, gamma, and inverse Gaussian distributions (*see* ▶Inverse Gaussian Distribution), respectively. A natural way to generate a Lévy process observed at times $0 = t_0 < t_1 < \cdots < t_c$ is to generate the independent increments $Y(t_j) - Y(t_{j-1})$ successively, for $j = 1, \ldots, c$. This is the *random walk* method.

For certain ▶Lévy processes (such as those mentioned above), for any $t_1 < s < t_2$, it is also easy to generate $Y(s)$ from its distribution *conditional* on $\{Y(t_1) = y_1, Y(t_2) = y_2\}$ for arbitrary y_1, y_2. Then the trajectory can be generated via the following *Lévy bridge sampling* strategy, where we assume for simplicity that c is a power of 2. We start by generating $Y(t_c)$ from the distribution of the increment over $[0, t_c]$, then we generate $Y(t_{c/2})$ from its distribution conditional on $(Y(t_0), Y(t_c))$, then we apply the same technique recursively to generate $Y(t_{c/4})$ conditional on $(Y(t_0), Y(t_{c/2}))$, $Y(t_{3c/4})$ conditional on $(Y(t_{c/2}), Y(t_c))$, $Y(t_{c/8})$ conditional on $(Y(t_0), Y(t_{c/4}))$, and so on. This method is convenient if one wishes to later refine the approximation of a trajectory. It is also effective for reducing the effective dimension in the context of quasi-Monte Carlo methods (L'Ecuyer 2009).

For the Poisson process, one usually wishes to have the individual jump times, and not only the numbers of jumps in predetermined time intervals. For a stationary Poisson process, the times between successive jumps are easy to generate, because they are independent exponential random variables. For a non-stationary Poisson process, one way is to apply a nonlinear time transformation to turn it into a standard stationary Poisson process of rate 1, generate the jumps times of the standard process, and apply the reverse time transformation to recover the jump times of the target non-stationary Poisson process. This idea applies to other continuous-time stochastic processes as well, as we now explain.

Given a process $X = \{X(t), t \ge 0\}$, and another process $T = \{T(t), t \ge 0\}$ with nondecreasing trajectories, called a *subordinator*, we can define a new process $Y = \{Y(t) \stackrel{\text{def}}{=} X(T(t)), t \ge 0\}$, which is the process X to which we have applied a random time change. This can be applied to any process X with index $t \in \mathbb{R}$. If both X and T are Lévy processes, then so is Y. If X is a stationary Poisson process with rate 1 and we want a nonstationary Poisson process Y with rate function $\{\lambda(t), t \ge 0\}$, then we must take $T(t) = \Lambda(t) \stackrel{\text{def}}{=} \int_0^t \lambda(s)\mathrm{d}s$. To simulate Y, we generate the jump times $Z_1 < Z_2 < \cdots$ of the stationary process X by generating $Z_j - Z_{j-1}$ as independent exponentials with mean 1, and define the jump times of Y as $T_j = \Lambda^{-1}(Z_j)$ for $j \ge 1$.

If X is a one-dimensional Brownian motion, the random time change is equivalent to replacing the constant volatility parameter σ of the Brownian motion by a stochastic (time-varying) volatility process $\{\sigma(t), t \ge 0\}$. Two notable examples of Lévy processes that can act as subordinators are the gamma process and the inverse Gaussian process, respectively. Their use as subordinators

for the Brownian motion yields the variance gamma and the normal inverse Gaussian processes. Brownian motions with such a random time change do provide a much better fit to various types of financial data (such as the log prices of stocks and commodities, etc.) than standard Brownian motions, and they recently became popular for this reason.

Brief Historical Background

The normal distribution is used extensively in probability theory, statistics, and the natural and social sciences. It is also called the Gaussian distribution because Carl Friedrich Gauss (1809) used it to analyze astronomical data. The normal distribution was (a) first introduced by Abraham de Moivre (1733), as an approximation to a ►binomial distribution (b) used by Laplace (1774), as an approximation to hypergeometric distribution to analyze errors of experiments and (c) employed, in the past, by Legendre, Peirce, Galton, Lexis, Quetelet, etc. The normal distribution can be used as an approximation to other distributions because the standardized sum of a large number of independent and identically distributed random variables is approximately normally distributed. Thus, the normal distribution can be used when a large number

of non-normal distribution correspond more closely to observed values. The 1816 work of Gauss (Gauss 1816) is the earliest result of this kind when he derived the normal distribution as the sum of a large number of independent astronomical data errors. The central limit theorem (see ►Central Limit Theorems) for independent and identically distributed random variables was established by Lyapunov (1900). This result was extended to non identically distributed random variables by Lindeberg (1922) and for non-independent random variables later on (see Loève 1963; Gnedenko and Kolmogorov 1954).

Important Properties and Results

The normal distribution has a continuous probability density function which is bell-shaped and has its maximum at the mean (Figs. 1 (Normal densities) and 2 (Cumulative distribution functions)).

The expression for density function along with various basic important results are listed below:

1. Notation: $X \sim N(\mu, \sigma^2)$
2. Probability density function:

$$f(x) = ((2\pi)^{1/2}\sigma)^{-1} \exp[-(x-\mu)^2/(2\sigma^2)], -\infty < x, \mu < \infty, \sigma > 0$$

3. Mean (location parameter), Median, and Mode: $E(X) = \mu$ = median = mode.
4. Variance (shape parameter): $V(X) = \sigma^2$
5. Coefficient of skewness: $\tau_3 = 0$
6. Coefficient of kurtosis: $\tau_4 = 3$
7. Standard normal variate: $Y = (X-\mu)/\sigma \sim N(0,1)$
8. Standard normal density function: $\phi(y) = (2\pi)^{-1/2} \exp(-y^2/2), -\infty < y < \infty$
9. Folded normal density function: $g(y) = 2((2\pi)^{1/2}\sigma)^{-1} \exp[-y^2/(2\sigma^2)], y > 0, \sigma > 0$
10. Cumulative distribution function corresponding to (8):

$$\varphi(x) = \left[1 + erf\left(x/\sqrt{2}\right)\right]/2,$$

$$\text{where } erf(x) = (2/\pi^{1/2}) \int_0^x e^{-t^2} dt = (2/\pi^{1/2}) \sum_{n=0}^{\infty} [(-1)^n x^{2n+1}/\{n!(2n+1)\}].$$

11. ►Moment generating function:

$$M_X(t) = \exp(\mu t + \sigma^2 t^2/2)$$

12. Characteristic function:

$$\phi_X(t) = \exp(i\mu t - \sigma^2 t^2/2), i = (-1)^{1/2}$$

13. nth central moment:

$$\mu_n = E(X-\mu)^n = \begin{cases} 0, & n\text{-odd} \\ n!\sigma^n/[2^{n/2}(n/2)!], & n\text{-even} \end{cases}$$

14. L-moments: $\lambda_1 = \mu, \lambda_2 = \sigma/\pi^{1/2}, \lambda_3 = 0$
15. Shannon entropy: $H(X) = (1/2)\ln(2\pi e\sigma^2)$
16. Rényi entropy of order α:

$$H_\alpha(X) = (1/2)\ln(2\pi\sigma^2) - (\ln\alpha)/[2(1-\alpha)]$$

17. Song measure: $V(\ln f(X)) = -2 \lim_{\alpha \to 1} \frac{dH_\alpha(X)}{d\alpha} = 1/2$

Normal Distribution, Univariate. Fig. 2 $N(-1,1/4):\ldots;N(0,1):$ _____; $N(1.5,4):$ _____

18. Fisher information: (a) of the distribution of X is $I(X)=\sigma^{-2}$, (b) with respect to μ is $I(\mu)=\sigma^{-2}$ and (c) with respect to σ^2 is $I(\sigma^2)=(2\sigma^4)^{-1}$

Some properties of the normal distribution are given below:

19. If $X\sim N(\mu,\sigma^2)$, then (a) $aX+b\sim N(a\mu+b,a^2\sigma^2)$, where a and b are real numbers and (b) $Y=e^X\sim \log normal(\mu,\sigma^2)$.
20. If $X_1,\ldots,X_n$ with $X_i\sim N\left(\mu_i,\sigma_i^2\right),i=1,\ldots,n$ are independent, then $\sum_{i=1}^{n}a_iX_i\sim N\left(\sum_{i=1}^{n}a_i\mu_i,\sum_{i=1}^{n}a_i^2\sigma_i^2\right)$ where $a_1,\ldots,a_n$ are real numbers.
21. If $X_1,\ldots,X_n$, $X_i\sim N(0,1),i=1,\ldots,n$ are independent, then $\sum_{i=1}^{n}X_i^2\sim\chi_n^2$.
22. For a sample of size n from $N(\mu,\sigma^2)$, the sample mean $\overline{X}=\sum_{i=1}^{n}X_i/n$ and sample variance $S^2=\sum_{i=1}^{n}(X_i-\overline{X})^2/(n-1)$ are independent.
23. If $X_i\sim N(0,1),i=1,2$, then $Y=X_1/X_2$ has the Cauchy distribution with density function $g(y)=[\pi(1+y^2)]^{-1},y\in\Re$.
24. If $X\sim N(0,\sigma^2)$, then $|X|$ is folded normal.
25. Central Limit Theorem (Lyapunov): If $X_1,\ldots,X_n$ are independent and identically distributed random variables with finite mean and variance, then $[\overline{X}-E(\overline{X})]/[V(\overline{X})^{1/2}]\sim N(0,1)$, as $n\to\infty$.

Importance of Normal Distribution in Statistics

26. The sample mean $\overline{X}$: (a) is the maximum likelihood estimator for the population mean μ and (b) has the distribution $N(\mu,\sigma^2/n)$.
27. The sample variance S^2 is the unbiased estimator for the population variance σ^2.
28. $(n-1)S^2/\sigma^2\sim\chi_{n-1}^2$.
29. $S^2\sim\Gamma((n-1)/2,2\sigma^2/(n-1))$.
30. Moment Estimators: The method of moments leads to estimating μ by $\overline{X}$ and σ^2 by $\sum_{i=1}^{n}(X_i-\overline{X})^2/n$.
31. The sample mean of i.i.d random variables $X_i\sim N(\mu,\sigma^2),i=1,\ldots,n$ is consistent for μ and the sample variance for σ^2.
32. The statistic $(\overline{X},S^2)$ is a sufficient statistic for (μ,σ^2).
33. ▶Cramér-Rao inequality implies that $\overline{X}$ is the minimum variance unbiased estimator of μ. In other words, $\overline{X}$ is efficient.
34. Confidence Intervals: Let $X_1,\ldots,X_n$ be i.i.d random variables with $X_i\sim N(\mu,\sigma^2),i=1,\ldots,n$. Then the symmetric $(1-\alpha)$-level confidence interval:
    (a) for μ, given σ^2, is $(\overline{X}-z_{\alpha/2}\sigma/n^{1/2},\overline{X}+z_{\alpha/2}\sigma/n^{1/2})$, where $z_{\alpha/2}$ is given by $P(Y\geq z_{\alpha/2})=\alpha/2$, for $Y\sim N(0,1)$;
    (b) for σ^2, with μ unknown, is $((n-1)S^2/\chi_{n-1,\alpha/2}^2,(n-1)S^2/\chi_{n-1,1-\alpha/2}^2)$, and
    (c) for σ^2, with μ known, is

$$\left(\sum_{i=1}^{n}(X_i-\mu)^2/\chi_{n,\alpha/2}^2,\sum_{i=1}^{n}(X_i-\mu)^2/\chi_{n,1-\alpha/2}^2\right).$$

The confidence intervals are used in hypotheses testing problems involving μ and σ^2.

An Approximation to the Normal Distribution

Several approximations to the normal distribution are available in the literature. In 2006, Rathie and Swamee (see Rathie et al. 2008) defined a family of invertible distributions by taking the generalized logistic distribution function as

35. $F(x) = \left[1 + \exp\{-x(a + b|x|^p)\}\right]^{-1}, x \in \Re, a, b, p > 0.$

This distribution is a very good approximation for $a = 1.59413, b = 0.07443$, and $p = 1.939$ with a maximum error of (a) 4×10^{-4} at $x = 0$, to the standard normal density function, and (b) 7.757×10^{-5} at $x = \pm 2.81$ to the cumulative standard normal distribution function. It may be pointed out that for certain sets of values of the parameters a, b, and p, this distribution approximates very well the Student t-distribution. The density function corresponding to (35) is given by

36. $f(x) = [a + b(1+p)|x|^p] \exp[-x(a + b|x|^p)] / [1 + \exp\{-x(a + b|x|^p)\}]^2,$
$x \in \Re, a, b, p > 0.$

Some Applications and Computational Aspects

The normal distribution is used in various practical applications occurring in many areas such as Economics (used earlier to analyze exchange rates, stock markets, etc.; nowadays heavy tailed distributions, such as Lévy distribution, are used), Medical Sciences (blood pressure of adults (males or females)), Physics (measurement errors, heat equation), Election predictions, etc.

Most statistical and mathematical packages may be used for numerical and symbolical calculations of several results concerning the normal distribution as well as for verifying if a given data set is approximately normally distributed. There are several methods to generate values that have normal distribution. Box and Muller (see Rubinstein and Kroese 2008) gave an easy method of generating variables from $N(0,1)$ based on the following result. Let U_1 and U_2 be independent random variables from uniform distribution $U(0,1)$. Then the random variables

37. $X = (-2\ln U_1)^{1/2} \cos(2\pi U_2)$

and

38. $Y = (-2\ln U_1)^{1/2} \sin(2\pi U_2)$

are independent $N(0,1)$.

Alternatively, variables from approximate $N(0,1)$ given in Eq. (35) can be generated from the following expressions derived by Rathie and Swamee (2006) (see Rathie et al. 2008):

39. $$x = \begin{cases} -\sum_{k=0}^{\infty} [(-b/a)^k \Gamma(kp+k+1)/\{k\Gamma(kp+2)\}] \\ \quad \times [a^{-1} \ln\{(1-F)/F\}]^{kp+1}, \quad F \le 0.5 \\ \sum_{k=0}^{\infty} [(-b/a)^k \Gamma(kp+k+1)/\{k!\Gamma(kp+2)\}] \\ \quad \times [a^{-1} \ln\{F/(1-F)\}]^{kp+1}, \quad F \ge 0.5 \end{cases}$$

About the Author

Normal Scores

Lelys Bravo de Guenni
Professor
Universidad Simón Bolívar, Caracas, Venezuela

Normal scores use the ranks of a data set to calculate standard normal quantiles of the same size than the original data set. The aim of this calculation is mainly to compare each sample value with the expected value of the order statistic of the same rank from a standard normal distribution sample of the same sample size than the original data set. The expected values of the ▶order statistics of a sample from a standard normal distribution are the sorted values in increasing order. Plots of the original data or sample quantiles versus the quantiles or scores derived from the standard normal distribution are best known as the *Normal Quantile–Quantile plots* or *Normal Q–Q plots* where Q stands for quantile. These plots are commonly used as a simple test for normality in a graphical way. If the data set is a sample from a normal probability distribution, the Q–Q plot should show a linear relationship (Barnnet 1975).

The best way to explain how to calculate the normal scores is through an example. Suppose we have the sample $X = (x_1, \ldots, x_n)$, which arises from a certain distribution function F with location and scale parameters μ and σ. The ordered sample values are denoted as $x_{(1)}, \ldots, x_{(n)}$. As a specific case assume $X = (2.3, 4.2, 0.1, 3.3, 2.1, 0.3, 2.7)$ with sample size $n = 7$. Associated to this sample we can calculate the standard normal quantile $z_{k/(n+1)}$ for each x_k where k is the rank of the observation; $k/(n+1)$ is the plotting position and Φ is the standard normal probability distribution function. In other words, $z_{k/(n+1)} = \Phi^{-1}(k/(n+1))$. In our example the rank of the observation 2.3 is $i = 4$. The quantile $z_{4/(7+1)} = z_{0.5}$ is 0. Detailed calculations for the sample data set are presented in Table 1.

Plotting positions are plausible empirical estimates of $F[(x_{(k)} - \mu)/\sigma]$. To calculate the plotting position there are several options as summarized by Hyndman and Fan (1996). If $p(k)$ is the plotting position of rank k the following expressions for $p(k)$ may be considered:

1. $p(k) = k/n$
2. $p(k) = (k - 0.5)/n$
3. $p(k) = k/(n+1)$
4. $p(k) = (k-1)/(n-1)$
5. $p(k) = (k - 1/3)/(n + 1/3)$
6. $p(k) = (k - 3/8)/(n + 1/4)$

The differences of using different plotting position formulas in the resulting Q–Q plots will be very small. For small sample size ($n < 10$) R Development Core Team (2007) uses option 6 and has implemented the function *qqnorm* to produce Normal Q–Q plots. For our sample data set *qqnorm* produces Fig. 1. Other authors as Hyndman and Fan (1996) recommend the use of option 5.

Normal Scores. Table 1 Normal scores for the sample data *X*

Ordered sample data	Plotting position	Normal scores
0.1	1/8	−1.150
0.3	2/8	−0.674
2.1	3/8	−0.319
2.3	4/8	0
2.7	5/8	0.319
3.3	6/8	0.674
4.2	7/8	1.150

Normality Tests

Henry C. Thode
Associate Professor
Stony Brook University, Stony Brook, NY, USA

The Importance of Testing for Normality

Many statistical procedures such as estimation and hypothesis testing have the underlying assumption that the sampled data come from a normal distribution. This requires either an effective test of whether the assumption of normality holds or a valid argument showing that non-normality does not invalidate the procedure. Tests of normality are used to formally assess the assumption of the underlying distribution.

Much statistical research has been concerned with evaluating the magnitude of the effect of violations of the normality assumption on the true significance level of a test or the efficiency of a parameter estimate. Geary (1947) showed that for comparing two variances, having a symmetric non-normal underlying distribution can seriously affect the true significance level of the test. For a value of 1.5 for the kurtosis of the alternative distribution, the actual significance level of the test is 0.000089, as compared to the nominal level of 0.05 if the distribution sampled were normal. For a distribution with a kurtosis value of 6, the probability of rejection was 0.215. On the other hand, for the *t*-test the distortion of a Type I error is small if the underlying distribution is symmetric; however, if the underlying distribution is asymmetric or skewed, marked changes to the probability of rejection can occur. For the two sample *t*-test Geary concluded that if the underlying distribution is the same for both populations, regardless of the type of non-normality, the changes in the probability that the null hypothesis is rejected are small. Large differences can occur if the distributions are different. Others have corroborated these findings (e.g., Box (1953), Pearson and Please (1975), Subrahmaniam et al. (1975)): that comparative tests on means are not very sensitive when the departure from normality is the same in the different groups. Type I error in tests of variance and single sample

t-tests can be greatly affected depending on the type and degree of non-normality.

Tukey (1960) addressed the problem of robustness in estimation against slight departures from normality. He showed the effects of non-normality on estimates of location and scale parameters of a distribution which was an unbalanced mixture of two normal distributions with common mean and different variances. Under such circumstances he stated that "... neither mean nor variance is likely to be a wisely chosen basis for making estimates from a large sample." D'Agostino and Lee (1977) compared the efficiency of several estimates of location, including the sample mean, when the underlying distribution was either a Student's t or exponential power distribution, both of which are symmetric families of distributions. The efficiencies of the estimates were compared based on the kurtosis value of the underlying distributions. For the t distribution the relative efficiency of the sample mean only decreases to about 90% for a kurtosis value of 6 (corresponding to a t distribution with 6 degrees of freedom) compared to when the sample is from a normal distribution. For the exponential power distribution family, however, the relative efficiency of the sample mean drops quickly and decreases to about 50% when the kurtosis value is 6 (the Laplace distribution).

Tests for normality are useful for applications other than checking assumptions for estimates and tests. For example, some tests for normality have been found to be effective at detecting ►outliers in a sample. They also have promise as a tool in cluster analysis (see ►Cluster Analysis: An Introduction) where the alternative is a normal mixture model, with applications to genetics as an example.

Testing Distributional Hypotheses

There are more tests designed to assess normality than for any other specific distribution. Many normality tests take advantage of special properties of the normal distribution, for example, general absolute moment tests are based on unique relations among the moments of the normal distribution. The usual measure of the worth of a test for normality is its power, i.e., the probability of detecting a non-normal distribution.

Suppose you have a random sample of n independent and identically distributed observations of a random variable X, labeled $x_1, x_2, \ldots, x_n$, from an unspecified probability density $f(x)$. The general goodness of fit problem consists of testing the null hypothesis

$$H_0 : f(x) = f_0(x)$$

against an alternative hypothesis. The probability density in the null hypothesis $f_0(x)$ has a specified distributional form. When the parameters are completely specified, the null hypothesis is called a simple hypothesis. If one or more of the parameters in H_0 are not specified, H_0 is called a composite hypothesis. We will only consider tests of the composite hypothesis of normality

$$H_0 : f(x) = N(\mu, \sigma^2)$$

where both the mean μ and standard deviation σ are unknown. This is more commonly the case of interest in practice. The tests which we will describe are also location and scale invariant, i.e., they have the property that a change in the location or scale of the observations do not affect the test statistic T, i.e.,

$$T(x_1, x_2, \ldots, x_n) = T(kx_1 - u, kx_2 - u, \ldots, kx_n - u)$$

for constants k and u. This is a desirable property of a test since the parameters do not affect the shape of the normal distribution. For most statistical procedures, distribution assumptions which are made usually only concern shape.

Types of Normality Tests

Which of the many tests for normality is the best to use in a specific situation depends on how much is known or assumed about the alternative hypothesis. Normality tests have been derived based on alternative hypotheses ranging from specific distributions to non-normality of a completely unspecified nature.

Likelihood ratio tests and most powerful location and scale invariant (MPLSI) tests were derived for detecting specific alternative distributions to normality. These tests are based on the joint probabilities of the null and alternative distributions, conditional on the values of the observations. The likelihood ratio test (LRT) for the uniform (David et al. 1954) and for the double exponential alternatives (Uthoff 1973) are among the most powerful for these specific alternatives and distributions that are similar in shape; MPLSI tests show good power for specific alternatives of uniform, exponential and double exponential alternatives (Uthoff 1970, 1973) and Cauchy alternatives (Franck 1981). These would be the tests of choice when the alternative hypothesis is specified as one of these distributions.

More often the specific alternative is not known and a more general alternative hypothesis must be considered. The general shape of the alternative may be known, or only a certain type of departure from normality may be of concern. Conventionally, non-normal alternatives have been divided into three shape classes based on the comparison of their third and fourth standardized moments (denoted $\sqrt{\beta_1}$ and β_2, respectively) to those of the normal distribution. A distribution whose value of $\sqrt{\beta_1}$ (skewness) is

different from 0 has a skewed shape. The value of β_2 (kurtosis) for a normal distribution is 3, although a value of 3 does not necessarily indicate a normal distribution (e.g., Johnson et al. 1980). Symmetric alternatives are often separated into those shapes with β_2 less than 3 (sometimes called light-tailed distributions) and those shapes with β_2 greater than 3 (heavy-tailed distributions).

Among the best tests for detecting skewed or symmetric non-normality are the moment tests $\sqrt{b_1}$ (sample skewness) and b_2 (sample kurtosis), respectively. Defining the kth sample moment as

$$m^k = \sum (x_i - \bar{x})^k / n$$

then $\sqrt{b_1} = m_3/(m_2)^{3/2}$ and $b_2 = m_4/(m_2)^2$. These tests perform even better as directional or single tail tests, i.e., when the type of skewness or kurtosis is known (skewed left vs. skewed right; light- vs. heavy-tailed). For simplicity of calculation, the uniform likelihood ratio test u (range/standard deviation) and an asymptotic equivalent to the double exponential MPLSI test, Geary's (1936) absolute moment test a, are useful for detecting light- and heavy-tailed alternatives, respectively.

Omnibus tests are designed to cover all possible alternatives. They are not usually as powerful as specific or shape tests when the characteristics of the true alternative can be correctly identified. One of the better tests for detecting unspecified departures from normality is the Shapiro-Wilk W (Shapiro and Wilk 1965), which is the ratio of an estimate of σ^2 obtained from the regression of the sample order statistics on their expected values to s^2. The performance of $\sqrt{b_1}$ and b_2 at detecting shape alternatives suggest that combinations of moment tests would have acceptable power as omnibus tests; the Jarque-Bera test (1980, 1987) is computationally the simplest of these tests, calculated as $JB = n(\sqrt{b_1}/6 + b_2/24)$.

Empirical distribution function (EDF) goodness of fit tests are less powerful than tests for normality, with the most notable exception being the Anderson-Darling A^2 test (Anderson and Darling 1954) which performs very well from a power standpoint. Most of these procedures operate by using the cumulative distribution function to reduce the general problem to the specific one of testing the hypothesis of uniformity. The ►Kolmogorov–Smirnov test in particular has poor power compared to most normality tests in most situations. Similarly, the very common χ^2 and goodness of fit tests based on spacing should be avoided as tests for normality.

The following table shows some of the more powerful tests under a variety of alternatives

Test (symbol)	Source	Type of test	Good power at detecting this type of alternative
Anderson–Darling (A^2)	Anderson and Darling 1954	EDF	Any
Shapiro–Wilk (W)	Shapiro and Wilk 1965	Regression	Any
Jarque–Bera (JB)	Jarque and Bera 1980, 1987	Joint moment	Any
Skewness ($\sqrt{b_1}$)	Thode 2002	Moment	Skewed
Kurtosis (b_2)	Thode 2002	Moment	Symmetric
Geary (a)	Geary 1936	Absolute moment	Double exponential, symmetric $\beta_2 > 3$
Range (u)	David et al. 1954	LRT	Uniform, symmetric $\beta_2 < 3$

Test Recommendations

As indicated previously, the number of normality tests is large, too large for even the majority of them to be mentioned here. Overall the best tests appear to be the moment tests, Shapiro–Wilk W, Anderson–Darling A^2 (see ►Anderson-Darling Tests of Goodness-of-Fit), and the ►Jarque–Bera test. Specifics on these and many other normality tests and their characteristics can be found in Thode (2002) and on general goodness of fit issues, including normality tests, in D'Agostino and Stephens (1986).

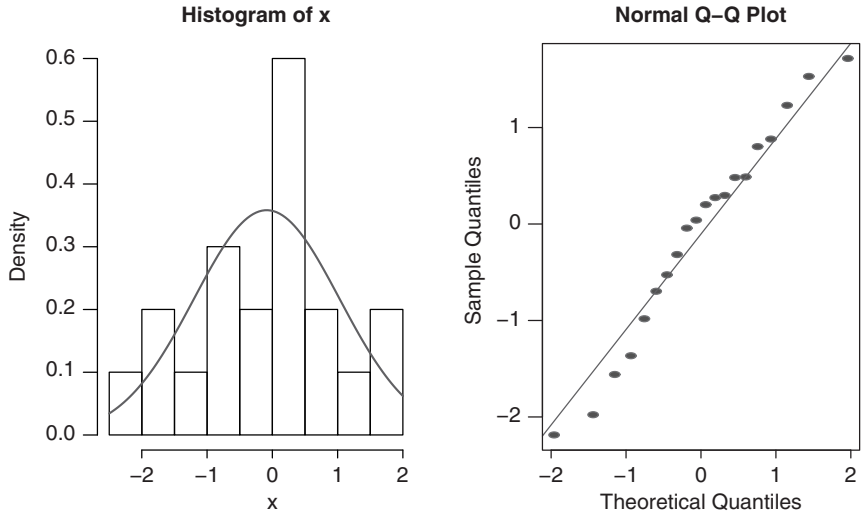
Normality Tests: Power Comparison

Edith Seier
Professor
East Tennessee State University, Johnson City, TN, USA

The assumption of normality is required by several methods in parametric statistical inference, some of which are robust toward mild or moderate non-normality. The histogram in Fig. 1a was prepared with 20 values randomly generated with the standard normal distribution; however, one could argue that the normality of the variable is not evident from the histogram. If these were real observations instead of generated data, a test would be applied with the null hypothesis being that the variable has a normal distribution; frequently no specific distribution is mentioned as alternative hypothesis. The normal quantile plot (Fig. 1b) compares the ordered values $x_{(i)}$ in the sample, also called ►order statistics, with the n corresponding quantiles of the normal distribution. If the sample comes from a normal distribution, the dots tend to suggest a linear pattern. Other versions of the quantile plot do exist.

Numerous tests for normality have been defined. Tests are generally compared in terms of their power, i.e. the probability of finding out when the sample does not come from a normal distribution; every few years a systematic comparison of tests is published. A recent and comprehensive comparison that involves thirty three different tests for normality can be found in Romão et al (2010). Previous comparisons include those of Gan and Koehler (1990) and Seier (2002), among others. All those articles provide tables that compare the power of tests against several non-normal distributions for different sample sizes. That detailed information is useful when we want to test for normality, specially if we have in mind a certain type of alternative distribution. Historical information and a discussion on power comparison is included in Chap. 7 of Thode (2002). There is not one single test that is the most powerful against all the possible non-normal distributions. There are tests that are more powerful against skewed distributions, or tests that are more powerful against distributions that are symmetric but have heavier tails than the normal. However, if the practitioner does not have in mind a specific type of non-normal distribution, a test that is more powerful on average against a wide range of distributions is usually preferred.

To test the hypothesis of normality, based on a data set, one can use one of various statistical software or write a computer program if the test of our preference is not



Normality Tests: Power Comparison. Fig. 1 Histogram and normal quantile plot for 20 values generated with a normal distribution

implemented by the available software. Different tests will produce different ▶p-values for the same data set. For the data in Fig. 1, the p-values for four different tests are as follows: Shapiro–Wilk 0.7277, Pearson 0.4337, Anderson–Darling 0.7988, Lilliefors (Kolmogorov–Smirnov) 0.691. In this example, the four tests agree in not rejecting the null hypothesis of normality. However, for a different example some tests might reject the hypothesis of normality and some others might not, it is from such cases that the differences in power originate.

A special program needs to be written in order to systematically compare tests for normality in terms of power. A non-normal distribution is used to generate a large number of samples of a given size and each one of the tests is applied to each sample, keeping track of the number of times that the null hypothesis is rejected. The empirical power of the normality test, when the true distribution is that specific one, is the number of times that the null hypothesis is rejected divided by the number of samples generated. To make the comparison fair, tests are first compared in terms of their control of α. The proportion of samples for which the hypothesis of normality is rejected, when the samples are generated by a normal distribution, should be as close as possible to the nominal probability (α) of type I error.

The normal distribution has well known density and distribution functions, it is symmetric, has Pearson's kurtosis equal to 3, and if $X \sim N(\mu, \sigma^2)$ then $X = \mu + \sigma Z$ where $Z \sim N(0,1)$. To define a new test of normality one usually focuses on one or more of those characteristics. Tests might use Pearson's skewness and kurtosis statistics or some other ones. The empirical distribution function can be compared with the normal CDF using different criteria. Some tests compare the order statistics with the expected values of the order statistics under normality, the summary of that comparison can be done in different manners. Some tests rely on concepts such as ▶entropy or ▶likelihood. After the test statistic is defined, it is necessary to derive the distribution of the statistic under normality in order to calculate either critical values or p-values. Some tests work with exact distributions that require special tables, some others strive for simplicity using one of the standard statistical distributions as an approximation (sometimes sacrificing a little power in the process). The diverse possibilities in the definition of the tests explains in part why there are so many tests for normality and why they might differ in power depending on the true distribution of the variable. Thode (2002) describes thirty tests of normality and in recent years new ones have been defined.

Most tests of normality have high power when the sample is large, it is the small and moderate sample sizes the ones that provide the setting for interesting comparisons among tests. The more different from the normal the true distribution looks like, the smaller the sample size needed to achieve high power. For example, the Student's t-distributions look very similar to the normal except that they have heavier tails, as the number of degrees of freedom n increases the $t_{(n)}$ and the normal look more alike. A certain normality test requires a sample size 150 to have a power 0.793 when the true distribution is $t_{(5)}$, the same test requires a sample size of only 35 to have power 0.812 when the true distribution is $t_{(2)}$ (Bonett and Seier 2002).

When the true distribution is severely skewed, e.g. the log-normal(0,1), there are several tests that have a power larger than 0.95 when the sample size is 25.

Considering the way tests are defined helps to understand why some of them have more power than others. One of the first approaches used to test for normality was to apply the Chi-square goodness of fit test, comparing the observed frequency of each interval with the expected frequency (something similar to the visual comparison of the histogram to the normal curve in Fig. 1a) Currently more powerful tests are available.

Kurtosis is a characteristic of distributions related to the heaviness of the tails and the concentration of mass toward the center of the distribution. There are some tests defined specifically to test for normality against symmetric distributions that have heavier tails or large kurtosis; these distributions are of interest in the fields of economics and finance. Two such tests are the ones defined by Bonnet and Seier (2002) and Gel et al. (2007), both represent kurtosis with a ratio that has the standard deviation in the numerator and another measure of spread in the denominator. They have good power when the true distribution is symmetric with high kurtosis such as Laplace, $t_{(2)}$, some *SU* distributions, Cauchy and some scale contaminated normals where the contaminating distribution has smaller variance. The kurtosis test in D'Agostino et al. (1990) has good performance against symmetric distributions with kurtosis moderately higher than 3 and against some scale contaminated distributions where the contaminating distribution has larger variance. It is recommended to accompany kurtosis based tests by a test of symmetry.

There is a class of tests that first summarize the empirical distribution using some skewness and kurtosis statistics and then compare their values with the skewness and kurtosis of the normal distribution. Tests described by D'Agostino et al. (1990) and the ▶Jarque–Bera test, popular in econometrics, are based on Pearson's skewness and kurtosis statistics. A modification to the Jarque–Bera test (Gel and Gastwirth 2007) uses a robust measure of variability and improves the power of the JB test when the true distribution is symmetric with moderately higher kurtosis than the normal and the sample size is small.

The Anderson–Darling (see ▶Anderson-Darling Tests of Goodness-of-Fit) and Kolmogorov–Smirnov tests are both based on the comparison of the empirical distribution function and the normal CDF. The Lilliefors test is the version of the ▶Kolmogorov–Smirnov test that uses the sample mean and variance. The Lilliefors or KS test focuses on the maximum difference between the empirical and theoretical distribution. The Anderson–Darling test summarizes all the differences between the empirical and theoretical distributions, tending to be more powerful than the KS test. The Shapiro–Wilk test is more powerful than the Anderson–Darling test against many non-normal distributions, but the AD test is more powerful than the SW when the true distribution is the Tukey (10), a distribution that has a very sharp peak and tails that end abruptly.

There is a group of tests of normality called regression type tests. Those tests, in one way or other, compare one by one sample quantiles with quantiles from the normal distribution. The most well known of these tests is the Shapiro–Wilk test, defined in terms of the order statistics and the expected values of the order statistics. Originally defined in 1965 for $n \leq 50$, it required special constants and critical values. Several extensions and modifications of that test have been published since then, such as the one in Royston (1992). The Chen–Shapiro test (1995) compares the spacings in between the quantiles in both the empirical and the normal distribution. The Chen–Shapiro test is also quite powerful against a wide range of non-normal distributions, it is even slightly more powerful than the Shapiro–Wilk test against some distributions when the sample size is small. When working with rounded data, both the CS test and the SW test benefit from the adjustment for ties proposed by Royston (1989).

Romão et al. (2010) conclude that when testing normality against symmetric alternatives, the best choices are the already mentioned tests by Gel et al. (2007), Bonett and Seier (2002), Chen and Shapiro (1995), and the test defined by Coin (2008). The first two are kurtosis based tests and the last two are regression type tests that work with the order statistics. Coin's test consists in fitting a polynomial model to a standardized version of the normal quantile plot and testing for the coefficient ($Ho : \beta_3 = 0$) of the third power of the expected values of the order statistics under normality. To test for normality against skewed distributions they recommend the Chen–Shapiro test, Shapiro–Wilk test and two tests based on the likelihood ratio defined by Zhang and Wu (2005). To detect normal distributions with ▶outliers Romão et al. (2010) recommend tests based on a trimmed version (defined in 2003 by Elamir and Seheult) of Hosking's L-moments, which are considered to be less sensitive to outliers than the classical moments. To test for normality in general without having a particular type of alternative distribution in mind, Romão et al. (2010) recommend: Shapiro–Wilk, Chen–Shapiro and Del Barrio et al. (2005), the three of them are regression type tests.

Most statistical software include some tests of normality. However, some powerful tests have not been implemented by statistical software yet. The base package of

R calculates the Shapiro–Wilk test and five more tests with the *normtest* package: Anderson–Darling, Cramer–von Mises, Kolmogorov–Smirnov (Lilliefors), Pearson chi-square test, and Shapiro–Francia. MINITAB has three options: KS, AD and Ryan–Joiner (similar to SW). SPSS calculates KS(L) and SW. SAS calculates SW, CM, AD and KS(L).

Null-Hypothesis Significance Testing: Misconceptons

Raymond S. Nickerson
Research Professor
Tufts University, Medford, MA, USA

Null-hypothesis significance testing (NHST) has for many years been the most widely used statistical tool for evaluating the outcomes of psychological experiments. It is routinely taught to college students in elementary statistics courses and courses in experimental methodology and design. Despite these facts, there are many misconceptions about null-hypothesis significance testing—about what conclusions the results of such testing do or do not justify. Here several of these misconceptions are briefly summarized. More substantive treatments of these and related misconceptions may be found in several publications, including Rozeboom (1960), Clark (1963), Bakan (1966), Morrison and Henkel (1970), Carver (1978), Lakatos (1978), Berger and Sellke (1987), Falk and Greenbaum (1995), Gigerenzer (1998), and Wilkinson and APA Task Force on Statistical Inference (1999).

Many criticisms have been directed at the use of NHST. Some of these criticisms challenge the logic on which it is based; some contend that its use is not productive because it does not advance an understanding of the phenomena of interest; others focus on what are seen as arbitrary aspects of the rules for its use and interpretation of the statistics it provides; still others contend that its widespread use has undesirable effects on the way experiments are designed and on the reporting – or the failure to report – experimental results.

Although *null hypothesis* has more than one connotation as it has been used by different people in a variety of contexts, the meaning that is taken for purposes of this article is one that is likely to be found in statistics texts: The hypothesis that two groups – usually an experimental group and a control group – do not differ with respect to a specified quantitative measure of interest, and that any observed difference between the means of that measure is due strictly to chance. Assuming the data obtained from the two groups satisfy certain assumptions underlying the use of the null-hypothesis test, the test yields a statistic and a p value, the latter of which indicates the probability that the value of the statistic, or a larger one, would be obtained if the observed difference between the means were due strictly to chance. Conventionally, the null hypothesis is rejected when the value of p that is obtained is less than some specified criterion, generally referred to

as *alpha*, and typically set at .05 or .01. The theory admits of only two possible outcomes of null-hypothesis testing: either the hypothesis is rejected on the basis of obtaining a *p* value not exceeding *alpha*, or it is not rejected if the *p* value does exceed *alpha*. Never, strictly speaking, is the null hypothesis said to have been shown to be true. The obvious bias in the test reflects the view that rejecting the null hypothesis when it is true (generally referred to as a *Type-I* error) is a much less acceptable outcome of testing than is failing to reject it when it is false (*Type-II* error).

Apparently null-hypothesis statistical testing is easily misunderstood, and the misunderstandings can take a variety of forms. Space does not permit an exhaustive, or even extensive, listing and explanation of all the misunderstandings that can occur. This note focuses on certain misconceptions that are fairly common. The evidence of their commonality is found in numerous published reports of experiments in which NHST has been used in the data analyses. The format for what follows is a statement of each of several misconceptions, accompanied by a brief explanatory comment. The misconceptions noted have been discussed in more detail in Nickerson (2000); many have also been discussed in other publications cited in that article and in the reference list for this one.

- *The value of p is the probability that the null hypothesis is true and that of 1-p is the probability that the alternative to the null hypothesis is true*. Given this belief, a *p* value of .001 would be taken to mean that there is one chance in one-thousand that the obtained difference between the means is due to chance, and that it is almost certain that the alternative to the null hypothesis – the hypothesis that the observed difference is not due to chance – is true. This misconception is an example of confusion between the probability of *A* conditional on *B*, $p(A|B)$, and the probability of *B* conditional on *A*, $p(B|A)$. Letting *A* represent "the observed value of the statistic is *X*," and *B* "the null hypothesis is true," obtaining a *p* of .001 means that $p(A|B) = 0.001$; it does not mean that $p(B|A) = 0.001$.
- *Rejection of the null hypothesis establishes the truth of a theory that predicts it to be false*. The reasoning, expressed as a conditional syllogism is: *If the theory is true, the null hypothesis will prove to be false; the null hypothesis proved to be false, therefore the theory is true*. This is a case of *affirming the consequent*, a common fallacy in conditional reasoning.
- *A small p is evidence that the results are replicable* (*sometimes accompanied by the belief that 1-p is the probability that the results will replicate*). A case can be made that a small *p* indicating a statistically significant difference justifies a greater expectation than does a large *p* that a follow-up experiment under the same conditions will also produce a statistically significant difference, but a small *p* does not guarantee that the results will replicate, and 1-*p* is not the probability that they will do so.
- *A small p means a large treatment effect*. Although, other things equal, a large effect is likely to yield a small *p*, and a small *p* is suggestive of a large effect, *p* is also sensitive to sample size (with a large sample, a small effect can yield a small *p*), so a small *p* is not a reliable indication of a large effect.
- *Statistical significance means theoretical or practical significance*. Statistical significance indicates only that two samples selected at random from the same population are unlikely to produce the observed result; it reveals nothing about whether the finding has any theoretical or practical significance.
- *Alpha is the probability that if one has rejected the null hypothesis, one has made a Type-I error*. This is another case of confusing $p(A|B)$ and $p(B|A)$. *Alpha* – or more specifically $p \leq alpha$ – is the probability of rejecting the null hypothesis, given that the hypothesis is true, which is different from the probability that the null hypothesis is true, given that one has rejected it.
- *The value of alpha selected for a given experiment is the probability that a Type-I error will be made in interpreting the results of that experiment*. *Alpha* is the probability of making a Type-I error when the null hypothesis is true; a Type-I error cannot be made when the null hypothesis is false. So *alpha* could be the probability of a Type-I error only on the assumption that the null hypothesis is always true, but presumably for most experiments there are prior reasons to believe that the null hypothesis is false.
- *The value of alpha is the probability of Type-I error across a large set of experiments in which alpha is set at the same value*. The counter for this misconception is similar to that for the last one. It would be true only on the assumption that across the set of experiments of interest the null hypothesis is always true.

Just as there are faulty beliefs about Type-I errors and *alpha*, there are faulty beliefs about Type-II errors and *beta*. A Type-II error is made when a null hypothesis that is false is not rejected; *beta* is the probability of failing to reject the null hypothesis, given that it is false. Sometimes *beta* is taken to be the probability that the null hypothesis is false, given that it has not been rejected, and sometimes it is taken to be the absolute probability of making a Type-II

error. Both of these beliefs are wrong, and for reasons comparable to those given for the corresponding beliefs about Type-I errors and *alpha*.

- *Failing to reject the null hypothesis is equivalent to demonstrating it to be true.* In view of the convention of selecting a very small value for *alpha* (0.05, 0.01), thus, in effect, setting a high bar for rejecting the null hypothesis, failure to reach this bar to claim the hypothesis to be false is very weak evidence that it is true. Nevertheless, experimenters often take the failure to find a statistically significant difference between two groups as sufficient evidence to proceed as though no difference exists.
- *Failure to reject the null hypothesis is evidence of a failed experiment.* Probably most experiments for which null hypothesis testing is used to analyze data are planned and run with the expectation that the results will reveal a hypothesized difference, or differences, of interest .If a difference that is sufficiently distinct to permit rejection of the null hypothesis is not obtained, it may be because the experiment was not adequately planned or executed, in which case one might argue that it should be considered a failed experiment. On the other hand, it may be too that there is no difference to be found. The failure to reject the null hypothesis, by itself, does not suffice to distinguish between these possibilities.

The focus here has been on misconceptions of NHST. Critics of the use of NHST in the analysis and interpretation of data from psychological experiments have raised other issues as well, discussion of which is beyond the scope of this article. It must be noted, too, that NHST has many defenders (Abelson 1995; Baril and Cannon 1995; Chow 1996; Cortina and Dunlap 1997; Dixon 1998; Frick 1996; Harris 1997; Mulaik et al. 1997; Wilson et al. 1967; Winch and Campbell 1969), but defense of the NHST is also beyond the scope of this article. Defenders of NHST generally acknowledge that it is often misunderstood and misapplied, but contend that it is an effective tool when used appropriately.

About the Author

Raymond S. Nickerson is a research professor at Tufts University, from which he received a PhD in experimental psychology, and is retired from Bolt Beranek and Newman (BBN), where he was a senior vice president. He is a Fellow of the American Association for the Advancement of Science, the American Psychological Association, the Association for Psychological Science, the Human Factors and Ergonomics Society, and the Society of Experimental Psychologists. He is a past Chair of the U.S. National Research Council's Committee on Human Factors and a recipient of the Franklin V. Taylor Award from the American Psychological Association. Dr. Nickerson was the Founding Editor of *The Journal of Experimental Psychology: Applied* and of *Reviews of Human Factors and Ergonomics*, an annual publication of the Human Factors and Ergonomics Society. He is author or co-author of about 200 published works, including eight books, the latest of which is *Mathematical Reasoning: Patterns, Problems, Conjectures, and Proofs* (Psychology Press, 2010).

Numerical Integration

James E. Gentle
Professor of Computational Statistics
George Mason University, Fairfax, VA, USA

One of the most common mathematical operations in scientific computing is quadrature, the evaluation of a definite integral. It is used to determine volume, mass, or total charge, for example. In the evaluation of probabilities, of expectations, and of marginal or conditional densities, integration is the basic operation.

Most of the integrals and differential equations of interest in real-world applications do not have closed-form solutions; hence, their solutions must be approximated or estimated numerically.

The general problem is to approximate or estimate

$$I = \int_D f(x)\,\mathrm{d}x. \tag{1}$$

There are basically two approaches. One is based on sums of integrals of approximations of the integrand over subregions of the domain:

$$\int_D f(x)\,\mathrm{d}x \approx \sum_{i=0}^{n} \int_{D_i} \tilde{f}_i(x)\,\mathrm{d}x, \tag{2}$$

where $\cup_{i=0}^{n} D_i = D$ and $\tilde{f}_i(x) \approx f(x)$ within D_i.

In the other approach, the integrand is decomposed into a probability density function (PDF) and another factor:

$$\int_D f(x)\,\mathrm{d}x = \int_D h(x) p_X(x)\,\mathrm{d}x, \tag{3}$$

where p_X is the probability density function of a random variable X with support on D. In this formulation, we have

$$I = \mathrm{E}(h(X)), \tag{4}$$

where $\mathrm{E}(\cdot)$ represents the expectation operator with respect to the probability distribution of X. Notice that this is exact.

The second approach, called Monte Carlo integration, is fundamentally different from the first, because it leads to a statistical *estimate* rather than a *numerical approximation*.

Each approach has many variations and there are many details that we cannot address in the brief space here. The references at the end of this article contain fuller descriptions.

Numerical Approximations

One type of numerical approximation is based on direct approximation of the Riemann sum, which we take as the basis for the definition of the integral. Another type of approximation is based on an approximation of the function using one of the methods discussed above. We begin with approximations that are based on Riemann sums. We also generally limit the discussion to univariate integrals.

Although some of the more interesting problems are multivariate and the region of integration is not rectangular, we begin with the simple integral,

$$I = \int_a^b f(x)\,\mathrm{d}x. \tag{5}$$

Newton–Cotes Quadrature

The Riemann integral is defined as the limit of the *Riemann sums*:

$$\frac{1}{n}\sum_{i=1}^{n}(x_i - x_{i-1}) f(\widetilde{x}_i), \tag{6}$$

where $a = x_0 < x_1 < \cdots < x_n = b$ and $\widetilde{x}_i \in [x_{i-1}, x_i]$.

Instead of a simple step function, the function $f(x)$ may be approximated by a piecewise linear function $p_1(x)$ that agrees with f at each of the points. The integral (5) can be approximated by a sum of integrals, each of which is particularly easy to evaluate:

$$\begin{aligned}\int_a^b f(x)\,\mathrm{d}x &\approx \sum_{i=0}^{n} \int_{x_i}^{x_{i+1}} p_1(x)\,\mathrm{d}x,\\ &= h\big(f(a) + 2f(x_1) + 2f(x_2) + \cdots + 2f(x_{n-1})\\ &\quad + f(b)\big)/2.\end{aligned} \tag{7}$$

The expression (7) is called the *trapezoid rule*.

Many other quadrature rules can be built using this same idea of an approximating function that agrees with f at each of some set of points. Quadrature formulas that result from this kind of approach are called *Newton–Cotes formulas*.

Rather than the linear functions of the trapezoid rule, a more accurate approximation would probably result from use of polynomials of degree k that agree with f at each of $k+1$ successive points. Use of polynomials in this way leads to what are called *Simpson's rules*.

Error in Newton–Cotes Quadrature

There are generally multiple sources of error. The error in approximations must be considered separately from the error in rounding, although at some level of discretization, the rounding error may prevent any decrease in approximation error, even though the approximation is really the source of the error.

In Newton–Cotes quadrature, we get an expression for the error of the general form $O(g(h))$.

To approximate the error, we consider a polynomial of degree n over that region, because we could have a single such polynomial that corresponds to f at each of the break points. Using a Taylor series, we find that the error in use of the trapezoid rule can then be expressed as

$$-\frac{1}{12}(b-a)h^2 f''(x^*)$$

for some $x^* \in [a,b]$. This is not very useful in practice. It is important, however to note that the error is $O(h^2)$.

Using similar approaches we can determine that the error for Simpson's rules is $O(h^4)$.

Extrapolation in Quadrature Rules

We can use Richardson extrapolation (see, for example, Gentle 2009) to improve the approximation in Newton–Cotes formulas. In the trapezoid rule, for example, we consider various numbers of intervals. Let T_{0k} represent the value of the expression in Eq. 7 when $n = 2^k$; that is, when there are n intervals, and we examine the formula for $1, 2, 4, \ldots$ intervals, that is, $T_{00}, T_{01}, T_{02}, \ldots$. Now, we use Richardson extrapolation to form

$$T_{1,k} = (4T_{0,k+1} - T_{0,k})/3. \tag{8}$$

Generalizing this, we define

$$T_{m,k} = (4^m T_{m-1,k} - T_{m-1,k-1})/(4^m - 1). \tag{9}$$

Notice in $T_{m,k}$, m represents the extent of extrapolation, and k determines the number of intervals. (This kind of scheme is used often in numerical analysis. It can be represented as a triangular table in which the ith row consists of the i terms $T_{0,i-1}, \ldots, T_{i-1,0}$.)

This application of Richardson extrapolation in quadrature with the trapezoid rule is called *Romberg quadrature*.

Adaptive Quadrature Rules

It is not obvious how to choose the interval width in Newton–Cotes formulas. Obviously if the interval width is too large, finer structure in the integrand will be missed. On the other hand, if the interval width is too small, in addition to increased cost of evaluation of the integrand, rounding error can become significant. There are various ways of trying to achieve a balance between accuracy and number of function evaluations. In most cases these involve approximation of the integral over different subintervals with different widths used in each of the subintervals. Initially, this may identify subintervals of the domain of integration that require smaller widths in the Newton–Cotes formulas (that is, regions in which the integrand is rougher). Evaluations at different widths over the different subintervals may lead to a good choice of both subintervals and widths within the different subintervals. This kind of approach is called *adaptive quadrature*.

Gaussian Quadrature

We now briefly discuss another approach to the evaluation of the integral (5) called *Gaussian quadrature*. Gaussian quadrature uses the idea of expansion of the integrand. Like the Newton–Cotes approaches, Gaussian quadrature arises from the Riemann sum (6), except here we interpret the interval widths as weights:

$$\sum_{i=0}^{n} w(x_i) f(x_i). \tag{10}$$

In Gaussian quadrature, we put more emphasis on choosing the points, and by so doing, we need a smaller number of points. Whether or not this is a good idea of course depends on how we choose the points and how we define $w(x_i)$.

Determination of Weights in Gaussian Quadrature

If f is a polynomial of degree $2n-1$, it is possible to represent the integral $\int_a^b f(x)\mathrm{d}x$ exactly in the form (10). Use of the formula (10) yields $2n$ equations in $2n$ unknowns to determine the x_i's and w_i's. In Gaussian quadrature, the x_i's and w_i's are chosen so that the approximation is correct when f is a polynomial, and it can provide a approximation in many cases with a relatively small n. Often only five or six points provide a good approximation.

To make this a useful method for any given (reasonable) integrand over a finite range, the obvious approach is to represent the function as a series in a standard sequence of orthogonal polynomials.

Error in Gaussian Quadrature

The error in Gaussian quadrature is

$$\int_a^b f(x)\,\mathrm{d}x - \sum_{i=0}^{n} w_i g(x_i),$$

which we can write as

$$\int_a^b g(x)w(x)\,\mathrm{d}x - \sum_{i=0}^{n} w_i g(x_i) = \frac{g^{(2n)}(x^*)}{(2n)!c_n^2}, \qquad (11)$$

for some point x^* in (a, b).

A problem with Gaussian quadrature is that it is not easy to use the results for n to compute results for $\tilde{n}$, and hence the kinds of extrapolation and adaptation we discussed above for Newton–Cotes quadrature are not very useful for Gaussian quadrature.

Monte Carlo Methods for Quadrature

In the Monte Carlo method of quadrature we first formulate the integral to be evaluated as an expectation of a function of a random variable, as in Eq. 4. To estimate this expected value, that is, the integral, we simulate realizations of the random variable, and take the average of the function evaluated at those realizations,

$$\widehat{I} = \frac{1}{m}\sum_{i=1}^{m} h(x_i), \qquad (12)$$

where $x_1, x_2, \ldots, x_m$ is a random sample (or pseudorandom sample) of the random variable X.

If we formulate the estimator $\widehat{I}$ as a sum of functions of independent random variables, each with density p_X, instead of a sum of realizations of random variables, the estimator itself is a random variable. An obviously desirable property of this random variable is that its expectation be equal to the quantity being estimated. Assuming the expectations exist, this is easily seen to be the case:

$$\mathrm{E}\left(\widehat{I}\right) = \frac{1}{m}\sum_{i=1}^{m}\mathrm{E}(h(X_i)) = \frac{1}{m}\sum_{i=1}^{m} I = I.$$

We therefore say the estimator is unbiased.

An advantage of Monte Carlo quadrature is that the nature of the domain of integration is not as critical as in the other quadrature methods we have discussed above. Monte Carlo quadrature can be performed equally easily for improper integrals as for integrals over finite domains.

Another advantage of Monte Carlo quadrature is that the computations can be performed in parallel without any special coding.

Variance of Monte Carlo Estimators

Monte Carlo methods are sampling methods; therefore the estimates that result from Monte Carlo procedures have associated *sampling errors*.

In the case of scalar functions, the variance of the estimator $\widehat{I}$ is a rather complicated function involving the original integral (assuming the integrals exist):

$$\begin{aligned}\mathrm{V}\left(\widehat{I}\right) &= \frac{1}{m}\mathrm{E}\left(\left(h(X) - \mathrm{E}(h(X))\right)^2\right)\\ &= \tfrac{1}{m}\int_D \left(h(x) - \int_D h(y)p_X(y)\,\mathrm{d}y\right)^2 p_X(x)\,\mathrm{d}x.\end{aligned} \qquad (13)$$

We see that the magnitude of the variance depends on the variation in

$$h(x) - \int_D h(y)p_X(y)\,\mathrm{d}y,$$

which depends in turn on the variation in $h(x)$. If $h(x)$ is constant, the variance of $\widehat{I}$ is 0. Of course, in this case, we do not need to do the Monte Carlo estimation; we have the solution $I = h(\cdot)\int_D \mathrm{d}y$.

While the variance in (13) is complicated, we have a very simple estimate of the variance; it is just the sample variance of the observations $h(x_i)$.

Reducing the Variance

As we see from Eq. 13 the variance of the Monte Carlo estimator is linear in m^{-1}; hence, the variance is reduced by increasing the Monte Carlo sample size. More effective methods of variance reduction include use of antithetic variates, importance sampling, and stratified sampling (see Gentle 2003).

Error in Monte Carlo Quadrature

As we have emphasized, Monte Carlo quadrature differs from quadrature methods such as Newton–Cotes methods and Gaussian quadrature in a fundamental way; Monte Carlo methods involve random (or pseudorandom) sampling. The expressions in the Mont Carlo quadrature formulas do not involve any approximations, so questions of bounds of the error of approximation do not arise. Instead of error bounds or order of the error as some function of the integrand, we use the variance of the random estimator to indicate the extent of the uncertainty in the solution.

The square root of the variance, that is, the standard deviation of the estimator, is a good measure of the

range within which different estimators of the integral may fall.

Because of the dependence of the confidence interval on the standard deviation the standard deviation is sometimes called a "probabilistic error bound." The word "bound" is misused here, of course, but in any event, the standard deviation does provide some measure of a sampling "error."

The important thing to note from Eq. 13 is the order of error in the Monte Carlo sample size; it is $O\left(m^{-\frac{1}{2}}\right)$. This results in the usual diminished returns of ordinary statistical estimators; to halve the error, the sample size must be quadrupled.

Higher Dimensions

The most significant difficulties in numerical quadrature occur in multiple integration.

The Monte Carlo quadrature methods extend directly to multivariate integrals, although, obviously, it takes larger samples to fill the space. It is, in fact, only for multivariate integrals that Monte Carlo quadrature should ordinarily be used. The preference for Monte Carlo in multivariate quadrature results from the independence of the pseudoprobabilistic error bounds and the dimensionality mentioned above.

An important fact to be observed in Eq. 13 the order of the error in terms of the number of function evaluations is independent of the dimensionality of the integral so the order of the error remains $O\left(m^{-\frac{1}{2}}\right)$. On the other hand, the usual error bounds for numerical quadrature are $O\left((g(n))^{-\frac{1}{d}}\right)$, where d is the dimensionality, and $g(n)$ is the order for one-dimensional quadrature. This is one of the most important properties of Monte Carlo quadrature.

The papers in the book edited by Flournoy and Tsutakawa (1991) provide good surveys of specific methods for multiple integrals, especially ones with important applications in statistics. Evans and Schwartz (2000) provide a good summary of methods for numerical quadrature, including both the standard deterministic methods of numerical analysis and Monte Carlo methods.

Numerical Methods for Stochastic Differential Equations

Peter E. Kloeden
Professor
Goethe-Universität, Frankfurt, Germany

A stochastic differential equation (SDE)

$$dX_t = f(t, X_t)\, dt + g(t, X_t)\, dW_t$$

is, in fact, not a differential equation at all, but only a symbolic representation for the stochastic integral equation

$$X_t = X_{t_0} + \int_{t_0}^{t} f(s, X_s)\, ds + \int_{t_0}^{t} g(s, X_s)\, dW_s,$$

where the first integral is a deterministic Riemann integral for each sample path. The second integral is an Itô stochastic integral, which is defined as the mean-square limit of sums of products of the integrand g evaluated at the start of each discretization subinterval times the increment of the Wiener process W_t (which is often called a Brownian motion, see ►Brownian Motion and Diffusions). It is not possible to define this stochastic integral pathwise as a Riemann–Stieltjes integral, because the sample paths of a Wiener process, although continuous, are nowhere differentiable and not even of bounded variation on any bounded time interval.

The simplest numerical method for the above SDE is the *Euler-Maruyama scheme* given by

$$Y_{n+1} = Y_n + f(t_n, Y_n)\, \Delta_n + g(t_n, Y_n)\, \Delta W_n,$$

where $\Delta_n = t_{n+1} - t_n$ and $\Delta W_n = W_{t_{n+1}} - W_{t_n}$. This is intuitively consistent with the definition of the ►Itô integral. Here Y_n is random variable, which is supposed to be an approximation on X_{t_n}. The stochastic increments

ΔW_n, which are $\mathcal{N}\left(0, \sqrt{\Delta_n}\right)$ distributed, can be generated using, for example, the Box-Muller method. In practice, however, only individual realizations can be computed.

Depending on whether the realizations of the solutions or only their probability distributions are required to be close, one distinguishes between strong and weak convergence of numerical schemes, respectively, on a given interval $[t_0, T]$. Let $\Delta = \max_n \Delta_n$ be the maximum step size. Then a numerical scheme is said to converge with *strong order* γ if, for sufficiently small Δ,

$$\mathbb{E}\left(\left|X_T - Y_{N_T}^{(\Delta)}\right|\right) \le K_T\, \Delta^{\gamma}$$

and with *weak order* β if

$$\left|\mathbb{E}\left(p(X_T)\right) - \mathbb{E}\left(p\left(Y_{N_T}^{(\Delta)}\right)\right)\right| \le K_{p,T}\, \Delta^{\beta}$$

for each polynomial p. These are global discretization errors, and the largest possible values of γ and β give the corresponding strong and weak orders, respectively, of the scheme for a whole class of stochastic differential equations, e.g., with sufficiently often continuously differentiable coefficient functions. For example, the Euler-Maruyama scheme has strong order $\gamma = \frac{1}{2}$ and weak order $\beta = 1$, while the *Milstein scheme*

$$\begin{aligned} Y_{n+1} = {} & Y_n + f(t_n, Y_n)\,\Delta_n + g(t_n, Y_n)\,\Delta W_n \\ & + \frac{1}{2}\, g(t_n, Y_n)\frac{\partial g}{\partial x}(t_n, Y_n)\left\{(\Delta W_n)^2 - \Delta_n\right\} \end{aligned}$$

has strong order $\gamma = 1$ and weak order $\beta = 1$. Note that these convergence orders may be better for specific SDE within the given class, e.g., the Euler-Maruyama scheme has strong order $\gamma = 1$ for SDE with additive noise, i.e., for which g does not depend on x, since it then coincides with the Milstein scheme.

The Milstein scheme is derived by expanding the integrand of the stochastic integral with the Itô formula, the stochastic chain rule. The additional term involves the double stochastic integral $\int_{t_n}^{t_{n+1}} \int_{t_n}^{s} dW_u\, dW_s$, which provides more information about the non-smooth Wiener process inside the discretization subinterval and is equal to $\frac{1}{2}\left\{(\Delta W_n)^2 - \Delta_n\right\}$. Numerical schemes of even higher order can be obtained in a similar way. In general, different schemes are used for strong and weak convergence. The strong stochastic Taylor schemes have strong order $\gamma = \frac{1}{2}$, 1, $\frac{3}{2}$, 2, ..., whereas weak stochastic Taylor schemes have weak order $\beta = 1{,}2, 3, \ldots$. See Kloeden and Platen (1992) for more details. In particular, one should not use heuristic adaptations of numerical schemes for ordinary differential equations such as Runge–Kutta schemes, since these may not converge to the right solution.

The proofs of convergence rates in the literature assume that the coefficient functions in the above stochastic Taylor schemes are uniformly bounded, i.e., the partial derivatives of appropriately high order of the SDE coefficient functions f and g exist and are uniformly bounded. This assumption, however, is not satisfied in many basic and important applications, for example with polynomial coefficients such as

$$dX_t = -(1 + X_t)\left(1 - X_t^2\right)\, dt + \left(1 - X_t^2\right)\, dW_t,$$

or with square-root coefficients such as in the Cox-Ingersoll-Ross volatility model

$$dV_t = \kappa\left(\vartheta - V_t\right)\, dt + \mu\sqrt{V_t}\, dW_t,$$

which requires $V_t \ge 0$. The second is more difficult because there is a small probability that numerical iterations may become negative and various ad hoc methods have been suggested to prevent this. The paper (Jentzen et al. 2009) provides a systematic method to handle both of these problems by using pathwise convergence, i.e.,

$$\sup_{n=0,\ldots,N_T} \left|X_{t_n}(\omega) - Y_n^{(\Delta)}(\omega)\right| \longrightarrow 0 \text{ as } \Delta \to 0, \qquad \omega \in \Omega.$$

It is quite natural to consider pathwise convergence since numerical calculations are actually carried out path by path. Moreover, the solutions of some SDE do not have bounded moments.

Vector valued SDE with vector valued Wiener processes can be handled similarly. The main new difficulty is how to simulate the multiple stochastic integrals since these cannot be written as simple formulas of the basic increments as in the double integral above when they involve different Wiener processes.

O

Omnibus Test for Departures from Normality

Kimiko O. Bowman[1], L. R. Shenton[2]
[1]Oak Ridge National Laboratory, Oak Ridge, TN, USA
[2]Professor Emeritus of Statistics
University of Georgia, Athens, GA, USA

An omnibus *test* for departures from normality is an idea developed by E.S. Pearson (letter to Bowman); he thought a test including skewness b_1 and kurtosis b_2, both of which scale and location free, would give more information than the test using lower moments only. For the normal distribution, the population skewness is $\sqrt{\beta_1} = 0$ and the population kurtosis is $\beta_2 = 3$.

D'Agostino and Pearson (1973) introduced a goodness-of-fit test for departures from normality using sample skewness $\sqrt{b_1}$ and sample kurtosis b_2, thus

$$K_S^2 = X_S^2\left(\sqrt{b_1}\right) + X_S^2(b_2)$$

where $\sqrt{b_1} = m_3/m_2^{3/2}$, $b_2 = m_4/m_2^2$, and $m_s = \sum_1^n (x_j - \bar{x})^s/n, j = 1, 2, \cdots, n$, n sample size. D'Agostino and Pearson considered the Johnson's (1965) S_U and S_B transformed distribution for $\sqrt{b_1}$ and b_2. Johnson's system of distributions has the advantage that it transforms the distribution to the normal distribution, so the K_S^2 is considered as χ^2 with degree of freedom $v = 2$. Bowman and Shenton (1975b) continued the study further and introduced the contours for this test. They found S_U gives a good fit to $\sqrt{b_1}$ for $n \geq 8$ or so, and reasonable fit to b_2 for $n \geq 25$. For smaller sample size, the S_B system was used for the b_2.

$$X_S\left(\sqrt{b_1}\right) = \delta_1 \sinh^{-1}\left(\sqrt{b_1}/\lambda_1\right),$$
$$X_S(b_2) = \gamma_2 + \delta_2 \sinh^{-1}[(b_2 - \zeta)/\lambda_2],$$

and small sample $n < 25$ for b_2

$$X_S(b_2) = \gamma_2 + \delta_2 \ln\left(\frac{b_2 - \zeta}{\lambda_2 - b_2}\right).$$

γ, δ, λ and ζ are parameters for the Johnson system of distributions and derived by sample moments m_1', m_2, m_3 and m_4. The 90%, 95%, and 99% contours are made for $n = 20(5)65, 75, 85, 100, 120, 150, 200, 250, 800, 500, 1000$. The contours are shown in Fig. 1.

Extensive simulation study found the areas of the contours will contain the percentiles contents satisfactory; however they are not the smallest areas that represent the true shape of distribution. For the normal distribution, $\sqrt{b_1}$ and b_2 are not independent only asymptotically independent.

Pearson et al. (1977) studied the power of the test of normality for a variety of tests and found the omnibus test to be one of the most powerful tests for the departures from normality.

Bowman and Shenton (1986) further studied the subject and improved the K_S^2 test to include the correlation of $\left(\sqrt{b_1}, b_2\right)$. The new improved test is

$$K_{SR}^2 = \frac{X_S^2\left(\sqrt{b_1}\right) - 2RX_S\left(\sqrt{b_1}\right)X_S(b_2) + X_S^2(b_2)}{1 - R^2}$$

where $R = \rho\left(X_S\left(\sqrt{b_1}\right), X_S(b_2)\right)$, and is treated as χ^2 $(v = 2)$.

The new bivariate model contours follow the true distribution shapes and are shown in Fig. 2.

Figure 3 shows the contrast of two sets of contours old and new.

If the 99% level is chosen, then reject samples 2, 11, 12, 14, 15, and 17 immediately without further complicated calculations. This brings out the striking simplicity of the omnibus test approach.

In concluding remarks, a contour can be constructed for any distribution which has moments. Bowman and Shenton (1975a) tabulated the values of moments of the skewness and kurtosis statistics in non-normal sampling, power series in power of (n^{-1}). Figure 4 shows several Pearson type I distributions including normal distribution for 90% with sample size $n = 200$. It is surprising to find 90% area of normal distribution is not necessarily smallest. Also the shape of contours are different for each distribution. The test could be used for non-normal distribution as well as computing the power of test for a particular distribution.

Patrinos and Bowman (1980) used the test to determine the thermal effect of rainfall amount around the nuclear plant.

Online Statistics Education

David Lane
Rice University, Houston, TX, USA

The Internet is a great resource for statistics education providing numerous online resources including textbooks, interactive simulations/demonstrations, practical applications of statistics, assessment tools, and data analysis facilities. With the continuing advances in web technologies and means for accessing the Internet, the number of resources and their use will very likely increase greatly in the coming years.

Textbooks

Textbooks on the Internet offer many advantages over their written counterparts. One advantage is the capability of having links to glossary items embedded in the text. Over 20 years ago Lachman (1989) showed that the availability of glossary items enhances the comprehension of online texts. Links to glossary items are incorporated in several online statistics books (e.g., Online Statistics Education: A Multimedia Course of Study, SurfStat, SticiGui, and Learner.org). Similarly, many online statistics books incorporate hyperlinks to related materials (e.g., Hyperstat, SurfStat, Online Statistics Education: A Multimedia Course of Study, StatSoft, and New View of Statistics). Hyperlinks are particularly valuable in technical topics such as statistics because they make it easy for students to find prerequisite material that they may need to review before proceeding. Hyperlinks can be especially useful for students who consult a book for information about a topic covered in one of the later chapters of the book.

A second advantage of online statistics textbooks is that they can provide interactive exercises. For example, Learner.org offers interactive hints as well as solutions to homework problems. SticiGui's exercises are graded interactively with correct answers and explanations shown after the student answers. Online Statistics Education: A Multimedia Course of Study also provides automatically-graded questions with explanations. In addition, some questions from this site involve randomly-generated data. For example, a student may be asked to compute an independent-groups *t* test. Data are generated randomly and presented to the student for analysis. After the student enters the

answer, the website calculates the correct answer and provides feedback. The student then has the option to do a similar problem with newly generated data.

Gregory Francis of Purdue University developed an innovative way to take advantage of the online aspect of an online textbook. Using a modified version of Online Statistics Education: A Multimedia Course of Study, Dr. Francis added the capability to monitor the time students spent on individual pages. Each page had an assigned time period and students were given credit for the page only if they had the page open for the required amount of time. Although there was no way to know if students were really reading the page during that time, the idea was that most would be reading the page since they had it open anyway. The class using this method performed remarkably better than previous classes who had used a traditional text book: the modal grade jumped from a C in the previous year's class that used a traditional text book to an A with the online textbook. There is no way to know, of course, how much of this difference was due to student differences, differences in the quality of the textbooks per se, or other advantages of online texts. In any case, this finding, if confirmed in a more controlled study, would indicate that online statistics texts have the potential to greatly improve student learning.

Most online statistics textbooks contain non-mathematical introductions to statistical analysis. However, more advanced methods such as multivariate statistics are covered by some (PsychStat, Electronic Statistics Textbook, VisualStatistics, StatNotes: Topics in Multivariate Analysis).

Interactive Simulations/Demonstrations

Many of the concepts in statistics are inherently abstract. Interactive simulations and demonstrations can help make these concepts more concrete and facilitate understanding. Accordingly, the well-respected Guidelines for Assessment and Instruction in Statistics Education (GAISE) report recommended that technology tools should be used to help students visualize concepts and develop an understanding of abstract ideas by simulations.

Technologies such as Java and Flash have made it possible for interactive simulations to be hosted on the web and run within a web browser. A large number of these educational resources based on these technologies have become available over the last 10–15 years. Among the sites offering large numbers of interactive simulations and demonstrations are "Statistics Online Computational Resource (SOCR)," the "Web Interface for Statistics Education (WISE)," the Rice Virtual Laboratory in Statistics (RVLS)," and "Computer-Assisted Statistics Textbooks (CAST). Collections of educational resources including interactive simulations and demonstrations can also be found at the websites of the "Consortium for the Advancement of Undergraduate Statistics Education (CauseWeb)" and "Multimedia Educational Resource for Learning and Online Teaching (MERLOT)."

Real World Applications

One of the key recommendations of the GAISE report was that real data be used to illustrate statistical principles. This recommendation is in accordance with Weinberg and Abramowitz (2000) who concluded that statistical principles "come alive" through the use of real data.

There are many online resources for statistics education that include real data. Among them are the "Data and Story Library (DASL)," "Australasian Data and Story Library (OzDASL)," "Journal of Statistics Education Data Archive," "Stat Labs: Mathematical Statistics through Applications," "UCLA Statistics Case Studies," and "Online Statistics Education: A Multimedia Course of Study." These datasets can play an integral part of an online statistics course.

Chance News is an outstanding resource reviewing issues in the news that use probability or statistical concepts. Back issues of this monthly publication are available online starting with May 2005.

Assessment

Assessment is a critical part of instruction. The "Assessment Resource Tools for Improving Statistical Thinking (ARTIST)" project contains numerous resources for assessment including an item database, references to articles on assessment, and research instruments. The items in the database are categorized in terms of whether they measure statistical thinking, statistical reasoning, and/or basic statistical literacy. Other assessment items can be found in the "Database of Sample Statistics Quiz Questions" and on the "Chance Evaluation" page.

Data Analysis

The Internet contains a large number of resources for online statistical analysis. These resources are valuable for online statistics education because they enable students to do statistical analyzes without downloading additional software or learning complex procedures. Most of the resources are free although a few have small costs associated with their use.

StatCrunch can perform a wide range of statistical analyzes and create several types of statistical graphs. Statistical analyzes include ANOVA, simple, multiple and ►logistic regression, and ►control charts. StatCrunch also has calculators for several statistical distributions.

The site "Web Pages that Perform Statistical Calculations" contains an extensive list of online statistics analysis calculators. Topics include (1) Selecting the right kind of analysis, (2) Calculators, plotters, function integrators, and interactive programming environments, (3) Probability distribution functions: tables, graphs, random number generators, (4) Descriptive statistics, histograms, charts, (5) Confidence intervals, single-population tests, (6) Sample comparisons: t-tests, ANOVAs, non-parametric comparisons, (7) Contingency tables, cross-tabs, ►Chi-Square tests, (8) Regression, correlation, least squares curve-fitting, non-parametric correlation, (9) Analysis of ►survival data, (10) Bayesian Methods, and (11) Power, sample size and experimental design.

About the Author

Optimal Designs for Estimating Slopes

Shahariar Huda
Professor
Kuwait University, Safat, Kuwait

Introduction

In classical designs, comparison of the treatment effects is of primary interest. Response surface designs are concerned with experiments in which treatments are combinations of various levels of factors that are quantitative. Consequently, the response is assumed to be a smooth function of the factors and the experimenter is usually interested in estimating the absolute response at various

points in the factor space. However, even in response surface designs, sometimes the experimenter may have greater interest in estimating the differences between response at various points rather than the response at individual locations (Herzberg 1967; Box and Draper 1980; Huda 1985). If differences in response at points close together in the factor space are involved, estimation of local slopes of the response surface becomes important. Optimal designs for estimating slopes are concerned with developing various meaningful optimality criteria and deriving designs that are best according to these criteria when the experimenter's primary objective is to estimate slopes. Such designs can be useful to investigators wishing to optimize (minimize or maximize) the response in a given region of the factor space.

Preliminaries

Typical response surface design set-up involves an univariate response y and k quantitative factors $x_1, \ldots, x_k$. It is assumed that $y = \phi(\mathbf{x}, \boldsymbol{\theta})$, a smooth function, where $\mathbf{x} = (x_1, \ldots, x_k)'$ and $\boldsymbol{\theta} = (\theta_1, \ldots, \theta_p)'$ is a p-component column vector of unknown parameters. A design ξ is a probability measure on the experimental region χ. Let y_i be the observation on the response at point $\mathbf{x}_i = (x_{i1}, \ldots, x_{ik})'$ $(i = 1, \ldots, N)$ selected according to the design. It is assumed that $y_i = \phi(\mathbf{x}_i, \boldsymbol{\theta}) + \varepsilon_i$ where the ε_i's are uncorrelated, $E(\varepsilon_i) = 0$ and $\mathrm{var}(\varepsilon_i) = \sigma^2$ $(i = 1, \ldots, N)$.

The parameters θ_j's are usually estimated by the method of ▶least squares. Let $\hat{\boldsymbol{\theta}}$ be the estimate of $\boldsymbol{\theta}$, then $\hat{y}(\mathbf{x}) = \phi(\mathbf{x}, \hat{\boldsymbol{\theta}})$ is the corresponding estimate of the response at the point $\mathbf{x}$. The column vector of estimated slopes along the factor axes at point $\mathbf{x}$ is given by $d\hat{y}(\mathbf{x})/d\mathbf{x} = (\partial\hat{y}(\mathbf{x})/\partial x_1, \ldots, \partial\hat{y}(\mathbf{x})/\partial x_k)'$. Let $\mathbf{V}(\xi, \mathbf{x}) = (N/\sigma^2)Cov(d\hat{y}/d\mathbf{x})$, the normalized covariance matrix of estimated slopes. $\mathbf{V}(\xi, \mathbf{x})$ depends on the point at which slopes are estimated as well as the design used. The vector $dy(\mathbf{x})/d\mathbf{x}$ not only displays the rates of change in y along the axial directions but also provides information about the rates of change in other directions. The directional derivative at point $\mathbf{x}$ in the direction specified by the vector of direction cosines $\mathbf{c} = (c_1, \ldots, c_k)'$ is $\mathbf{c}'\, dy(\mathbf{x})/d\mathbf{x}$. Also, the direction in which the derivative is largest is given by $\{(dy(\mathbf{x})/d\mathbf{x})'(dy(\mathbf{x})/d\mathbf{x})\}^{-1/2} dy(\mathbf{x})/d\mathbf{x}$.

Linear Model Set-Up

Most of the available work on response surface designs is concerned with situations where the model is linear in the parameters, that is, $\phi(\mathbf{x}, \boldsymbol{\theta}) = \mathbf{f}'(\mathbf{x})\boldsymbol{\theta}$ with $\mathbf{f}'(\mathbf{x}) = (f_1(\mathbf{x}), \ldots, f_p(\mathbf{x}))$ containing p linearly independent functions of $\mathbf{x}$. In this case for the least squares estimate $\hat{\boldsymbol{\theta}}$,

$$(N/\sigma^2)Cov(\hat{\boldsymbol{\theta}}) = \mathbf{M}^{-1}(\xi),$$

assuming the information matrix $\mathbf{M}(\xi) = \int_{\chi} \mathbf{f}(\mathbf{x})\mathbf{f}'(\mathbf{x})\, \xi(d\mathbf{x})$ to be nonsingular. Then

$$(N/\sigma^2)Cov(d\hat{y}(\mathbf{x})/d\mathbf{x}) = \mathbf{H}(\mathbf{x})\mathbf{M}^{-1}(\xi)\mathbf{H}'(\mathbf{x}) = \mathbf{V}(\xi, \mathbf{x}),$$

where $\mathbf{H}(\mathbf{x})$ is a $k \times p$ matrix whose ith row is $\partial\mathbf{f}'(\mathbf{x})/\partial x_i = (\partial f_1(\mathbf{x})/\partial x_i, \ldots, \partial f_p(\mathbf{x})/\partial x_i)$.

The commonly used linear models are the polynomial models for which $\mathbf{f}(\mathbf{x})$ consists of terms of a polynomial of order (degree) d in $\mathbf{x}$. If all the terms of a polynomial of degree d are included in the model then $\mathbf{f}(\mathbf{x})$ (and $\boldsymbol{\theta}$) contains ${}_{k+d}C_d$ components. A design ξ is called a dth order design if it permits estimation of all the parameters of a dth order model. A design ξ of order d is called symmetric if all the "odd moments" up to order $2d$ are zero, i.e., if

$$\int_{\chi} x_1^{d_1} \ldots x_k^{d_k}\, \xi(d\mathbf{x}) = 0$$

whenever one or more of the d_i's are odd integers and $\sum_{i=1}^{k} d_i \le 2d$. A design is balanced (permutation invariant) if the moments are invariant with respect to permutations of the factors $x_1, \ldots, x_k$. The class of "symmetric balanced" designs is simpler to analyze and also very rich in the sense that it contains optimal designs under many commonly used criteria.

Optimality Criteria

Research into design of experiments to estimate the slopes of a response surface was initiated by Atkinson (1970) who proposed minimization of trace of the "integrated mean squared error matrix" of the estimated slopes as a design criterion and investigated first-order designs when the true model may be a second-order model. Since then the problem of optimal design for estimating slopes has been investigated by many other researchers. Ott and Mendenhall (1972) considered univariate second-order model over an interval and used criterion of minimizing the variance of the estimated slope maximized over the design region. Murty and Studden (1972) also considered univariate polynomial model of order d over an interval and obtained optimal designs to minimize variance of the estimated slope at a fixed point in the interval as well as averaged over the interval. Myers and Lahoda (1975) considered integrated mean squared error criterion for first- and second-order designs in the presence of second- and third-order terms in the true model, respectively when the integration is done with respect to an uniform measure. Vaughan (1993) obtained a new optimal second-order design for

estimating slopes near a stationery region, taking account of both variance and bias in the estimation.

If the model assumed is correct and primary goal of the experimenter is to estimate slopes, it is natural to consider design criteria based on $\mathbf{V}(\xi,\eta)$ rather than $Cov(\hat{\theta})$ or $\mathrm{var}(\hat{y}(\mathbf{x}))$ where

$$\mathbf{V}(\xi,\eta) = \int_R (N/\sigma^2) Cov(d\hat{y}(\mathbf{x})/d\mathbf{x})\eta(d\mathbf{x}) = \int_R \mathbf{H}(\mathbf{x})\mathbf{M}^{-1}(\xi)\mathbf{H}'(\mathbf{x})\eta(d\mathbf{x}),$$

with R being the region of interest and η a measure reflecting the pattern of the experimenters interest.

Then in analogy with the traditional set-up A-, D- and E-average optimal designs for estimating slopes are defined as those minimizing

$$\beta = tr\mathbf{V}(\xi,\eta)/k = \sum_{i=1}^{k}\beta_i/k, \quad |\mathbf{V}(\xi,\eta)|^{1/k} = \prod_{i=1}^{k}\beta_i^{1/k}, \quad Max\{\beta_1,\ldots,\beta_k\}$$

respectively, where β_i are e-values of $\mathbf{V}(\xi,\eta)$.

One possibility is to take η as the measure putting all its mass at a single point $\mathbf{x}^*$ where $tr\mathbf{V}(\xi,\mathbf{x}), |\mathbf{V}(\xi,\mathbf{x})|$ and $Max\{\beta_1(\xi,\mathbf{x}),\ldots,\beta_k(\xi,\mathbf{x})\}$ is maximized, respectively, the $\beta_i(\xi,\mathbf{x})$ being e-values of $\mathbf{V}(\xi,\mathbf{x})$. These objective functions are not necessarily maximized at the same point and the measure η may be different in each case. This is the minimax approach and A-, D- and E-minimax optimality criteria of designs for estimating slopes are defined as minimization (with respect to ξ) of

$$\beta(\xi,\mathbf{x}) = \sum_{i=1}^{k}\beta_i(\xi,\mathbf{x})/k, \; |\mathbf{V}(\xi,\mathbf{x})|^{1/k} = \prod_{i=1}^{k}\{\beta_i(\xi,\mathbf{x})\}^{1/k}, \; Max\{\beta_1(\xi,\mathbf{x}),\ldots,\beta_k(\xi,\mathbf{x})\}$$

maximized with respect to $\mathbf{x} \in R$, respectively. Under "MV-minimax optimality" criterion the objective is to minimize the largest diagonal element of $\mathbf{V}(\xi,\mathbf{x})$ maximized with respect to $\mathbf{x} \in R$.

Available Results

The A-criterion is the easiest to handle and has been extensively used in the past. The A-minimax second- and third-order designs for regression over spheres were derived in Mukerjee and Huda (1985), some results for the set-up with $R \neq \chi$ being given in Huda (1990). For the cubic regions the A-minimax second-order designs were presented in Huda and Shafiq (1992) while the third-order designs were derived in Huda and Al-Shiha (1998).

The D-criterion is much more difficult to tackle. For second-order models over spherical regions the D-minimax designs were derived in Huda and Al-Shiha (1999) while the E-minimax designs were presented in Al-Shiha and Huda (2001). More recently, Huda and Al-Shingiti (2004) obtained A-, D- and E-minimax designs over spherical regions when $R \neq \chi$. Huda and Al-Shiha (2000) provided the D- and E-minimax second-order designs over cubic regions.

A-average optimal second- and third-order designs for spherical regions were studied in Huda (1986). The A-average second-order designs for cubic regions were studied in Huda (1998).

Concluding Remarks

Many interesting problems remain unsolved in optimal design of experiments for estimating the slopes. For example, the D- and E-minimax criteria have not yet been applied for third- and higher-order designs. Very little work in general has been done for third-order designs and practically none for higher order designs in more than one variable. The derivation of optimal designs for models of order three and higher is likely to be very difficult but certainly deserves the attention of researchers in the field. Researchers also need to consider situations that take account of the possibility of bias in the assumed models.

About the Author

Dr. Shahariar Huda is Professor of Statistics, Department of Statistics and O.R., Faculty of Science, Kuwait University. He is Editor-in-Chief for *International Journal of Statistical Sciences* (IJSS) (Bangladesh, 2007–2012). He is Associate editor for the following journals: *Journal of Applied Statistical Sciences* (USA), *Aligarh Journal of Statistics* (India), *Journal of Statistical Research* (Bangladesh), and *Journal of Statistical Sciences* (Bangladesh). He has received an award for the best paper on Experimental Design (during 1986–1987) in *Journal of Indian Society of Agricultural Statistics*. He is Elected Ordinary Member of International Statistical Institute (1993), Member of Royal Statistical Society, American Statistical Association and Institute of Mathematical Statistics. Professor Huda has written 26 papers in international journals on slope estimation. He is co-author of the book *Markov Models with Covariate Dependence for Repeated Measures* (with M.A. Islam and R.I. Chowdhury, Nova Science, USA, 2009).

Optimal Regression Design

Saumen Mandal
Associate Professor
University of Manitoba, Winnipeg, MB, Canada

Introduction

There are a variety of problems in statistics, which demand the calculation of one or more probability distributions or measures. Optimal regression design is a particular example. Other examples include parameter estimation, adaptive design and stratified sampling.

Consider the problem of selecting an experimental design to furnish information on models of the type $y \sim \pi(y|\underline{x}, \underline{\theta}, \sigma)$, where y is the response variable; $\underline{x} = (x_1, x_2, \ldots, x_m)^T$ are design variables, $\underline{x} \in \mathcal{X} \subseteq \mathbb{R}^m$, $\mathcal{X}$ is the design space; $\underline{\theta} = (\theta_1, \theta_2, \ldots, \theta_k)^T$ are unknown parameters; σ is a nuisance parameter, fixed but unknown; and $\pi(.)$ is a probability model. In most applications, $\mathcal{X}$ is taken to be compact. For each $\underline{x} \in \mathcal{X}$, an experiment can be performed whose outcome is a random variable $y(\underline{x})$, where $var(y(\underline{x})) = \sigma^2$. In linear models, it is further assumed that $y(\underline{x})$ has an expected value of the explicit form $E(y|\underline{v}) = \underline{v}^T\underline{\theta}$, where $\underline{v} \in \mathcal{V}$, $\mathcal{V} = \{\underline{v} \in \mathbb{R}^k : \underline{v} = \underline{\eta}(\underline{x}), \underline{x} \in \mathcal{X}\}$ with $\underline{\eta}(\underline{x}) = (\eta_1(\underline{x}), \eta_2(\underline{x}), \ldots, \eta_k(\underline{x}))^T$. That is, $\mathcal{V}$ is the image under a set of regression functions η of $\mathcal{X}$, called the induced design space.

Clearly choosing a vector $\underline{x}$ in the design space $\mathcal{X}$ is equivalent to choosing a k-vector $\underline{v}$ in the closed bounded k-dimensional space $\mathcal{V}$. Typically this design space is continuous but we can assume that $\mathcal{V}$ is discrete. Suppose that $\mathcal{V}$ consists of J distinct vectors $\underline{v}_1, \underline{v}_2, \ldots, \underline{v}_J$. In order to obtain an observation on y, a value for $\underline{v}$ must first be chosen from the J elements of $\mathcal{V}$ to be the point at which to take this observation.

Exact and Approximate Designs

A natural question to consider is at what values of $\underline{v}$ should observations, say n, on y be taken in order to obtain a "best" inference or as reliable an inference as possible for all or some of the parameters $\underline{\theta}$. Such a "best" selection of $\underline{v}$ (or $\underline{x}$ values) or allocation of the n observations to the elements of $\mathcal{V}$ (or $\mathcal{X}$) is termed an optimal regression design. Given n observations, we must decide how many of these, say n_j, to take at $\underline{v}_j$, $\sum n_j = n$. Given that the n_j's must be integer this is an integer programming problem and in the optimal design context is described as an "exact design" problem. Typically interger programming

problems are difficult or at least laborious to solve, mainly because the theory of calculus cannot be used to define the existence of or to identify optimal solutions.

However, we could find a simpler or more flexible problem to solve and yet is not much visibly different from the original problem. If $\underline{\hat{\theta}}$ is the least squares estimator of $\underline{\theta}$, then $cov(\underline{\hat{\theta}}) \propto M^{-1}(p)$, where $M(p)$ is the per observation information matrix:

$$M(p) = \sum_{j=1}^{J} p_j \underline{v}_j \underline{v}_j^T = VPV^T = \sum_{j=1}^{J} p_j \underline{\eta}(\underline{x}_j)\underline{\eta}^T(\underline{x}_j)$$

where V is the $k \times J$ matrix $[\underline{v}_1\, \underline{v}_2 \ldots \underline{v}_J]$, $P = \text{diag}\,(p_1, p_2, \ldots, p_J)$, $p_j = n_j/n$. So p_j is the proportion of observations taken at $\underline{v}_j$, so that $p_j \geq 0$, $\sum p_j = 1$; and $p = (p_1, p_2, \ldots, p_J)$ represents the resultant distribution on $\mathcal{V}$. Thus our problem becomes that of choosing p to make $M(p)$ large subject to $p_j = n_j/n$. Relaxing the latter to $p_j \geq 0$ and $\sum p_j = 1$ yields an "approximate design" problem. Naturally an approximate solution that would be preferred to the original exact design problem would be np, rounded to a nearest exact design.

We wish to choose the proportion p_j of observations, taken at $\underline{x}_j$ (or $\underline{v}_j$) to ensure good estimation of $\underline{\theta}$ by optimizing some criterion. The most important criterion in design applications is that of D-optimality, in which the criterion $\phi(p) = \psi\{M(p)\} = log\{det(M(p))\}$, is maximized. A D-optimal design minimizes the volume of the conventional ellipsoidal confidence region for the parameters of the linear model. Other choices of maximizing criteria are $\psi\{M(p)\} = -\underline{c}^T M^{-1}(p)\underline{c}$ for a given vector $\underline{c}$ (c-optimality; appropriate if there is interest only in $\underline{c}^T\underline{\theta}$) or $\psi\{M(p)\} = -Trace(AM^{-1}(p)A^T)$ and $\psi\{M(p)\} = -logdet(AM^{-1}(p)A^T)$ for a given $s \times k$ matrix A, $s < k$ (linear optimality and D_A-optimality respectively and appropriate if there is interest in inference only for $A\underline{\theta}$). A-optimality is the special case of linear optimality with $A = I$, the identity matrix. There is a vast statistical literature on optimal design and optimality criteria. Useful texts in optimal design are Fedorov (1972), Atkinson and Donev (1992), Pukelsheim (1993), and Silvey (1980).

Optimality Conditions and Algorithms

Our general problem is to maximize a criterion $\phi(p)$ subject to $p_j \geq 0, j = 1, 2, \ldots, J$ and $\sum p_j = 1$. To solve the problem, we first define optimality conditions in terms of point to point directional derivatives. Making use of differential calculus, we exploit the directional derivative of Whittle (1973). The directional derivative $F_\phi\{p, q\}$ of a criterion function $\phi(.)$ at p in the direction of q is defined as

$$F_\phi\{p, q\} = \lim_{\varepsilon \downarrow 0} \frac{\phi\{(1-\varepsilon)p + \varepsilon q\} - \phi(p)}{\varepsilon}.$$

The derivative $F_\phi\{p, q\}$ exists even if $\phi(.)$ is not differentiable. If $\phi(.)$ is differentiable, $F_\phi(p, q) = (q - p)^T \partial\phi/\partial p$. Let

$$F_j = F_\phi(p, e_j) = \frac{\partial \phi}{\partial p_j} - \sum_{i=1}^{J} p_i \frac{\partial \phi}{\partial p_i} = d_j - \bar{d},$$

$$d_j = \frac{\partial \phi}{\partial p_j},\ \bar{d} = \sum_{i=1}^{J} p_i d_i$$

where e_j is the jth unit vector in $\mathbb{R}^J$. We call F_j the vertex directional derivative of $\phi(.)$ at p. If $\phi(.)$ is differentiable at an optimizing distribution p^*, then the first-order conditions for $\phi(p^*)$ to be a local maximum of $\phi(.)$ in the feasible region of the problem are

$$F_j^* = F_\phi\{p^*, e_j\} \begin{cases} = 0 & \text{for } p_j^* > 0 \\ \leq 0 & \text{for } p_j^* = 0. \end{cases}$$

If $\phi(.)$ is concave on its feasible region, then the above first-order stationarity conditions are both necessary and sufficient for optimality, a result known as the general equivalence theorem in optimal design (Kiefer 1974).

In order to determine the optimal weights, we often require an algorithm because it is typically not possible to evaluate an optimal solution explicitly. Several algorithms exist in the literature. A class of algorithms which neatly satisfy the basic constraints of the optimal weights take the form $p_j^{(r+1)} \propto p_j^{(r)} f\left(d_j^{(r)}\right)$, where $d_j^{(r)} = \partial\phi/\partial p_j$ at rth iterate $p = p^{(r)}$ and the function $f(.)$ satisfies certain conditions and may depend on a free positive parameter δ. Torsney (1977) first proposed this type of iteration by taking $f(d) = d^\delta$ with $\delta > 0$. Subsequent empirical studies include Silvey et al. (1978) and Torsney (1988). Torsney (1983) explores monotonicity of particular values of δ for particular $\phi(p)$. Mandal and Torsney (2006) modified the algorithm for more than one optimizing distributions based on a clustering approach. Mandal et al. (2005) used the algorithm for constructing designs subject to additional constraints.

There are many other algorithms in the literature. Vertex direction algorithms which perturb one p_j and change the others proportionately were first proposed by Fedorov (1972) and Wynn (1972). When all p_j are positive at the optimum or when it has been established which are positive, constrained steepest ascent or Newton type iterations may be appropriate. See Wu (1978) and Atwood (1980) on these respectively. Molchanov and Zuyev (2001)

consider steepest descent algorithms based on the gradient function.

Conclusion

Finally, as a concluding remark, one important advantage of optimal regression designs is that we can find the best selection of the inputs (factors) for which the optimal value of each response occurs. Another advantage of optimal design is that it reduces the costs of experimentation by allowing statistical models to be estimated with fewer experimental runs.

Acknowledgments

The author thanks the reviewer for helpful suggestions that led to some improvement over an earlier version of the manuscript. The research of the author is supported by a Discovery Grant from the Natural Sciences and Engineering Research Council (NSERC) of Canada.

To fix the idea, we consider the estimation of means in the following one-way ANOVA model,

$$Y_{ij} = \theta_i + \epsilon_{ij}, \quad i = 1, \ldots, k, \quad j = 1, , \ldots, n_i. \qquad (1)$$

For brevity sake, we consider that ϵ_{ij} are identically and independently normally distributed with mean 0 and common finite variance σ^2. The statistical objective is to estimate simultaneously the mean parameter $\boldsymbol{\theta} = (\theta_1, \ldots, \theta_k)'$. Let $\bar{Y}_i = \sum_{j=1}^{n_i} y_{ij}/n_i$, $i = 1, 2, \ldots, k$. If σ is known, the vector $\left(\bar{Y}_1, \ldots, \bar{Y}_k\right)'$ is a complete sufficient statistic for $\boldsymbol{\theta}$. Further, it is the best unbiased, maximum likelihood, and minimax estimator of $\boldsymbol{\theta}$. However, we wish to improve the performance of the maximum likelihood estimator (MLE), $\bar{Y}_i$ by incorporating the information (which may not be certain) regarding the parameter vector of interest, $\boldsymbol{\theta}$. In other words, it is possible that $\boldsymbol{\theta} = \boldsymbol{\theta}^o$, where $\boldsymbol{\theta}^o$ is a known prior guess of $\boldsymbol{\theta}$. On the other hand, in many applications one considers that $\boldsymbol{\theta} = \theta 1_k$, where θ is the unknown common parameter of interest and 1_k is a k-column vector with all entries equal to 1. Indeed, it is not unusual to encounter the above information regarding the parameter of interest in many practical situations. Hence, in either situation we assume that a prior guess of $\boldsymbol{\theta}$, say $\tilde{\boldsymbol{\theta}}$, is available or can be evaluated from the data. For example, $\tilde{\boldsymbol{\theta}}$ is the restricted maximum likelihood estimator (RMLE) under the assumption that $\boldsymbol{\theta} = \theta 1_k$. In this case, $\tilde{\boldsymbol{\theta}} = (\tilde{\theta}, \ldots, \tilde{\theta})' = \tilde{\theta} 1_k$, where $\tilde{\theta} = \bar{Y} = \sum_{i=1}^{k} \sum_{j=1}^{n_i} y_{ij}/n$, where $n = n_1 + \ldots + n_k$. It is well-documented in the scientific literature that restricted estimator yields smaller risk (under quadratic loss) when a priori information is

nearly correct, however at the expense of poorer performance in the rest of the parameter space induced by the restriction. The incorrect or imprecise restrictions on $\boldsymbol{\theta}$ may lead to biased (or even inconsistent) and inefficient estimators of $\boldsymbol{\theta}$. Now, the question is how to combine $\tilde{\boldsymbol{\theta}}$ and $\hat{\boldsymbol{\theta}}$ to get a better estimation strategy for $\boldsymbol{\theta}$. A natural way to balance the potential bias of the estimator under the restriction against the benchmark estimator is to take a weighted average of $\hat{\boldsymbol{\theta}}$ and $\tilde{\boldsymbol{\theta}}$. Such shrinkage estimator (SE) or integrated estimator is defined as

$$\hat{\boldsymbol{\theta}}^{S} = \pi\hat{\boldsymbol{\theta}} + (1-\pi)\tilde{\boldsymbol{\theta}} = \tilde{\boldsymbol{\theta}} + \pi(\hat{\boldsymbol{\theta}} - \tilde{\boldsymbol{\theta}}), \tag{2}$$

for a judiciously chosen weight π $(0 \le \pi \le 1)$. Many of the estimators proposed in the reviewed literature, both design-based and model-based, have the integrated form (2). A major drawback of $\hat{\boldsymbol{\theta}}^{S}$ is that it is not uniformly better than either component estimators in terms of risk. Another approach is to employ shrinkage estimation based on Stein rule, which in turn yields the optimal weight for $\hat{\boldsymbol{\theta}}^{S}$. To construct a shrinkage estimator, we consider the preliminary test approach as advocated by Sclove (1968) or empirical Bayes consideration. This approach had been implemented by Ahmed (2001) and others. In this technique, the prior information regarding $\boldsymbol{\theta}$ can be displayed in the form of the null hypothesis. Let us consider the following null hypothesis:

$$H_o: \theta_1 = \cdots = \theta_k = \theta \text{ (unknown)}. \tag{3}$$

For the preliminary test on the null hypothesis in (3), we consider the following F-test statistic

$$D = \frac{(\hat{\boldsymbol{\theta}} - \tilde{\boldsymbol{\theta}})'\boldsymbol{\Lambda}(\hat{\boldsymbol{\theta}} - \tilde{\boldsymbol{\theta}})}{(k-1)S^2}, \quad \boldsymbol{\Lambda} = \text{diagonal}(n_1, \ldots, n_k),$$
$$S^2 = \frac{1}{n-k}\sum_{i=1}^{k}\sum_{j=1}^{n_i}(y_{ij}). \tag{4}$$

A preliminary test estimator (PTE) is defined as

$$\hat{\boldsymbol{\theta}}^{P} = \tilde{\boldsymbol{\theta}} + (\hat{\boldsymbol{\theta}} - \tilde{\boldsymbol{\theta}})I(D \ge d_\alpha), \tag{5}$$

where $I(A)$ is an indicator function of the set A and d_α is the upper $100\alpha\%$ $(0 < \alpha < 1)$ point of the test statistic under the null hypothesis. The PTE is essentially obtained by repacking π by a random quantity $I(D \ge d_\alpha)$; however, this is not an optimal value of π. The PTE does not uniformly improve upon $\hat{\boldsymbol{\theta}}$ which merits further enhancement. Hence we replace this indicator function by a smooth function of D to obtain James–Stein (J–S) type estimator (see ▶James-Stein Estimator).

Optimal Shrinkage Estimation Strategy

The J-S type shrinkage estimator of $\boldsymbol{\theta}$ is defined by

$$\hat{\boldsymbol{\theta}}^{JS} = \tilde{\boldsymbol{\theta}} + \{1 - cD^{-1}\}(\hat{\boldsymbol{\theta}} - \tilde{\boldsymbol{\theta}}), \quad k > 2, \tag{6}$$

where c is the shrinkage constant chosen in an interval in such a way that $\hat{\boldsymbol{\theta}}^{JS}$ dominates $\hat{\boldsymbol{\theta}}$. We notice that although this estimator resembles the J-S rule, its construction is based on the preliminary test approach. Further, as it shrinks the $\hat{\boldsymbol{\theta}}$ toward $\tilde{\boldsymbol{\theta}}$, this estimator is generally called a shrinkage estimator. Clearly, if the value of D is small then a relatively large weight is placed on $\tilde{\boldsymbol{\theta}}$. Otherwise, more weight is placed on $\hat{\boldsymbol{\theta}}$. Consequently, $\hat{\boldsymbol{\theta}}^{JS}$ is a special case of $\hat{\boldsymbol{\theta}}^{S}$ with $\pi = (1 - cD^{-1})$. It is important to note that $\hat{\boldsymbol{\theta}}^{JS}$ may over-shrink $\hat{\boldsymbol{\theta}}$ toward the $\tilde{\boldsymbol{\theta}}$, thus causing a possible inversion of the sign of the benchmark estimator $\hat{\boldsymbol{\theta}}$. A positive-rule shrinkage estimator (PSE) $\hat{\boldsymbol{\theta}}^{JS+}$ is obtained from (6) by changing the factor $1-c/D$ to 0 whenever $D \le c$, that is,

$$\hat{\boldsymbol{\theta}}^{JS+} = \tilde{\boldsymbol{\theta}} + \left(1 - cD^{-1}\right)^{+}(\hat{\boldsymbol{\theta}} - \tilde{\boldsymbol{\theta}}), \tag{7}$$

where $z^{+} = max(0, z)$. The PSE is particularly important to control the over-shrinking inherent in $\hat{\boldsymbol{\theta}}^{JS+}$. For this reason, Ahmed (2001) recommended using the shrinkage estimator as a tool to develop the PSE instead of as an estimator in its own right. Rewriting the above relation in the following weighted form

$$\hat{\boldsymbol{\theta}}^{JS+} = \tilde{\boldsymbol{\theta}} + \left(1 - cD^{-1}\right)[1 - I(D > c)](\hat{\boldsymbol{\theta}} - \tilde{\boldsymbol{\theta}}), \tag{8}$$

we easily see that $\hat{\boldsymbol{\theta}}^{JS+} = \hat{\boldsymbol{\theta}}^{S}$ with $\pi = (1 - cD^{-1})I(cD^{-1} > 1)$ keeping in mind all the shrinkage estimators are biased estimators of $\boldsymbol{\theta}$. Since bias is a part of the risk, we shall only compare the risk function of the estimators. Assuming that $\hat{\boldsymbol{\theta}}^{*}$ is an estimator of $\boldsymbol{\theta}$ and Q is a positive semi-definite matrix, let us define the quadratic loss function

$$\mathcal{L}(\hat{\boldsymbol{\theta}}^{*}; \boldsymbol{\theta}) = (\hat{\boldsymbol{\theta}}^{*} - \boldsymbol{\theta})'Q(\hat{\boldsymbol{\theta}}^{*} - \boldsymbol{\theta}) = trace[Q(\hat{\boldsymbol{\theta}}^{*} - \boldsymbol{\theta})(\hat{\boldsymbol{\theta}}^{*} - \boldsymbol{\theta})']. \tag{9}$$

The risk of $\hat{\boldsymbol{\theta}}^{*}$ is $\mathcal{R}(\hat{\boldsymbol{\theta}}^{*}; \boldsymbol{\theta}) = \mathcal{E}[\mathcal{L}(\hat{\boldsymbol{\theta}}^{*}; \boldsymbol{\theta})] = trace(Q\boldsymbol{\Gamma})$, where $\boldsymbol{\Gamma}$, the mean squared error matrix, is defined as $\boldsymbol{\Gamma} = \mathcal{E}([\hat{\boldsymbol{\theta}}^{*} - \boldsymbol{\theta})(\hat{\boldsymbol{\theta}}^{*} - \boldsymbol{\theta})']$. Noting that $\mathcal{R}(\hat{\boldsymbol{\theta}}; \boldsymbol{\theta}) = \sigma^2\boldsymbol{\Lambda}^{-1}$, so to appraise the relative risk performance in meaningful way it makes sense that we consider $Q = \sigma^{-2}\boldsymbol{\Lambda}$ what follows in the remaining discussions. For this particular choice of Q, we have $\mathcal{R}(\hat{\boldsymbol{\theta}}; \boldsymbol{\theta}) = k$. The risk of the shrinkage estimators are given below. These results originated from the work of

James and Stein (1961). For detailed derivation we refer to Ahmed and Ullah (1999).

$$R(\hat{\boldsymbol{\theta}}^{JS};\boldsymbol{\theta}) = k - c_o m(k-1)\mathcal{E}\left[2\chi_{k+1}^{-2}(\Delta) - (k-3)\chi_{k+1}^{-4}(\Delta)\right] + c_o m(k+1)\Delta\mathcal{E}\left(\chi_{k+3}^{-4}(\Delta)\right),$$

where $c_o = (k-3)(m+2)^{-1}$ is optimal shrinkage constant with $m = n-k$. Further, $\Delta = \sigma^{-2}(A\boldsymbol{\theta})'\boldsymbol{\Lambda}(A\boldsymbol{\theta})$, with $A = I_k - n^{-1}1_k 1_k'\boldsymbol{\Lambda}$, I_k is the $k\times k$ identity matrix. The above relation reveals that $R(\hat{\boldsymbol{\theta}}^{JS};\boldsymbol{\theta}) \le R(\hat{\boldsymbol{\theta}};\boldsymbol{\theta})$ for all the values of Δ and strict inequality holds for some Δ. The maximum reduction in the risk for $\hat{\boldsymbol{\theta}}^{JS}$ is achieved at $\Delta = 0$, i.e., $\boldsymbol{\theta} = \theta 1_k$.

$$\begin{aligned} R(\hat{\boldsymbol{\theta}}^{JS+};\boldsymbol{\theta}) = R(\hat{\boldsymbol{\theta}}^{JS};\boldsymbol{\theta}) &- (k-1)G_{k+1,m}(k_1;\Delta) \\ &- m(k-1)c_o\mathcal{E}\left[\left\{(k-3)\chi_{k+1}^{-4}(\Delta)\right.\right. \\ &\left.\left.-2\chi_{k+1}^{-2}(\Delta)\right\} I\left(\chi_{k+1}^2(\Delta)/\chi_m^2 \le c_o\right)\right] \\ &- mc_o\Delta\left[\left\{(k-3)\chi_{k+1}^{-2}(\Delta)\right.\right. \\ &\left.\left.-2\chi_{k+3}^{-4}(\Delta)\right\} I\left(\chi_{k+3}^2(\Delta)/\chi_m^2 \le c_o\right)\right. \\ &\left.+2\chi_{k+1}^{-2}(\Delta) I\left(\chi_{k+1}^2(\Delta)/\chi_m^2 \le c_o\right)\right] \\ &+ \Delta\{G_{k+1,m}(k_1;\Delta) - G_{k+3,m}(k_2;\Delta)\}, \end{aligned}$$

where $G_{p_1,\,p_2}(.\,,\,\Delta)$ is the cumulative distribution of a non-central F-distribution with p_1 and p_2 degrees of freedom and non-centrality parameter Δ with $k_1 = c_o m(k+1)^{-1}$ and $k_2 = c_o m(k+3)^{-1}$. The above risk expression leads to the relation that $R(\hat{\boldsymbol{\theta}}^{JS+};\boldsymbol{\theta}) \le R(\hat{\boldsymbol{\theta}}^{JS});\boldsymbol{\theta}) \le R(\hat{\boldsymbol{\theta}});\boldsymbol{\theta})$ for all the values of Δ, and strict inequality holds for some Δ. The maximum reduction in the risk is achieved at $\Delta = 0$. Therefore, the $\hat{\boldsymbol{\theta}}^{JS+}$ outperforms both $\hat{\boldsymbol{\theta}}^{JS}$ and $\hat{\boldsymbol{\theta}}$ in the entire parameter space induced by Δ and the upper of risk function of $\hat{\boldsymbol{\theta}}^{JS+}$ is obtained when $\Delta \to \infty$. Thus, for $\pi = \pi_o = (1 - c_o D^{-1})\ I(c_o D^{-1} \le 1)$ in $\hat{\boldsymbol{\theta}}^{S}$ given in (2), we obtain an optimal shrinkage strategy which provides a basis for optimally combining the estimation problems. This approach yields a well-defined data-based shrinkage estimator that combines estimation problem by shrinking a benchmark estimator to plausible alternative quantity. The optimal shrinkage estimator is similar to the most celebrated J–S estimator in which they shrink the benchmark estimator toward the null vector for estimating the mean vector of a multivariate normal distribution (see ►Multivariate Normal Distributions). There is no mystery about the origin; these estimators can shrink toward any point. Here we use the restricted estimator instead in the formulations and evaluations for optimal shrinkage strategy in one-way ANOVA. These formulations have been extended in regression problems pertaining to parametric, non-parametric and semi-parametric setup by a host of researchers including Ahmed (2001) and Ahmed et al. (2006, 2007). Now we present the formulation in a regression set-up.

Regression Model

Let us consider the linear regression model $\boldsymbol{y_n} = \boldsymbol{X_n}\boldsymbol{\beta} + \boldsymbol{\epsilon_n}$, where $\boldsymbol{y_n}$ is a $n\times 1$ random vector, $\boldsymbol{X_n}$ is a known $n\times k$ matrix $(n > k)$ of regression constant and, as the sample size n becomes infinitely large, $\lim_{n\to\infty}\left(\boldsymbol{X_n'}X_n\right)/n = \boldsymbol{C}$ where $\boldsymbol{C}$ is finite and nonsingular matrix. Further, $\boldsymbol{\beta}$ is a column vector of k unknown regression parameters, and $\boldsymbol{\epsilon} = (\epsilon_1,\ldots,\epsilon_n)'$ are independent and identically distributed random variables with a distribution function F on real line $\Re = (-\infty,+\infty)$. Here we do not make any assumption about the functional form of the F. We assume that $E(\boldsymbol{\epsilon}) = \boldsymbol{0}$ and $E(\boldsymbol{\epsilon\epsilon}') = \sigma^2\boldsymbol{I_n}$, where σ^2 is unknown positive finite parameter.

We are primarily interested in the estimation of $\boldsymbol{\beta}$ when $\boldsymbol{\beta}$ is suspected to lie in the subspace defined by $\boldsymbol{H\beta} = \boldsymbol{h}$, where $\boldsymbol{H}$ is a given $q\times k$ matrix of rank $q \le k$ and $\boldsymbol{h}$ is a given $q\times 1$ vector of constants. The test statistic for the null hypothesis $H_o : \boldsymbol{H\beta} = \boldsymbol{h}$ is

$$D = (\boldsymbol{H\hat{\beta}} - \boldsymbol{h})'\left[\boldsymbol{H}\left(\boldsymbol{X_n'X_n}\right)^{-1}\boldsymbol{H}'\right]^{-1}(\boldsymbol{H\hat{\beta}} - \boldsymbol{h})/S^2,$$

$$S^2 = (\boldsymbol{Y_n} - \boldsymbol{X_n\hat{\beta}})'(\boldsymbol{Y_n} - \boldsymbol{X_n\hat{\beta}})/n-k,$$

where $\hat{\boldsymbol{\beta}}$ is the least square estimator (LSE) of $\boldsymbol{\beta}$. The restricted estimator of $\boldsymbol{\beta}$ is given by

$$\tilde{\boldsymbol{\beta}} = \hat{\boldsymbol{\beta}} - \boldsymbol{C_n^{-1}H'}\left(\boldsymbol{HC_n^{-1}}H'\right)^{-1}(\boldsymbol{H\hat{\beta}} - \boldsymbol{h}).$$

with $\boldsymbol{C}_n = \boldsymbol{X}_n'\boldsymbol{X}_n$. Consequently, placing $\tilde{\boldsymbol{\beta}}$, $\hat{\boldsymbol{\beta}}$ and D appropriately in (6) and (7), we can obtain shrinkage estimators for $\boldsymbol{\beta}$ respectively. Theses estimator preserve the dominance property over LSE. Recently, Nkurunziza and Ahmed (2010) extended shrinkage methodology to the matrix estimation. The literature on shrinkage estimation strategy is vast; and research on the statistical implications of these and other combining possibilities for a range of statistical models is ongoing and growing in statistical, econometric, and related scientific literatures.

Optimal Shrinkage Preliminary Test Estimation

S. Ejaz Ahmed, S. Chitsaz, S. Fallahpour
University of Windsor, Windsor, ON, Canada

Statistical models parameters are estimated in an effort to have knowledge about unknown quantities. In many situations, however, statisticians provide the estimation of the parameters by using not only information based on the sample, but other information as well. This information may be regarded as *nonsample information(NSI)* or *uncertain prior information (UPI)* about the parameter of interest. It is advantageous to utilize the *NSI* in the estimation procedure, especially when the information based on the sample may be rather limited or even the data quality is questionable. But in some experimental cases, it is not certain whether or not this information holds. Consider the data arising from tumor measurements in mice, for example, at various times following injection of carcinogens. Such data should be thought as coming from an *in vivo* experiment. Biologists are interested in estimating growth rate parameter θ when it suspected a priori that $\theta = \theta_0$. Such θ_0 can be obtained directly from *in vitro* experiments in which cell behavior may or may not be different because of different environmental conditions. Thus, biologists may have reason to suspect that θ_0 is the true value of the growth parameter for the *in vivo* experiment, but are not sure. Generally speaking, consequences of incorporating NSI depend on the *quality or reliability* of information introduced in the estimation process. This uncertain prior information in the form of the null hypothesis can be used in the estimation procedure. It is natural to perform a preliminary test on the validity of the *UPI* in the form of the parametric restrictions, and then choose between the restricted and unrestricted estimation procedure, depending upon the outcome of the preliminary test. This idea was initially conceived by T.A. Bancroft in 1944. However, this may be partly motivated by the remarks made by Berkson (1942). The *preliminary test estimators (PTE)* are widely used by researchers, as is evident from the extensive bibliographies and research articles. A standard reference on the PTE is Judge and Bock (1978).

For illustrative purposes, let us consider one sample problem. Suppose we observe $Y_1, \cdots, Y_n$ satisfying $Y_i = \theta + \epsilon_i, \quad i = 1, \cdots, n$, where the errors ϵ_i are independently and identically normally distributed with a mean of 0 and variance σ^2.

The statistical problem is to estimate θ when $\theta = \theta_0$ is suspected. To estimate θ, one need only to consider

the sufficient statistic $T(y) = \sum_{i=1}^{n} y_i$. The *benchmark or unrestricted estimator (UE)* θ is $\hat{\theta}^U = T(y)/n$, with variance $\frac{\sigma^2}{n}$.

Preliminary Test Estimation

The preliminary test estimation strategy involves a statistical test of the available NSI based on an appropriate test statistic and a decision is made on the outcome of the test. Thus, the *preliminary test estimator (PTE)* of θ denoted by $\hat{\theta}^P$ is defined as

$$\hat{\theta}^P = \theta_0 I(D_n < d_\alpha) + \hat{\theta}^U I(D_n \geq d_\alpha), \tag{1}$$

where D_n is any suitable test statistic and $I(A)$ is an indicator function of the set A, and d_α is the upper $100\alpha\%$ $(0 < \alpha < 1)$ point of the test statistic. For our estimation problem to test the null hypothesis $H_0 : \theta = \theta_0$ against $H_1 : \theta \neq \theta_0$, we use the test statistic $D_n = \frac{n(\hat{\theta}^U - \theta_0)^2}{s^2}$, where s^2 is the sample estimate of σ^2. Under the null hypothesis, D_n follows an F-distribution. Thus, at the α-level of significance we reject the null hypothesis if $D_n \geq F_{(\alpha;\,1,\,n-1)}$, where $F_{(\alpha;\,1,\,n-1)}$ is the upper α-level critical values of the central F-distribution with $(1, n-1)$ degrees of freedom. Thus, we can replace d_α by $F_{(\alpha;\,1,\,n-1)}$ in (1) and the remaining discussion follows. By construction, $\hat{\theta}^P$ is a biased estimator and the mean squared error (MSE) of the $\hat{\theta}^P$ is given by

$$MSE(\hat{\theta}^P) = \frac{\sigma^2}{n} - \frac{\sigma^2}{n}\left[H_{3,n-1}(F_a, \delta) - \delta\left\{2H_{3,n-1}(F_a, \delta) + H_{5,n-1}(F_b, \delta)\right\}\right], \tag{2}$$

where, $H_{k,\,n-1}(.\,,\,\delta/2,)$ is the cumulative distribution of a non-central F-distribution with k and $n-1$ degrees of freedom and non-centrality parameter $\delta/2$, where $\delta = n(\theta - \theta_0)^2/\sigma^2$. Further, $F_a = 1/3\ F_{(\alpha;\,1,\,n-1)}$ and $F_b = 1/5\ F_{(\alpha;\,1,\,n-1)}$.

The MSE expression reveals the typical characteristics of the preliminary test estimator. For small values of δ the performance of $\hat{\theta}^P$ is better than $\hat{\theta}^U$. Alternatively, for larger values of δ, the value of the $MSE(\hat{\theta}^P)$ increases, reaches its maximum after crossing the $MSE(\hat{\theta}^U) = \sigma^2/n$ and then monotonically decreases and approaches towards it. Further, as α, approaches to one, $MSE(\hat{\theta}^P)$ tends to $MSE(\hat{\theta}^U)$. Thus, the relative performance of $\hat{\theta}^P$ to $\hat{\theta}^U$ will also depend on the size of the preliminary test. It was recommended in the literature to use a level of significance of at least 0.25 or more for such preliminary testing to achieve reasonable MSE reduction. Use of such a large significance level helps maximizing the minimum efficiency of $\hat{\theta}^P$. Hence, the use of $\hat{\theta}^P$ was limited due to the large size of the preliminary test. To resolve this issue Ahmed (1992) introduced the shrinkage technique in the preliminary test estimation to overcome this difficulty. The proposed methodology remarkably improves upon the *PTE* with respect to the size of the preliminary test while maintaining the minimum efficiciecy.

A *shrinkage estimator (SE)* of θ is defined by $\hat{\theta}^{SR} = \pi\theta_0 + (1-\pi)\hat{\theta}^U$, where $\pi \in (0,1)$ is a coefficient reflecting the degree of confidence in the prior information. However, the key question in this type of estimator is how to select an optimal value for the shrinkage parameter π. In some situations, it may suffice to fix the parameter at some given value. The second choice, is to choose the parameter in a data-driven fashion by explicitly minimizing a suitable risk function. A common but also computationally intensive approach to estimate π is using cross-validation. On the other hand, from a Bayesian perspective one can employ the empirical Bayes technique. In this case π is treated as a hyper-parameter and may be estimated from the data by optimizing the marginal likelihood. For brevity sake, we assume that the value of π may be completely determined by the experimenter, depending upon the reliability of *NSI*. The SE performs better than $\hat{\theta}^U$ near the null hypothesis, but as the hypothesis error grows, $\hat{\theta}^{SR}$ may be considerably biased, inefficient and inconsistent, while the performance of $\hat{\theta}^U$ remains constant over such departures. Hence, this estimator is not preferable in its own right, however it can be used in constructing another estimators.

Shrinkage Preliminary Test Estimation

The *shrinkage preliminary test estimator (SPTE)* of θ denoted by $\hat{\theta}^{SP}$ is defined by replacing θ_0 by $\hat{\theta}^{SR}$ in the definition of $\hat{\theta}^P$ given in (1)

$$\hat{\theta}^{SP} = \{\pi\theta_0 + (1-\pi)\hat{\theta}^U\} I(D_n < d_\alpha) + \hat{\theta}^U I(D_n \geq d_\alpha). \tag{3}$$

The expression for the MSE of $\hat{\theta}^{SP}$ is

$$MSE(\hat{\theta}^{SP}) = \frac{\sigma^2}{n} - \frac{\sigma^2}{n}\pi(2-\pi)H_{3,\,n-1}(F_a,\,\delta) + \frac{\sigma^2}{n}\pi\delta\{2H_{3,\,n-1}(F_a,\,\delta) - (2-\pi)H_{5,\,n-1}(F_b,\,\delta)\}. \tag{4}$$

It appears from the MSE expression of $\hat{\theta}^{SP}$ that as π increases, the MSE of $\hat{\theta}^{SP}$ becomes smaller than that of $\hat{\theta}^{SR}$ and $\hat{\theta}^P$, and approaches to MSE of $\hat{\theta}^U$ faster than that of $\hat{\theta}^P$. Further, $\hat{\theta}^{SP}$ dominates $\hat{\theta}^U$ over a wider range than $\hat{\theta}^P$. More importantly, $\hat{\theta}^{SP}$ has a good control on the maximum of MSE as compared with $\hat{\theta}^P$. Hence the $\hat{\theta}^{SP}$ provides much more meaningful size for the preliminary test than $\hat{\theta}^P$. The trick is in selecting the value of π. In this sense, $\hat{\theta}^{SP}$ can be considered as an optimal strategy.

Summary

When there is uncertainty concerning the appropriate statistical model-estimator to use in representing a data sampling process, the estimation rule based on preliminary test estimation provides a basis for optimally combining the estimation problems. This approach yields a well-defined data-based shrinkage preliminary test estimator that combines estimation problem by shrinking a benchmark estimator to plausible alternative quantity. Bearing in mind, neither $\hat{\theta}^{SP}$ nor $\hat{\theta}^{P}$ uniformly dominate $\hat{\theta}^{U}$. Thus, the performance of the estimators based on preliminary test procedures depends on the quality of the *NSI*. In this communication we considered formulations and evaluations for $\hat{\theta}^{SP}$ in one-sample-problems. The formulations have been extended to multiple estimation and regression problems in parametric, non-parametric and semi-parametric setup by a host of researchers including Ahmed (2001) and Ahmed et al. (2006, 2007). The literature on PTE is vast and research on the statistical implications of these and other combining possibilities for a range of statistical models is ongoing and growing in statistical and econometric literatures.

Optimal Statistical Inference in Financial Engineering

Masanobu Taniguchi
Professor
Waseda University, Tokyo, Japan

The field of financial engineering has developed as a huge integration of economics, mathematics, probability theory, statistics, time series analysis, operation research etc. We describe financial assets as ►stochastic processes. Using stochastic differential equations, probabilists developed a highly sophisticated mathematical theory in this field. On the other hand empirical people in financial econometrics studied various numerical aspects of financial data by means of statistical methods.

Black and Scholes (1973) provided the modern option pricing theory assuming that the price process of an underlying asset follows a geometric Brownian motion (see ►Brownian Motion and Diffusions). But, a lot of empirical studies for the price processes of assets show that they do not follow the geometric Brownian motion. Concretely, we often observe that the sample autocorrelation function

$$\hat{\rho}_{X_t}(l) = \frac{\sum_{t=1}^{n-|l|}(X_{t+l}-\overline{X}_n)(X_t-\overline{X}_n)}{\sum_{t=1}^{n}(X_t-\overline{X}_n)^2}, \left(\overline{X}_n = n^{-1}\sum_{t=1}^{n} X_t\right)$$

of the return process $\{X_t\}$ of assets with time lag l becomes near 0 for $l \neq 0$, i.e., X_t's are almost uncorrelated, and that $\hat{\rho}_{X_t^2}(l)$, $l \neq 0$, of the square-transformed return X_t^2 are not near 0 for $l \neq 0$, i.e., X_t^2's are not uncorrelated. Hence we may suppose that

"return processes $\{X_t\}$ are non-Gaussian dependent." (1)

Based on this, it is important to investigate which stochastic models can describe the actual financial data sufficiently, and how to estimate the proposed models optimally, which lead to the theme of this section. Let $\{\mathbf{X}_t\}$ be an m-dimensional vector process whose components consist of the return of assets. A typical candidate for (1) is the following non-Gaussian linear process :

$$\mathbf{X}_t = \boldsymbol{\mu} + \sum_{j=0}^{\infty} A_{\boldsymbol{\theta}}(j)\mathbf{U}_{t-j}, \quad (2)$$

where $\boldsymbol{\mu}$ is an m-dimensional non-random vector, $A_{\boldsymbol{\theta}}(j)$'s are $m \times m$-non-random matrices, $\boldsymbol{\theta}$ is a p-dimensional unknown parameter and $\mathbf{U}_s$'s are i.i.d. m-dimensional random vectors with probability density function $g(\mathbf{u})$, $\mathbf{u} \in \mathbf{R}^m$.

Lucien LeCam (e.g., LeCam 1986) established the most important and sophisticated foundation of the general statistical asymptotic theory. He introduced the concept of local asymptotic normality (LAN) for the likelihood ratio between contiguous hypotheses of general statistical models. Once LAN is proved, the asymptotic optimality of various statistical methods (estimators, tests and discriminant statistics etc.) is described in terms of the LAN property.

Under appropriate regularity conditions, Taniguchi and Kakizawa (2000) proved the LAN for (2), and showed the asymptotic optimality of the maximum likelihood estimator (MLE) for $\boldsymbol{\theta}$. The philosophy of optimal statistical inference in financial engineering is to develop the financial analysis (option pricing, VaR problem, portfolio construction and credit rating etc.) based on the optimally estimated statistical models. In what follows we explain a few topics in this stream.

Suppose that $\mathbf{X}_t$ is the random return on m assets at time t, and that $\mathbf{X}_t$ is generated by (2). Let $\boldsymbol{\alpha} = (\alpha_1, \ldots, \alpha_m)'$ be the vector of portfolio weights. Then the return of portfolio is $\boldsymbol{\alpha}'\mathbf{X}_t$, and the mean and variance are, respectively, given by $\boldsymbol{\alpha}'\boldsymbol{\mu}$ and $\boldsymbol{\alpha}'\Sigma\boldsymbol{\alpha}$, where $\Sigma = Var(\mathbf{X}_t)$. Optimal portfolio weights have been proposed by various criteria. The most famous one is given by the solution of

$$\begin{cases} \max_{\boldsymbol{\alpha}} \{\boldsymbol{\alpha}'\boldsymbol{\mu} - \beta\boldsymbol{\alpha}'\Sigma\boldsymbol{\alpha}\} \\ \text{subject to } \mathbf{e}'\boldsymbol{\alpha} = 1 \end{cases} \tag{3}$$

where $\mathbf{e} = (1, \ldots, 1)'$ (m×1-vector), and β is a given positive number. Then the optimal portfolio for (3) becomes

$$\boldsymbol{\alpha}_I = \frac{1}{2\beta}\left\{\Sigma^{-1}\boldsymbol{\mu} - \frac{\mathbf{e}'\Sigma^{-1}\boldsymbol{\mu}}{\mathbf{e}'\Sigma^{-1}\mathbf{e}}\Sigma^{-1}\mathbf{e}\right\} + \frac{\Sigma^{-1}\mathbf{e}}{\mathbf{e}'\Sigma^{-1}\mathbf{e}}. \tag{4}$$

The criterion (3) is so called the "mean-variance method." If we use the other criterion, the optimal portfolio $\boldsymbol{\alpha}_{opt}$ is of the form

$$\boldsymbol{\alpha}_{opt} = g(\boldsymbol{\mu}, \Sigma), \tag{5}$$

i.e., a measurable function of $\boldsymbol{\mu}$ and Σ. A natural estimator of $\boldsymbol{\alpha}_{opt}$ is

$$\hat{\boldsymbol{\alpha}}_{opt} \equiv g(\hat{\boldsymbol{\mu}}, \hat{\Sigma}) \tag{6}$$

where $\hat{\boldsymbol{\mu}}$ is the sample mean and $\hat{\Sigma}$ is the sample covariance matrix from the observations with length n. Shiraishi and Taniguchi (2008) gave a necessary and sufficient condition for $\hat{\boldsymbol{\alpha}}_{opt}$ to be asymptotically efficient in terms of the spectral density matrix of $\{\mathbf{X}_t\}$. This condition shows that if $\{\mathbf{X}_t\} \sim VARMA(p_1, p_2)$ with $p_1 < p_2$, then $\hat{\boldsymbol{\alpha}}_{opt}$ is not asymptotically efficient, which gives a strong warning for use of the classical mean-variance estimator. In view of the asymptotic efficiency, based on LAN, Shiraishi and Taniguchi (2008) showed that the MLE of $\boldsymbol{\alpha}_{opt}$ is asymptotically efficient.

So far we have assumed that the return process $\{\mathbf{X}_t\}$ is stationary. However, stationary models are not plausible to describe the real world. In fact, time series data with a long stretch often contain slow or rapid changes in the spectra. For this Dahlhaus (1997) introduced an important class of non-stationary processes, called locally stationary processes which have the time varying spectral density $f(u, \lambda)$ where u is a standardized time parameter and λ is the frequency. In the case of locally stationary return processes, Shiraishi and Taniguchi (2007) discussed the optimal estimation of $\boldsymbol{\alpha}_{opt}$.

Various approaches in financial engineering with optimal statistical properties can be found in Taniguchi et al. (2008).

About the Author

Masanobu Taniguchi joined the Department of Mathematics, Hiroshima University, and the Department of Mathematical Science, Osaka University, in 1983 and 1990, respectively. He was a Visiting Professor at the University of Bristol, UK, in 2000. He is currently a Professor in the Department of Applied Mathematics, Waseda University, Japan. His main contributions in time series analysis are collected in his book *Asymptotic Theory of Statistical Inference for Time Series* (New York, Springer, 2000). He is also a co-author (with Junichi Hirukawa and Kenichiro Tamaki) of the text *Optimal Statistical Inference in Financial Engineering* (Chapman and Hall, 2007). Professor Taniguchi is a Fellow of the Institute of Mathematical Statistics. He was awarded the Ogawa Prize (Japan, 1989), the Econometric Theory Award (USA, 2000), and the Japan Statistical Society Prize (2004). Currently, he is Editor of the *Journal of the Japan Statistical Society* (2006–).

Optimal Stopping Rules

Albert N. Shiryaev
Professor, Head of the Probability Theory Department at the Moscow State University
Moscow, Russia

The theory of *Optimal Stopping* was considerably stimulated by A. Wald (1947). He showed that – in contrast to the classical methods of the Mathematical Statistics, according to which the decision is taken in a fixed (and nonrandom) time – the methods of the sequential analysis take observations sequentially and the decision is taken, generally speaking, at a random time whose value is determined by the rule (strategy) of observation of a statistician. Wald discovered the remarkable advantage of the sequential methods in the problem of testing (from i.i.d. observations) two simple hypotheses. He proved that there is a sequential method (sequential probability-ratio test) which requires on average a smaller number of observations than any other method using fixed sample size (and the same probabilities of wrong decisions). It turned out that the problem of optimality of a sequential statistical decision can be reformulated as an "optimal stopping problem," and this was the essential step in constructing the General Optimal Stopping Theory.

The basic notions and results of the Optimal Stopping Theory are the following.

In the discrete-time case, one assumes that a filtered probability space $(\Omega, \mathcal{F}, (\mathcal{F}_n)_{n\geq 0}, \mathsf{P})$ is given, where we interpret $\mathcal{F}_n$ as the information available up to time n. Let $G = (G_n)_{n\geq 0}$ be a sequence of random variables such that each G_n is $\mathcal{F}_n$-measurable. All our decisions in regard to optimal stopping at time n must be based on the information $\mathcal{F}_n$ only. In other words, no anticipation is allowed.

By definition, a *Markov time* is a random variable $\tau\colon \Omega \to \{0, 1, \ldots, \infty\}$ such that $\{\tau \leq n\} \in \mathcal{F}_n$ for all $n \geq 0$. A Markov time with the property $\tau < \infty$ is usually called a *stopping time* (the class of all stopping times will be denoted by $\mathfrak{M}$).

A basic problem of the Optimal Stopping Theory consists of finding the *value* function

$$V = \sup_{\tau\in\mathfrak{M}} \mathsf{E}G_\tau$$

and a stopping time τ^* (if it exists) such that $\mathsf{E}G_{\tau^*} = V$. (We assume that $\mathsf{E}\sup_{n\geq 0}|G_n| < \infty$.)

For solving this problem it is useful to introduce the value functions

$$V_n^N = \sup_{\tau\in\mathfrak{M}_n^N} \mathsf{E}G_\tau, \quad 0 \leq n \leq N < \infty, \quad \text{and} \quad V_n = \sup_{\tau\in\mathfrak{M}_n} \mathsf{E}G_\tau, \quad 0 \leq n < \infty,$$

where $\mathfrak{M}_n^N = \{\tau \in \mathfrak{M}\colon n \leq \tau \leq N\}$ and $\mathfrak{M}_n = \{\tau \in \mathfrak{M}\colon \tau \geq n\}$.

The usual method of finding the value functions V_n^N is the *method of backward induction*, which deals with a sequence of *random* variables $\left(S_n^N\right)_{0\leq n\leq N}$ defined recursively as follows:

$$S_n^N = G_N \qquad \text{for } n = N,$$

$$S_n^N = \max\left\{G_n, \mathsf{E}\left(S_{n+1}^N \mid \mathcal{F}_n\right)\right\} \qquad \text{for } n = N-1, \ldots, 0.$$

The method also suggests that we consider the time

$$\tau_n^N = \inf\left\{n \leq k \leq N\colon S_k^N = G_k\right\} \quad \text{for } 0 \leq n \leq N.$$

The following theorem (which we formulate for the case $0 \leq n \leq N < \infty$) plays a central role in the Optimal Stopping Theory.

Theorem 1 *The stopping time τ_n^N is optimal ($\mathsf{E}G_{\tau_n^N} = V_n^N$) in the class $\mathfrak{M}_n^N$. The value V_n^N equals $\mathsf{E}S_n^N$.*

To find the value functions $V_n = \sup_{\tau\geq n} \mathsf{E}G_\tau$, $n \geq 0$, we consider the sequence of random variables $(S_n)_{n\geq 0}$ defined by

$$S_n = \operatorname*{ess\,sup}_{\tau\geq n} \mathsf{E}(G_\tau \mid \mathcal{F}_n)$$

and the stopping time

$$\tau_n = \inf\{k \geq n\colon S_k = G_k\}.$$

Here ess sup is an abbreviation for essential supremum; the sequence $(S_n)_{n\geq 0}$ is often referred to as the *Snell envelope* of G.

Theorem 2 *The following recurrent relations hold:*

$$S_n = \max\{G_n, E(S_{n+1} \mid \mathcal{F}_n)\}.$$

If $\tau_n < \infty$, *then this stopping time* τ_n *is optimal:* $EG_{\tau_n} = V_n$ *and* $ES_{\tau_n} = V_n$.

Theorem 3 *Under assumption* $E \sup_{n\geq 0} |G_n| < \infty$ *we have* $S_n = \lim_{N\to\infty} S_n^N$ *and* $V_n = \lim_{N\to\infty} V_n^N$.

Theorems 1–3 cover the main results of the so-called *martingale approach* to the optimal stopping. A lot of attention in the Optimal Stopping Theory is paid to the so-called *Markovian approach*. This approach assumes that the gain functions G_n admit the *Markovian representation*, *i.e.*, there exist a Markov process $X = (X_n)_{n\geq 0}$ defined on $(\Omega, \mathcal{F}, (\mathcal{F}_n)_{n\geq 0}, \mathsf{P})$ and a measurable function $G = G(x)$ such that $G_n = G(X_n)$ for all $n \geq 0$. The assumption about the Markovian representation allows one to use for solving the optimal stopping problems the theory of ▶Markov processes, which has a well-developed tools, methods, and remarkable results.

To describe the Markovian approach to the Optimal Stopping, let us assume that $G = G(x)$ is a measurable function, $X = (X_n)_{n\geq 0}$ is a homogeneous Markov chain (see ▶Markov Chains) with values in $\mathbb{R}$. We denote by P_x the distribution of X under assumption $X_0 = x \in \mathbb{R}$ and by E_x the expectation with respect to P_x.

We assume $\mathsf{E}_x \sup_{n\geq 0} |G(X_n)| < \infty$, $x \in \mathbb{R}$, and use the following notation: for $n \geq 0$,

$$V^n(x) = \sup_{\tau\in\mathfrak{M}_0^n} \mathsf{E}_x G(X_\tau), \qquad V(x) = \sup_{\tau\in\mathfrak{M}} \mathsf{E}_x G(X_\tau);$$

for $N \geq 0$ fixed and $n \leq N$,

$$C^{N-n} = \{x \in \mathbb{R}: V^{N-n}(x) > G(x)\},$$
$$D^{N-n} = \{x \in \mathbb{R}: V^{N-n}(x) = G(x)\},$$

and

$$\tau_D^N = \inf\{0 \leq n \leq N: X_n \in D^{N-n}\}.$$

Denote also by T the transition operator of X:

$$TF(x) = \mathsf{E}_x F(X_1),$$

where $F(x)$ is a real function such that $\mathsf{E}_x F(|X_1|) < \infty$.

Theorem 4 *For all* $n \leq N$ *the function* $V^n(x)$ *satisfies the Wald–Bellman equation*

$$V^n(x) = \max\{G(x), TV^{n-1}(x)\}$$

with $V^0 = G$. *The stopping time* τ_D^N *is optimal:* $\mathsf{E}_x G\left(X_{\tau_D^N}\right) = V^N(x)$.

We see that optimal stopping time τ_D^N has a very transparent form: if $x_n \in C^{N-n}$, then we continue observations, and we stop, if $x_n \in D^{N-n}$. (The sets C^{N-n} and D^{N-n} are called sets of *continuation* and *stopping* of observations, respectively.)

For case of infinite horizon ($N = \infty$) the following theorem holds.

Theorem 5 *Under assumption* $E \sup_{n\geq 0} |G(X_n)| < \infty$, $x \in \mathbb{R}$, *the value function* $V(x)$ *solves the Wald–Bellman equation*

$$V(x) = \max\{G(x), TV(x)\}$$

for $x \in \mathbb{R}$. *If the stopping time* $\tau_D = \inf\{n \geq 0: X_n \in D\}$, *where* $D = \{x \in \mathbb{R}: V(x) = G(x)\}$, *is finite* ($\tau_D < \infty$), *then this stopping time is optimal:* $\mathsf{E}_x G(X_{\tau_D}) = V(x)$, $x \in \mathbb{R}$.

Remark 1. In Theorems 2 and 5 it suffices to assume that $\tau_n < \infty$ (P-a.s.) and $\tau_D < \infty$ (P-a.s.), respectively. For case $\tau_n = \infty$ and $\tau_D = \infty$ we put $G_{\tau_n} = 0$ and $G(X_{\tau_D}) = 0$.

The results formulated above give the basis for solving different concrete optimal stopping problems in the theory of probability, mathematical statistics, financial mathematics.

Above we presented the optimal stopping theory only for the discrete-time case. For the case of continuous time, the formulations of problems are very similar (one should consider the continuous-time filtered probability space $(\Omega, \mathcal{F}, (\mathcal{F}_t)_{t\geq 0}, \mathsf{P})$ instead of the discrete-time filtered probability space $(\Omega, \mathcal{F}, (\mathcal{F}_n)_{n\geq 0}, \mathsf{P})$). The corresponding general theory is exposed in Chow et al. (1971), DeGroot (1970), Peskir and Shiryaev (2006) and Shiryaev (2007), where one can also find solutions to many concrete optimal stopping problems from different fields of probability theory, mathematical statistics, financial mathematics.

About the Author

Albert Nikolayevich Shiryaev was born on 12 October 1934. He has been a professor at the department of Mechanics and Mathematics of Moscow State University, since 1971. He has also been working in Steklov Mathematical Institute. He earned his candidate degree in 1961 (Andrey Kolmogorov was his advisor) and a doctoral degree in 1967. He was elected a corresponding member of the Russian Academy of Sciences in 1997. Professor Shiryaev was awarded the A.N. Markov Prize of USSR Academy of Sciences (1974), the A.N. Kolmogorov Prize of Russian Academy of Sciences (1994), and Humboldt Research Award (1996). He was President of the Bernoulli Society (1989–1991), President of the Russian Actuarial Society (1994–1998) and President of the Bachelier Finance Society (1998–1999). Professor Shiryaev is a Honorary Fellow of the Royal Statistical Society (1985), Member of the Academia Europea (1990) and Member of the New York

Academy of Science (1997). He holds two Honorary Doctorates. He is the author of more than 150 research papers in probability theory, mathematical and applied statistics, stochastic control, and financial mathematics. Professor Shiryaev is internationally known for his work in probability theory, statistics and financial mathematics. He is one of the leading experts in the field of Optimal stopping rules, and has published the text *Optimal Stopping Rules* (Springer, 3rd Rev. ed., 2007), and *Optimal Stopping and Free-Boundary Problems* (with G. Peskir; Lectures in Mathematics, ETH Zürich, Birkhäuser, 2005). He was advisor of more than 50 Ph.D. students (including one of our contributors, Professor Boris Rozovsky).

Professor Shiryaev is the third head in the history of the department (since 1996), the first and founding head was A.N. Kolmogorov in 1936, and the second Kolmogorov's student B.V. Gnedenko (from 1966 to 1995).

Optimality and Robustness in Statistical Forecasting

Yuriy S. Kharin
Professor, Head of the Department of Mathematical Modeling and Data Analysis, Director
Belarus State University, Minsk, Belarus

Introduction

Many applied problems in engineering, economics, finance, and medicine lead to the important problem of statistical data analysis – forecasting of time series. The mathematical substance of the forecasting problem is quite simple: to estimate the future value $x_{T+\tau} \in \mathbb{R}^d$ of the d-variate time series in $\tau \in \mathbb{N}$ steps ahead by $T \in \mathbb{N}$ successive observations $\{x_1, \ldots, x_T\} \subset \mathbb{R}^d$.

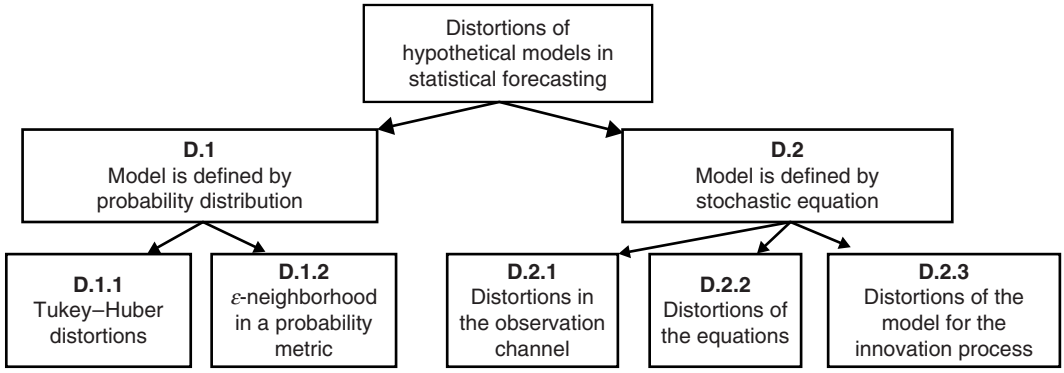
We can distinguish two stages in the history of attacks on the forecasting problem. The research on the first stage (before the year 1974) was oriented to the development of forecasting statistics and algorithms that minimize the mean square risk (error) of forecasting for a set of basic mathematical models, e.g., stationary time series with some known spectral density, time series with a trend from some known parametric family, and autoregressive integrated moving-average (ARIMA) time series (Bowerman and O'Connel 1993).

It was detected by many researchers that the "optimal" forecasting algorithms on the real statistical data have the risk values that are much more than the expected theoretical values. In his lecture at the World Congress of Mathematicians in 1974, Peter Huber explained the reason for this strange situation (Huber 1974): "Statistical inferences (including statistical forecasts) depend only in part upon the observations. An equally important base is formed by prior assumptions about the underlying situation." The system of prior assumptions is called the hypothetical model of the data M_0. In applied problems, the hypothetical model assumptions M_0 are often distorted, and this fact leads to the unstability of the "optimal" forecasting statistics that are optimal only under M_0. Huber has proposed to construct robust statistical inferences that are "weak-sensitive w.r.t. small distortions of the hypothetical model M_0"; this event has opened the second stage in statistical forecasting of time series. The present-day state of the research in ►robust statistics is displayed in analytic reviews (Davies and Gather 2004; Maronna et al. 2006; Morgenthaler 2007).

Distortions of Hypothetical Models

The probability model of the observed time series under distortions is determined by the family of probability distributions $\{P^{\varepsilon}_{T,\theta^0}(A),\ A \in B^{Td}\colon\ T \in \mathbb{N},\ \theta^0 \in \Theta \subseteq \mathbb{R}^m,\ \varepsilon \in [0, \varepsilon_+]\}$, where B^{Td} is the Borel σ-algebra in $\mathbb{R}^{Td}$, θ^0 is an unknown true value of the model parameters, ε is the distortion level, $\varepsilon_+ \geq 0$ is its maximal admissible value. If $\varepsilon_+ = 0$, then the distortions are absent, and we have the hypothetical model M_0.

A short scheme of classification for typical distortions of hypothetical models is presented in Fig. 1; a more detailed scheme of classification is given in Kharin (2008). Let us describe briefly the distortions indicated on Fig. 1.



Optimality and Robustness in Statistical Forecasting. Fig. 1 Classification for types of distortions

With respect to (w.r.t.) the form of presentation of the hypothetical model M_0, the set of all types of distortions can be split into two classes: the model in the explicit form (**D.1**), i.e., in the form of some probability distribution $P^0(\cdot)$; the model in the implicit form (**D.2**) determined by a stochastic equation

$$x_t = G(x_{t-1}, \ldots, x_{t-s}, u_t, u_{t-1}, \ldots, u_{t-L}; \theta^0),\ t \in \mathbb{Z},$$

where $u_t \in \mathbb{R}^v$ is an innovation process (usually the white noise), $s, L \in \mathbb{N}$ are some natural numbers indicating the memory depth, $\theta^0 \in \Theta \subseteq \mathbb{R}^m$ is the vector of model parameters.

Tukey–Huber distortions (**D.1.1**) for the observation vector X are described by the mixture: $p(X) = (1 - \varepsilon)p^0(X) + \varepsilon h(X)$, where $p^0(\cdot)$ is some "non-distorted" (hypothetical) p.d.f., $h(\cdot)$ is the so-called contaminating p.d.f., $\varepsilon \in [0, \varepsilon_+)$ is the distortion level. If $\varepsilon = 0$, then $p(\cdot) = p^0(\cdot)$, and distortions are absent.

Distortions of the type **D.1.2** are described by ε-neighborhoods in any probability metric: $0 \le \rho(p(\cdot), p^0(\cdot)) \le \varepsilon$, where $\rho(\cdot)$ is some probability metric.

The class **D.2** consists of three subclasses. The subclass **D.2.1** describes distortions in the observation channel: $X = H(X^0, V)$, where $X^0 = \left(x_k^0\right) \in \mathbb{R}^{Td}$ is the "non-observable prehistory" of the process, $X \in \mathbb{R}^{Td}$ is the vector of observations, that is the "observable prehistory," $V = \left(v_1', \ldots, v_T'\right) \in \mathbb{R}^{Tl}$ is the non-observable random vector of distortions (errors in the observation channel), $H(\cdot)$ is a function that describes the registration algorithm.

The subclass (**D.2.1**) includes five types of distortions.

Additive (**D.2.1.1**) and multiplicative (**D.2.1.2**) distortions in the observation channel are described by the equations

$$x_t = x_t^0 + \varepsilon v_t,\ x_t = (1 + \varepsilon v_t)x_t^0,\ t \in \mathbb{N},$$

respectively, where $\{v_t\}$ are i.i.d. random variables, $\mathbb{E}\{v_t\} = 0$, $\mathbb{D}\{v_t\} = \sigma^2 < +\infty$.

The subclass **D.2.1.3** (ε-non-homogeneities) includes the cases where the random vectors of distortions $v_t \in \mathbb{R}^l$ are nonidentically distributed, but their probability distributions differ not more than on ε in some probability metric.

The subclass **D.2.1.4** describes the ▸outliers in the data. The replacement outliers (RO) and the additive outliers (AO) in the observation channel are described by the equations:

$$x_t = (1 - \xi_t)x_t^0 + \xi_t v_t,\ x_t = x_t^0 + \xi_t v_t,\ t \in \mathbb{N},$$

respectively, where $\{\xi_t\}$ are i.i.d. Bernoulli random variables, $\mathbb{P}\{\xi_t = 1\} = 1 - \mathbb{P}\{\xi_t = 0\} = \varepsilon$, $\{v_t\}$ are random variables describing outliers, ε is the probability of the outlier appearance, and $\mathbb{E}\{v_t\}, \mathbb{D}\{v_t\}$ characterize the level of outliers.

The subclass **D.2.1.5** considers the missing values in $X^0 \in \mathbb{R}^{Td}$. To describe the missing values, it is convenient to define the binary $(T \times d)$-matrix $O = (o_{ti})$: $o_{ti} = \{1,$ if x_{ti}^0 is observed; $0,$ if x_{ti}^0 is a missing value$\}$.

The subclass **D.2.2** describes distortions of the generating stochastic equation ("misspecification errors") and includes two types of distortions:

- Parametric distortions (**D.2.2.1**), when instead of the true parameter value θ^0 we get (or estimate by statistical data) a different value $\tilde{\theta}$, with $|\tilde{\theta} - \theta^0| \le \varepsilon$
- Functional distortions (**D.2.2.2**), when instead of the true function $G(\cdot)$ we get a different function $\tilde{G}(\cdot)$, and in some metric $\|\tilde{G}(\cdot) - G(\cdot)\| \le \varepsilon$

The subclass **D.2.3** describes distortions of the innovation process $u_t \in \mathbb{R}^v$ in the generating stochastic

equation and includes distortions of three types: ε-non-homogeneities (**D.2.3.1**), probabilistic dependence (**D.2.3.2**), "innovation outliers" (**D.2.3.3**).

Characteristics of Optimality and Robustness in Forecasting

Let $\hat{x}_{T+\tau} = f(X)$: $\mathbb{R}^{Td} \to \mathbb{R}^d$ be any forecasting statistic. Its performance is evaluated by the mean square risk of forecasting:

$$r_\varepsilon = r_\varepsilon(f) = \mathbb{E}_\varepsilon\{\|\hat{x}_{T+\tau} - x_{T+\tau}\|^2\} \geq 0,\ \varepsilon \in [0, \varepsilon_+],$$

where $\mathbb{E}_\varepsilon\{\cdot\}$ is the expectation symbol w.r.t. the probability distribution $P^\varepsilon_{T,\theta^0}(\cdot)$. If the distortions are absent ($\varepsilon = 0$) and the hypothetical model M_0 is valid, this functional is called the hypothetical risk $r_0 = r_0(f)$. The guaranteed (upper) risk is

$$r_+ = r_+(f) = \sup_{0 \leq \varepsilon \leq \varepsilon_+} r_\varepsilon(f),$$

where the supremum is taken on all admissible distortions of the hypothetical model M_0.

Let further $\hat{x}^0_{T+\tau} = f^0(X; \theta^0)$ be the optimal forecasting statistic under the known hypothetical model M_0 ($\varepsilon = 0$) that gives the minimal value to the hypothetical risk:

$$r_0 = r_0(f^0) = \inf_{f(\cdot)} r_0(f).$$

In practice, the family of the so-called plug-in forecasting statistics is often used: $\hat{x}_{T+\tau} = f(X) := f^0(X; \hat{\theta})$, where $\hat{\theta} \in \mathbb{R}^m$ is some consistent statistical estimator of the unknown parameter θ^0 based on the observed time series X. A forecasting statistic $\hat{x}_{T+\tau} = f(X)$ is called the asymptotically optimal forecasting statistic if $\lim_{T\to\infty}(r_0(f) - r_0(f^0)) = 0$.

The risk unstability coefficient κ is the relative increment of the guaranteed risk w.r.t. the minimal hypothetical risk

$$\kappa = \kappa(f) = (r_+(f) - r_0)/r_0 \geq 0.$$

For any $\delta > 0$ define another characteristic of robustness that is quite useful in applications:

$$\varepsilon^* = \varepsilon^*(\delta) = \sup\{\varepsilon \in [0, \varepsilon_+] :\ \kappa(f) \leq \delta\},$$

that is called the δ-admissible distortion level. It indicates the maximal level of distortions for which the relative increment of the risk is yet not greater than the fixed value $\delta \cdot 100\%$.

The smaller the value κ is and the greater the value ε^* is, the more robust the forecasting statistic is. The minimax robust forecasting statistic $\hat{x}^*_{T+\tau} = f^*(X)$ minimizes the risk unstability coefficient

$$\kappa(f^*) = \inf_{f(\cdot)} \kappa(f).$$

In Hampel et al. (1986), a characteristic of the "qualitative robustness" is introduced – the Hampel breakdown point ε^{**}; it is the maximal fraction of "arbitrary large outliers" in the sample X such that the considered forecasting statistic $f(X)$ is bounded: $\varepsilon^{**} = \max\{\varepsilon \in [0,1] : \sup|f(X)| \leq C < +\infty\}$.

Some Approaches to Construct Robust Forecasting Statistics

There are three main approaches to construct robust forecasting statistics.

The first approach is based on minimization of the risk unstability coefficient $\kappa(f)$ in some family of forecasting statistics $\mathcal{F}$: $\kappa(f) \to \min_{f\in\mathcal{F}}$. This approach is theoretically complicated. Because of the computational complexity, the minimization problem can be solved for some cases only; relevant examples are given in Kharin (2008).

The second approach is the "plug-in" approach: $\tilde{x}_{T+\tau} = f^0(X; \tilde{\theta})$, where $\tilde{\theta}$ is some robust estimator of parameters θ^0 by the distorted data X; the methods for robust estimation of parameters can be found in Davies and Gather (2004), Hampel et al. (1986), Kharin (2008), Maronna et al. (2006), Morgenthaler (2007), and Rousseeuw and Leroy (1987). Robustness of the "plug-in" forecasting statistics can be evaluated by the characteristics indicated in the previous section ("►Characteristics of Optimality and Robustness in Forecasting").

The third approach is based on the idea of preliminary filtering ("cleaning") of the observed time series X. Some methods of forecasting based on filtering are discussed in Maronna et al. (2006) and Rousseeuw and Leroy (1987).

About the Author

Yuriy S. Kharin is Director of the Research Institute for Applied Problems of Mathematics and Informatics at the Belarusian State University, Minsk, Republic of Belarus. He is also Head of the Department of Mathematical Modeling and Data Analysis at the Belarusian State University, Correspondent Member of the National Academy of Sciences (from 2004), Past President of the Belarusian Statistical Association. He has authored and coauthored more than 350 papers, 15 monographs and textbooks, including the monograph *Robustness in Statistical Pattern Recognition* (Kluwer 1996). Professor Kharin has received the National State Prize in Science of the Republic of Belarus (2002).

Optimum Experimental Design

Anthony C. Atkinson
Professor of Statistics
London School of Economics, London, UK

Introduction

Experimental design is concerned with the allocation of treatments to units. The methods of optimum design were originally developed for the choice of those values of the explanatory variables x in a regression model at which observations should be taken (Smith 1918). For example, in a chemical experiment there may be several factors, such as time of reaction, temperature, pressure and catalyst concentration, that affect the response which is a smooth function of these variables (*see* ►Response Surface Methodology). At what combination of variables should measurements be taken in order to obtain good estimates of the dependence of responses, such as yield or purity of product, on these variables? More recent developments include the design of experiments for the nonlinear models occurring in pharmacokinetic experiments in drug development (Gagnon and Leonov 2005).

Perhaps after data transformation (*see* ►Box-Cox Transformations), efficient analysis of regression experiments requires the use of least squares parameter estimation (*see* ►Least Squares). In a good experiment the variances and covariances of the estimated parameters will be small. Optimal experimental designs minimize functions of these variances and so provide good estimates of the parameters.

Since optimal designs focus on the variances of the estimated parameters, it is necessary to specify a model or models. Also needed is an experimental region $\mathcal{X}$ that specifies the range of values of the experimental variables. The modern statistical theory of optimum experimental design was developed in a series of papers by Kiefer (Brown et al. 1985). A succinct introduction to the theory is given by Fedorov and Hackl (1997), which Atkinson et al. (2007) fleshes out with examples and SAS programs.

Least Squares and the Information Matrix

The linear regression model (see ►Linear Regression Models) is written $E(y) = F\beta$ with y the $N \times 1$ vector of responses, β a vector of p unknown parameters and F the $N \times p$ *extended* design matrix that may contain functions of the explanatory variables such as powers and interactions. The ith row of F is $f^T(x_i)$, a known function of the m explanatory variables. It is usual to assume that the observational errors are independent with constant variance σ^2. This value does not affect the design.

The least squares estimator of the parameters is $\hat{\beta}$ with information matrix F^TF. The "larger" F^TF, the greater is the information in the experiment. Depending on the scientific purpose, different optimality criteria are chosen which maximize different functions of the information matrix.

Criteria of Optimality

D-optimality. The volume of the confidence region for all p elements of β is proportional to the square root of $\sigma^2/|F^TF|$, the generalized variance of $\hat{\beta}$. Designs which maximize $|F^TF|$ minimize this generalized variance and are called D-optimum (for Determinant).

G-optimality. The prediction from the fitted model at a point x is $\hat{y}(x) = \hat{\beta}^T f(x)$, with variance var $\hat{y}(x)$. Designs which minimize the maximum over $\mathcal{X}$ of var $\hat{y}(x)$ are called G-optimum. A famous result, the "General Equivalence Theorem" (Kiefer and Wolfowitz 1960), shows that as N increases, D-optimality and G-optimality give increasingly similar designs. The designs may also be identical for some specific smaller values of N.

I or **V-optimality.** An alternative to this minimax approach to var $\hat{y}(x)$ is to find designs that minimize the average value of the variance over $\mathcal{X}$. Such designs are variously called I-optimum or V-optimum from Integrated Variance.

c-optimality. Another criterion of importance in applications, particularly for ▶nonlinear models, is that of C-OPTIMALITY in which the variance of the linear combination $c^T\hat{\beta}$ is minimized, where c is a $p \times 1$ vector of constants.

T-optimality. If there is uncertainty about the true model, T-optimality provides powerful designs for discriminating between models.

Details of these and other design criteria are in Chap. 10 of Atkinson et al. (2007). Compound designs in which provide good designs for several criteria are in Chap. 21. The optimum designs consist of a list of N values of x, often with replication. The indicated sets of conditions should be run in random order.

Some D-optimum Designs

Many standard designs which have been derived over the years by a variety of methods share the property that they are D- and G-optimum. One example is the series of 2^m factorial designs and their symmetric fractions forming the 2^{m-f} fractional factorial designs, which can also be used to construct D-optimally blocked 2^m designs. However, if N is not a power of 2, numerical methods for the construction of optimal designs will be needed. In the case of the blocked 2^m factorial, we might be forced by the size of batches of raw materials, to have blocks which were not all of size 2^{m-f}.

The dependence of the optimum design on the value of N is illustrated by D-optimum designs for the second-order response surface, that is a quadratic model in two factors including an interaction (x_1x_2) term. For $N = 9$, the optimum design is the 3^2 factorial. For $N = 13$, the points of the 2^2 factorial are added to this design. Increasing N to 14 duplicates the centre point. Addition of a few further design points destroys the symmetry of the designs and produces designs that have a lower efficiency per observation, although of course the overall information increases. The choice of design size as well as the values of the x_i are both important.

Advantages of Optimum Designs

Here are some advantages of optimum experimental design:

1. The availability of algorithms for the construction of designs
2. The calculation of good designs for a specified number of trials
3. The provision of simple, but incisive, methods for the comparison of designs
4. The ability to divide designs into blocks of a specified size
5. The determination of good response surface designs over non-regular regions
6. The construction of designs for ▶mixture models, perhaps again over non-regular regions

Further Models

The methods of optimum design, sketched here for linear models, can be extended to several important classes of model.

Nonlinear models. These models, nonlinear in the parameters, are particularly important in chemical and pharmaco-kinetics. Informative experiments are often concentrated in a small part of $\mathcal{X}$ and it is easy to waste experimental effort. Because of the non-linearity of the models, techniques incorporating prior information are important. See Chaps. 17 and 18 of Atkinson et al. (2007) and ▶Nonlinear Models.

Generalized Linear models. Particularly if the responses are binomial, the models need extending, although the principles of optimum design remain the same. See Chap. 22 of Atkinson et al. (2007) and ▶Designs for Generalized Linear Models.

Discrete Designs. In the designs appropriate in agriculture, many of the factors are discrete, rather than continuous as in regression, and analysis of variance models are appropriate (*see* ▶Analysis of Variance). The experimental units, for example plots in a field, may be highly variable and require division into blocks (*see* ▶Statistical Design of Experiments, ▶Agriculture, Statistics in and ▶Incomplete Block Designs). In addition to D-optimality, such designs are often compared using A-OPTIMALITY, in which the Average variance of treatment contrasts is minimized and E-OPTIMALITY in which the variance of the least well-estimated, or Extreme, linear combination $a^T\hat{\beta}$ is minimized subject to $a^Ta = 1$. Design construction is often facilitated by the use of combinatorial methods.

About the Author

Professor Atkinson has been elected a Fellow of the American Statistical Association "for outstanding contributions to data analysis methods, including variable selection in regression and multivariate data, and methods of optimum experimental design and for service to the profession." Professor Atkinson has served as editor of *The Journal of the Royal Statistical Society*, Series B and as associate editor of *Biometrika* and *Technometrics*. He has published five books and 200 articles in these and other journals including *Biometrics*, *The Journal of the American Statistical Association*, and *Statistics and Computing*.

Order Statistics

Herbert A. David
Distinguished Professor Emeritus
Iowa State University, Ames, IA, USA

Consider a *life test* in which n like items are tested until they fail. The failure times may be denoted by

$$x_{(1)} \le x_{(2)} \le \ldots \le x_{(r)} \le \ldots \le x_{(n)}.$$

Here $x_{(r)}$ is the *r-th order statistic*, also denoted by $x_{r:n}$ if the sample size needs to be emphasized. The duration of the test, $x_{(n)}$, may be unduly long, so that it becomes desirable to *censor* the test after, say, the r-th failure.

More commonly, the observations come to us unordered as $x_1, x_2, \ldots, x_n$, say the diameters of n mass-produced items. Here n is usually small, e.g., $n = 5$, but such samples are taken frequently and charts of both sample means and sample *ranges* $x_{(n)} - x_{(1)}$ plotted. The range is more convenient than the standard deviation and almost as efficient in small samples from the underlying normal populations generally assumed.

Basic Distribution Theory

Let $X_1, X_2, \ldots, X_n$ be independent random variables drawn from a population with cumulative distribution function (cdf) $F(x)$. Then the cdf of $X_{(r)}$ is given by

$$\begin{aligned} F_{X_{(r)}}(x) &= Pr(X_{(r)} \le x) \\ &= Pr\ (\text{at least } r \text{ of } X_1, \ldots, X_n \text{ are} \le x) \\ &= \sum_{i=r}^{n} \binom{n}{i} F^i(x)[1-F(x)]^{n-i} \end{aligned} \quad (1)$$

since the term in the summand is the binomial probability that exactly i of $X_1, \ldots, X_n$ are less than or equal to x.

This result holds whether X is a continuous or discrete variate. In the former case differentiation gives the probability density function (pdf) of $X_{(r)}$ in terms of the underlying $f(x) = F'(x)$ as

$$f_{X_{(r)}}(x) = \frac{n!}{(r-1)!(n-r)!} F^{r-1}(x) f(x) [1-F(x)]^{n-r}. \quad (2)$$

If X is discrete, taking integral values, we have simply

$$f_{X_{(r)}}(x) = Pr\left(X_{(r)} = x\right) = F_{X_{(r)}}(x) - F_{X_{(r)}}(x-1).$$

In the continuous case the joint pdf of $X_{(r)}$ and $X_{(s)}$ $(1 \le r < s \le n)$ is

$$\begin{aligned} f_{X_{(r)},\, X_{(s)}}(x,y) = {} & \frac{n!}{(r-1)!(s-r-1)!(n-s)!} F^{r-1}(x) f(x) \\ & \times [F(y) - F(x)]^{s-r-1} f(y) [1-F(y)]^{n-s}. \end{aligned} \quad (3)$$

The distribution of functions of two order statistics may now be obtained from (3) by standard transformation of variables methods. For example, the pdf of the range $W_n = X_{(n)} - X_{(1)}$ is

$$f_{W_n}(x) = n(n-1) \int_{-\infty}^{\infty} f(x) [F(x+w) - F(x)]^{n-2} f(x+w)\, dx,$$

giving after integration the useful formula

$$F_{W_n}(x) = n \int_{-\infty}^{\infty} f(x) [F(x+w) - F(x)]^{n-1}\, dx.$$

For a $N(\mu, \sigma^2)$ population, both $E(W_n/\sigma)$ and percentage points of W_n/σ have been widely tabulated (e.g., Pearson and Hartley 1970), providing the basis for ►control charts on μ and σ.

Confidence Intervals and Tolerance Intervals

The population qauntile of order p, denoted by ξ_p, is defined by $F(\xi_p) = p, 0 < p < 1$. In particular, $\xi_{\frac{1}{2}}$ is the

population median. Since, for $r < s$,

$$Pr\left(X_{(r)} < \xi_p < X_{(s)}\right) = Pr\left(X_{(r)} < \xi_p\right) - Pr\left(X_{(s)} < \xi_p\right)$$

it follows from (1) that the confidence interval $(X_{(r)},\ X_{(s)})$ covers ξ_p with probability

$$P_1 = \sum_{i=r}^{s-1} \binom{n}{i} p^i (1-p)^{n-i}.$$

We can choose r and s to make P_1 satisfactorily large.

A tolerance interval $(X_{(r)}, X_{(s)})$ covers a proportion γ of the underlying population with probability P_2. Thus

$$P_2 = Pr\left\{F\left(X_{(s)}\right) - F\left(X_{(r)}\right) \geq \gamma\right\}.$$

Since $F(X)$ is a uniform variate, U, over the interval $(0,1)$

$$P_2 = Pr\left(U_{(s)} - U_{(r)} \geq \gamma\right) = 1 - I_\gamma\left(n-r, n-s+r+1\right),$$

with the help of (3), where $I_\gamma(a,b)$ is the incomplete beta function.

Note that both intervals require only that the underlying distribution is absolutely continuous, i.e., these procedures are distribution-free or nonparametric. In this they are exceptional in the theory of order statistics, which is largely distribution-dependent. Order statistics are an aid to but not a branch of nonparametric statistics.

About the Author

Herbert Aron David was born in Berlin, Germany, on December 19, 1925. He earned a Ph.D. (1953) in statistics from University College London. He is Emeritus Distinguished Professor in Liberal Arts and Sciences at Iowa State University. He is a Fellow of the American Statistical Association, the American Association for the Advancement of Science and the Institute of Mathematical Statistics. He is an elected member of the International Statistical Institute. Professor David served as Department Head (1972–1984). He was Editor of *Biometrics* (1967–1972) and President of Biometric Society (1982–1983). He has authored/coauthored over 100 articles on order statistics, paired comparisons, experimental designs, competing risks, and the history of statistics. Professor David is author of *Order Statistics* (Wiley 1970, 3*rd* edition with H.N. Nagaraja, 2003).

"I am convinced that Order Statistics will continue to be the most valuable source of reference for students and researchers alike." (Paul Embrechts, September 2004, *Journal of the American Statistical Association*, Vol. 99, No. 467, p. 907).

Ordered Statistical Data: Recent Developments

Mohammad Z. Raqab
Professor of Statistics, Acting Dean, Faculty of Science
University of Jordan, Amman, Jordan

The term "order statistics" (see ►Order Statistics) was introduced by Wilks in 1942. The history of the ordered variates goes back to older years. Throughout the last thirty years, order statistics and other related statistics have changed considerably and moved to be involved in statistical modeling, inferences, decision procedures and the study of the reliability systems.

Let $X_1, X_2, \ldots, X_n$ be a random sample of size n from a distribution with probability density function (pdf) f and cumulative distribution function (cdf) F. If the random variables are arranged in ascending order of magnitude, then the ordered quantities $X_{1:n} \leq X_{2:n} \leq \ldots \leq X_{n:n}$ are called order statistics. Since there are $n!$ equally orderings of the x_i's, the joint pdf of $X_{1:n}, X_{2:n}, \ldots, X_{n:n}$ is

$$f_{1,2,\ldots,n}(x_1, \ldots, x_n) = n! \prod_{i=1}^{n} f(x_i), \quad x_1 \leq \ldots \leq x_n.$$

Let $F_{k:n}(x)(k = 1, \ldots, n)$ denote the cdf of the kth order statistic $X_{k:n}$. Its form can be derived as follows:

$$\begin{aligned} F_{k:n}(x) &= \mathbb{P}(X_{k:n} \le x) \\ &= \mathbb{P}(\text{at least k of the } X_i \text{ are less than or equal to x}) \\ &= \sum_{j=k}^{n} \binom{n}{j} [F(x)]^j \, [1 - F(x)]^{n-j}. \end{aligned} \tag{1}$$

The binomial probability in the summand represents the probability that exactly k of the X_i's are less than or equal to x. From the relationship between the binomial sum of probabilities and the incomplete beta, we write the cdf of $X_{k:n}$ in (1) as

$$F_{k:n}(x) = \frac{n!}{(k-1)!(n-k)!} \int_0^{F(x)} u^{k-1}(1-u)^{n-k} \, du. \tag{2}$$

The expression (2) holds for continuous and discrete variates. If we assume that X_i is continuous with pdf $f(x) = F'(x)$, then the pdf of $X_{k:n}$ will have the form

$$f_{k:n}(x) = \frac{n!}{(k-1)!(n-k)!} [F(x)]^{k-1} [1 - F(x)]^{n-k} f(x).$$

In the last few decades, the ordered statistics are naturally engaged in reliability theory. In many applications, a $(n - k + 1)$-out-of-n technical system of n identical components with independent and identically distributed (iid) life-lengths, functions if at least $(n - k + 1)$ of the components function. In this context, the life-length of the system is the same as the life-length of $X_{k:n}(1 \le k \le n)$. For $k = 1$, the system is a series system where any component failure is disastrous. When $k = n$, the system is also known as a parallel system. Statistical inference on the model of order statistics can be found in David and Nagaraja (2003). Recent years have been seen a rapid growth on techniques and applications involving order statistics. Its connection with reliability theory, survival studies and biostatistical sciences is the main reason for its wide applications.

Kaminsky and Rhodin (1985) and Raqab and Nagaraja (1995) have examined the maximum likelihood prediction (MLP) of the future failure time $X_{s:n}$ based on the observed failure times $X_{1:n}, X_{2:n}, \ldots, X_{r:n}, 1 \le r < s \le n$. The corresponding prediction likelihood function (PLF) is

$$L \propto \prod_{i=1}^{r} f(x_{i:n}) [F(x_{s:n}) - F(x_{r:n})]^{s-r-1} [1 - F(x_{s:n})]^{n-s} f(x_{s:n}).$$

It is observed that the MLP is biased in general and it may lead to a smaller mean square error when compared with best linear unbaised predictor (Kaminsky and Nelson 1975). Raqab (1997) has approximated the PLF and obtained some approximate MLPs. It is found that the approximate MLPs perform well in some cases compared to the MLPs.

Applications of the ordered statistical data can be observed in the analysis of the two most common censoring schemes termed as Type-I and Type-II censoring. Let us assume that n items are placed on a life-testing experiment. In a Type-I censoring scheme, the experiment continues up to a specified time T and the failures occurring after T are not observed. The Type-II scheme requires the experiment to continue until a pre-specified number of failures $m \le n$ occurs. If a practitioner desires to remove experimental units at points other than the terminal point of the experiment, then a generalization of the above mentioned schemes can be put forward in a similar manner. This generalization is referred to as progressive Type-II censoring. Under this general censoring scheme, n units are placed on a life-testing experiment and only $m(< n)$ are completely observed until failure. The censoring occurs progressively in m stages. These m stages offer failure times of the m completely observed units. At the time of the first failure (the first stage), r_1 of the $n - 1$ surviving units are randomly withdrawn (censored) from the experiment, r_2 of the $n - 2 - r_1$ surviving units are withdrawn (censored) at the time of the second failure (the second stage), and so on. Finally, at the time of the *mth* failure (the *mth* stage), all the remaining $r_m = n - m - r_1 - \ldots - r_{m-1}$ surviving units are withdrawn. This scheme includes the conventional Type II right censoring scheme $(r_1 = r_2 = \ldots = r_{m-1} = 0, r_m = n - m)$ and the complete sampling scheme $(r_1 = r_2 = \ldots = r_{m-1} = 0, n = m)$. In the approximately ten years since the publication of the Progressive Censoring, Theory, Methods and Applications (Balakrishnan and Aggrawala 2000), various optimal techniques of estimation have appeared in the literature (Balakrishnan 2007).

Predictions of order statistics are of natural interest. Prediction problems can be generally classified into two types. In the first type, the variable to be predicted comes from the same sequence of variables observed and is therefore correlated with the observed data. This is referred to as the *one-sample prediction problem*. In the second type, referred to as the *two-sample prediction problem*, the variable to be predicted comes from another independent future sample. Considerable work has been done on the one-sample prediction problem, and both parametric and nonparametric inferential methods have been developed in this regard. Interested readers may refer to Gulati and Padgett (2003) for details on these developments. In contrast, the two-sample prediction problem has not received much attention.

Let $Y_{1:m:n}, Y_{2:m:n}, \ldots, Y_{m:m:n}$, denote the above mentioned progressively type II right censored observed sample. It is of interest to predict the life-lengths $Z_{s:r_i}$

$(s = 1, 2, \ldots, r_i;\ i = 1, 2, \ldots, m)$ of all censored units in all m stages of censoring. Here $Z_{s:r_i}$ $(s = 1, 2, \ldots, r_i;\ i = 1, 2, \ldots, m)$ denotes the sth order statistic from a sample of size r_i removed at stage $i = 1, 2, \ldots, m$. Basak et al. (2006) used different classical prediction methods such as best linear unbiased, maximum likelihood and conditional median to predict the times to failure $Z_{s:r_i}$ $(s = 1, 2, \ldots, r_i;\ i = 1, 2, \ldots, m)$. The prediction of times to failure of the last r_m units still surviving at the observation Y_m has been discussed by Balakrishnan and Rao (1997). Madi and Raqab (2009) have discussed the prediction of unobserved failure times from the generalized exponential (GE) distribution using the Gibbs and Metropolis samplers.

Other related statistics are the record values, which are introduced by Chandler (1952). Record statistics arise naturally in many practical problems, and there are several situations pertaining to meteorology, hydrology, sporting and athletic events wherein only record values may be recorded. Let $\{X_i, i \geq 1\}$ be a sequence of iid random variables with common absolutely continuous cdf F and pdf f. Define a sequence of record times $U(n), n = 1, \ldots,$ as follows:

$$U(1) = 1,$$

$$U(n) = \min\left\{j : j > U(n-1),\ X_j > X_{U(n-1)}\right\}, \quad n \geq 2.$$

Then the r.v.'s $X_{U(n)}, n \geq 0$ are called upper records. That is; an observation X_j is an upper record value (or simply a record) if its value exceeds that of all previous observations. The joint pdf of $X_{U(1)}, \ldots, X_{U(n)}$ is

$$f_{U(1),\ldots,U(n)}(x_1, \ldots, x_n) = \prod_{i=1}^{n-1} \frac{f(x_i)}{1-F(x_i)} f(x_n), \quad -\infty < x_1 < \ldots < x_n < \infty. \tag{3}$$

By integrating the expression in (3) out of $x_1, \ldots, x_{n-1}$, we obtain the pdf of the nth upper record value as

$$f_{U(n)}(x) = \frac{[-log(1-F(x))]^{n-1}}{(n-1)!} f(x), \quad -\infty < x < \infty.$$

It is clear that the upper record values are the largest values observed to date. If the second or third largest values are observed to date then the model of kth record values is adequate when k is a positive integer (cf. Dziubdziela and Kopociński 1976). Record values are closely connected with the occurrence times of some corresponding non-homogeneous Poisson processes (see ►Poisson Processes) and used in so-called shock models. The successive shocks may be considered as realizations of record values from a sequence of identically independent random variables. In the context of statistical inference, maximum likelihood, best linear unbiased and best linear invariant are used to estimate the model parameters based on record data (Arnold et al. 1998). A Bayesian parametric approach via the Gibbs and Metropolis samplers is also used to predict the behavior of further future records (Madi and Raqab 2007).

The order statistics and record values are included in a more general model called generalized order statistics (cf. Kamps 1995). The concept of generalized order statistics allows us to unify the models and examine the similarities and analogies. Through the last twenty years, it was observed that many well-known distributional properties of order statistics and record values are also valid for generalized order statistics. The best linear unbiased estimation is applied by Burkschat et al. (2007) to estimate location and scale parameters of generalized Pareto distribution based on generalized order statistics.

About the Author

Dr. Mohammad Raqab is Professor of Statistics and Acting Dean, Faculty of Science, University of Jordan. He completed his B.Sc. (1981) in mathematics at University of Jordan, M. Sc. (1989) and Ph.D. (1992) in statistics at Ohio State University, Ohio State, USA. He has received five Scientific Awards, as a distinguished researcher in statistics. Raqab is an elected member of the International Statistical Institute (2007), a Fellow of American Association for the Advancement of Science (2003–present), New York Academy of Sciences (1998–present), American Statistical Association (1992–present), and International Biometric Society, USA (2000). Professor Raqab is currently an Associate Editor of the *Journal of Applied Statistical Science* (2000–present), *Journal of Statistical Theory and Applications* (2002–present), and *Journal of Probability and Statistical Science* (2003–present). He has (co-)authored more than 80 refereed articles and five books including, *Recent Development in Ordered Random Variables* (with M. Ahsanullah, Nova Science, New York, USA, 2007).

Outliers

Toby Lewis
Professor
University of East Anglia, Norwich, UK

A familiar problem in analyzing data is the occurrence of one or more values in a data set which appear to the analyst, (who thus makes an individual subjective judgment, see Collett and Lewis (1976)), to be inconsistent or out of line with the rest of the data, relative to the probability model – call it F – assumed for the data. Such a surprising value is called an *outlying observation* or *outlier*. The term 'outlier' also applies to a value in the data which would have appeared surprising if the analyst had observed it. The damaging effect of such an unobserved outlier is illustrated by Ho and Naugher (2000); see the discussion of *Accommodation* below.

In what follows, some references are given to particular topics, but the reader is otherwise referred to the comprehensive treatment of outliers and outlier problems in Barnett and Lewis (1994).

Outliers are encountered in a variety of situations, e.g., an outlying value or a subset of 2 or more outlying values (the multiple outlier situation) in a univariate sample, an outlying point (x, y) in the regression of a variable y on a regressor variable x, an outlying value in a time series or in a contingency table, and so on. The general principles and the range of procedures for dealing with outliers are first discussed in the case of an upper outlier in a univariate sample of n observations $x_1, x_2, \ldots, x_n$ of a variable X, denoted in ascending order $x_{(1)} < x_{(2)} < \ldots < x_{(n)}$. If the greatest observation $x_{(n)}$ is not only higher than the rest of the sample but appears surprisingly high, it is an outlier, relative to the assumed model F for the data. If an appropriate statistical test is carried out of the null hypothesis H_0 that all n values belong to F against an alternative H_1 that $n-1$ values belong to F and $x_{(n)}$ does not, and H_0 is rejected, the value $x_{(n)}$ is judged to be not credible (at the level of the test) as the highest value in the sample of size n from F. This value is then said to be *discordant*; the *discordancy test* has shown it to be a *discordant outlier*. The value $x_{(n)}$ is taken not to come from the distribution modeled, and it is conventionally called a *contaminant*.

"This apparently pejorative term . . . does not necessarily have any undesirable implications, sometimes quite the contrary; for instance, in a study of performance in examinations a phenomenally high mark by a student of exceptional ability might be called a 'contaminant'!" (Langford and Lewis 1998).

Examples of a discordancy test statistic for an upper outlier $x_{(n)}$ in a univariate sample of size n are $(x_{(n)}/\bar{x})/s$ for an assumed normal sample and $x_{(n)}/n\bar{x}$ for an exponential sample.

Note that some writers use the word "outlier" for a discordant outlier, and refer to an outlier (as said above, a value which looks unusual but may or may not be discordant) as a "suspicious" or "suspect" value.

What action is called for with an outlier? In some cases the value is deleted from the data set without the need for statistical assessment, e.g., because it is known to have been misrecorded or miscalculated. Again there are cases when a discordancy test is carried out on an outlier, say the greatest value $x_{(n)}$ in a univariate sample, the null hypothesis

H_0 is not rejected and $x_{(n)}$ is declared non-discordant. All the n sample values are then taken to belong to F, and the outlier is retained in the data set although it has appeared to the analyst to be somewhat unusual.

When, on the other hand, H_0 is rejected and the outlier is declared discordant on the assumption of model F, three possibilities arise, depending on the aim of the investigation. If its concern is with characteristics of the population that has been sampled, e.g., to obtain a confidence interval for the population mean, the discordant outlier, judged not to belong to F, should be rejected from the data set. (A valuable alternative strategy, to use a robust method of estimating the population parameter of interest and dispense with testing the outlier for discordancy, is discussed below – see ►Accommodation.) If on the other hand the concern of the investigation is with the outlying value ($x_{(n)}$, say) and the information conveyed by it (showing, for example, that a duration of pregnancy as long as $x_{(n)}$ years has been known to occur), further examination of this information and its implications would naturally follow.

These two possibilities assume acceptance of the model F, and conclude that the outlying value is discordant. There is a third possibility, that the value belongs to the same distribution as the rest of the data, but that the appropriate model for this distribution is not F but some other distribution G. A fresh analysis is then called for with a suitable choice of model G (e.g., a gamma distribution G with unknown shape parameter instead of an exponential distribution F), on the basis of which the discordant outlier relative to F is a non-discordant member of the data set, and the outlier problem disappears.

The *multiple outlier* situation is now considered. The choice of procedures for dealing with data sets with two or more outliers is first discussed in the context of two upper outliers $x_{(n-1)}, x_{(n)}$, in a univariate sample of n observations $x_1, \ldots, x_n$, of a continuous variable X. In testing the two outliers for discordancy the analyst has a three-way choice between a *block procedure*, an *inward consecutive procedure,* and an *outward consecutive procedure.*

Block procedure: $x_{(n-1)}$ and $x_{(n)}$ are tested together as an outlying pair in the data set of n values, with alternative hypothesis that $x_{(1)}, \ldots, x_{(n-2)}$. belong to F while $x_{(n-1)}$ and $x_{(n)}$ do not. There are two possible outcomes: (1) $x_{(n)}$ and $x_{(n-1)}$ are both judged non-discordant, (2) they are both judged discordant.

Inward consecutive procedure: first, $x_{(n)}$ is tested as an outlier in the complete data set of n values. If $x_{(n)}$ is judged discordant, $x_{(n-1)}$ is then tested as an outlier in the data set of $n-1$ values $x_{(1)}, \ldots, x_{(n-1)}$. There are three possible outcomes: (l) $x_{(n)}$ and therefore also $x_{(n-1)}$ are judged non-discordant, (2) $x_{(n)}$ is judged discordant, $x_{(n-1)}$ non-discordant, (3) $x_{(n)}$ and $x_{(n-1)}$ are both judged discordant.

Outward consecutive procedure: first, $x_{(n-1)}$ is tested as an outlier in the data set of $n-1$ values $x_{(1)}, \ldots, x_{(n-1)}$. If $x_{(n-1)}$ is judged non-discordant, $x_{(n)}$ is then tested as an outlier in the complete data set of n values. There are clearly three possible outcomes: (1) $x_{(n-1)}$ and therefore also $x_{(n)}$ are judged discordant, (2) $x_{(n-1)}$ is judged non-discordant, $x_{(n)}$ discordant, (3) $x_{(n-1)}$ and $x_{(n)}$ are both judged non-discordant.

Block testing may well be appropriate when the outliers form, from non-statistical characteristics, a natural subset of the data, for example when some measure of an individual's performance is being studied in an analysis of a random sample of individuals, two of whom happen to be siblings. However, a possible danger to the use of a block test arises when *swamping* occurs. This is when a non-discordant value $x_{(n-1)}$ is much nearer to $x_{(n-2)}$ than to $x_{(n)}$, but when $x_{(n)}$ is extreme enough to make $x_{(n)}$ and $x_{(n-1)}$ jointly declared discordant in a block test. $x_{(n-1)}$ is then wrongly judged, having been *swamped* by $x_{(n)}$ in the block test.

Conversely, a possible danger to the use of an *inward consecutive procedure* arises when *masking* occurs. The procedure starts with the test for discordancy of an outlier $x_{(n)}$ which is in fact discordant. If $x_{(n-1)}$ is near in value to $x_{(n)}$ its presence in the test may cause the outlier $x_{(n)}$ to be judged non-discordant. $x_{(n)}$ is then wrongly judged, having been *masked* by $x_{(n-1)}$. In an outward consecutive procedure, masking does not occur.

Accommodation

In analyzing a data set, say a sample of values of a variable X, with the aim of making inferences about the population being sampled, the approach described so far for dealing with any outlier in the data set has been to test it for discordancy and remove it from the data set if it is judged discordant. As already mentioned, an alternative approach is to dispense with discordancy testing and to *accommodate* the outlier by giving extreme values in the data set reduced weight in the analysis whether they are discordant or not; in short, to use a procedure *robust against the presence of outliers*. For example, a well known robust procedure for accommodating possible outliers in a sample $x_{(1)} < x_{(2)} < \ldots < x_{(n)}$ when estimating the population mean $E(X)$ is *trimming* – working with a "trimmed sample" from which the r lowest and s highest values, with an appropriate choice of r and s, have been

removed. This replaces the sample mean $\bar{x}$ by the (r,s)-fold trimmed mean $(x_{(r+1)} + \cdots + x_{(n-s)})/(n-r-s)$ when estimating $E(X)$.

Clearly, an important advantage of accommodation as against discordancy testing is the protection it gives against the danger of unobserved outliers Ho and Naugher (2000).

There is a range of relevant robust procedures available in the literature; see Huber (1981), Rousseeuw and Leroy (1987).

Directional data: The mean of a number of directions is not given by the simple arithmetic average, so different test and accommodation procedures are needed for outliers in data sets where the observations are directions of occurrences in two or in three dimensions, represented respectively by points on the circumference of a circle or on the surface of a sphere. Examples of "circular data" are vanishing directions of homing pigeons and arrival times on a 24-hour clock of patients at a hospital's accident and emergency department; examples of "spherical data" are arrival directions of showers of cosmic rays and wind directions. See Fisher (1993) and Fisher et al. (1987) for treatment of directional outliers.

The discussion has, for convenience, mainly been in the context of outliers in univariate samples; however, as stated earlier, outliers are encountered in a variety of more complex situations.

Much work has been done on the treatment of outliers in the following data situations:
Multivariate data, Regression, Designed experiments, Contingency tables, Time series, and some work also on Multilevel data and Sample surveys.

For discussion of outliers in these data situations [except Multilevel data – but see Langford and Lewis (1998)] see Barnett and Lewis (1994).

About the Author

Toby Lewis was Honorary Professor at the University of East Anglia from 1986 and Director of the Centre for Statistics there from 1989, both to 2010. He was previously Professor of Statistics at the Open University (1980–1986) and Professor of Mathematical Statistics at the University of Hull (1968–1979), at each university as first occupant of a newly created chair. He is a Fellow of the Royal Statistical Society, a Chartered Statistician, and a member of the International Statistical Institute. He is the co-author (with V. Barnett) of the first comprehensive text on outlier methods in statistical analysis: *Outliers in Statistical Data*, Wiley (1st edition 1978; 3rd edition 1994). He is 91 and is still-active professor. "I leave it to others to work out exactly how much of an outlier that will make him in the world of statisticians" (Julian Champkin (2008). P

Panel Data

Markku Rahiala
Professor (emeritus) of Econometrics
University of Oulu, Oulu, Finland

Panel data (or longitudinal data) are data sets, where information on a number of observational units have been collected at several time points. These observational units are usually called *individuals* or *subjects*. In economic applications they might be households, firms, individual persons, countries, investors or other economic agents. In medical, biological and social applications the subjects might be patients, test animals, individual persons etc.

Panel data are most often used to study unidirectional relationships between some explanatory variables $X_{it} = (x_{1,i,t} \ \ldots \ x_{m,i,t})'$ and a continuous dependent variable y_{it}, where i ($i = 1, \ldots, N$) refers to individual and t ($t = t_{oi}, \ldots, T_i$) refers to time or period. (To simplify notation, we will assume $t_{oi} \equiv 1$ and $T_i \equiv T$.) Panel data have many advantages over cross sectional data or single aggregated time series. One can for instance study the dynamic effects of the covariates on a micro level and one can explore heterogeneities among the individuals. Regression models of the linear type (for suitably transformed variables)

$$y_{it} = \alpha_i + \beta' X_{it} + \varepsilon_{it} \tag{1}$$

are especially popular as model frameworks. The error terms ε_{it} are assumed to be independent of the explanatory variables X_{it}, the processes $\{\varepsilon_{it}\}$ are assumed stationary with zero means and the data from different individuals are assumed independent of each other. The length of the data T is often fairly short, whereas the number of subjects N might be large. The levels of any dependent variable usually show considerable individual variation, which makes it necessary to allow for individually varying intercept terms α_i in model (1). If these intercepts are taken as fixed parameters, the model is called a *fixed effects* model. When N is large, this will however lead to some inferential problems. For instance ML estimators of the variance–covariance structure of the error processes would be inconsistent for fixed T and increasing N. This is why the intercept terms are often treated as mutually independent random variables $\alpha_i \sim \mathrm{IID}(\alpha, \tau^2)$ (α_i also independent of $\{\varepsilon_{it}\}$), whenever the observed subjects can be interpreted as a sample from a larger population of potential subjects. These *random effects* models are special cases of so-called *mixed* models or *variance components* models. If the effects of the covariates X_{it} vary over individuals, the regression coefficients $\beta_{(i)}$ can similarly be interpreted as random variables, $\begin{pmatrix}\alpha_i & \beta_{(i)}'\end{pmatrix}' \sim \mathrm{IID}_{m+1}\left(\begin{pmatrix}\alpha & \beta'\end{pmatrix}', G\right)$. If all the random elements in the model were assumed normally distributed, the whole model for subject i could be written as

$$\begin{aligned} Y_i &= (y_{i1} \ \ldots \ y_{iT})' \\ &= \alpha + X_i\beta + Z_i U_i + \varepsilon_i, \quad \varepsilon_i \text{ independent of } U_i, \\ U_i &\sim \mathrm{NID}_{m+1}(0, G), \quad \varepsilon_i = (\varepsilon_{i1} \ \ldots \ \varepsilon_{iT})' \nu \\ &\sim \mathrm{NID}_T(0, R), \end{aligned} \tag{2}$$

where $U_i = \begin{pmatrix}\alpha_i & \beta_{(i)}'\end{pmatrix}' - \begin{pmatrix}\alpha & \beta'\end{pmatrix}'$, $X_i = (X_{i1} \ \ldots \ X_{iT})'$, $Z_i = (\mathbf{1}_T \quad X_i)$ and $\mathbf{1}_T = (1 \ \ldots \ 1)'$. This is a standard form of a mixed model leading to GLS estimators for α and β once the parameters incorporated in the matrices G and R have been estimated.

To take account of possible unobserved changes in the general (either economic or biological) environment, one can include an additive term $\gamma_{(i)}' F_t$ in model (1), where F_t denotes an r-dimensional vector of common factors and $\gamma_{(i)}$ is a vector containing the factor loadings for individual i. These common factors will induce dependencies between the y_{it}-observations from different individuals. (See e.g., Pesaran 2006.)

In model (1), all the explanatory variables were assumed *exogenous*. However, econometric models quite often include also lagged values of the dependent variable as regressors. Much of economic theory starts from the assumption that the economic agents are optimizing an *intertemporal* utility function, and this assumption often induces an autoregressive, dynamic model

$$\begin{aligned} y_{it} &= \alpha_i + \phi_1 y_{i,t-1} + \ldots + \phi_p y_{i,t-p} + \beta' X_{it} + \varepsilon_{it}, \\ \varepsilon_{it} &\sim \mathrm{IID}(0, \sigma^2) \end{aligned} \tag{3}$$

for the dependent variable y_{it}. In case of random intercepts α_i, the lagged values of the dependent variable and

Miodrag Lovric (ed.), *International Encyclopedia of Statistical Science*, DOI 10.1007/978-3-642-04898-2,

the combined error terms $(\alpha_i - \alpha) + \varepsilon_{it}$ will be correlated. This would lead to inconsistent least squares estimators for the ϕ-parameters. The problem can be circumvented by the GMM estimation method (Generalized Method of Moments). (See e.g., the Appendices in Arellano 2003.) Once the order p of the autoregressive model (3) has been correctly specified, it will be easy to find valid instruments for the GMM estimationt among the lagged differences of the dependent variable. Model (3) can be straightforwardly extended to the vector-valued case. (See e.g., Hsiao 2003, Chap. 4.7.)

If the dependent variable y_{it} is *discrete* (either a count variable or measured on a nominal or ordinal scale), one can combine the basic idea of model (1) and the concept of ►*generalized linear models* by assuming that the covariates X_{it} and the heterogeneity terms α_i affect the so-called *linear predictors* analogously to (1),

$$\eta_{it} = g\left(E\left(y_{it} \mid X_{it}, \alpha_i\right)\right) = \alpha_i + \beta' X_{it} \qquad (4)$$

and by assuming that conditionally on X_{it} and α_i , y_{it} follows a distribution belonging to the exponential family of distributions.1 (See e.g. Diggle et al. 2001, Chap. 11, or Fitzmaurice et al. 2004, Chap. 12.) Function g is called the *link* function, and models (4) are called *generalized linear mixed models* (GLMM). If for instance y_{it} would be dichotomous obtaining the values 0 or 1, *logit* link function would lead to the model

$$P\left(y_{it} = 1 \mid X_{it}, \alpha_i\right) = \exp(\alpha_i + \beta' X_{it}) / \left(1 + \exp(\alpha_i + \beta' X_{it})\right).$$

The resulting likelihood function contains complicated integral expressions, but they can be effectively approximated by numerical techniques.

Parametric and Nonparametric Reliability Analysis

Chris P. Tsokos
Distinguished University Professor
University of South Florida, Tampa, FL, USA

Introduction

Reliability is "the probability that a piece of equipment (component, subsystem or system) successfully performs its intended function for a given period of time under specified (design) conditions" (Martz and Waller 1982). Failure means that an item does not perform its required functions. To evaluate the performance of an item, to predict its failure time and to find its failure pattern is the subject of Reliability.

Mathematically we can define reliability, $R(t)$, as follows:

$$R(t) = \Pr(T > t) = 1 - \int_0^t f(\tau)\, d\tau, \quad (t \geq 0)$$

where T denotes the failure time of the system or component, and $f(t)$ the failure probability distribution.

The main entity in performing accurate reliability analysis depends on having properly identified a classical discrete or continuous probability distribution that will characterize the behavior of the failure data. In practice, scientists and engineers either assume one, such as the exponential, Weibull, Poisson, etc., or a perform goodness of fit test to properly identify the failure distribution and then proceed with the reliability analysis. It is possible that the assumed failure distribution is not the correct one and

furthermore, the goodness of fit test methodology failed to identify a classical probability distribution. Thus, proceeding with the reliability analysis will result in misleading and incorrect results.

In this brief document we discuss a nonparametric reliability procedure when one cannot identify a classical failure distribution, $f(t)$, to characterize the failure data of the system. The method is based on estimating the failure density through the concept of distribution-free kernel density method. Utilizing such methods on the subject area offers significant computation difficulties. Therefore, in order to use this method, one must be able to obtain the optimal bandwidth for the kernel density estimate. Here, we recommend a six-step procedure which one can apply to compute the optimal nonparametric probability distribution that characterizes the failure times. Some useful references on the subject matter are Bean and Tsokos (1980, 1982), Liu and Tsokos (2001, 2002a, b), Qiao and Tsokos (1994, 1995), Rust and Tsokos (1981), Silverman (1986), and Tsokos and Rust (1980). First we briefly discuss the parametric approach to reliability using the popular three-parameter Weibull probability distribution as the failure model. Some additional useful failure models can be found in Tsokos (1998, 1995).

Parametric Approach to Reliability

The two-parameter Weibull probability distribution is universally used to characterize the failure times of a system or component to study its reliability behavior instead of the three-parameter Weibull model. Recently, methods have been developed along with effective algorithms for which one can obtain estimates of the three-parameter Weibull probability distribution. Here we will use the three-parameter Weibull failure model.

The three-parameter Weibull failure model is given by

$$\hat{f}(t) = \frac{\hat{c}\,(t-\hat{a})^{\hat{c}-1}}{\hat{b}^{\hat{c}}} \exp\left\{-\left(\frac{t-\hat{a}}{\hat{b}}\right)^{\hat{c}}\right\},$$

where $\hat{a}$, $\hat{b}$ and $\hat{c}$ are the maximum likelihood estimates to the location, scale and shape parameters, respectively. For calculation of the estimates of a, b and c, see Qiao and Tsokos (1994, 1995).

Thus, the parametric reliability estimation $\hat{R}_p(t)$ of the three-parameter Weibull model is given by

$$\hat{R}_p(t) = \exp\left\{-\left(\frac{t-\hat{a}}{\hat{b}}\right)^{\hat{c}}\right\}.$$

The goodness of fit criteria that one can use in identifying the appropriate classical failure probability distribution to characterize the failure times is the popular ►Kolmogorov–Smirnov test.

Briefly, it tests the null hypothesis that the data $\{t_j\}_{j=1}^n$ is from some specified classical probability distribution against the alternative hypothesis that it is from another probability distribution. That is,

$$\begin{cases} H_0 : \{t_j\}_{j=1}^n \sim F(t), \\ H_1 : \{t_j\}_{j=1}^n \not\sim F(t). \end{cases}$$

Let $F_n^*(t)$ be the empirical distribution function for the failure data. The Kolmogorov–Smirnov statistic is defined by

$$D_n = \sum_t \left|F_n^*(t) - F(t)\right|.$$

The statistic D_n can be easily calculated from the following formula:

$$D_n = \max\left\{\max_{1\le i\le n}\left[\frac{i}{n} - F\left(t_{(i)}\right)\right], \max_{1\le i\le n}\left[\frac{i-1}{n} - F\left(t_{(i)}\right)\right]\right\},$$

where $t_{(1)} \le t_{(2)} \le \cdots \le t_{(n)}$ is the order statistic of $\{t_j\}_{j=1}^n$.

Let $D_{n,\alpha}$ be the upper α-percent point of the distribution of D_n, that is,

$$P\{D_n > D_{n,\alpha}\} \le \alpha.$$

Tables for the exact critical values $D_{n,\alpha}$ are available. See Miller (1956) and Owen (1962), among others, to make the appropriate decision.

Nonparametric Approach to Reliability

Let $\{t_j\}_{j=1}^n$ be the failure data characterized by the probability density function $f(t)$. Then the nonparametric probability density estimation $\hat{f}$ can be written as

$$\hat{f}_{\hat{h}}(t) = \frac{1}{n\hat{h}} \sum_{j=1}^{n} K\left(\frac{t-t_j}{\hat{h}}\right)$$

where $K(t)$ is the kernel and assumed to be Gaussian given by

$$K(t) = \frac{1}{\sqrt{2\pi}}\, e^{-\frac{1}{2}t^2}$$

and $\hat{h}$ is the estimate of the optimal bandwidth. There are several other choices for the kernel, namely, Epanechnikov, Corine, biweight, triweight, triangle and uniform. For further information regarding the selection process, see Silverman (1986). The most important element in $\hat{f}_{\hat{h}}(t)$ being effective to characterize the failure data is the bandwidth, $\hat{h}$. Given below is a procedure that works fairly well in obtaining optimal $\hat{h}$ and then $\hat{f}_{\hat{h}}(t)$ for the failure data,

(Bean and Tsokos 1982; Silverman 1986). This procedure is summarized below.

- Calculate S^2 and T_4 using the failure data $t_1, t_2, \ldots, t_n$:

$$S^2 = (n-1)^{-1} \sum_{j=1}^{n} (t_j - \bar{t})^2 \text{ and } T_4 = \frac{1}{n} \sum_{j=1}^{n} (t_j - \bar{t})^4.$$

- Determine a value for U_2 and U_4 as defined below:

$$U_2 \approx S^2 \text{ and } U_4 \approx \frac{n^3}{(n-1)(n^2-2n+3)} \left(T_4 - \frac{3(n-1)(2n-3)}{n^3} S^2 \right).$$

- Find estimates of the parameters μ and σ:

$$\hat{\mu} = \sqrt[4]{\frac{3U_2^2 - U_4}{2}} \text{ and } \hat{\sigma} = \sqrt{U_2 - \hat{\mu}^2}.$$

- Calculate $\int_{-\infty}^{\infty} f''^2(t)\, dt$ from the following:

$$\int_{-\infty}^{\infty} f''^2(t)\, dt = \frac{3}{16\sqrt{\pi}\hat{\sigma}^5} + \frac{1}{4\sqrt{\pi}\hat{\sigma}^5} e^{-\frac{\hat{\mu}^2}{\hat{\sigma}^2}} \left(\frac{3}{4} - \frac{3\hat{\mu}^2}{\hat{\sigma}^2} + \frac{\hat{\mu}^4}{\hat{\sigma}^4} \right).$$

- Find h_{opt} from the following:

$$h_{opt} = 2^{-\frac{1}{5}} \pi^{-\frac{1}{10}} n^{-\frac{1}{5}} \left\{ \int_{-\infty}^{\infty} f''^2(t) dt \right\}^{-\frac{1}{5}}.$$

- Obtain the estimate of the nonparametric failure distribution of the data:

$$\hat{f}(t) = \frac{1}{n h_{opt}} \sum_{j=1}^{n} K\left(\frac{t - t_j}{h_{opt}} \right).$$

There are other methods for dealing with the optimal bandwidth selection, see Bean and Tsokos (1982) and Silverman (1986).

The nonparametric estimate of the failure probability distribution $\hat{R}_{np}(t)$ can be obtained,

$$\begin{aligned} \hat{R}_{np}(t) &= \int_t^{\infty} \hat{f}(\tau)\, d\tau \\ &= \int_t^{\infty} \frac{1}{n\hat{h}} \sum_{j=1}^{n} K\left(\frac{\tau - t_j}{\hat{h}} \right) d\tau \\ &= \frac{1}{n\hat{h}} \sum_{j=1}^{n} \int_t^{\infty} K\left(\frac{\tau - t_j}{\hat{h}} \right) d\tau \\ &= \frac{1}{n} \sum_{j=1}^{n} \int_{-\infty}^{\frac{t-t_j}{\hat{h}}} K(\tau)\, d\tau. \end{aligned}$$

To evaluate the integral in the above equation, let

$$\Phi(t) = \int_{-\infty}^{t} K(x)\, dx = \frac{1}{\sqrt{2\pi}} \int_{-\infty}^{t} e^{-\frac{x^2}{2}} dx.$$

Then we have

$$\begin{aligned} \hat{R}_{np}(t) &= \frac{1}{n} \sum_{j=1}^{n} \left[1 - \Phi\left(\frac{t - t_j}{\hat{h}} \right) \right] \\ &= 1 - \frac{1}{n} \sum_{j=1}^{n} \Phi\left(\frac{t - t_j}{\hat{h}} \right). \end{aligned}$$

To calculate $\Phi(t)$, let

$$\int_0^u e^{-x^2} dx = e^{-u^2} \sum_{k=0}^{\infty} \frac{2^k \cdot u^{2k+1}}{(2k+1)!!}.$$

It follows that we can write

$$\begin{aligned} \Phi(t) &= \int_0^t K(x)\, dx + 0.5 \\ &= \frac{1}{\sqrt{2\pi}} \int_0^t e^{-\frac{x^2}{2}} dx + 0.5 \\ &= \frac{1}{\sqrt{2\pi}} \sqrt{2} \int_0^{\frac{t}{\sqrt{2}}} e^{-\tau^2} d\tau + 0.5 \\ &= \frac{1}{\sqrt{\pi}} \cdot e^{-\frac{t^2}{2}} \cdot \sum_{k=0}^{\infty} \frac{2k \left(\frac{t}{\sqrt{2}} \right)^{2k+1}}{(2k+1)!!} + 0.5 \\ &= \frac{1}{\sqrt{2\pi}} \cdot e^{-\frac{t^2}{2}} \cdot \sum_{k=0}^{\infty} \frac{t^{2k+1}}{(2k+1)!!} + 0.5. \end{aligned}$$

Note that $\Phi(t) \approx 0$ when $t < -4$, and $\Phi(t) \approx 1$ when $t > 4$. Then we need to carry out the summation in the interval $|t| \le 4$.

Since the sum converges quite fast, when $|t| < 4$, we have overcome the numerical difficulty in the calculation of the nonparametric reliability. An efficient numerical procedure is given below to evaluate the above summation.

Step 1 Construct a subroutine for calculating $\Phi(t)$ as follows:

1. Notations: At input, t stores the point; at output, p stores $\Phi(t)$. Other values for the computation: cc, each term of the sum; tt stores the value $t * t$, to save computer time.
2. Let $p = t$, $cc = t$, $tt = t * t$.
3. For $k = 1, 2, 3, \ldots$, perform (4) through (5) that follows.
4. If $|cc| <$ tolerance (we use 10^{-4} for tolerance), then

$$p = \frac{1}{\sqrt{2\pi}} e^{-\frac{tt}{2}} \cdot p + 0.5,$$

output p and exit. Otherwise continue with (5).

5. $cc = cc \cdot tt/(2k+1)$, $p = p + cc$.

Step 2 Find the optimal bandwidth $\hat{h}$ from the six-step procedure introduced in section "►Parametric Approach to Reliability".

Step 3 The reliability function at any given point t is given by

$$\hat{R}_{np}(t) = 1 - \frac{1}{n}\sum_{j=1}^{n} \Phi\left(\frac{t - t_j}{\hat{h}}\right).$$

Several applications of real data, along with Monte Carlo simulations and the nonparametric kernel probability estimate of reliability, give very good results in comparison with the parametric version of the reliability function.

Parametric Versus Nonparametric Tests

David J. Sheskin
Professor of Psychology
Western Connecticut State University, Danbury, CT, USA

A common distinction made with reference to statistical tests/procedures is the classification of a procedure as *parametric* versus *nonparametric*. This distinction is generally predicated on the number and severity of assumptions regarding the population that underlies a specific test. Although some sources use the term *assumption free* (as well as *distribution free*) in reference to nonparametric tests, the latter label is misleading, in that nonparametric tests are not typically assumption free. Whereas *parametric statistical tests* make certain assumptions with respect to the characteristics and/or parameters of the underlying population distribution upon which a test is based, *nonparametric tests* make fewer or less rigorous assumptions. Thus, as Marascuilo and McSweeney (1977) suggest, nonparametric tests should be viewed as *assumption freer* tests. Perhaps the most common assumption associated with parametric tests that does not apply to nonparametric tests is that data are derived from a normally distributed population.

Many sources categorize a procedure as parametric versus nonparametric based on the level of measurement a set of data being evaluated represents. Whereas parametric tests are typically employed when interval or ratio data are evaluated, nonparametric tests are used with rank-order (ordinal) and categorical data. Common example of parametric procedures employed with interval or ratio data are ►*Student's t tests*, *analysis of variance* procedures (see ►Analysis of Variance), and the *Pearson product moment coefficient of correlation* (see ►Correlation Coefficient). Examples of commonly

described nonparametric tests employed with rank-order data are the *Mann–Whitney U test*, *Wilcoxon's signed–ranks and matched–pairs signed ranks tests*, the *Kruskal–Wallis one-way analysis of variance by ranks*, the *Friedman two–way analysis of variance by ranks*, and *Spearman's rank order correlation coefficient*. Examples of commonly described nonparametric tests employed with categorical data are ►*chi-square tests* such as the *goodness-of-fit test*, *test of independence*, and *test of homogeneity* and the *McNemar test*.

Researchers are in agreement that since ratio and interval data contain a greater amount of information than rank-order and categorical data, if ratio or interval data are available it is preferable to employ a parametric test for an analysis. One reason for preferring a parametric test is that the latter type of test generally has greater *power* than its nonparametric analog (i.e., a parametric test is more likely to reject a false null hypothesis). If, however, one has reason to believe that one or more of the assumptions underlying a parametric test have been saliently violated (e.g., the assumption of underlying normal population distributions associated with the *t test for independent samples*), many sources recommend that a nonparametric test (e.g., a rank-order test that does not assume population normality such as the *Mann–Whitney U test*, which can also be used to evaluate data involving two independent samples) will provide a more reliable analysis of the data. Yet other sources argue it is still preferable to employ a parametric test under the latter conditions, on the grounds that parametric tests are, for the most part, *robust*. A *robust test* is one that still allows a researcher to obtain reasonably reliable conclusions even if one or more of the assumptions underlying the test are violated. As a general rule, when a parametric test is employed in circumstances when one or more of its assumptions are thought to be violated, an adjusted probability distribution is employed in evaluating the data. Sheskin (2007, p. 108) notes that in most instances, the debate concerning whether a researcher should employ a parametric or nonparametric test for a specific experimental design turns out to be of little consequence, since in most cases data evaluated with both a parametric test and its nonparametric analog will result in a researcher reaching the same conclusions.

Pareto Sampling

Lennart Bondesson
Professor Emeritus
Umeå University, Umeå, Sweden

Introduction

Let $\mathcal{U} = \{1, 2, \ldots, N\}$ be a population of units. To get information about the population total Y of some interesting y-variable, unequal probability sampling is a widely applied method. Often a random sample of a fixed number, n, of distinct units is to be selected with prescribed inclusion probabilities π_i, $i = 1, 2, \ldots, N$, for the units in $\mathcal{U}$. These π_i should sum to n and are usually chosen to be proportional to some auxiliary variable. In this form unequal

probability sampling is called fixed size πps sampling (ps = proportional to size). By the help of a πps sample and recorded y-values for the units in the sample, the total Y can be estimated unbiasedly by the ►Horvitz–Thompson estimator $\hat{Y}_{HT} = \sum_{i\in s} y_i/\pi_i$, where s denotes the sample. There are many possible fixed size πps sampling designs, see, e.g., Brewer and Hanif (1983) and Tillé (2006).

This article treats Rosén's (1997a,b) Pareto order πps sampling design. Contrary to many other fixed size πps designs, it is very easy to implement. However, it is only approximate. Independently of Rosén, Saavedra (1995) suggested the design. Both were inspired by unpublished work of Ohlsson, cf. Ohlsson (1998).

The Pareto Design

Let U_i, $i = 1, 2, \ldots, N$, be independent $U(0,1)$-distributed random numbers. Further, let

$$Q_i = \frac{U_i/(1-U_i)}{p_i/(1-p_i)}, \quad i = 1, 2, \ldots, N,$$

be so-called ranking variables. Put $p_i = \pi_i$, $i = 1, 2, \ldots, N$, and select as sample those n units that have the smallest Q-values. The factual inclusion probabilities π_i^* do not equal the desired π_i but approximately. For $d = \sum_{i=1}^{N} \pi_i(1-\pi_i)$ not too small ($d > 1$), the agreement is surprisingly good and better the larger d is.

The main advantages of the method are its simplicity, its high ►entropy, and that the U_is can be used as permanent random numbers, i.e., can be reused when at a later occasion the population, more or less altered, is re-sampled. In this way changes can be better estimated.

The name of the method derives from the fact that $u/(1-u) = F^{-1}(u)$, where F^{-1} is the inverse of the special Pareto distribution function $F(x) = x/(1+x)$ on $(0, \infty)$. A general order sampling procedure uses instead $Q_i = F^{-1}(U_i)/F^{-1}(\pi_i)$ for any specified F. As $d \to \infty$, correct inclusion probabilities are obtained but Rosén showed that the Pareto choice gives smallest possible asymptotic bias for them. Ohlsson (1998) uses $Q_i = U_i/\pi_i$, i.e., the distribution function $F(x)$ of a uniform distribution over (0,1).

Probabilistically the Pareto design is very close to Sampford's (1967) design for which the factual inclusion probabilities agree with the desired ones. Let $\mathbf{x}$ be a binary N-vector such that $x_i = 1$ if unit i is sampled and otherwise 0. The probability function $p(\mathbf{x})$ of the Sampford design is given by

$$p(\mathbf{x}) = C \prod_{i=1}^{N} \pi_i^{x_i}(1-\pi_i)^{1-x_i} \times \sum_{k=1}^{N}(1-\pi_k)x_k, \quad \sum_{i=1}^{N} x_i = n,$$

where C is a constant. For the Pareto design the probability function has the same form but the factor $1-\pi_k$ is replaced by c_k, where c_k is given by an integral that is closely proportional to $1-\pi_k$ if d is large (Bondesson et al. 2006).

For the Pareto design the factual inclusion probabilities π_i^* can be calculated in different ways (Aires 1999; Bondesson et al. 2006). By an iterative procedure based on recalculated factual inclusion probabilities, it is possible to adjust the parameters $p_i = \pi_i$ for the Pareto procedure, so that the desired inclusion probabilities π_i are exactly obtained (Aires 2000). The iterative procedure is time consuming. It is also possible to get good improvement by a simple adjustment. The ranking variables Q_i are replaced by the adjusted ranking variables

$$Q_i^{Adj} = Q_i \exp\left(\pi_i(1-\pi_i)\left(\pi_i - \frac{1}{2}\right)/d^2\right).$$

For $N = 6$ and $n = 3$ the following table illustrates the improvement:

	π_i	0.1	0.3	0.4	0.5	0.75	0.95
Pareto	π_i^*	0.0963	0.2916	0.3952	0.5040	0.7610	0.9519
AdjPar	π_i^*	0.0987	0.2987	0.3993	0.5018	0.7510	0.9505

Restricted Pareto Sampling

Pareto sampling can be extended to cases where there are further restrictions on the sample than just fixed sample size (Bondesson 2010). Such restrictions appear if the population is stratified in different ways. The restrictions are usually of the form $\mathbf{Ax} = \mathbf{b}$, where $\mathbf{A}$ is an $M \times N$ matrix. Then

$$\sum_{i=1}^{N} x_i \log Q_i = \sum_{i=1}^{N} x_i \left(\log \frac{U_i}{1-U_i} - \log \frac{\pi_i}{1-\pi_i}\right)$$

is minimized with respect to $\mathbf{x}$ given the linear restrictions. This minimization can be done by using a program for combinatorial optimization but it usually also suffices to use linear programming and the simplex algorithm with the additional restrictions $0 \le x_i \le 1$ for all i. Under some conditions asymptotically correct inclusion probabilities are obtained. However, in practice some adjustment is often needed. A simple adjustment is to replace Q_i by

$$Q_i^{Adj} = Q_i \exp\left(\pi_i(1-\pi_i)\left(\pi_i - \frac{1}{2}\right)\left(\mathbf{a}_i^T \boldsymbol{\Sigma}^{-1} \mathbf{a}_i\right)^2\right),$$

where $\boldsymbol{\Sigma} = \mathbf{ADA}^T$ with $\mathbf{D} = \mathrm{diag}(\pi_1(1-\pi_1), \ldots, \pi_N(1-\pi_N))$, and $\mathbf{a}_i$ is the ith column vector in $\mathbf{A}$. This method

is suggested by Bondesson (2010), who also presents another method for improvement, conditional Pareto sampling. For the latter method, the random numbers are conditioned to satisfy $\mathbf{AU} = \frac{1}{2}\mathbf{A1}$.

About the Author

Lennart Bondesson (academically a grand-son of Harald Cramér) received his Ph.D. in 1974. In 1983 he became professor of mathematical statistics in forestry at the Swedish University of Agricultural Sciences in Umeå, and in 1999 professor of mathematical statistics at Department of Mathematics and Mathematical Statistics, Umeå University. He has published more than 80 papers and one research book *Generalized Gamma Convolutions and Related Classes of Distributions and Densities* (Lecture Notes in Statistics 76, Springer, 1992). Professor Bondesson was Editor of *Scandinavian Journal of Statistics* (2001–2003).

Partial Least Squares Regression Versus Other Methods

Smail Mahdi
Professor of Mathematical Statistics
Mathematics and Physics, University of The West Indies, Cave Hill Campus, Barbados

Introduction

The concept of regression originated from genetics and the word *regression* was introduced into statistical literature in the published paper by Sir Francis Galton (1886) on the relationship between the stature of children and their parents. The relationship was found to be approximately linear with an approximate gradient of 2/3, and this suggested that very tall parents tend to have children shorter than themselves and vice versa. This phenomena was referred to as regression or return to mediocrity or to an average value. The general framework of the linear regression model (see ►Linear Regression Models)

$$\mathbf{Y} = X\boldsymbol{\beta} + \boldsymbol{\epsilon}$$

where $\mathbf{Y}$ is an $n \times q$ matrix of observations on q dependent variables, $\mathbf{X}$ is an $n \times p$ explicative matrix on p variables, $\boldsymbol{\beta}$ is a $p \times q$ matrix of unknown parameters, and $\boldsymbol{\epsilon}$ is $n \times q$ matrix of errors. The rows of $\boldsymbol{\epsilon}$ are independent and identically distributed, often assumed to be Gaussian. The justification for the use of a linear relationship comes from the fact that the conditional mean of a Gaussian random vector given the value of another Gaussian random vector is linear when the joint distribution is Gaussian. Without loss of generality, we will assume throughout that $\boldsymbol{X}$ and $\boldsymbol{Y}$ are mean centered and scaled. The aim is to estimate the unknown matrix $\boldsymbol{\beta}$. The standard approach is to solve in L2 the optimization problem:

$$L(\boldsymbol{\beta}) = \min_{\boldsymbol{\beta}} \|\boldsymbol{Y} - \boldsymbol{\beta}\boldsymbol{X}\|_2.$$

If $\boldsymbol{X}$ has a full rank, then a unique solution exists and is given by

$$\hat{\boldsymbol{\beta}}_{OLS} = (\boldsymbol{X}^T\boldsymbol{X})^{-1}\boldsymbol{X}^T\boldsymbol{Y}.$$

When the errors are assumed Gaussian, $\hat{\boldsymbol{\beta}}_{OLS}$ is also the maximum likelihood estimator and therefore, the best unbiased linear estimator (BLUE) of $\boldsymbol{\beta}$. Unfortunately, when some of the dependent variables are collinear, the matrix $\boldsymbol{X}$ does not have full rank and the ordinary least squares estimator may not exist or

becomes inappropriate. To overcome this multicollinearity problem (see ►Multicollinearity), many other estimators have been proposed in literature. This includes ridge regression estimator (RR), principal component regression estimator (PCR), and more recently the partial least squares regression estimator (PLSR).

Ridge Regression

The slightest multicollinearity of the independent vectors may make the matrix $\boldsymbol{X}^T\boldsymbol{X}$ ill conditioned and increase the variance of the components of $\hat{\boldsymbol{\beta}}_{OLS}$, which can lead to an unstable estimation of $\boldsymbol{\beta}$. Hoerl (1962) proposed the ridge regression method (see ►Ridge and Surrogate Ridge Regressions) that consists in adding a small positive constant λ to the diagonal of the standardized matrix $\boldsymbol{X}^T\boldsymbol{X}$ to obtain the RR estimator as

$$\hat{\boldsymbol{\beta}}_{RR} = (\boldsymbol{X}^T\boldsymbol{X} + \lambda\boldsymbol{I})^{-1}\boldsymbol{X}^T\boldsymbol{Y}$$

where $\boldsymbol{I}$ is the $p \times p$ identity matrix. The matrix $\boldsymbol{X}^T\boldsymbol{X} + \lambda\boldsymbol{I}$ is always invertible since it is positive definite. Several techniques are available in literature for finding the optimum value of λ. Another solution for the collinearity problem is given by the principal component regression (PCR) technique that is outlined below.

Principal Component Regression

Principal component regression is a ►principal component analysis (PCA) followed by a linear regression. In this case, the response variables are regressed on the leading principal components of the matrix $\boldsymbol{X}$, which can be obtained from its singular value decomposition (SVD). PCA is a compressing data technique that consists of finding a k-rank, $k = 1, \ldots, p$, projection matrix $\boldsymbol{P}_k$ such that the variance of the projected data $\boldsymbol{X} \times \boldsymbol{P}_k$ is maximized. The columns of the matrix $\boldsymbol{P}_k$ consist of the k unit-norm leading eigenvectors of $\boldsymbol{X}^T\boldsymbol{X}$. Using the matrix $\boldsymbol{P}_k$, we regress $\boldsymbol{Y}$ on the orthogonal score matrix $\boldsymbol{T}_k$ satisfying $\boldsymbol{X} = \boldsymbol{T}_k\boldsymbol{P}_k$; this yields the k latent-component regression coefficients matrix

$$\hat{\boldsymbol{\beta}}_{PCR} = \boldsymbol{P}_k\left(\boldsymbol{T}_k^T\boldsymbol{T}_k\right)^{-1}\boldsymbol{T}_k^T\boldsymbol{Y}.$$

However, two major problems may occur: firstly the choice of k and secondly, how, if the ignored principal components that correspond to the small eigenvalues are in fact relevant for explaining the covariance structure of the $\boldsymbol{Y}$ variables. For this reason, PLS comes into play to better deal with the multicollinearity problem by creating $\boldsymbol{X}$ latent components for explaining $\boldsymbol{Y}$, through the maximization of the covariance structure between the $\boldsymbol{X}$ and $\boldsymbol{Y}$ spaces.

Partial Least Squares Regression

Partial least squares (PLS), also known as projection method to latent structures, is applied to a broad area of data analysis including ►generalized linear models, regression, classification, and discrimination. It is a multivariate technique that generalizes and combines ideas from principal component analysis (PCA) and ordinary least squares (OLS) regression methods. It is designed to not only confront situations of correlated predictors but also relatively small samples and even the situation where the number of dependent variables exceeds the number of cases. The original idea came in the work of the Swedish statistician Herman Wold (1966) in the 1960s and became popular in computational chemistry and sensory evaluation by the work of his son Svante who developed the popular software soft independent modeling of class analogies (SIMCA) (Wold 1976). PLS find first two sets of weights $\boldsymbol{\omega} = (w_1, \ldots, w_m)$ and $\boldsymbol{U} = (u_1, \ldots, u_m)$ for $\boldsymbol{X}$ and $\boldsymbol{Y}$ such that $Cov\left(\boldsymbol{t}_l^X, \boldsymbol{t}_l^Y\right)$, where $\boldsymbol{t}_l^X = \boldsymbol{X} \times \boldsymbol{\omega}_l$, $\boldsymbol{t}_l^Y = \boldsymbol{Y} \times \boldsymbol{U}_l$ and $l = 1, \ldots, m$, is maximal. Then, the $\boldsymbol{Y}$ variables are regressed on the latent matrix $\boldsymbol{T}$ whose columns are the latent vectors $\boldsymbol{t}_i$, see, e.g., (Vinzi et al. 2005) for more details. Classically, the ordinary least squares regression (OLS) is used but other methods have been considered along with the corresponding algorithms. We describe the PLS technique through the algorithm, outlined, for instance in Mevik and Wehrens (2007), which is based on the singular value decomposition (SVD) of the cross product $\boldsymbol{X}^T\boldsymbol{Y}$ types. First, we set $\boldsymbol{E} = \boldsymbol{X}$ and $\boldsymbol{F} = \boldsymbol{Y}$. Then, we perform the singular decomposition of $\boldsymbol{E}^T\boldsymbol{F}$ and take the first left-singular vector $\boldsymbol{\omega}$ and the right-singular vector $\boldsymbol{q}$ of $\boldsymbol{E}^T\boldsymbol{F}$ to obtain the scores $\boldsymbol{t}$ and $\boldsymbol{u}$ as follows:

$$\boldsymbol{t} = \boldsymbol{E}\boldsymbol{\omega}$$

and

$$\boldsymbol{u} = \boldsymbol{F}\boldsymbol{q}.$$

The first score then is obtained as $\boldsymbol{t} = \boldsymbol{t}_1 = \frac{\boldsymbol{t}}{(\boldsymbol{t}^T\boldsymbol{t})^{1/2}}$. The effect of this score $\boldsymbol{t}_1$ on $\boldsymbol{E}$ and $\boldsymbol{F}$ is obtained by regressing $\boldsymbol{E}$ and $\boldsymbol{F}$ on $\boldsymbol{t}_1$. This gives $\boldsymbol{p} = \boldsymbol{E}^T\boldsymbol{t}$ and $\boldsymbol{q} = \boldsymbol{F}^T\boldsymbol{t}$. This effect is then subtracted from $\boldsymbol{E}$ and $\boldsymbol{F}$ to obtain the deflated matrices, with one rank less, $\boldsymbol{E}'$ and $\boldsymbol{F}'$, see, for example, Wedderburn (1934). The matrices $\boldsymbol{E}'$ and $\boldsymbol{F}'$ are then substituted for $\boldsymbol{E}$ and $\boldsymbol{F}$ and the process is reiterated again from the singular value decomposition of $\boldsymbol{E}^T\boldsymbol{F}$ to obtain the second normalized latent component $\boldsymbol{t}_2$. The process is continued until the required number m of latent components is obtained. The optimal value of m is often obtained by cross-validation or bootstrap, see, for example, Tenenhaus (1998). The obtained latent components $\boldsymbol{t}_l$, $l = 1, \ldots, m$ are

saved after each iteration as column of the latent matrix $\boldsymbol{T}$. Finally, the original Y variables are regressed on the latent components $\boldsymbol{T}$ to obtain the regression estimator

$$\hat{\boldsymbol{\beta}}_{PLS} = (\boldsymbol{T}^T\boldsymbol{T})^{-1}\boldsymbol{T}^T\boldsymbol{Y}$$

and the estimator

$$\hat{\boldsymbol{Y}} = \boldsymbol{T}(\boldsymbol{T}^T\boldsymbol{T})^{-1}\boldsymbol{T}^T\boldsymbol{Y}$$

of $\boldsymbol{Y}$. Note that several of the earlier PLS algorithms, available in literature, lack robustness. Recently, Simonetti et al. (2006) substituted systematically the least median of squares regression, Rousseeuw (1984), for the least squares regression in Garthwaite (1994) PLS setup to obtain a robust estimation for the considered data set.

Introduction

Recognition is regarded as a basic attribute of human beings and other living organisms. A pattern is a description of an object (Tou and Gonzalez 1974). Pattern recognition is a process of assigning category labels to a set of patterns. For instance, visual patterns "A," "a," and "***A***" are members of the same category, which is labeled as "letter A" and can easily be distinguished from the patterns, "B," "b," and "***B***," which belong to another category labeled as "letter B." Humans perform pattern recognition very well and the central problem is how to design a system to match human performance. Such systems find practical applications in many domains such as medical diagnosis, image analysis, face recognition, speech recognition, handwritten character recognition, and more (Duda et al. 2001; Fukunaga 1990).

The problem of pattern recognition can be tackled using handcrafted rules or heuristics for distinguishing the category of objects, though in practice such an approach leads to proliferation of the rules and exceptions to the rules, and invariably gives poor results (Bishop 2006). Some classification problems can be tackled by syntactic (linguistic) pattern recognition methods, but most real-word problems are tackled using the machine learning approach. Pattern recognition is an interdisciplinary field involving statistics, probability theory, computer science, machine learning, linguistics, cognitive science, psychology, etc. Pattern recognition systems involve the following phases: sensing, feature generation, feature selection, classifier design, and system performance evaluation (Tou and Gonzalez 1974).

In the previous example, the pattern was a set of black and white pixels. However, patterns might be a set of continuous variables. In statistical pattern recognition, features are treated as random variables. Therefore, patterns are random vectors that are assigned to a class or category with certain probability. In this case, patterns could be conceived as points in a high-dimensional feature space. Pattern recognition is the task of estimating a function that divides the feature space into regions, where each region corresponds to one of the categories (classes).

Such a function is called the decision or discriminant function and the surface that is realized by the function is known as the decision surface.

Feature Generation and Feature Selection

Before the measurement data obtained from the sensor could be utilized for the design of the pattern classifier, sometimes it is necessary to perform several preprocessing steps such as outlier removal, data normalization, and treatment of the missing data. After preprocessing, features are generated from measurements using data reduction techniques, which exploits and removes redundancies in the original data set. A popular way of generating features is to use linear transformations such as the Karhunen–Loeve transformation (▶principal component analysis), independent component analysis, discrete Fourier transform, discrete cosine and sine transforms, and Hadamard and Haar transforms. Important consideration in using these transformations is that they should preserve as much of the information that is crucial for classification task as possible, while removing as much redundant information as possible (Theodoridis and Koutroumbas 2009).

After the features are generated, they could be independently tested for their discriminatory capability. We might select features based on the statistical hypothesis testing. For instance, we may employ t-test or Kruskall–Wallis test to investigate the difference in mean feature values for two classes. Another approach is to construct the characteristic receiver operating curve and to explore how much overlap exists between distributions of feature values for two classes. Furthermore, we might compute class separability measures that take into account correlations between features such as Fisher's discriminant ratio and divergence. Besides testing individual features, we might ask what is the best feature vector or combination of features that gives the best classification performance. There are several searching techniques such as sequential backward or forward selection that can be employed in order to find an answer (Theodoridis and Koutroumbas 2009).

Design of a Pattern Classifier

The principled way to design a pattern classifier would involve characterization of the class probability density functions in the feature space and finding an appropriate discriminant function to separate the classes in this space. Every classifier can make an error by assigning the wrong class label to the pattern. The goal is to find the classifier with the minimal probability of classification error. The best classifier is based on the Bayes decision rule (Fukunaga 1990). The basic idea is to assign a pattern to the class having the highest a posteriori probability for a given pattern. A posteriori probabilities for a given pattern are computed from a priori class probabilities and conditional density functions. However, in practice, it is often difficult to compute a posteriori probabilities as a priori class probabilities are not known in advance.

Therefore, although the Bayesian classifiers are optimal they are rarely used in practice. Instead, classifiers are designed directly from the data. A simple and computationally efficient approach to the design of the classifier is to assume that the discriminant function is linear. In that case, we can construct a decision hyperplane through the feature space defined by

$$g(x) = w^T x + w_0 = 0$$

where $w = [w_1, w_2, \ldots]^T$ are unknown coefficients or weights, $x = [x_1, x_2, \ldots]$ is a feature vector, and w_0 is a threshold or bias. Finding unknown weights is called learning or training. In order to find an appropriate value for the weights, we can use iterative procedures such as the perceptron learning algorithm. The basic idea is to compute error or cost function, which measures the difference between actual classifier output and desired output. Error function is used to adjust current values of the weights. This process is repeated until perceptron converges, that is, until all patterns are correctly classified. This is possible if patterns are linearly separable. After the perceptron converges, new patterns could be classified according to the simple rule:

$$\text{If } w^T x + w_0 > 0 \text{ assign } x \text{ to class } \omega_1$$
$$\text{If } w^T x + w_0 < 0 \text{ assign } x \text{ to class } \omega_2$$

where $\omega 1$ and $\omega 2$ are class labels.

The problem with linear classifiers is that they lead to suboptimal performance when classes are not linearly separable. An example of pattern recognition problem that is not linearly separable is the logical predicate XOR where the patterns (0,1) and (1,0) belong to class $\omega 1$, and the patterns (0,0) and (1,1) belong to $\omega 2$. It is not possible to draw a straight line (linear decision boundary) in two-dimensional feature space that will discriminate between these two classes. One approach to deal with such problems is to build a linear classifier that will minimize the mean square error between the desired and the actual output of the classifier. This can be achieved using least mean square (LMS) or Widrow–Hoff algorithm for weight

adjustment. Another approach is to design a nonlinear classifier (Bishop 1995). Examples of nonlinear classifiers are multilayer perceptron trained with error backpropagation, radial basis functions network, k-nearest neighbor classifier, and decision trees. In practice, it is possible to combine outputs from several different classifiers in order to achieve better performance. Classification is an example of so-called supervised learning in which each feature vector has a preassigned target class.

Performance Evaluation of the Pattern Classifier

An important task in the design of a pattern classifier is how well it will perform when faced with new patterns. This is an issue of generalization. During learning, the classifier builds a model of the environment to which it is exposed. The model might vary in complexity. A complex model might offer a better fit to the data, but might also capture more noise or irrelevant characteristics in the data, and thus be poor in the classification of new patterns. Such a situation is called over-fitting. On the other hand, if the model is of low complexity, it might not fit the data well. The problem is how to select an appropriate level of complexity that will enable the classifier to fit the observed data well, while preserving enough flexibility to classify unobserved patterns. This is known as a bias-variance dilemma (Bishop 1995).

The performance of the designed classifier is evaluated by counting the number of errors committed during a testing with a set of feature vectors. Error counting provides an estimation of classification error probability. The important question is how to choose a set of feature vectors that will be used for building the classifier and a set of feature vectors that will be used for testing. One approach is to exclude one feature vector from the sample, train the classifier on all other vectors, and then test the classifier with the excluded vector. If misclassification occurs, error is counted. This procedure is repeated N times with different excluded feature vectors every time. The problem with this procedure is that it is computationally demanding. Another approach is to split the data set into two subsets: (1) a training sample used to adjust (estimate) classifier parameters and (2) a testing sample that is not used during training but is applied to the classifier following completion of the training. The problem with this approach is that it reduces the size of the training and testing samples, which reduces the reliability of the estimation of classification error probability (Theodoridis and Koutroumbas 2009).

Permanents in Probability Theory

Ravindra B. Bapat
Professor, Head New Delhi Centre
Indian Statistical Institute, New Delhi, India

Preliminaries

If A is an $n \times n$ matrix, then the permanent of A, denoted by per A, is defined as

$$\text{per } A = \sum_{\sigma \in S_n} \prod_{i=1}^{n} a_{i\sigma(i)},$$

where S_n is the set of permutations of $1, 2, \ldots, n$. Thus the definition of the permanent is similar to that of the determinant except that all the terms in the expansion have a positive sign.

Example: Consider the matrix

$$A = \begin{bmatrix} 2 & -1 & 3 \\ 1 & 2 & 3 \\ -2 & 4 & 1 \end{bmatrix}.$$

Then

$$\text{per } A = 4 + 6 + 12 - 12 + 24 - 1 = 33.$$

Permanents find numerous applications in probability theory, notably in the theory of discrete distributions and ▶order statistics. There are two main advantages of employing permanents in these areas. Firstly, permanents serve as a convenient notational device, which makes it feasible to write complex expressions in a compact form. The second advantage, which is more important, is that some theoretical results for the permanent lead to statements of interest in probability theory. This is true mainly of the properties of permanents of entrywise nonnegative matrices.

Although the definition of the permanent is similar to that of the determinant, many of the nice properties of the determinant do not hold for the permanent. For example, the permanent is not well behaved under elementary transformations, except under the transformation of multiplying a row or column by a constant. Similarly, the permanent of the product of two matrices does not equal the product of the permanents in general. The Laplace expansion for the determinant holds for the permanent as well and is a convenient tool for dealing with the permanent. Thus, if $A(i,j)$ denotes the submatrix obtained by deleting row i and column j of the $n \times n$ matrix A, then

$$\text{per } A = \sum_{k=1}^{n} a_{ik} \text{per } A(i,k) = \sum_{k=1}^{n} a_{ki} \text{per } A(k,i), \quad i = 1, 2, \ldots, n.$$

We refer to van Lint and Wilson (2001) for an introduction to permanents.

Combinatorial Probability

Matrices all of whose entries are either 0 or 1, the so called $(0,1)$-matrices, play an important role in combinatorics. Several combinatorial problems can be posed as problems involving counting certain permutations of a finite set of elements and hence can be represented in terms of $(0,1)$-matrices. We give two well-know examples in combinatorial probability.

Consider n letters and n envelopes carrying the corresponding addresses. If the letters are put in the envelopes at random, what is the probability that none of the letters goes into the right envelope? The probability is easily seen to be

$$\frac{1}{n!}\text{per}\begin{bmatrix} 0 & 1 & \cdots & 1 \\ 1 & 0 & \cdots & 1 \\ \vdots & \vdots & \ddots & \vdots \\ 1 & 1 & \cdots & 0 \end{bmatrix},$$

which equals $1 - \frac{1}{1!} + \frac{1}{2!} - \frac{1}{3!} + \cdots + (-1)^n \frac{1}{n!}$. The permanent in the above expression counts the number of *derangements* of n symbols.

Another problem, which may also be posed as a probability question, is the *problème des ménages* (Kaplansky and Riordan 1946). In how many ways can n couples be placed at a round table so that men and women sit in alternate places and no one is sitting next to his or her spouse? This number equals $2n!$ times the permanent of the matrix $J_n - I_n - P_n$, where J_n is the $n \times n$ matrix of all ones, I_n is the $n \times n$ identity matrix, and P_n is the full cycle permutation matrix, having ones at positions $(1,2), (2,3), \ldots, (n-1,n), (n,1)$ and zeroes elsewhere. The permanent can be expressed as

$$\text{per } (J_n - I_n - P_n) = \sum_{i=0}^{n} (-1)^i \frac{2n}{2n-i} \binom{2n-i}{i} (n-i)!.$$

Discrete Distributions

The densities of some discrete distributions can be conveniently expressed in terms of permanents. We illustrate by an example of multiparameter ▶multinomial distribution.

We first consider the multiparameter binomial. Suppose n coins, not necessarily identical, are tossed once, and let X be the number of heads obtained. Let p_i be the probability of heads on a single toss of the i-th coin, $i = 1, 2, \ldots, n$. Let $\mathbf{p}$ be the column vector with components $p_1, \ldots, p_n$, and let $\mathbf{1}$ be the column vector of all ones. Then it can be verified that

$$Prob(X = x) = \frac{1}{x!(n-x)!} \text{per } [\underbrace{\mathbf{p}, \ldots, \mathbf{p}}_{r} \underbrace{(\mathbf{1}-\mathbf{p}), \ldots, (\mathbf{1}-\mathbf{p})}_{n-r}]. \tag{1}$$

Now consider an experiment which can result in any of r possible outcomes, and suppose n trials of the experiment are performed. Let p_{ij} be the probability that the experiment results in the j-th outcome at the i-th trial, $i = 1, 2, \ldots, n; j = 1, 2, \ldots, r$. Let P denote the $n \times r$ matrix (p_{ij}) which is row stochastic. Let $P_1, \ldots, P_r$ be the columns of P. Let X_j denote the number of times the j-th outcome is obtained in the n trials, $j = 1, 2, \ldots, r$. If $k_1, \ldots, k_r$ are nonnegative integers summing to n, then as a generalization of (1) we have (Bapat 1990)

$$Prob(X_1 = k_1, \ldots, X_r = k_r) = \frac{1}{k_1! \cdots k_r!} \text{per } [\underbrace{P_1, \ldots, P_1}_{k_1}, \ldots, \underbrace{P_r, \ldots, P_r}_{k_r}].$$

Similar representations exist for the multiparameter negative binomial.

Order Statistics

Permanents provide an effective tool in dealing with order statistics corresponding to independent random variables, which are not necessarily identically distributed. Let $X_1, \ldots, X_n$ be independent random variables with distribution functions $F_1, \ldots, F_n$ and densities $f_1, \ldots, f_n$ respectively. Let $Y_1 \leq \cdots \leq Y_n$ denote the corresponding order statistics. We introduce the following notation. For a fixed y, let

$$\hat{f}(y) = \begin{bmatrix} f_1(y) \\ \vdots \\ f_n(y) \end{bmatrix} \text{ and } \hat{F}(y) = \begin{bmatrix} F_1(y) \\ \vdots \\ F_n(y) \end{bmatrix}.$$

For $1 \leq r \leq n$, the density function of Y_r is given by Vaughan and Venables (1972)

$$g_r(y) = \frac{1}{(r-1)!(n-r)!} \text{per} \left[\underbrace{\hat{f}(y)}_{1} \underbrace{\hat{F}(y)}_{r-1} \underbrace{\mathbf{1} - \hat{F}(y)}_{n-r}\right], \infty < y < \infty$$

For $1 \leq r \leq n$, the distribution function of Y_r is given by Bapat and Beg (1989)

$$Prob(Y_r \leq y) = \sum_{i=r}^{n} \frac{1}{i!(n-i)!} \text{per} \left[\underbrace{\hat{F}(y)}_{i} \underbrace{\mathbf{1} - \hat{F}(y)}_{n-i}\right], \quad \infty < y < \infty$$

The permanental representation can be used to extend several recurrence relations for order statistics from the i.i.d. case to the case of nonidentical, independent random variables. Using the Alexandroff inequality for the permanent of a nonnegative matrix, it can be shown (Bapat 1990) that for any y, the sequence $Prob(Y_i \leq y | Y_{i-1} \leq y)$, $i = 2, \ldots, n$ is nonincreasing.

For additional material on applications of permanents in order statistics we refer to Balakrishnan (2007) and the references contained therein.

About the Author

Past President of the Indian Mathematical Society (2007–2008), Professor Bapat joined the Indian Statistical Institute, New Delhi, in 1983, where he holds the position of Head, Delhi Centre at the moment. He held visiting positions at various Universities in the U.S., including University of Connecticut and Oakland University, and visited several Institutes abroad in countries including France, Holland, Canada, China and Taiwan for collaborative research and seminars. The main areas of research interest of Professor Bapat are nonnegative matrices, matrix inequalities, matrices in graph theory and generalized inverses. He has published more than 100 research papers in these areas in reputed national and international journals. He has written books on Linear Algebra, published by Hindustan Book Agency, Springer and Cambridge University Press. He has recently written a book on Mathematics for the general readers, in Marathi, which won the state government award for best literature in Science for 2004. He is Elected Fellow of the Indian Academy of Sciences, Bangalore and Indian National Science Academy, Delhi.

Permutation Tests

Markus Neuhäuser
Professor
Koblenz University of Applied Sciences, Remagen, Germany

A permutation test is illustrated here for a two-sample comparison. The notation is as follows: Two independent groups with sample sizes n and m have independently and

identically distributed values $X_1, \ldots, X_n$ and $Y_1, \ldots, Y_m$, respectively, $n + m = N$. The means are denoted by $\overline{X}$ and $\overline{Y}$, and the distribution functions by F and G. These distribution functions of the two groups are identical with the exception of a possible location shift: $F(t) = G(t - \theta)$ for all $t, -\infty < \theta < \infty$. The null hypothesis states $H_0 : \theta = 0$, whereas $\theta \neq 0$ under the alternative H_1.

In this case Student's t test (see ▶Student's t-Tests) can be applied. However, if F and G were not normal distributions, it may be better to avoid using the t distribution. An alternative method is to use the permutation null distribution of the t statistic.

In order to generate the permutation distribution all possible permutations under the null hypothesis have to be generated. In the two-sample case, each permutation is a possible (re-)allocation of the N observed values to two groups of sizes n and m. Hence, there are $\binom{N}{n}$ possible permutations. The test statistic is calculated for each permutation. The null hypothesis can then be accepted or rejected using the permutation distribution of the test statistic, the p-value being the probability of the permutations giving a value of the test statistic as or more supportive of the alternative than the observed value. Thus, inference is based upon how extreme the observed test statistic is relative to other values that could have been obtained under the null hypothesis.

Under H_0 all permutations have the same probability. Hence, the p-value can simply be computed as the proportion of the permutations with a test statistic's value as or more supportive of the alternative than the observed value.

The order of the permutations is important, rather than the exact values of the test statistic. Therefore, modified test statistics can be used (Manly 2007, pp. 16–17). For example, the difference $\overline{X} - \overline{Y}$ can be used instead of the t statistic

$$t = \frac{\overline{X} - \overline{Y}}{S \cdot \sqrt{\frac{1}{n} + \frac{1}{m}}}$$

where S is the estimated standard deviation.

This permutation test is called Fisher–Pitman permutation test or randomization test (see ▶Randomization Tests), it is a nonparametric test (Siegel 1956; Manly 2007). However, at least an interval measurement is required for the Fisher-Pitman test because the test uses the numerical values $X_1, \ldots, X_n$ and $Y_1, \ldots, Y_m$ (Siegel 1956).

The permutation distribution depends on the observed values, therefore a permutation test is a conditional test, and a huge amount of computing is required. As a result, the Fisher–Pitman permutation test was hardly ever applied before the advent of fast PCs, although it was proposed in the 1930s and its high efficiency was known since decades. Nowadays, the test is often recommended and implemented in standard software such as SAS (for references see Lehmann 1975, or Neuhäuser and Manly 2004).

Please note that the randomization model of inference does not require randomly sampled populations. For a permutation test it is only required that the groups or treatments have been assigned to the experimental units at random (Lehmann 1975).

A permutation test can be applied with other test statistics, too. Rank-based statistics such as Wilcoxon's rank sum can also be used as test statistic (see the entry about the Wilcoxon–Mann–Whitney test). Rank tests can also be applied for ordinal data. Moreover, rank tests had advantages in the past because the permutation null distribution can be tabulated. Nowadays, with modern PCs and fast algorithms, permutation tests can be carried out with any suitable test statistic. However, rank tests are relatively powerful in the commonly-occurring situation where the underlying distributions are non-normal (Higgins 2000). Hence, permutation tests on ranks are still useful despite the fact that more complicated permutation tests can be carried out (Neuhäuser 2005).

When the sample sizes are very large, the number of possible permutations can be extremely large. Then, a ▶simple random sample of M permutations can be drawn in order to estimate the permutation distribution. A commonly used value is $M = 10,000$. Please note that the original observed values must be one of the M selected permutations (Edgington and Onghena 2007, p. 41).

It should be noted that permutation procedures do have some disadvantages. First, they are computer-intensive, although the computational effort seems to be no longer a severe objection against permutation tests. Second, conservatism is often the price for exactness. For this reason, the virtues of permutation tests continue to be debated in the literature (Berger 2000).

When a permutation test is performed for other situations than the comparison of two samples the principle is analogue. The Fisher-Pitman test can also be carried out with the ANOVA F statistic. Permutation tests can also be applied in case of more complex designs. For example, the residuals can be permuted (ter Braak 1992; Anderson 2001).

Permutation tests are also possible for other situations than the location-shift model. For example, Janssen (1997) presents a permutation test for the ▶Behrens-Fisher problem where the population variances may differ.

In the terminology of pharmacokinetics, the *bioavailability* (BA) of a drug product refers to the rate and extent of its absorbed active ingredient or active moiety that becomes available at the site of action. A new/test drug product (T) is considered *bioequivalent* to an existing/reference product (R) if there is no significant difference in the bioavailabilities between the two products when they are administered at the same dose under similar conditions in an appropriately designed study. Studies to demonstrate either *in-vivo* or *in-vitro* bioequivalence are required for government regulatory approvals of generic drug products, or new formulations of existing products with known chemical entity.

Statistically an *in-vivo* bioequivalence (BE) study employs a crossover design with T and R drug products administered to healthy subjects on separate occasions according to a pre-specified randomization schedule, with ample washout between the occasions. The concentration of the active ingredient of interest in blood is measured over time per subject in each occasion, resulting in multiple concentration-time profiles curves for each subject. From which a number of bioavailability measures, such as area under the curve (AUC) and peak concentration (C_{max}) in either raw or logarithmic scale, are then computed, statistically modeled, and analyzed for bioequivalence. Let Y_{ijkt} be a log-transformed bioavailability measure of subject j in treatment sequence i at period t, having the treatment k. In a simplest 2×2 crossover design with two treatment sequences T/R ($i=1$) and R/T ($i=2$), is assumed to follow a mixed-effects ANOVA model

$$Y_{ijkt} = \mu_0 + \omega_i + \phi_k + \pi_t + S_{ij} + \varepsilon_{ijkt}$$

where μ_0 is an overall constant, ω_i, ϕ_k and π_t are, respectively, (fixed) effects of sequence i, formulation k and period t, S_{ij} is the (random) effect of subject j in sequence i, and ε_{ijkt} the measurement error. In this model, the between-subject variation is captured by the random component $S_{ij} \sim N\left(0, \sigma_B^2\right)$ and the within-subject variation $\varepsilon_{ijkt} \sim N\left(0, \sigma_{Wk}^2\right)$ is allowed to depend on formulation k. Bioequivalence of T and R is declared when the null hypothesis $H_0 : \phi_T \le \phi_R - \varepsilon$ or $\phi_T \ge \phi_R + \varepsilon$ can be rejected against the alternative $H_1 : -\varepsilon \le \phi_T - \phi_R \le \varepsilon$ at some significance level α, where $\varepsilon = \log(1.25) = 0.2231$ and $\alpha = 0.05$ are set by regulatory agencies. This last sentence is referred to as the criterion for *average BE*. A common method to establish average BE is to calculate the shortest $(1-2\alpha)\times 100\%$ confidence interval of $\delta = \phi_T - \phi_R$ and show that it is contained in the equivalence interval $(-\varepsilon, \varepsilon)$.

Establishing average BE using any nonreplicated $k \times k$ crossover design can be conducted along the same line as described above. For certain types of drug products, such as those with Narrow Therapeutic Index (NTI), questions were raised regarding the adequacy of the average BE method (e.g., Blakesley et al. 2004). To address this issue,

other criteria and/or statistical methods for bioequivalence have been proposed and studied in the literature. In partic-h ular, *population BE* (PBE) assesses the difference between T and R in both means and variances of bioavailability measures, and *individual BE* (IBE) assesses, in addition, the variation in the average T and R difference among individuals. Some of these new concepts, notably individual bioequivalence, would require high-order crossover designs such as TRT/RTR. Statistical designs and analyses for population BE and individual BE are described in detail in a statistical guidance for industry (USA FDA, 2001) and several monographs (Chow and Shao 2002; Wellek 2003). Hsuan and Reeve (2003) proposed a unified procedure to establish IBE using any high-order crossover design and a multivariate ANOVA model. Recently the USA FDA (2007) proposes a process of making available the public guidance(s) on how to design bioequivalence studies for specific drug products.

About the Author

Dr. Francis Hsuan has been a faculty member in the Department of Statistics at the Fox School, Temple University, for more than 25 years. He received his Ph.D. in Statistics from Cornell University and his B.S. in Physics from the National Taiwan University. He was also a visiting scholar at the Harvard School of Public Health from 1998 to 1999, working on projects related to the analysis of longitudinal categorical data with informative missingness.

Philosophical Foundations of Statistics

Inge S. Helland
Professor
University of Oslo, Oslo, Norway

The philosophical foundations of statistics involve issues in theoretical statistics, such as goals and methods to meet these goals, and interpretation of the meaning of inference using statistics. They are related to the philosophy of science and to the ►philosophy of probability.

As with any other science, the philosophical foundations of statistics are closely connected to its history, which again is connected to the men with whom different philosophical directions can be associated. Some of the most important names in this connection are Thomas Bayes (1702–1761), Ronald A. Fisher (1890–1962) and Jerzy Neyman (1894–1981).

The standard statistical paradigm is tied to the concept of a statistical model, an indexed family of probability measures $P^{\theta}(\cdot)$ on the observations, indexed by the parameters θ. Inference is done on the parameter space. This paradigm was challenged by Breiman (2001), who argued for an algorithmical, more intuitive model concept. Breiman's tree models are still much in use, together with other algorithmical bases for inference, for instance within chemometry. For an attempt to explain some of these within the framework of the ordinary statistical paradigm, see Helland (2010).

On the other hand, not all indexed families of distributions lead to sensible models. McCullagh (2002) showed that several absurd models can be produced.

The standard statistical model concept can be extended by implementing some kind of model reduction (Wittgenstein 1961: "The process of induction is the process of assuming the simplest law that can be made to harmonize with our experience") or by, e.g., adjoining a symmetry group to the model (Helland 2004, 2010).

To arrive at methods of inference, the model concept must be supplemented by certain principles. In this connection, an experiment is ordinarily seen as given by a statistical model together with some focus parameter. Most

statisticians agree at least to some variants of the following three principles: The conditionality principle (When you choose an experiment randomly, the information in this large experiment, including the ►randomization, is not more than the information in the selected experiment.), the sufficiency principle (Experiments with equal values of a sufficient statistics have equal information.) and the likelihood principle (All the information about the parameter is contained in the likelihood for the parameter, given the observations.). Birnbaum's famous theorems says that likelihood principle follows from the conditionality principle together with the sufficiency principle (for some precisely defined version of these principles). This, and the principles themselves are discussed in detail in Berger and Wolpert (1984).

Berger and Wolpert (1984) also argue that the likelihood principle "nearly" leads to Bayesian inference, as the only mode of inference which really satisfies the likelihood principle. This whole chain of reasoning has been countered by Kardaun et al. (2003) and by leCam (1984), who states that he prefers to be a little "unprincipled."

To arrive at statistical inference, whether it is point estimates, confidence intervals (credibility intervals for Bayesians) or hypothesis testing, we need some decision theory (see ►Decision Theory: An Introduction, and ►Decision Theory: An Overview). Such decision theory may be formulated differently by different authors. The foundation of statistical inference from a Bayesian point of view is discussed by Good (1988), Lindley (2000) and Savage (1972). From the frequentist point of view it is argued by Efron (1986) that one should be a little more informal; but note that a decision theory may be very useful also in this setting.

The philosophy of foundations of statistics involves many further questions which have direct impact on the theory and practice of statistics: Conditioning, randomization, shrinkage, subjective or objective priors, reference priors, the role of information, the interpretation of probabilities, the choice of models, optimality criteria, nonparametric versus parametric inference, the principle of an axiomatic foundation of statistics etc. Some papers discussing these issues are Cox (1997) with discussion, Kardaun et al. (2003) and Efron (1978, 1979). The last paper takes up the important issue of the relationship between statistical theory and the ongoing revolution of computers.

The struggle between ►Bayesian statistics and frequentist statistics is not so hard today as it used to be some years ago, partly since it has been realized that the two schools often lead to similar results. As hypothesis testing and confidence intervals are concerned, the frequentist school and the Bayesian school must be adjoined by the Fisherian or fiducian school, although largely out of fashion today. The question of whether these three schools in some sense can agree on testing, is addressed by Berger (2003).

The field of design of experiments also has its own philosophical foundation, touching upon practical issues like randomization, blocking and replication, and linked to the philosophy of statistical inference. A good reference here is Cox and Reid (2000).

About the Author

Inge Svein Helland is Professor, University of Oslo (1996–present). He was Head of Department of Mathematical Sciences, Agricultural University of Norway (1987–1989) and Head of Statistics Division, Department of Mathematics, University of Oslo (1999–2001). He was Associate Editor, *Scandinavian Journal of Statistics* (1994–2001). Professor Helland has (co-)authored about 65 papers, reports, manuscripts, including the book *Steps Towards a Unified Basis for Scientific Models and Methods* (World Scientific, Singapore, 2010).

Philosophy of Probability

Martin Peterson
Associate Professor
Eindhoven University of Technology, Eindhoven, Netherlands

The probability calculus was created in 1654 by Pierre de Fermat and Blaise Pascal. The philosophy of probability is the philosophical inquiry into the semantic and epistemic properties of this mathematical calculus. The question at the center of the philosophical debate is *what it means to say* that the probability of an event or proposition equals a certain numerical value, or in other words, what the *truth-conditions* for a probabilistic statement are. There is significant disagreement about this, and there are two major camps in the debate, viz., *objectivists* and *subjectivists*.

Objectivists maintain that statements about probability refer to some features of the external world, such as the relative frequency of some event. Probabilistic statements are thus objectively true or false, depending on whether they correctly describe the relevant features of the external world. For example, some objectivists maintain that it is true that the probability that a coin will land heads is ½ if and only if the relative frequency of this type of event is ½ (Other objective interpretations will be discussed below).

Subjectivists disagree with this picture. They deny that statements about probability should be understood as claims about the external world. On their view, they should rather be understood as claims about the speaker's degree of belief that an event will occur. Consider, for example, Mary's probability that her suitor will propose. What is Mary's probability that this event will occur? It seems rather pointless to count the number of marriage proposals that other people get, because this does not tell us anything about the probability that *Mary* will be faced with a marriage proposal. If it is true that Mary's probability is, say, 1/2 then it is true because of her mental state, i.e., her degree of belief that her suitor will propose. Unfortunately, nothing follows from this about whether her suitor actually will propose or not. Mary's probability that her suitor will propose may be high even if the suitor feels that marriage is totally out of the question.

Both the objective and subjective interpretations are compatible with Kolmogorov's axioms. These axioms come out as true, irrespective of whether we interpret them along the lines suggested by objectivists and subjectivists. However, more substantial questions about what the probability of an event is may depend on which interpretation is chosen. For example, Mary's subjective belief that her suitor will propose might be low, although the objective probability is quite high.

The notion of subjective probability is closely related to ►Bayesian statistics, presented elsewhere in this book. (In recent years some authors have, however, also developed objectivist accounts of Bayesian statistics.)

In what follows we shall give a more detailed overview of some of the most well-known objective and subjective interpretations, viz. the relative-frequency view, the propensity interpretation, the logical interpretation, and the subjective interpretation. We shall start, however, with the classical interpretation. It is strictly speaking neither an objective nor a subjective interpretation, since it is salient about many of the key questions discussed by objectivists and subjectivists.

The *classical interpretation*, advocated by Laplace, Pascal, Bernoulli and Leibniz, holds the probability of an event to be a fraction of the total number of possible ways in which the event can occur. Hence, the probability that you will get a six if you roll a six-sided die is 1/6. However, it takes little reflection to realize that this interpretation presupposes that all possible outcomes are equally likely. This is not always a plausible assumption, as Laplace and others were keen to stress. For an extreme example, consider the weather in the Sahara desert. It seems to be much more probable that it will be sunny in the Sahara desert tomorrow than not, but according to the classical interpretation the probability is ½ (since there are two possible outcomes, sun or no sun). Another problem with the classical interpretation is that it is not applicable when the number of possible outcomes is infinite. Then the probability of every possibility would be zero, since the ratio between any finite number and infinity is zero.

The *frequency interpretation*, briefly mentioned above, holds that the probability of an event is the ratio between the numbers of times the event has occurred divided by the total number of observed cases. Hence, if you toss a coin 1,000 times and it lands heads up 508 times then the relative frequency, and thus the probability,

would be 508/1000 = 0.508. A major challenge for anyone seeking to defend the frequency interpretation is to specify which reference class is the relevant one and why. For example, suppose I toss the coin another 1,000 times, and that it lands heads up on 478 occasions. Does this imply that the probability has changed from 0.508 to 0.486? Or is the "new" probability 508 + 486/2.000? The physical constitution of the coin is clearly the same.

The problem of identifying the relevant reference class becomes particularly pressing as the frequency interpretation is applied to unique events, i.e., events that only occur once, such as the US presidential election in 2000 in which George W Bush won over Al Gore. The week before the election the probability was – according to many political commentators – about 50% that Bush would win. Now, to which reference class does this event belong? If this was a *unique* event the reference class has, by definition, just one element, viz., the event itself. So according to the frequency interpretation the probability that Bush was going to win was 1/1, since Bush actually won the election. This cannot be the right conclusion.

Venn famously argued that the frequency interpretation makes sense only if the reference class is taken to be infinitely large. More precisely put, he pointed out that one should distinguish sharply between the underlying *limiting* frequency of an event and the frequency *observed* so far. The limiting frequency is the proportion of successful outcomes *would* get if one were to repeat *one and the same* experiment infinitely many times. So even though the US presidential election in 2000 did *actually* take place just once, we can nevertheless *imagine* what would have happened had it been repeated infinitely many times.

Of course, we cannot actually toss a coin infinitely many times, but we could imagine doing so. Therefore, the limiting frequency is often thought of as an abstraction, rather than as a series of events that take place in the real world. This point has some important philosophical implications. First, it seems that one can never be sure that a limiting relative frequency exists. When tossing a coin, the relative frequency of heads will perhaps never converge towards a specific number. In principle, it could oscillate forever. Moreover, the limiting relative frequency seems to be inaccessible from an epistemic point of view, even in principle. If you observe that the relative frequency of a coin landing heads up is close to 1/2 in a series of ten million tosses, this does not exclude that the true long-run frequency is much lower or higher than 1/2. No finite sequence of observations can prove that the limiting frequency is even close to the observed frequency.

According to the *propensity interpretation*, probabilities should be identified with another feature of the external world, namely the propensity (or disposition or tendency) of an object to give rise to a certain effect. For instance, symmetrical coins typically have a propensity to land heads up about every second time they are tossed, which means that their probability of doing so is about one in two.

The propensity interpretation was developed by Popper in the 1950s. His motivation for developing this view was that it avoids the problem of assigning probabilities to unique events faced by the frequency view. Even an event that cannot take place more than once can nevertheless have a certain propensity (or tendency) to occur. However, Popper's version of the theory also sought to connect propensities with long-run frequencies whenever the latter existed. Thus, his theory is perhaps best thought of as a hybrid between the two views. Contemporary philosophers have proposed "pure" versions of the propensity interpretation, which make no reference what so ever to long-run frequencies.

A well-known objection to the propensity interpretation is Humphreys' paradox. To state this paradox, recall that conditional probabilities can be "inverted" by using ▶Bayes' theorem. Thus, if we know the probability of A given B we can calculate the probability of B given A, given that we know the priors. The point made by Humphreys is that propensities cannot be inverted in this sense. Suppose, for example, that we know the probability that a train will arrive on time at its destination given that it departs on time. Then it makes sense to say that if the train departs on time, it has a propensity to arrive on time at its destination. However, even though it makes sense to speak of the inverted probability, i.e., the probability that the train departed on time given that it arrived on time, it makes no sense to speak of the corresponding inverted propensity. No one would admit that the on-time arrival of the train has a propensity to make it depart on time a few hours earlier.

The thrust of Humphreys' paradox is thus the following: Even though we may not know exactly what a propensity (or disposition or tendency) is, we do know that propensities have a temporal direction. If A has a propensity to give rise to B, then A cannot occur after B. In this respect, propensities function very much like causality; if A causes B, then A cannot occur after B. However, probabilities lack this temporal direction. What happens now can tell us something about the probability of past events, and reveal information about past causes and propensities, although the probability in itself is a non-temporal concept. Hence, it seems that it would be a mistake to identify probabilities with propensities.

The *logical interpretation* of probability was developed by Keynes and Carnap. Its basic idea is that probability is a logical relation between a hypothesis and the evidence

supporting it. More precisely put, the probability relation is best thought of as a generalization of the principles of deductive logic, from the deterministic case to the indeterministic one. For example, if an unhappy housewife claims that the probability that her marriage will end in a divorce is 0.9, this means that the evidence she has at hand (no romantic dinners, etc.) entails the hypothesis that the marriage will end in a divorce to a certain degree, which can be represented by the number 0.9. Coin tossing can be analyzed along the same lines. The evidence one has about the shape of the coin and past outcomes entails the hypothesis that it will land heads up to a certain degree, and this degree is identical with the probability of the hypothesis being true.

Carnap's analysis of the logical interpretation is quite sophisticated, and cannot be easily summarized here. However, a general difficulty with logical interpretations is that they run a risk of being too dependent on evidence. Sometimes we wish to use probabilities for expressing mere guesses that have no correlation whatsoever to any evidence. For instance, I think the probability that it will be sunny in Rio de Janeiro tomorrow is 0.4. This guess is not based on any meteorological evidence. I am just guessing – the set of premises leading up to the hypothesis that it will be sunny is empty; hence, there is no genuine "entailment" going on here. So how can the hypothesis that it will be sunny in Rio de Janeiro tomorrow be entailed to degree 0.4, or any other degree?

It could be replied that pure guesses are irrational, and that it is therefore not a serious problem if the logical interpretation cannot handle this example. However, it is not evident that this is a convincing reply. People do use probabilities for expressing pure guesses, and the probability calculus can easily be applied for checking whether a set of such guesses are coherent or not. If one thinks that the probability for sun is 0.4 it would for instance be correct to conclude that the probability that it will not be sunny is 0.6. This is no doubt a legitimate way of applying the probability calculus. But if we accept the logical interpretation we cannot explain why this is so, since this interpretation defines probability as a *relation* between a (non-empty) set of evidential propositions and a hypothesis.

Let us now take closer look at the *subjective* interpretation. The main idea is that probability is a kind of mental phenomenon. Probabilities are not part of the external world; they are entities that human beings somehow create in their minds. If you claim that the probability for sun tomorrow is, say, 0.8 this merely means that your subjective degree of belief that it will be sunny tomorrow is strong and that the strength of this belief can be represented by the number 0.8. Of course, whether it *actually* will rain tomorrow depends on objective events in the external world, rather than on your beliefs. So it is *probable* that it will rain tomorrow just in case you believe that it will rain to a certain degree, irrespective of what the weather is actually like tomorrow. However, this should not be taken to mean that any subjective degree of belief is a probability. Advocates of the subjective approach stress that for a partial belief to qualify as a probability, one's degrees of belief must be compatible with the axioms of the probability calculus.

Subjective probabilities can vary across people. Mary's degree of belief that it will rain tomorrow might be strong, at the same time as your degree of belief is much lower. This just means that your mental dispositions are different. When two decision makers hold different subjective probabilities, they just happen to believe something to different degrees. It does not follow that at least one person has to be wrong. Furthermore, if there were no humans around at all, i.e., if all believing entities were to be extinct, it would simply be false that some events happen with a certain probability, including quantum-mechanical events. According to the pioneering subjectivist Bruno de Finetti, "Probability does not exist."

Subjective views have been around for almost a century. de Finetti's pioneering work was published in 1931. Ramsey presented a similar subjective theory in a paper written in 1926 and published posthumously in 1931. However, most modern accounts of subjective probability start off from Savage's theory, presented in 1954, which is more precise from a technical point of view. The key idea in all three accounts is to introduce an ingenious way in which subjective probabilities can be measured. The measurement process is based on the insight that the degree to which a decision maker believes something is closely linked to his or her behavior. Imagine, for instance, that we wish to measure Mary's subjective probability that the coin she is holding in her hand will land heads up the next time it is tossed. First, we ask her which of the following very generous options she would prefer.

(a) "If the coin lands heads up you win a trip to Bahamas; otherwise you win nothing"
(b) "If the coin *does not* land heads up you win a trip to Bahamas; otherwise you win nothing"

Suppose Mary prefers A to B. We can then safely conclude that she thinks it is *more probable* that the coin will land heads up rather than not. This follows from the assumption that Mary prefers to win a trip to Bahamas rather than nothing, and that her preference between uncertain prospects is entirely determined by her beliefs and desires with respect to her prospects of winning the trip to Bahamas. If she on the other hand prefers B to A, she thinks it is *more probable* that the coin will not land heads

up, for the same reason. Furthermore, if Mary is indifferent between A and B, her subjective probability that the coin will land heads up is exactly 1/2. This is because no other probability would make both options come out as equally attractive, irrespective of how strongly she desires a trip to Bahamas, and irrespective of which decision rule she uses for aggregating her desires and beliefs into preferences.

Next, we need to generalize the measurement procedure outlined above such that it allows us to always represent Mary's degree of belief with precise numerical probabilities. To do this, we need to ask Mary to state preferences over a *much larger* set of options and then *reason backwards*. Here is a rough sketch of the main idea: Suppose that Mary wishes to measure her subjective probability that her etching by Picasso worth $20,000 will be stolen within one year. If she considers $1,000 to be a fair price for insuring her Picasso, that is, if that amount is the highest price she is prepared to pay for a gamble in which she gets $20,000 if the event *S*: "The Picasso is stolen within a year" takes place, and nothing otherwise, then Mary's subjective probability for *S* is $\frac{1,000}{20,000} = 0.05$, given that she forms her preferences in accordance with the principle of maximizing expected monetary value. If Mary is prepared to pay up to $2,000 for insuring her Picasso, her subjective probability is $\frac{2,000}{20,000} = 0.1$, given that she forms her preferences in accordance with the principle of maximizing expected monetary value.

Now, it seems that we have a general method for measuring Mary's subjective probability: We just ask her how much she is prepared to pay for "buying a contract" that will give her a fixed income if the event we wish to assign a subjective probability to takes place. The highest price she is prepared to pay is, by assumption, so high that she is indifferent between paying the price and not buying the contract. (This assumption is required for representing probabilities with precise numbers; if buying and selling prices are allowed to differ we can sometimes use intervals for representing probabilities. See e.g., Borel and Baudain 1962 and Walley 1991.)

The problem with this method is that very few people form their preferences in accordance with the principle of maximizing expected monetary value. Most people have a decreasing marginal utility for money. However, since we do not know anything about Mary's utility function for money we cannot replace the monetary outcomes in the examples with the corresponding utility numbers. Furthermore, it also makes little sense to *presuppose* that Mary uses a specific decision rule, such as the expected utility principle, for forming preferences over uncertain prospects. Typically, we do not know anything about how people form their preferences.

Fortunately, there is a clever solution to all these problems. The main idea is to impose a number of structural conditions on preferences over uncertain options. The structural conditions, or axioms, merely restrict what *combinations* of preferences it is legitimate to have. For example, if Mary strictly prefers option A to option B in the Bahamas example, then she must not strictly prefer B to A. Then, the subjective probability function is established by reasoning backwards while taking the structural axioms into account: Since the decision maker preferred some uncertain options to others, and her preferences over uncertain options satisfy a number of structural axioms, the decision maker behaves *as if* she were forming her preferences over uncertain options by first assigning subjective probabilities and utilities to each option, and thereafter maximizing expected utility. A peculiar feature of this approach is, thus, that probabilities (and utilities) are derived from "within" the theory. The decision maker does not prefer an uncertain option to another *because* she judges the subjective probabilities (and utilities) of the outcomes to be more favorable than those of another. Instead, the well-organized structure of the decision maker's preferences over uncertain options logically imply that they can be described *as if* her choices were governed by a subjective probability function and a utility function, constructed such that a preferred option always has a higher expected utility than a non-preferred option. These probability and utility functions need not coincide with the ones outlined above in the Bahamas example; all we can be certain of is that there exist *some* functions that have the desired technical properties.

Point Processes

David Vere-Jones
Professor Emeritus
Victoria University of Wellington, Wellington, New Zealand

"Point Processes" are locally finite (i.e., no finite accumulation points) families of events, typically occurring in time, but often with additional dimensions (marks) to describe their locations, sizes and other characteristics.

The subject originated in attempts to develop life-tables. The first such studies included one by Newton and another by his younger contemporary Halley.

Newton's study was provoked by his life-long religious concerns. In his book, "Chronology of Ancient Kingdoms Amended" he set out to estimate the dates of various biblical events by counting the number of kings or other rulers between two such biblical events and allowing each ruler a characteristic length of reign. The value he used seems to have been arrived at by putting together all the observations from history that he could find (he included rulers from British, classical, European and biblical histories and even included Methuselah's quoted age among his data points) and taking some average of their lengths of rules, but he acknowledged himself that his methods were informal and personal.

Halley, by contrast, was involved in a scientific exercise, namely the development of actuarial tables for use in calculating pensions and annuities. Indeed, he was requested by the newly established Royal Society to prepare such a table from records in Breslau, a city selected because it had been less severely affected by the plague than most of the larger cities in Europe, so that its mortality data were felt more likely to be typical of those of cities and periods in normal times.

Another important early stimulus for point process studies was the development of telephone engineering. This application prompted Erlang's early studies of the Poisson process (see ▶Poisson Processes), which laid down many of the concepts and procedures, such as ▶renewal processes, and forward and backward recurrence times, subsequently entering into point process theory. It was also the context of Palm's (1943) deep studies of telephone-traffic issues. Palm was the first to use the term "point process" (Punkt-Prozesse) itself.

A point process can be treated in many different ways: for example, as a sequence of delta functions, as a sequence of time intervals between event occurrences; as an integer-valued random measure; or as the sum of a regular increasing component and a jump-type martingale.

Treating each point as a delta-function in time yields a time series which has generalized functions as realizations, but in other respects has many similarities with a continuous time series. In particular, stationarity, ergodicity, and a "point process spectrum" can be developed through this approach.

If attention is focused on the process of intervals between successive points, the paradigm example is the renewal process, where the intervals between events are independent, and, save possibly for the first interval, identically distributed.

Counting the number of events, say $N(A)$ falling into a pre-specified set A (an interval, or more general Borel set), leads to treating the point process as an integer-valued random measure.

An important underlying theorem, first enunciated and analyzed by Slivnyak (1962), asserts the equivalence of the counting and interval based approaches.

Random measures form a generalization of point processes which are of considerable importance in their own right. Their first and second order moment measures

$$M_1(A) = E[N(A)]$$
$$M_2(A \times B) = E[N(A)N(B)]$$

and the associated signed measure, the covariance measure

$$C_2(A \times B) = M_2(A \times B) - M_1(A)M_1(B)$$

form non-random measures which have been extensively studied.

A third point of view originated more recently from martingale ideas applied to point processes, and has proved a rich source of both new models and new methods of analysis. The key here is to define the point process in terms of its conditional intensity (or conditional hazard) function, representing the conditional rate of occurrence of events, given the history (record of previously occurring events and any other relevant information) up to the present.

These ideas are closely linked to the martingale representation of point processes. This takes the form of an increasing step function, with unit steps at the time points when the events occur, less a continuous increasing part given by the integral of the conditional intensity.

The Hawkes' processes [introduced by Hawkes (1971a, b)] form an important class of point processes introduced and defined by their conditional intensities, which take the general form

$$\lambda(t) = \mu + \sum_{i:t_i - t} g(t - t_i)$$

where μ is a non-negative constant ("the arrival rate") and g is a non-negative integrable function ("the infectivity function").

The archetypal point process is the simple Poisson process, where the intervals between successive events in time are independent, and, (with the possible exception of the initial interval) are identically and exponentially distributed with a common mean, say m. For this process, the conditional intensity is constant, equal to the rate of occurrence (intensity) of the Poisson process, here $1/m$. Processes with continuous conditional intensities are sometimes referred to as "processes of Poisson type" since they behave locally like Poisson processes over intervals small enough for the conditional intensity to be considered approximately constant.

For the Poisson process itself, and also Poisson cluster processes, where cluster centers follow a simple Poisson process, and the clusters are independent subprocesses, identically distributed relative to their cluster centers, it is possible to write down simple expressions for the characteristic functional

$$\Phi[h] = E\left[e^{i\int h(t)dN(t)}\right]$$

where the carrying function h is integrable against M_1, or the essentially equivalent probability generating functional

$$G[\xi] = E[\Pi\xi(t_i)]$$

where ξ plays the role of h in the characteristic functional.

For example, the Poisson process with continuous intensity m has probability generating functional

$$G[h] = \exp\left\{-m\int [1 - h(u)]du\right\}.$$

Such functionals provide a comprehensive summary of the process and its attributes, especially the moment structure.

However, the usefulness of characteristic or generating functionals in practice is restricted by the relatively few examples for which they can be obtained in convenient closed form. Nevertheless, where available, their form is essentially independent of the space (phase space) in which the points are located. By contrast, finding extensions of the conditional intensity to spaces of more than one dimension has proved extremely difficult, on account of the absence of a clear linear ordering, a problem which equally affects other attempts to extend martingale ideas to higher dimensions.

About the Author

Dr. David Vere-Jones is Emeritus Professor, Victoria University of Wellington (since 2000). He is Past President, New Zealand Statistical Association (1981–1983), Past President of Interim Executive of International Association for Statistical Education (1991–1992), Founding President of the New Zealand Mathematical Society (1974). He received the Rutherford Medal, New Zealand's top science award, in 1999 for "outstanding and fundamental contributions to research and education in probability, statistics and the mathematical sciences, and for services to the statistical and mathematical communities, both within New Zealand and internationally." Professor Vere-Jones was also awarded the NZ Science and Technology Gold Medal (2000), and the NZSA Campbell Award for 2009, in recognition for his contributions to the statistical sciences. He has (co-)authored over 100 refereed publications, and three books. In 2001 (April 19–21), a Symposium in Honor of David Vere-Jones on the Occasion of His 65th Birthday was held in Wellington.

"David Vere-Jones is New Zealand's leading resident mathematical statistician. He has made major contributions to the theory of statistics, its applications, and to the teaching of statistics in New Zealand. He is highly regarded internationally and is involved in numerous international activities. One of his major research areas has been concerned with Point Processes... . A substantial body of the existing theory owes its origins to him, either directly or via his students. Of particular importance and relevance to New Zealand is his pioneering work on the applications of point process theory to seismology" (NZMS Newsletter 24, August 1982).

Poisson Distribution and Its Application in Statistics

Lelys Bravo de Guenni
Professor
Universidad Simón Bolívar, Caracas, Venezuela

The Poisson distribution was first introduced by the French Mathematician Siméon-Denis Poisson (1781–1840) to describe the probability of a number of events occurring in a given time or space interval, with the probability of occurrence of these events being very small. However, since the number of trials is very large, these events do actually occur.

It was first published in 1837 in his work *Recherches sur la probabilité des jugements en matières criminelles et matière civile* (Research on the Probability of Judgments in Criminal and Civil Matters). In this work, the behavior of certain random variables X that count the number of occurrences (or *arrivals*) of such events in a given interval in time or space was described. Some examples of these events are infant mortality in a city, the number of misprints in a book, the number of bacteria on a plate, the number of activations of a geiger counter, and so on.

Assuming that λ is the expected value of such arrivals in a time interval of fixed length, the probability of observing exactly k events is given by the probability mass function

$$f(k|\lambda) = \frac{\lambda^k e^{-\lambda}}{k!}$$

for $k = 0, 1, 2, \ldots$. The parameter distribution λ is a positive real number, which represents the average number of events occurring during a fixed time interval. For example, if the event occurs on average three times per second, in 10 s the event will occur on average 30 times and $\lambda = 30$. When the number of trials n is large and the probability of occurrence of the event λ/n approaches to zero, the ►binomial distribution with parameters n and $p = \lambda/n$ can be approximated to a Poisson distribution with parameter λ. The binomial distribution gives the probability of x successes in n trials.

If X is a random variable with a Poisson distribution, the expected value of X and the variance of X are both equal to λ. To estimate λ by maximum likelihood, given a sample $k_1, k_2, \ldots, k_n$, the log-likelihood function

$$L(\lambda) = \log \prod_{i=1}^{n} \frac{\lambda_i^k e^{-\lambda}}{k_i!}$$

is maximized with respect to λ and the resulting estimate is $\hat{\lambda} = \frac{\sum_{i=1}^{n} k_i}{n}$. This is an unbiased estimator since the expected value of each k_i is equal to λ; and it is also an efficient estimator since its estimator variance achieves the Cramer–Rao lower bound. From the Bayesian inference perspective, a conjugate prior distribution for the parameter λ is the Gamma distribution. Suppose that λ follows a Gamma prior distribution with parameters α and β, such that

$$p(\lambda|\alpha, \beta) = \frac{\beta^\alpha}{\Gamma(\alpha)} \lambda^{\alpha-1} e^{-\beta\lambda} \quad \lambda > 0$$

If a sample $k_1, k_2, \ldots, k_n$ of size n is observed, the posterior probability distribution for λ is given by

$$p(\lambda|k_1, k_2, \ldots, k_n) \sim Gamma\left(\alpha + \sum_{i=1}^{n} k_i, \beta + n\right).$$

When $\alpha \to$ and $\beta \to 0$, we have a diffuse prior distribution, and the posterior expected value of λ ($E[\lambda|k_1, k_2, \ldots, k_n]$) approximates to the maximum likelihood estimator $\hat{\lambda}$.

A use for this distribution was not found until 1898, when an individual named Bortkiewicz (O'Connor and

Robertson 1950) was asked by the Prussian Army to investigate accidental deaths of soldiers attributed to being kicked by horses. In 1898, he published *The Law of Small Numbers*. In this work he was the first to note that events with low frequency in a large population followed a Poisson distribution even when the probabilities of the events varied. Bortkiewicz studied the distribution of 122 men kicked to death by horses among 14 Prussian army corps over 20 years. This famous data set has been used in many statistical textbooks as a classical example on the use of the Poisson distribution (see Yule and Kendall [1950] or Fisher [1954]). He found that in about half of every army corps–year combination, there were no deaths for horse kicking. For other combinations of corps–years, the number of deaths were from 1 to 4. Although the probability of horse kick deaths might vary from corps and years, the overall observed frequencies were very close to the expected frequencies estimated by using a Poisson distribution.

In epidemiology, the Poisson distribution has been used as a model for deaths. In one of the oldest textbooks of statistics published by Bowley in 1901 (cited by Hill [2002]), he fitted a Poisson distribution to deaths from splenic fever in the years 1875–1894 and showed a reasonable agreement with the theory. At that time, splenic fever was a synonym for present-day anthrax.

A more extensive use of the Poisson distribution can be found within the Poisson generalized linear models, usually called the *Poisson regression models* (see ►Poisson Regression). These models are used to model count data and contingency tables. For contingency tables, the Poisson regression model is best known as the *log-linear model*. In this case, the response variable Y has a Poisson distribution and usually, the logarithm of its expected value ($E[Y]$) is expressed as a linear predictor $X\beta$ where X is a $n \times p$ matrix of explanatory variables and β is a parameter vector of size p. In this case, the *link* function $g(.)$, which relates the expected value of the response variable Y with the linear predictor is the logarithm function, in such a way that the mean of the response variable $\mu = g^{-1}(X\beta)$.

Poisson regression can also be used to model what is called the *relative risk*. This is the ratio between the counts and an *exposure* factor E. For example, to model the relative risk of disease in a region, we make $\eta = Y/E$, where Y is the observed number of cases and E is the expected number of cases, which depends on the number of persons at risk. The usual model for Y is

$$Y|\eta \sim \text{Poisson}(E\eta)$$

where η is the true relative risk of disease (Banerjee et al. (2004)). When applying the Poisson model to data, the main assumption is that the variance is equal to the mean. In many cases, this may not be assumed since the variance of counts are usually greater than the mean. In this case, we have *overdispersion*. One way to deal with this problem is to use the negative binomial distribution, which is a two-parameter family that allows the mean and variance to be fitted separately. In this case, the mean of the Poisson distribution λ is assumed a random variable as drawn from a Gamma distribution.

Another common problem with Poisson regression is excess zeros: if there are two processes at work, one determining whether there are zero events or any events, and a Poisson process (see ►Poisson Processes) determining how many events there are, there will be more zeros than a Poisson regression would predict. An example would be the distribution of cigarettes smoked in an hour by members of a group where some individuals are nonsmokers. These data sets can be modeled as *zero inflated Poisson models*, where p is the probability of observing zero counts, and $1 - p$ is the probability of observing a count variable modeled as a Poisson(λ).

Poisson Processes

MR Leadbetter
Professor
University of North Carolina, Chapel Hill, NC, USA

Introduction

Poisson Processes are surely ubiquitous in the modeling of point events in widely varied settings, and anything resembling a brief exhaustive account is impossible. Rather we aim to survey several "Poisson Habitats" and properties, with glimpses of underlying mathematical framework for these processes and close relatives. We refer to three (of many) authoritative works (Cox and Lewis 1966; Daley and Vere-Jones 1988; Kallenberg 1986) for convenient detailed accounts of Poisson Process and general related theory, tailored to varied mathematical tastes.

In this entry we first consider Poisson Processes in their classical setting as series of random events (▶point processes) on the real line (e.g., in time), their importance in one dimension for stochastic modeling being rivaled only by the Wiener Process - both being basic (for different purposes) in their own right, and as building blocks for more complex models. Classical applications of the Poisson process abound - exemplified by births, radioactive disintegrations, customer arrival times in queues, instants of new cases of disease in an epidemic, and (a favorite of ours), the crossings of a high level by a stationary process. The classical format for Poisson Processes will be described in section "▶Poisson Processes on the Real Line", and important variants in section "▶Important Variants".

Unlike many situations in which generalizations to more than one dimension seem forced, the Poisson process has important and natural extensions to two and higher dimensions, as indicated in section "▶Poisson Processes in Higher Dimensions". Further, an even more attractive feature (at least to those with theoretical interests) is the fact that Poisson Processes can be defined on spaces with very little structure, as indicated in section "▶Poisson Processes on Abstract Spaces".

Poisson Processes on the Real Line

A *Point Process* on the real line is simply a sequence of events occurring in time (or some other 1-dimensional (e.g., distance) parameter) according to a probabilistic mechanism. One way to describe the probability structure is to define a sequence $0 \le \tau_1 < \tau_2 < \tau_3 \ldots < \infty$ where the τ_i are the "times" of occurrences of interest ("events" of the point process). They are assumed to be random variables (written here as distinct, i.e., strictly increasing, when the point process is termed "simple" but successive τ_i can be taken to be equal if "multiple events" are to be considered.) It is assumed that the points τ_i tend to infinity as $i \to \infty$ so that there are no "accumulation points". One may define a point process as a *random set* $\{\tau_i : i = 1, 2, \ldots\}$ of such points (cf Ryll-Nardzewski 1961). Alternatively the occurrence times τ_i are a family of random variables for $i = 1, 2, \ldots$ and may be discussed within the framework of *random sequences* (discrete parameter stochastic processes). However often the important quantities for a point process on the real line are the random variables $N(B)$ which are the (random) numbers of events (τ_i) in sets B of interest (usually Borel sets). When $B = (0, t]$ we write N_t for $N((0, t])$, i.e., the number of events occurring from time zero up to and including time t. $\{N_t\}$ is thus a family of random variables for positive t – or a non-negative integer-valued continuous parameter stochastic process on the positive real line. Likewise $\{N(B)\}$ defines a non-negative integer-valued stochastic process indexed by the (Borel) sets B (finite for bounded B).

Here (as is customary) we focus on the "counting" r.v.s $\{N_t\}$ or $\{N(B)\}$ rather than the consideration of more geometric properties of the sets $\{\tau_i\}$. Note that these two families are essentially equivalent since knowledge of $N(B)$ for each Borel set determines that of the sub-family $\{N_t\}(B = (0, t])$ and the converse is also true since $N(B)$ is a measure defined on the Borel sets and is determined by its values on the intervals $(0, t]$. Further their distributions are determined by those of the occurrence times τ_k and conversely, in view of equality of the events $(\tau_k > t)$, $(N_t < k)$.

We (finally!) come to the subject of this article – the Poisson Process. In its simplest context this is defined as a family $N(B)$, (or N_t) as above on the positive real line by the requirement that each N_t be Poisson, $P\{N_t = r\} = e^{-\lambda t}(\lambda t)^r/r!$, $r = 0, 1, 2, \ldots$ and that "increments" $(N_{t_2} - N_{t_1})$, $(N_{t_4} - N_{t_3})$, are independent for $0 < t_1 < t_2 \le t_3 < t_4$. Equivalently $N(B)$ is Poisson with mean $\lambda m(B)$ where m denotes Lebesgue measure, and $N(B_1)$, $N(B_2)$ are independent for disjoint B_1, B_2. $\lambda = \mathcal{E}N_1$ is the expected number of events per unit time, or the *intensity* of the Poisson process.

That the Poisson – rather than some other – distribution plays a central role is due in part to the long history of its use to describe rare events – such as the classical number of deaths by horse kicks in the Prussian army. But more significantly the very simplest modeling of a point process would surely require independence of increments which holds as noted above for the Poisson Process. Further this process has the stationarity property that the distribution of the "increment" $(N_{t+h} - N_t)$ depends only on the length

h of the interval, not on its starting point t. Moreover the probability of an event in a small interval of length h is approximately λh and the probability of more than one in that interval is of smaller order, i.e.,

$$P\{(N_{t+h} - N_t) = 1\} = \lambda h + o(h),$$
$$P\{(N_{t+h} - N_t) \geq 2\} = o(h) \text{ as } h \to o.$$

It turns out that the Poisson Process as defined is the *only* point process exhibiting stationarity and these two latter properties [see e.g., Durrett (2005) for proof] which demonstrates what Kingman aptly describes as the "inevitability" of the Poisson distribution, in his volume (Kingman 1993).

The Poisson Process has extensive properties which are well described in many works [e.g., Cox and Lewis (1966) and Daley and Vere-Jones (1988)] For example the equivalence of the events $(\tau_k > t)$, $(N_t < k)$ noted above readily shows that the inter-arrival times $(\tau_k - \tau_{k-1})$ are i.i.d. exponential random variables with mean $\lambda^{-1}(\tau_0 = 0)$, and τ_k itself is the sum of the first k of these, thus distributed as $(2\lambda)^{-1}\chi^2_{2k}$. On the other hand we have the famous apparent paradox that the random interval which contains a fixed point t_0 is distributed as the sum of two independent such exponential variables – the time from the preceding event plus that to the following event. This and a host of other useful properties may be conveniently found in Cox and Lewis (1966) and Daley and Vere-Jones (1988). Finally, the above discussion has focused on Poisson Processes on the positive real line. It is a simple matter to add an independent Poisson Process on the negative real line to obtain one on the entire real line $(-\infty, \infty)$.

Important Variants

The stationarity requirement of a constant intensity λ may be generalized to include a time varying intensity function $\lambda(t)$ for which the number of events $N(B)$ in a (Borel) set B is still Poisson but with mean $\Lambda(B) = \int_B \lambda(t)dt$, keeping independence of $N(B_1)$, $N(B_2)$ for disjoint B_1, B_2. Then N_t is Poisson with mean $\int_0^t \lambda(t)dt$. More generally one may take Λ to be a "measure" on the Borel sets but not necessarily of this integral (absolutely continuous) form which unlike the simple Poisson Process above, does not necessarily prohibit the occurrence of more than one event at the same instant, (multiple events) and may allow positive probability of an event occurring at a given fixed time point. Further one may consider random versions of the intensity e.g., with $\lambda(t)$ being itself a stochastic process ("*stochastic intensity*") as for example the blood pressure of an individual (varying randomly in time) leading to (conditionally) Poisson chest pain incidents. The resulting point processes are termed *doubly stochastic Poisson* or *Cox Processes*, and are widely used in medical trials e.g., of new treatments. For other widely used variants of Poisson Processes (e.g., "Mixed" and "Compound" Poisson processes) as well as extensive theory of point process properties, we recommend the very readable volume (Daley and Vere-Jones (1988)).

Poisson Processes in Higher Dimensions

Point processes (especially Poisson) have also been traditionally very useful in modeling point events in space and space-time dimensions. The locations of ore deposits in two or three spatial dimensions and the occurrences of earthquakes in two dimensions and perhaps time ("spatio-temporal") are important examples. The mathematical framework extends naturally from one dimension, $N(B)$ being the number of point events in the two- or 3-dimensional (Borel) set B, and notational extensions such as $N_t(B)$ for the number of events in a spatial set B up to time t.

Not infrequently a time parameter is considered simply as equivalent to the addition of just one more spatial dimension, but the obvious differences in the questions to be asked for space and time suggest that the notation reflect the different character of the parameters. Further natural dependence structure (correlation assumptions, mixing conditions, long range dependence) may differ for spatial and time parameters. Further "*coordinatewise mixing*" (introduced in Leadbetter and Rootzen (1998)) seems promising in current investigation to facilitate point process theory in higher dimensions, where the parameters have different roles. A reader interested in the theory and applications in higher dimensions should consult (Daley and Vere-Jones 1988) and the wealth of references therein.

Poisson Processes on Abstract Spaces

There is substantial development of point process (and more general "random measure") theory in more abstract spaces, usually with an intricate topological structure (see Kallenberg (1986)). However for discussion of existence and useful basic modeling properties, the topological assumptions are typically solely used for definition of a natural simple measure-theoretic structure without any necessary underlying topology - though useful for deeper considerations such as weak convergence, beyond pure modeling. Further a charming property of Poisson processes in particular is that they may be defined simply on spaces with very little structure as we now indicate.

Specifically let S be a space, and $\mathcal{S}$ a σ-ring (here a σ-field for simplicity) of subsets of S. For a givenprobability

space $(\Omega, \mathcal{F}, P)$, a *random measure* is defined to be any family of non-negative- (possibly infinite) valued random variables $N_\omega(B)$ for each $B \in \mathcal{S}$ which is a measure (countably additive) on $\mathcal{S}$ for each $\omega \in \Omega$. A point process is a random measure for which each $N_\omega(B)$ is integer-valued (or $+\infty$). In this very general context one may construct a Poisson Process (see ►Poisson Processes) by simple steps (cf Kallenberg (1986) and Kingman (1993)) which we indicate. Define i.i.d. random elements $\tau_1, \tau_2, \ldots, \tau_n$ on S for each positive integer n with common distribution $\nu = P\tau_j^{-1}$ yielding a point process on S consisting of a finite number (n) of points. By regarding n as random having a Poisson distribution with mean $a > 0$ (or mixing the (joint) distributions of this point process with Poisson weights) one obtains a finite valued Poisson process $\{N(B)\}$ with the finite intensity measure $\mathcal{E}N(B) = a\nu(B)$. Finally if λ is a σ-finite measure on $\mathcal{S}$ we may write $\mathcal{S} = \bigcup_1^\infty S_i$ where $\lambda(S_i) < \infty$. Let $\{N_i(B), i = 1, 2, \ldots\}$ be point processes with the finite intensity measures $\mathcal{E}N_i(B) = \lambda(B \cap S_i)$. The superposition of these point processes gives a Poisson Process with intensity λ.

Relatives of the Poisson Process such as those above (Mixed, Compound, Doubly Stochastic...) may be constructed in a similar way to the one-dimensional framework. These sometimes require small or modest additional assumptions about the space S such as measurability of singleton sets, and the separation of two of its points by measurable sets. One may also obtain many general results analogous results to those of one dimension by assuming the existence of a *countable semiring* which covers S, and plays the role of bounded sets on which the point process is finite-valued, in this general non-topological context. Finally, as noted, the reference Kingman (1993) gives an account of Poisson processes primarily in this general framework, along with the basic early paper (Kendall 1974). In a topological setting the monograph (Kallenberg 1986) gives a comprehensive development of random measures, motivating our own non-topological approach.

About the Author

M.R. Leadbetter obtained his B.Sc. (1953), M.Sc. (1954), University of New Zealand, and Ph.D. (1963), UNC-Chapel Hill. He is a Fellow of American Statistical Association, Institute of Mathematical Statistics and member of the International Statistical Institute. He has published a book with Harald Cramér, *Stationary and Related Stochastic Processes* (Wiley, 1967). Professor Leadbetter was awarded an Honorary Doctorate, from Lund University. His name is associated with the Theorem of Cramér and Leadbetter.

Poisson Regression

Gerhard Tutz
Professor
Ludwig-Maximilians-Universität München, Germany

Introduction

The Poisson regression model is a standard model for count data where the response variable is given in the form of event counts such as the number of insurance claims within a given period of timeor the number of cases with a

specific disease in epidemiology. Let $(Y_i, \boldsymbol{x}_i)$ denote n independent observations, where $\boldsymbol{x}_i$ is a vector of explanatory variables and Y_i is the response variable. It is assumed that the response given $\boldsymbol{x}_i$ follows a Poisson distribution which has probability function

$$P(Y_i = r) = \begin{cases} \frac{\lambda_i^r}{r!} e^{-\lambda_i} & \text{for } r \in \{0, 1, 2, \dots\} \\ 0 & \text{otherwise.} \end{cases}$$

Mean and variance of the Poisson distribution are given by $E(Y_i) = var(Y_i) = \lambda_i$. Equality of the mean and variances is often referred to as the *equidispersion property* of the Poisson distribution. Thus, in contrast to the normal distribution, for which mean and variance are unlinked, the Poisson distribution implicitly models stronger variability for larger means, a property which is often found in real life data. The support of the Poisson distribution is $0, 1, 2, \dots$, which makes it an appropriate distribution model for count data.

A Poisson regression model assumes that the conditional mean $\mu_i = E(Y_i|\boldsymbol{x}_i)$ is determined by

$$\mu_i = h\left(\boldsymbol{x}_i^T \boldsymbol{\beta}\right) \quad \text{or equivalently} \quad g(\mu_i) = \boldsymbol{x}_i^T \boldsymbol{\beta},$$

where g is a known link function and $h = g^{-1}$ denotes the response function. Since the Poisson distribution is from the simple exponential family the model is a *generalized linear model* (GLM, see ▶Generalized Linear Models). The most widely used model uses the canonical link function by specifying

$$\mu_i = \exp\left(\boldsymbol{x}_i^T \boldsymbol{\beta}\right) \quad \text{or} \quad \log(\mu_i) = \boldsymbol{x}_i^T \boldsymbol{\beta}.$$

Since the logarithm of the conditional mean is linear in the parameters the model is called a *log-linear* model. The log-linear version of the model is particularly attractive because interpretation of parameters is very easy. The model implies that the conditional mean given $\boldsymbol{x}^T = (x_1, \dots, x_p)$ has a multiplicative form given by

$$\mu(\boldsymbol{x}) = \exp(\boldsymbol{x}^T \boldsymbol{\beta}) = e^{x_1 \beta_1} \dots e^{x_p \beta_p}.$$

Thus e^{β_j} represents the multiplicative effect on $\mu(\boldsymbol{x})$ if variable x_j changes by one unit to $x_j + 1$.

Inference

Since the model is a generalized linear model inference may be based on the methods that are available for that class of models (see for example McCullagh and Nelder 1989). One obtains for the derivative of the log-likelihood, which is the so-called score function

$$s(\boldsymbol{\beta}) = \sum_{i=1}^{n} \boldsymbol{x}_i \frac{h'\left(\boldsymbol{x}_i^T \boldsymbol{\beta}\right)}{h(\boldsymbol{x}_i \boldsymbol{\beta})} \left(y_i - h\left(\boldsymbol{x}_i^T \boldsymbol{\beta}\right)\right),$$

and the Fisher matrix $F(\boldsymbol{\beta}) = E(-\partial h / \partial \boldsymbol{\beta} \partial \boldsymbol{\beta}^T) = \sum_{i=1}^{n} \boldsymbol{x}_i \boldsymbol{x}_i^T \frac{h'(\boldsymbol{x}_i^T \boldsymbol{\beta})^2}{h(\boldsymbol{x}_i^T \boldsymbol{\beta})}$. Under regularity conditions, $\hat{\boldsymbol{\beta}}$ defined by $s(\hat{\boldsymbol{\beta}}) = \mathbf{0}$ is consistent and asymptotically normal distributed,

$$\hat{\boldsymbol{\beta}} \sim N(\boldsymbol{\beta}, F(\boldsymbol{\beta})^{-1}),$$

where $F(\boldsymbol{\beta})$ may be replaced by $F(\hat{\boldsymbol{\beta}})$ to obtain standard errors.

Goodness-of fit and tests on the significance of parameters based on deviance are provided within the framework of GLMs.

Extensions

In many applications count data are overdispersed, with conditional variance exceeding conditional mean. Several extensions of the basic model that account for overdispersion are available, in particular *quasi-likelihood methods* and more general distribution models like the Gamma–Poisson or *negative binomial model*. Quasi-likelihood uses the same estimation equations as maximum likelihood estimates, which are computed by solving

$$\sum_{i=1}^{n} \boldsymbol{x}_i \frac{\partial \mu_i}{\partial \eta} \frac{y_i - \mu_i}{v(\mu_i)} = \mathbf{0},$$

where $\mu_i = h(\eta_i)$ and $v(\mu_i)$ is the variance function. But instead of assuming the variance function of the Poisson model $v(\mu_i) = \mu_i$ one uses a more general form. For example, Poisson with overdispersion uses $v(\mu_i) = \phi \mu_i$ for some unknown constant ϕ. The case $\phi > 1$ represents *overdispersion* of the Poisson model, the case $\phi < 1$, which is rarely found in applications, is called *underdispersion*. Alternative variance functions usually continue to model the variance as a function of the mean. The variance function $v(\mu_i) = \mu_i + \gamma \mu_i^2$ with additional parameter γ corresponds to the variance of the negative binomial distribution.

It may be shown that the asymptotic properties of quasi-likelihood estimates are similar to that for GLMs. In particular one obtains asymptotically a normal distribution with the covariance given in the form of a pseudo-Fisher matrix, see McCullagh (1983), and McCullagh and Nelder (1989).

A source book for the modeling of count data which includes many applications is Cameron and Trivedi (1998). An econometric view on count data is outlined in Winkelmann (1997) and Kleiber and Zeileis (2008).

About the Author

Prof. Dr. Gerhard Tutz works at the Department of Statistics, Ludwig-Maximilians University Munich. He served as Head of the department for several years. He coauthored

the book *Multivariate Statistical Modeling Based on Generalized Linear Models* (with Ludwig Fahrmeir, Springer, 2001).

Population Projections

Janez Malačič
Professor, Faculty of Economics
University of Ljubljana, Ljubljana, Slovenia

Population projections are a basic tool that demographers use to forecast a future population. They can be produced in the form of a *prognosis* or as *prospects*. The first is the most likely future development according to the expectations of the projections' author(s) and is produced in a single variant. The second type is based more on an "if-then" approach and is calculated in more variants. Usually, there are three or four variants, namely, low, medium, high, and constant variants. In practice, the medium variant is the most widely used and is taken as the most likely or accurate variant, that is, as a prognosis.

Population projections can be produced by *mathematical* or *analytical methods*. The *mathematical methods* use extrapolation(s) of various mathematical functions. For example, a census population can be extrapolated for a certain period into the future based on a linear, geometric, exponential, or some other functional form. The functional form is chosen on the basis of (1) past population development(s), (2) the developments of a neighboring and other similar populations, as well as (3) on the basis of general and particular demographic knowledge. In the great majority of cases, the mathematical methods are used for short- and midterm periods in the future. For population projections of small settlements and regions, only mathematical methods can be used in any reasonable way. Exceptionally, for very long-term periods (several centuries) a logistic curve can be used for a projection of the total population.

Analytical methods for population projections are much more complex. The population development in the projection period is decomposed at the level of basic components. These components are mortality, fertility, and migration. For each component, a special hypothesis of future development is produced. Very rich and complex statistical data are needed for analytical population projections. They are considered suitable for a period of 10–25 years into the future. They cannot be used to project populations in small areas because such life tables (see ►Life Table) and some other data will not be available. Analytical population projections offer very detailed information on particular population structures at present and in the future as well as data on the development of basic population components (e.g., mortality, fertility, and migration). They are also the basis for several other derived projections like those of households, of the active, rural, urban, and pensioned population.

Suppose that we have the census population divided by gender and age (in five-year age groups, say) as our starting point: ${}_{x+5}V^{t}_{m,x}$ and ${}_{x+5}V^{t}_{f,x}$, where V stands for population size, x for age, t for time, and m and f for male and female. To make a projection, we need three hypotheses. *The mortality hypothesis* is constructed on the basis of life table indicators. We take survival ratios ${}_{x+5}P_{m,x}$ and ${}_{x+5}P_{f,x}$ for all five-year age groups $(0-4, 5-9, \ldots, 80-84, 85+)$. Our hypothesis can be that mortality is constant, declining, or increasing, or we can have a combination of all three for each gender and each age group. Then we apply a population projection model aging procedure in the following form (spelled out for males):

$$ {}_{5}V^{t}_{m,0} * {}_{5}P_{m,0} = {}_{5}V^{t+5}_{m,5} \rightarrow {}_{5}V^{t+5}_{m,5} * {}_{5}P_{m,0} = {}_{5}V^{t+10}_{m,10}, \text{ etc.} $$

Evidently, in this case constant mortality hypothesis was used. The aging procedure would be applied for both genders and for all five-year age groups.

In the next step, we would construct a *fertility hypothesis*. This one can also be that fertility is constant, declining, increasing, or a combination of all three. It provides the newborn population for each year in the projection period. A set of different fertility indicators are available. The most convenient indicators are age-specific fertility rates, ${}_{x+5}f_{x}$,

where x is equal to 15, 20, 25, 30, 35, 40, and 45. In principle, we calculate the future number of births (N) for seven five-year age-groups with the formula:

$$ {}_5N_x^{t-(t+5)} = 5\left(\left({}_5V_{f,x}^{t} + {}_5V_{f,x}^{t+5}\right)/2 * {}_5f_x^{t}\right). $$

The number of births, $N^{t-(t+5)}$, should be subgrouped by gender. We can apply the demographic "constant" alternative and suppose that 485 girls are born per 1000 births. Then we calculate

$$ {}_5V_{m,0}^{t+5} = {}_5P_{m,r} * N_m^{t-(t+5)} \text{ and } {}_5V_{f,0}^{t+5} = {}_5P_{f,r} * N_f^{t-(t+5)} $$

${}_5P_m$, and ${}_5P_{f,r}$ are survival ratios for newborn boys and girls. In the case of a closed population or a population with zero migration, our projection is finished.

However, real populations have in- and out-migration. To cover this case, we should construct a *migration hypothesis*. The procedure is similar to the mortality and fertility hypotheses. Suppose we use net migration rates for five-year age groups, separately by gender. In principle, we calculate age-specific net migration factors (for males), nm is net migration:

$$ {}_5F_{m,x} = 1 + ({}_5nm_{m,x}/1,000). $$

The population aging procedure changes slightly:

$$ {}_5V_{m,x+5}^{t+5} = {}_5V_{m,x}^{t} * {}_5P_{m,x} * {}_5F_{m,x}. $$

The procedure for the female population is parallel to the procedure for the male population. The most serious problem in practice is that age-specific migration data may be unavailable or of poor quality.

Such simple analytical population projection procedures have been improved considerably in the literature during recent decades. Probably the most important improvement is the construction of *probabilistic population projections*, for which considerable progress has been made in recent decades (Lutz et al. 1998). Many analytical population projections for countries and regions are now supplemented by several national probabilistic population forecasts.

About the Author

Dr. Janez Malačić is a Professor of demography and labor economics, Faculty of Economics, Ljubljana University, Slovenia. He is a Former President of the Slovenian Statistical Society (1985–1987), a Former President of the Society of Yugoslav Statistical Societies (1986–1988), and a member of the IUSSP (from 1986). He has authored two books and more than 150 papers. His papers have been published in eight languages.

Portfolio Theory

Harry M. Markowitz
Professor, Winner of the Nobel Memorial Prize in Economic Sciences in 1990
University of California, San Diego, CA, USA

Portfolio Theory considers the trade-off between some measure of risk and some measure of return on the portfolio-as-a-whole. The measures used most frequently in practice are expected (or mean) return and variance or, equivalently, standard deviation. This article discusses the justification for the use of mean and variance, sources of data needed in a mean-variance analysis, how mean-variance tradeoff curves are computed, and semi-variance as an alternative to variance.

Mean-Variance Analysis and its Justification

While the idea of trade-off curves goes back at least to Pareto, the notion of a trade-off curve between risk and return (later dubbed the efficient frontier) was introduced in Markowitz (1952). Markowitz proposed expected return and variance as both a hypothesis about how investors act and as a rule for guiding action in fact. By Markowitz (1959) he had given up the notion of mean and variance as a hypothesis but continued to propose them as criteria for action.

Tobin (1958) said that the use of mean and variance as criteria assumed either a quadratic utility function or a

Gaussian probability distribution. This view is sometimes ascribed to Markowitz, but he never justified the use of mean and variance in this way. His views evolved considerably from Markowitz (1952) to Markowitz (1959). Concerning these matters Markowitz (1952) should be ignored. Markowitz (1959) accepts the views of Von Neumann and Morgenstern (1944) when probability distributions are known, and L.J. Savage (1954) when probabilities are not known. The former asserts that one should maximize expected utility; the latter asserts that when probabilities are not known one should maximize expected utility using probability beliefs when objective probabilities are not known.

Markowitz (1959) conjectures that a suitably chosen point from the efficient frontier will approximately maximize expected utility for the kinds of utility functions that are commonly proposed for cautious investors, and for the kinds of probability distributions that are found in practice. Levy and Markowitz (1979) expand on this notion considerably. Specifically, Levy and Markowitz show that for such probability distributions and utility functions there is typically a correlation between the actual expected utility and the mean-variance approximation between 0.95 and of 0.99. They also show that the Pratt (1964) and Arrow (1971) objection to quadratic utility does not apply to the kind of approximations used by Levy and Markowitz, or in Markowitz (1959).

Models of Covariance

If covariances are computed from historical returns with more securities than there are observations, e.g., 5,000 securities and 60 months of observations, then the covariance matrix will be singular. A preferable alternative is to use a model of covariance where the return on the *i*th security is assumed to obey the following relationship

$$r_i = \alpha_i + \sum \beta_{ik} f_k + u_i$$

where the u_i are independent of each other and the f_k. The f_k may be either factors or scenarios or some of each. These ideas are carried out in, for example, Sharpe (1963), Rosenberg (1974) and Markowitz and Perold (1981a, 1981b).

Estimation of Parameters

Covariance matrices are sometimes estimated from historical returns and sometimes from factor or scenario models such as the one-factor model of Sharpe, the many-factor model of Rosenberg, or the scenario models of Markowitz and Perold cited above.

Expected returns are estimated in a great variety of ways. I do not believe that anyone suggests that, in practice, historical average returns should be used as the expected returns of individual stocks. The Ibbotson and Sinquefield (2007) series are frequently used to estimate expected returns for asset classes. Black and Litterman (1991, 1992) propose a very interesting Bayesian approach to the estimation of expected returns. Richard Michaud (1989) proposes to use estimates for asset classes based on what he refers to as a "resampled frontier". Additional methods for estimating expected return are based on statistical methods for "disentangling" various anomalies, see Jacobs and Levy (1988), or estimates based on factors that Graham and Dodd (1940) might use: see Lakonishok et al. (1994), Ohlson (1979), and Bloch et al. (1993). The last mentioned paper is based on results obtained by back-testing many alternate hypotheses concerning how to achieve excess returns. When many estimation methods are tested, the expected future return for the best of the lot should not be estimated as if this were the only procedure tested. Estimates should be corrected for "data mining." See Markowitz and Xu (1994).

Computation of M-V Efficient Sets

The set of mean-variance efficient portfolios is piecewise linear. The critical line algorithm (CLA) traces out this set, one linear piece at a time, without having to search for optima. CLA is described in Appendix A of Markowitz (1959) and, less compactly, in Markowitz and Todd (2000).

Downside Risk

"Semi-variance" or downside risk is like variance, but only considers deviations below the mean or below some target return. It is proposed by Markowitz (1959) Chap. 9 and championed by Sortino and Satchell (2001). It is used less frequently in practice than variance.

About the Author

Professor Markowitz has applied computer and mathematical techniques to various practical decision making areas. In finance: in an article in 1952 and a book in 1959 he presented what is now referred to as MPT, "modern portfolio theory." This has become a standard topic in college courses and texts on investments, and is widely used by institutional investors for asset allocation, risk control and attribution analysis. In other areas: Dr. Markowitz developed "sparse matrix" techniques for solving very large mathematical optimization problems. These techniques are now standard in production software for optimization programs. Dr. Markowitz also designed and supervised the development of the SIMSCRIPT programming language. SIMSCRIPT has been widely used for programming computer simulations of systems like factories, transportation systems and communication networks.

In 1989 Dr. Markowitz received The John von Neumann Award from the Operations Research Society of America for his work in portfolio theory, sparse matrix techniques and SIMSCRIPT. In 1990 he shared The Nobel Prize in Economics for his work on portfolio theory.

Posterior Consistency in Bayesian Nonparametrics

Jayanta K. Ghosh[1], R. V. Ramamoorthi[2]
[1]Professor of Statistics
Purdue University, West Lafayette, IN, USA
[2]Professor
Michigan State University, East Lansing, MI, USA

Bayesian Nonparametrics (see ►Bayesian Nonparametric Statistics) took off with two papers of Ferguson (Ferguson 1974, 1983) and followed by Antoniak (Antoniak 1974). However consistency or asymptotics were not major issue in those papers, which were more concerned with taking the first steps towards a usable, easy to interpret prior with easy to choose hyperparameters and a rich support. Unfortunately, the fact that the Dirichlet sits on discrete distributions diminished the early enthusiasm.

The idea of consistency came from Laplace and informally may be defined as : Let $\mathcal{P}$ be a set of probability measures on a sample space $\mathcal{X}$, Π be a prior on $\mathcal{P}$. The posterior is said to be consistent at a true value P_0 if the following holds: For sample sequences with P_0 probability 1, the posterior probability of any neighborhood U of P_0 converges to 1.

The choice of neighborhoods U determines the strength of consistency. One choice, when the sample space is separable metric, is weak neighborhoods U of P_0. When elements of $\mathcal{P}$ have densities, L_1 neighborhoods of P_0 is often the relevant choice. If the family $\mathcal{P}$ is parametrized by θ, then these notions easily translate to θ, via continuity requirements of the map $\theta \mapsto P_\theta$.

The early papers on consistency were by Freedman (Freedman 1963, 1965) on multinomials with (countably) infinite classes. They were very interesting but provided a

somewhat negative picture, namely, that in a topological sense, for most priors (i.e., outside a class of first category) consistency fails to hold. This lead Freedman to consider tail-free priors including the Dirichlet prior for the countably many probabilities of the countably infinite multinomial. Around the same time, in her posthumous paper (Schwartz 1965) of 1965, arising from her thesis at Berkeley, written under Le Cam, Schwartz showed among other things that, if the prior assigned positive probability to all Kullback-Leibler neighborhoods of the true density, then consistency holds in the sense of weak convergence. This is an important result which showed that this is the right notion of support in these problems, not the more usual one adopted by Freedman.

These early papers were followed by Ferguson's Dirichlet process on the set of all probability measures along with Antoniak's study of mixtures. Even though the set of discrete measures had full measure under the Dirichlet process, it still enjoyed the property of consistency at all distributions. The paper by Diaconis and Freedman (Diaconis and Freedman 1986), along with the discussions revived interest in consistency issues. Diaconis and Freedman showed that with Dirichlet process prior consistency can go awry in the presence of a location parameter. Barron, in his discussion of the paper provided insight as to why it would be unreasonable to expect consistency in this example. Ghosh and Ramamoorthi (Ghosh and Ramamoorthi 2003) discuss several different explanation for lack of consistency if one uses the Dirichlet Process in a semiparametric problem with a location parameter.

Other major contributions have been made by Barron (Barron 1988), Barron, Schervish and Wasserman (Barron et al. 1999), Walker (Walker 2004) and Coram and Lalley (Coram and Lalley 2006). A thorough review up to 2008 is available in Choi and Ramamoorthi (Choi and Ramamoorthi 2008). Contributions to rates of convergence have been made by Ghosal, Ghosh and van der Vaart, (Ghosal et al. 2000), Ghosal and van der Vaart (Ghosal and van der Vaart 2001), Shen and Waseerman (2001), Kleijn and van der Vaart (Kleijn and van der Vaart 2006) and (van der Vaart and van Zanten 2009), (van der Vaart and van Zanten 2008). see also the book by Ghosh and Ramamoorthi (Ghosh and Ramamoorthi 2003) for many basic early results on consistency and other aspects of, like choice of priors and consistency for density estimation, semiparametric problems and survival analysis.

Ghosh and Ramamoorthi (Ghosh and Ramamoorthi 2003) deal only with nonparametric estimation problems. Work on nonparametric testing and consistency problems there have begun only recently. A survey is available in Tokdar, Chakravarti and Ghosh (Tokdar et al. 2010).

About the Authors

For biography of Professor Ghosh *see* the entry ►Bayesian P-Values.

Professor R.V. Ramamoorthi obtained his doctoral degree from the Indian Statistical Institute. His early work was on sufficiency and decision theory, a notable contribution there being the joint result with Blackwell showing that Bayes sufficiency is not equivalent to Fisherian sufficiency. Over the last few years his research has been on Bayesian nonparamterics where J.K. Ghosh and he authored one of the first books on the topic, *Bayesian Nonparametrics* (Springer 2003).

"This is the first book to present an exhaustive and comprehensive treatment of Bayesian nonparametrics. Ghosh and Ramamoorthi present the theoretical underpinnings of nonparametric priors in a rigorous yet extremely lucid style…It is indispensable to any serious Bayesian. It is bound to become a classic in Bayesian nonparametrics." (Jayaram Sethuraman, Review Of Bayesian Nonparametrics, *Sankhya*, 2004, 66, 208–209).

Power Analysis

Kevin R. Murphy
Professor
Pennsylvania State University, University Park, PA, USA

One of the most common applications of statistics in the social and behavioral science is in testing null hypotheses. For example, a researcher wanting to compare the outcomes of two treatments will usually do so by testing the hypothesis that in the population there is no difference in the outcomes of the two treatments. The power of a statistical test is defined as the likelihood that a researcher will be able to reject a specific null hypothesis when it is in fact false.

Cohen (1988), Lipsey (1990), and Kraemer and Thiemann (1987) provided excellent overviews of the methods, assumptions, and applications of power analysis. Murphy and Myors (2003) extended traditional methods of power analysis to tests of hypotheses about the size of treatment effects, not merely tests of whether or not such treatment effects exist.

The power of a null hypothesis test is a function of sample size (n), effect size (ES), and the standard used to define statistical significance (α), and the equations that define this relation can be easily rearranged to solve for any of four quantities (i.e., power, n, ES, and α), given the other three. The two most common applications of statistical power analysis are in: (1) determining the power of a study, given n, ES, and α, and (2) determining how many observations will be needed (i.e., n required), given a desired level of power, an ES estimate, and the α value. Both of these methods are widely used in designing studies; one widely-accepted convention is that studies should be designed so that they achieve power levels of 0.80 or greater (i.e., so that they have at least an 80% chance of rejecting a false null hypothesis; Cohen 1988; Murphy and Myors 2003).

There are two other applications of power analysis that are less common, but no less informative. First, power analysis may be used to evaluate the sensitivity of studies. That is, power analysis can indicate what sorts of effect sizes might be reliably detected in a study. If one expects the effect of a treatment to be small, it is important to know whether the study will detect that effect, or whether the study as planned only has sufficient sensitivity to detect larger effects. Second, one may use power analysis to make rational decisions about the criteria used to define "statistical significance."

Power analyses are included as part of several statistical analysis packages (e.g., SPSS provides Sample Power, a flexible and powerful program) and it is possible to use numerous websites to perform simple power analyses. Two notable software packages designed for power analysis are:

- *G*Power* (Faul et al. 2007; http://www.psycho.uni-duesseldorf.de/abteilungen/aap/gpower3/ is distributed as a freeware program that is available for both Macintosh and Windows environments. It is simple, fast, and flexible.
- *Power and Precision*, distributed by Biostat, was developed by leading researchers in the field (e.g., J. Cohen). This program is very flexible, covers a large array of statistical tests, and provides power analyses and confidence intervals for most tests.

About the Author

Kevin Murphy is a Professor of Psychology and Information Sciences and Technology at the Pennsylvania State University. He has served as President of the Society for Industrial and Organizational Psychology and Editor of *Journal of Applied Psychology*. He is the author if eleven books, including *Statistical Power Analysis: A Simple and General Model for Traditional and Modern Hypothesis Tests* (with Brett Myors, Erlbaum 2009), and over 150 articles and chapters.

Preprocessing in Data Mining

Edgar Acuña
Professor
University of Puerto Rico at Mayaguez, Mayaguez, Puerto Rico

Introduction

►Data mining is the process of extracting hidden patterns in a large dataset. Azzopardi (2002) breaks the data mining process into five stages:

(a) *Selecting the domain* – data mining should be assessed to determine whether there is a viable solution to the problem at hand and a set of objectives should be defined to characterize these problems.
(b) *Selecting the target data* – this entails the selection of data that is to be used in the specified domain; for example, selection of subsets of features or data samples from larger databases.
(c) *Preprocessing the data* – this phase is primarily aimed at preparing the data in a suitable and useable format, so that a knowledge extraction process can be applied.
(d) *Extracting the knowledge/information* – during this stage, the types of data mining operations (association rules, regression, supervised classification, clustering, etc.), the data mining techniques, and data mining algorithms are chosen and the data is then mined.
(e) *Interpretation and evaluation* – this stage of the data mining process is the interpretation and evaluation of the discoveries made. It includes filtering information that is to be presented, visualizing graphically, or locating the useful patterns and translating the patterns discovered into an understandable form.

In the process of data mining, many patterns are found in the data. Patterns that are interesting for the miner are those that are easily understood, valid, potentially useful, and novel (Fayyad et al. 1996). These patterns should validate the hypothesis that the user seeks to confirm. The quality of patterns obtained depends on the quality of the data analyzed. It is common practice to prepare data before applying traditional data mining techniques such as regression, association rules, clustering, and supervised classification.

Section "►Reasons for Applying Data Preprocessing" of this article provides a more precise justification for the use of data preprocessing techniques. This is followed by a description in section "►Techniques for Data Preprocessing" of some of the data preprocessing techniques currently in use.

Reasons for Applying Data Preprocessing

Pyle (1999) suggests that about 60% of the total time required to complete a data mining project should be spent on data preparation since it is one of the most important contributors to the success of the project. Transforming the data at hand into a format appropriate for knowledge extraction has a significant influence on the final models generated, as well as on the amount and quality of the knowledge discovered during the process. At the same time, the effect caused by changes made to a dataset during data preprocessing can either facilitate or complicate even further the knowledge discovery process; thus changes made must be selected with care.

Today's real-world datasets are highly susceptible to noise, missing and inconsistent data due to human errors, mechanical failures, and to their typically large size. Data affected in this manner is known as "dirty." During the past decades, a number of techniques have been developed to preprocess data gathered from real-world applications before the data is further processed for other purposes.

Cases where data mining techniques are applied directly to raw data without any kind of data preprocessing are still frequent; yet, data preprocessing has been recommended as an obligatory step. Data preprocessing techniques should never be applied blindly to a dataset, however. Prior to any data preprocessing effort, the dataset should be explored and characterized. Two methods for

exploring the data prior to preprocessing are *data characterization* and *data visualization*.

Data Characterization

Data characterization describes data in ways that are useful to the miner and begins the process of understanding what is in the data. Engels and Theusinger (1998) describe the following characteristics as standard for a given dataset: the number of classes, the number of observations, the percentage of missing values in each attribute, the number of attributes, the number of features with numeric data type, and the number of features with symbolic data type. These characteristics can provide a first indication of the complexity of the problem being studied.

In addition to the above-mentioned characteristics, parameters of location and dispersion can be calculated as single-dimensional measurements that describe the dataset. Location parameters are measurements such as minimum, maximum, arithmetic mean, median, and empirical quartiles. On the other hand, dispersion parameters such as range, standard deviation, and quartile deviation provide measurements that indicate the dispersion of values of the feature.

Location and dispersion parameters can be divided in two classes: those that can deal with extreme values and those that are sensitive to them. A parameter that can deal well with extreme values is called robust. Some statistical software packages provide the computation of robust parameters in addition to the traditional non-robust parameters. Comparing robust and non-robust parameter values can provide insight to the existence of ►outliers during the data characterization phase.

Data Visualization

Visualization techniques can also be of assistance during this exploration and characterization phase. Visualizing the data before preprocessing it can improve the understanding of the data, thereby increasing the likelihood that new and useful information will be gained from the data. Visualization techniques can be used to identify the existence of missing values, and outliers, as well as to identify relationships among attributes. These techniques can, in effect, assist in ranking the "impurity" of the data and in selecting the most appropriate data preprocessing technique to apply.

Techniques for Data Preprocessing

Applying the correct data preprocessing techniques can improve the quality of the data, thereby helping to improve the accuracy and efficiency of the subsequent mining process. Lu et al. (1996), Pyle (1999), and Azzopardi (2002) present descriptions of common techniques for preparing data for analysis. The techniques described by both authors can be summarized as follows:

(a) *Data cleaning* – filling in missing values, smoothing noisy data, removing outliers, and resolving inconsistencies.
(b) *Data reduction* – reducing the volume of data (but preserving the patterns) by removing repeated observations and applying *instance selection* as well as *feature selection* techniques. Discretization of continuous attributes is also a way of data reduction.
(c) *Data transformation* – converting text and graphical data to a format that can be processed, normalizing or scaling the data, aggregation, and generalization.
(d) *Data integration* – correcting differences in coding schemes due to the combining of several sources of data.

Data Cleaning

Data cleaning provides methods to deal with dirty data. Since dirty datasets can cause problems for data exploration and analysis, data cleaning techniques have been developed to clean data by filling in missing values (value imputation), smoothing noisy data, identifying and/or removing outliers, and resolving inconsistencies. Noise is a random error or variability in a measured feature, and several methods can be applied to remove it. Data can also be smoothed by using regression to find a mathematical equation to fit the data. Smoothing methods that involve *discretization* are also methods of data reduction since they reduce the number of distinct values per attribute. Clustering methods can also be used to remove noise by detecting outliers.

Data Integration

Some studies require the integration of multiple databases, or files. This process is known as *data integration*. Since attributes representing a given concept may have different names in different databases, care must be taken to avoid causing inconsistencies and redundancies in the data. Inconsistencies are observations that have the same values for each of the attributes but that are assigned to different classes. Redundant observations are observations that contain the same information.

Attributes that have been derived or inferred from others may create redundancy problems. Again, having a large amount of redundant and inconsistent data may slow down the knowledge discovery process for a given dataset.

Data Transformation

Many data mining algorithms provide better results if the data has been normalized or scaled to a specific range before these algorithms are applied. The use of normalization techniques is crucial when distance-based algorithms are applied, because the distance measurements taken on by attributes that assume many values will generally outweigh distance measurements taken by attributes that assume fewer values. Other methods of *data transformation* include data aggregation and generalization techniques. These methods create new attributes from existing information by applying summary operations to data or by replacing raw data by higher-level concepts. For example, monthly sales data may be aggregated to compute annual sales.

Data Reduction

The increased size of current real-world datasets has led to the development of techniques that can reduce the size of the dataset without jeopardizing the data mining results. The process known as *data reduction* obtains a reduced representation of the dataset that is much smaller in volume, yet maintains the integrity of the original data. This means that data mining on the reduced dataset should be more efficient yet produce similar analytical results. Han and Kamber (2006) mention the following strategies for data reduction:

(a) *Dimension reduction*, where algorithms are applied to remove irrelevant, weakly relevant, or redundant attributes.
(b) *Data compression*, where encoding mechanisms are used to obtain a reduced or compressed representation of the original data. Two common types of data compression are wavelet transforms and ►principal component analysis.
(c) *Numerosity reduction*, where the data are replaced or estimated by alternative, smaller data representations such as parametric models (which store only the model parameters instead of the actual data), or nonparametric methods such as clustering and the use of histograms.
(d) *Discretization and concept hierarchy generation*, where raw data values for attributes are replaced by ranges or higher conceptual levels. For example, concept hierarchies can be used to replace a low-level concept such as age, with a higher-level concept such as young, middle-aged, or senior. Some detail may be lost by such data generalizations.
(e) *Instance selection*, where a subset of best instances of the whole dataset is selected. Some of the instances are more relevant than others to perform a data mining, and working only with an optimal subset of instances, it will be more cost-and time-efficient. Variants of the classical sampling techniques can be used.

Final Remarks

Acuna (2009) has developed Drep, an R package for data preprocessing and visualization. Drep performs most of the data preprocessing techniques mentioned in this article. Currently, research is being done in order to apply preprocessing methods to data streams, see Aggarwal (2007) for more details.

About the Author

Dr. Edgar Acuña, is a Professor, Department of Mathematical Sciences, University of Puerto Rico at Mayaguez. He is also the leader of the group in Computational and statistical Learning from databases at the University of Puerto Rico. He has authored and co-authored more than 20 papers mainly on data preprocessing. He is the author of book (in Spanish) *Analisis Estadistico De Datos usando* Minitab (John Wiley & Sons, 2002). In 2003, he was honored with the Power Hitter Award in Business and Technology. In 2008, he was selected as a Fullbright visiting Scholar. Currently, he is an Associate editor for the *Revista Colombiana de Estadistica*.

Presentation of Statistical Testimony

Joseph L. Gastwirth
Professor of Statistics and Economics
George Washington University, Washington, DC, USA

Introduction

Unlike scientific research, where we have the luxury of carrying out new studies to replicate and determine the domain of validity of prior investigations, the law also considers other social goals. For example, in many nations one spouse cannot be forced to testify against the other. A main purpose of the law is to resolve a dispute, so a decision needs to be made within a reasonable amount of time after the charge is filed. Science is primarily concerned with determining the true mechanism underlying a phenomenon. Typically no limits are placed on the nature of the experiment or approach an investigator may take to a problem. In most uses of statistics in legal proceedings, the relevant events happened several years ago; rarely will you be able to collect additional data. (One exception occurs in cases concerned with violations of laws protecting intellectual property, such as the Lanham Act in the USA, which prohibits a firm from making a product that infringes on an established one. Surveys of potential consumers are conducted to estimate the percentage who might be confused as to the source of the product in question.) Often, the data base will be one developed for administrative purposes, e.g., payroll or attendance records, which you will need to rely on.

Civil cases differ from criminal cases in that the penalty for violating a civil statue is not time in prison but rather compensation for the harm done. Consequently, the burden of proof a plaintiff has in discrimination or tort case is to show that the defendant caused the alleged harm by "the preponderance of the evidence" rather than the stricter standard of "beyond a reasonable doubt" used in criminal cases. Thus, many statistical studies are more useful in civil cases.

A major difference between presenting testimony in court or a regulatory hearing and giving a talk at a major scientific conference is that expert witnesses, like all others, are only allowed to answer questions put to them by the lawyers. Thus, particular findings or analyses that you believe are very important may not be submitted as evidence if the lawyer who hired you does not ask you about them when you are testifying. Unless the judge, or in some jurisdictions a juror, asks you a question related to that topic you are not allowed to discuss it.

Courts have also adopted criteria to assess the reliability of scientific evidence as well as some traditional ways of presenting and analyzing some types of data. (The leading case is *Daubert v. Merrell-Dow Pharmaceuticals Inc.*, 509 U.S. 579 (1993). The impact of this case and two subsequent ones on scientific evidence is described by Berger (2000) and Rosenblum (2000). Some of the criteria courts consider are: can the methodology was subject to peer review, can it be replicated and tested and whether the potential error rates are known and considered in the expert's report and testimony.) This may limit the range of analyses you can use in the case at hand; although subsequently it can stimulate interesting statistical research. A potentially more serious threat to the credibility of your research and subsequent testimony case is due to the fact that the lawyers provide you with the data and background information. Thus, you may not even be informed that other information or data sets exist.

A related complication can arise when the lawyer hires both a consulting expert who has complete access to all the data as he or she is protected by the "work product" rule and then hires a "testifying expert". This second expert may only be asked to analyze the data favorable to the defendant and not told that any other data exists. Sometimes, the analytic approach, e.g., regression analysis, may be suggested to this expert because the lawyer already knows the outcome. If one believes an alternative statistical technique would be preferable or at least deserves exploration, the expert may be constrained as to the choice of methodology.

This entry describes examples of actual uses of statistical evidence, along with suggestions to aid courts in understanding the implications of the data. Section "►Presenting the Data or Summary Tables That will be Analyzed" discusses the presentation of data and the results of statistical tests. One dataset illustrates the difficulty of getting lawyers and judges to appreciate the statistical concept of "power", the ability of a test to detect a real or important difference. As a consequence an analysis that used a test with *no* power was accepted by a court. In section "►A More Informative Summary of Promotion Data: Hogan v. Pierce (31 F.E.P. 115 (D.D.C. 1983))" will show how in a subsequent case I was able to present more detailed data, which helped make the data clearer to the court. The last section offers some suggestions for improving the quality of statistical analyses and their presentation.

Presenting the Data or Summary Tables That will be Analyzed

In the classic *Castenada v. Partida* (430 U.S. 482, 97 S. Ct. 1272 (1997)) case concerning whether Mexican-Americans

were discriminated against in the jury selection process, the Court summarized the data by years, i.e., the data for *all* juries during the year were aggregated and the minority fraction compared to their fraction of the total population as well as the subgroup eligible for jury service. (The data is reported in footnote 7 of the opinion as well as in the texts: Finkelstein and Levin (2000) and Gastwirth (1988).) The data showed a highly significant difference between the Mexican-American fraction of jurors (39%) and both their fraction of the total population (79.1%) and of adults with some schooling (65%). From a statistical view the case is important as it established that formal statistical hypothesis testing would be used rather than intuitive judgments about whether the difference between the percentage of jurors who were from the minority group differed sufficiently from the percentage of minorities eligible for jury service. When the lower courts followed the methodology laid out in *Castenada*, they also adopted the tradition of presenting yearly summaries of the data in discrimination cases.

Unlike jury discrimination cases, which are typically brought by a defendant in a criminal case rather than the minority juror who was dismissed, in equal employment cases the plaintiff is the individual who suffered the alleged discriminatory act. In the United States the plaintiff has 180 days from the time of the alleged act, e.g., not being hired or promoted or of being laid off, to file a formal complaint with the Equal Employment Opportunity Commission (EEOC). Quite often after receiving notice of the complaint, the employer will modify their system to mitigate the effect of the employment practice under scrutiny on the minority group in question. The impact of this "change" in policy on statistical analysis has often been overlooked by courts. In particular, if a change occurs during the year the charge occurs and employer may change their policy and include the post-charge minority hires or promotions in their analysis.

Let me use data from a case, *Capaci v. Katz & Besthoff* (525 F. Supp. 317 (E.D. La. 1981), *aff'd in part, rev'd in part*, 711 F.2d 647 (5th Cir. 1983)), in which I was an expert for the plaintiffs to illustrate this. On January, 11, 1973 the plaintiff filed a charge of discrimination against women in promotions in the pharmacy department. One way such discriminatory practices may be carried out is to require female employees to work longer at the firm before promotion than males. Therefore, a study comparing the length of time males and female Pharmacists served before they were promoted to Chief Pharmacist was carried out. The time frame considered started in July 1, 1965 the effective date of the Civil Rights Act until the date of the charge. The times each Pharmacist who was promoted had served until they received their promotion are reported in Table 1. Only their initials of the employees are given.

Presentation of Statistical Testimony. Table 1 Months of service for male and female pharmacists employed at K&B during the period July 1, 1965 thru January 11, 1973 before receiving a promotion to chief pharmacist

Females: 229; 453.
Males: 5; 7; 12; 14; 14; 14; 18; 21; 22, 23; 24; 25; 25; 34; 34; 37; 47; 49; 64; 67; 69; 125; 192; 483.

Applying the Wilcoxon test (see ▶Wilcoxon–Mann–Whitney Test), incorporating ties yielded a statistically significant difference (p-value = 0.02). The average number of months the two females worked until they were promoted was 341, while the average male worked for 59 months before their promotion. The corresponding medians were 341 and 25 months, respectively. The defendant's expert presented the data, given in Table 1, broken out into two time periods ending at the end of a year. The first was from 1965 until the end of 1973 and the second was from 1974 until 1978. The defendant's data includes three more females and eight more males in the defendant's data because their expert included essentially the first year's data *subsequent* to the charge. Furthermore, the three females fell into the seniority categories of 20–29, 30–39 and 70–79 months, i.e., they had much less seniority than the two females who were promoted *prior* to the complaint

The defendant's expert did not utilize the Wilcoxon test; rather he analyzed all the data sets with the *median* test and found no significant difference differences. In contrast with the Wilcoxon analysis of the data in Table 1, the median test did not find the difference in time to promotion data in the pre-charge period to be statistically significant.

Because only two females were promoted from July 1, 1965 until the charge was filed in January 1973, the median test has *zero* power of detecting a difference between the two samples. Thus, I suggested that the plaintiffs' lawyer ask the following series of questions to the defendant's expert on cross exam:

1. What is the difference between the average time to promotion of the male and female pharmacists in Table 1.

   Expected Answer: about 20 years. The actual difference was 23 years as the mean female took 341 months while the mean male took 59 months to be promoted.
2. Suppose the difference in the two means or averages was *50* years, would the median test have found a

statistically significant difference between the times that females had to work before being promoted than males?

Expected Answer: No.

3. Suppose the difference in the two means or averages was *100* years, would the median test have found a statistically significant difference between the times that females had to work before being promoted than males?

   Expected Answer: No.

4. Suppose the difference in the two means or averages was *1,000* years, would the median test have found a statistically significant difference between the times that females had to work before being promoted than males?

   Expected Answer: No.

5. Suppose the difference in the two means or averages was *one million* years, would the median test have found a statistically significant difference between the times that females had to work before being promoted than males?

   Expected Answer: No.

   My thought was that the above sequence of questions would have shown the judge the practical implication of finding a non-significant result with a test that did not have any power, in the statistical sense. Unfortunately, after the lawyer asked the first question, she jumped to the last one. By doing so, the issue was not made clear to the judge. When I asked why, I was told that she felt that the other expert realized the point. Of course, the questions were designed to explain the practical meaning of statistical "power" to the trial judge, not the expert. A while later while describing the trial to another, more experienced lawyer, he told me that after receiving the No answers to the five questions he would have turned to the expert and asked him:

6. As your statistical test could not detect a difference of a million years between the times to promotion of male and female employees, just how long would my client and other females have to work without receiving a promotion before your test would find a statistically significant difference?

This experience motivated me to look further into the power properties of nonparametric tests, especially in the unbalanced sample size setting (Gastwirth and Wang 1987; Freidlin and Gastwirth 2000a). The data from the *Capaci* case is discussed by Finkelstein and Levin (2000, p. 344) and Gastwirth (1988, p. 312) and the need to be cautious when a test with low power accepts the null hypothesis is emphasized by Zeisel and Kaye (1997, p. 88).

To further illustrate the change in practices the employer made one could examine the data for 1974–1978. It turns out the mean (median) time to promotion for males was 65.725 (35) and for females was 11.66 (15). Thus, *after* the charge males had to work at least a year *more* than females before they were promoted to Chief Pharmacist. This is an example of a phenomenon I refer to as "A Funny Thing Happens on the Way to the Courtroom." From both a "common sense" standpoint as well as legal one, the employment actions in the period leading up to the complaint have the most relevance for determining what happened when the plaintiff was being considered for promotion. (Similar issues of timing occur in contract law, where the meaning and conditions of a contract at the time it was signed are used to determine whether it has been properly carried out by both parties. In product liability law, a manufacturer is not held liable for risks that were not known when the product was sold to the plaintiff but were discovered subsequently.) Indeed, quite often a plaintiff applies for promotion on several occasions and only after being denied it on all of them, files a formal charge. (For example, in *Watson v. Fort Worth Bank & Trust*, 487 U.S. 977 (1988) the plaintiff had applied for promotion four times. The opinion indicates that the Justices felt that she was unfairly denied promotion on her fourth attempt.)

Comment 1: Baldus and Cole (1987, p. 190) refer to the dispute concerning the Wilcoxon and Median tests in the *Capaci* case in a section concerning the difference between practical and statistical significance. Let me quote them:

> ► Exclusive concern for the ►statistical significance of a disparity encourages highly technical skirmishes between plaintiff's and defendants' experts who may find competing methods of computing statistical significance advantageous in arguing their respective positions (citing the *Capaci* case). The importance of such skirmishes maybe minimized by limiting the role of a test of significance to that of aiding in the interpretation of a measure of impact whose practical significance may be evaluated on nontechnical grounds.

Thus, even the authors of perhaps a commonly cited text on statistical proof of discrimination at the time did not appreciate the importance of the theory of hypothesis testing and the role of statistical power in choosing between tests. More importantly, a difference in the median time to promotion of 341 – 25 = 316 or about 15 years (or the difference in the average times of 23.5 years) would appear to me to be of practical significance. Thus, well respected authors as well as the judiciary allowed the defendant's expert to use

the median test, which had no power to detect a difference in time to promotion, to obfuscate a practically meaningful difference.

Comment 2: The expert for the defendant was a social scientist rather than a statistician. Other statisticians who have faced experts of this type have mentioned to me that often non-statisticians haven't had sufficient training in our subject to know how one should properly choose a procedure. They may select the first procedure that comes to mind or choose a method that helps their client even though it is quite inappropriate and their ignorance of statistical theory makes it difficult for the lawyer you are working for to get them to admit that their method is not as powerful (or accurate or reliable) as yours. An example of this occurred in a case concerning sex discrimination in pay when an "expert" compared the wages of small groups of roughly similar males and females with the t-test. It is well known that typically income and wage data are quite skewed and that the distribution of the two-sample t-test in small samples depends on the assumption of normality. I provided this information to the lawyer who then asked the other "expert" whether he had ever done any research using income or wage data (Ans. No) and whether he had ever carried out any research or read literature on the *t*-test and its properties (Ans. No). Thus, it was difficult for the lawyer to get this "expert" to admit that using the t-test in such a situation is questionable and the significance levels might not be reliable. On a more positive note, the *Daubert* (509 U.S. 579 (1993)) opinion listed several criteria for courts to evaluate expert scientific testimony, one of which is that the method used has a known error rate. Today one might be able to fit a skewed distribution to the data and then show by simulation that a nominal 0.05 level test has an actual level (α) of 0.10 or more. Similarly, if the one must use the t-test in such a situation one could conduct a simulation study to obtain "correct" critical values that will ensure that a nominal 0.05 level test has true level between 0.04 and 0.06. (Although I use the 0.05 level for illustration, I agree with Judge Posner (2001) that it should not be used as a talisman. Indeed, Judge P. Higginbotham's statement in *Vuyanich v. Republic National Bank*, 505 F. Supp. 224 (N.D. Texas 1980) that the p-value is a sliding-scale makes more sense than a simple yes-no dichotomy of significance or not in the legal context as the statistical evidence is only part of the story. The two-sided p-value 0.06 on the post-charge time until promotion data from the Capaci case illustrates the wisdom of the statements of these judges. Not only do the unbalanced sample sizes diminish the power of two-sample tests, the change in the promotion practices of the defendant subsequent to the charge are quite clear from the change in difference in average waiting times until promotion of males and females as well as the change from a significant difference in favor of males before the charge to a nearly significant change in favor of females after the charge.)

Another way of demonstrating that an expert does not possess relevant knowledge is for the lawyer to show them a book or article that states the point you wish to make and ask the expert to read it and then say they agree or disagree with the point. (Dr. Charles Mann told the author that he has been able to successfully use this technique.) If that expert disagrees, a follow-up question can inquire why or on what grounds does he or she disagree with it.

The tradition of reporting data by year also makes it more difficult to demonstrate that a change occurred after a charge was filed. In *Valentino v. USPS* (674 F.2d 56 (DC Circ. 1982)) the plaintiff had applied for a promotion in 1976 and filed the charge in May, 1976. The data is reported in Table 2 and has reanalyzed by Freidlin and Gastwirth (2000b) and Kadane and Woodworth (2004), suggested that females received fewer promotions than expected in the two previous years but after 1976 they received close to their expected number. Let me recall the data and analysis the yearly summaries enabled us to present.

The data for each year were analyzed by the Mantel-Haenszel test applied to the 2×2 tables for each grade grouping in Tables 2 and 3. This was done because the Civil Service Commission reported its data in this fashion. Notice that during two time periods, the number of grade advancements awarded to females for each year is significantly less than expected. After 1976, when the charge was filed the female employees start to receive their expected number of promotions.

My best recollection is that the promotion the plaintiff applied for was the 34th competitive one filled in 1976. Unfortunately, data on all of the applicants was not available even though EEOC guidelines do require employers to preserve records for at least 6 months. Of the 17 or so positions for which data on the actual applicants was available every one was given to a male candidate. Since females did receive their expected number of promotions over the entire year it would appear that the defendant changed its practices after the charge and consequently prevailed in the case. (The data discussed in the cited references considered employees in job categories classified by their level in the system. The district court accepted the defendant's criticism that since each job level contains positions in a variety of occupations, the plaintiffs should have stratified the data by occupation; see 511 F. Supp 917, 939 (D.C. DC, 1981). Later in the opinion, at 511 F. Supp. 951, the opinion accepted a regression analysis submitted by the defendant

Presentation of Statistical Testimony. Table 2 Number of employees and promotions they received: from the *Valentino v. U.S.P.S Case*

	Grade 17–19		Grade 20–22		Grade 23–25		Grade 26–28		Grade 29–31	
Time period	M	F	M	F	M	F	M	F	M	F
06/74–03/75	229	73	360	48	703	33	236	7	82	1
	67	5	74	9	132	2	28	1	8	0
03/75–01/76	205	89	373	43	716	36	277	9	85	1
	40	6	39	5	41	1	19	0	7	0
01/76–01/77	233	101	396	52	727	36	271	9	85	2
	31	10	32	4	54	5	28	2	5	0
01/77–01/78	200	86	377	52	680	35	262	8	89	3
	43	18	80	9	57	6	18	1	14	0
01/78–01/79	196	90	325	50	685	37	252	9	78	3
	29	8	45	7	42	3	14	1	6	1

Key to symbols: F=females; M=males; for any time period and grade group the number of promotions is below the number of employees. For example, in grades 17–19 during 06/74–03/75 period 67 out of 229 eligible males were promoted compared to 5 out of 73 eligible females

Presentation of Statistical Testimony. Table 3 The results obtained from Mantel-Haenszel test for equality of promotion rates applied to the stratified data for each period in Table 2

Year	Observed	Expected	p-value (two-sided)
1974–1975	17	34.1	0.0006
1975–1976	12	21.16	0.020
1976–1977	21	20.32	0.885
1977–1978	34	33.23	0.869
1978–1979	20	21.66	0.674

that used grade level as a predictor of salary noting that 'level" is a good proxy for occupation. While upholding the ultimate finding that U.S.P.S did not discriminate against women, the appellate opinion, fn. 15 at 71, did not accept the district court's criticism that a regression submitted by plaintiffs should have included the level of a position. The reason is that in a promotion case, it is advancement in one's job level that is the issue. Thus, courts do accept regressions that include the major other job-related characteristics such as experience, education, special training and objective measures of productivity.) There was one unusual aspect of the case; the Postal Service had changed the system of reviewing candidates for promotions as of January 1, 1976. As no other charges of discrimination in promotion had been filed in either 1974 or 1975, the analysis of data for those years is considered background information unless the plaintiff can demonstrate that the same process carried over into the time period when the promotion in question was made. (In *Evans v. United Airlines*, the Supreme Court stated that since charges of employment discrimination need to be filed within 180 days of the charge, earlier data is useful background information but is not sufficient by itself to establish a *prima facie* case of discrimination. If there is a continuing violation, however, then the earlier data can be used in conjunction with more recent data by the plaintiffs. The complex legal issues involved in determining when past practices have continued into the time period relevant to a particular case are beyond the scope of the present paper.)

When data is reported in yearly periods, invariably some post-charge data will be included in the data for the year in which the charge was file and statisticians should examine it to see if there is evidence of a change in employment practice subsequent to the charge. In the *Capaci* case, the defendant included eleven months of post-charge data in their first time period, 1965–1973. The inclusion of three additional females promoted in that period lessens the impact of the fact that only two female Pharmacists were promoted during the previous seven and a half years. Similarly, reporting the data by year in *Valentino* enabled the

defendant to monitor the new promotion system begun at the start of 1976 subsequent to the complaint, so females did receive their expected number of promotions for the 1976, the year of the charge.

A More Informative Summary of Promotion Data: Hogan v. Pierce (31 F.E.P. 115 (D.D.C. 1983))

The plaintiff in the case alleged that he had been denied a promotion to a GS-14 level position in the computer division of a government agency and filed a formal complaint in 1977. As the files on the actual applicants were unavailable, we considered all individuals employed in GS-13 level jobs whose records indicated that they met the Civil Service criteria for a promotion to the next job-level to be the pool of "qualified applicants." (These qualifications were that they were employed in an appropriate computer-related position and had at lest one year of experience at the previous level (GS-13) or its equivalent.) There were about ten opportunities for promotion to a GS-14 post during the several years prior to the complaint. About three of the successful GS-14 job applicants were outside candidates who had a Ph.D. in computer science; all of whom were white. Since they had a higher level of education than the internal candidates, they are excluded from Table 4, which gives the number of employees who were eligible and the number promoted, by race, for the ten job announcements.

Although the data is longitudinal in nature and technically one might want to apply a survival test such as the log-rank procedure, it was easier to analyze the data by the Mantel-Haenszel (MH) test that combines the observed minus expected numbers from the individual the individual 2×2 tables (this is, of course, the way the log-rank test is also computed and the resulting statistics are the same). Although there were only 18 promotions awarded to internal candidates during the period under consideration *none* of them went to a black. Moreover, the exact p-value of the MH test was 0.007, a clearly significant result. The analysis can be interpreted as a test for the effect of race controlling for eligibility by Feinberg (1989, p. 100) and has been discussed by Agresti (1996) in the STATXACT manual (2003, p. 597) where it is shown that the *lower* end of a 95% confidence interval of the odds a white employee receives a promotion relative to a minority employee is about two. Thus, we can conclude that the odds of a black employee had of being promoted were half those of a white, which is clearly of practical as well as statistical significance.

In order to demonstrate that the most plausible potential explanation of the promotion data, the white employees had greater seniority, data was submitted that showed that by 1977 the average black employee had worked over a year more at the GS-13 level than the average white one. Thus, if seniority were a major factor that could explain why whites received the earlier promotions, it should have worked in favor of the black employees in the later part of the period. The defendant did not suggest an alternative analysis of this data but concentrated on post-charge data but Judge A. Robinson observed at the trial that their analysis should have considered a time frame around the time of the complaint.

Presentation of Statistical Testimony. Table 4
Promotion data for GS-14 positions obtained by internal job candidates, by Race, from *Hogan v. Pierce* (From Plaintiff's exhibit on file with D.C. District Court. Reproduced in Gastwirth (1988, p. 266) and in the STATXACT manual (Version 6, p. 597))

	Whites		Blacks	
Date of Promotion	Eligible	Promoted	Eligible	Promoted

August 1974	17	4	7	0
Sept. 1974	15	2	8	0
April 1975	18	1	8	0
May 1975	18	1	8	0
Oct. 1975	30	1	10	0
Nov. 1975	31	2	10	0
Feb. 1976	31	1	10	0
March 1976	31	1	10	0
Nov. 1977	34	1	13	0

A Few Suggestions to Statisticians Desiring to Increase the Validity of and Weight Given to Statistical and Scientific Evidence

Mann (2000), cited and endorsed by Mallows (2003), noted that if your analysis does not produce results the lawyer who hired you desired; you will likely be replaced. Indeed, he notes that many attorneys act as though they will be able to find a statistician who will give them the results they want and that "regrettably they may often be correct." This state of affairs unfortunately perpetuates the statement that there are "lies, damn lies and statistics" attributed to both B. Disraeli and M. Twain. Statisticians

have suggested questions that judges may ask experts (Feinberg et al. 1995) and discussed related ethical issues arising in giving testimony (Meier 1986; Kadane 2005). Here we mention a few more suggestions for improving statistical testimony and close with a brief discussion questioning the wisdom of a recent editorial that appeared in *Science*.

1. Mann (2000) is correct in advising statisticians who are asked to testify inquire as to the existence of other data or the analysis of any other previous expert the lawyer consulted. I would add that these are especially important considerations if you are asked to examine data very shortly before a trial as you will have a limited time to understand the data and how it was generated so you will need to totally rely on the data and background information the lawyer provides. In civil cases, it is far preferable for an expert to be involved during the period when discovery is being carried out. Both sides are asking the other for relevant data and information and it is easier for you to tell the lawyer the type of data that you feel would help answer the relevant questions. If the lawyers ignore your requests or don't give you a sensible justification (let me give an example of a business justification. You are asked to work for a defendant in an equal employment case concerning the fairness of a layoff carried out in a plant making brakes for cars and SUVs. Data on absenteeism would appear to be quite useful. The employer knows that the rate of absenteeism in the plant was "higher" than normal for the industry and might be concerned that if this information was put into the public record, they might become involved in many suits arising from accidents involving cars with brakes made there. Since the corporation is a profit-making organization not a scientific one, they will carry out a "cost-benefit" analysis to decide whether you will be given the data), you should become concerned.

   The author's experience in *Valentino* illustrates this point. One reason the original regression equation we developed for the plaintiffs was considered incomplete was because it did not contain relevant information concerning any special degrees the employees had. This field was omitted from the original file we were given and we only learned about it a week or so before trial. After finding that employees with business, engineering or law degrees received about the same salary increase, we then included a single indicator for having a degree in one of the three areas. To assist the court, it would have been preferable to use separate indicators for each degree. (Both opinions, see 674 F.2d 56, 70 fn. 21, downplayed this factor because the defendant's expert testified that it was unreliable as the information depended on whether applicants listed any specialty on their form. More importantly, use of the single indicator variable for three different degrees may not have made it clear that they all had a similar effect on salary and that the indicator was restricted to employees in these three specialties.) Given the very short time available to incorporate the new, but important information that did reduce the estimated coefficient on sex by a meaningful amount, although it remained significant, one did not have time to explore how best to present the analysis.
2. When you are approached by counsel, you should ask for permission to write an article about any interesting statistical problems or data arising in the case. (Of course, data and exhibits submitted formally into evidence are generally considered to be in the public domain so one can use them in scholarly writings. Sometimes, however, the data in the exhibits are summaries and either the individual data or summaries of smaller sub-groups are required to illustrate the methodology.) While the lawyers and client might request that some details of the case not be reported so that the particular case or parties involved are not identifiable, you should be given permission to show the profession how you used or adapted existing methodology. If you perceive that the client or lawyer want to be very restrictive about the use and dissemination of the data and your analysis, you should think seriously about becoming involved. I realize that it is much easier for an academic statistician to say "no" in this situation, than statisticians who do consulting for a living; especially if they have a long-term business relationship with a law firm.
3. Statisticians are now being asked by judges to advise them in "*Daubert*" hearings, which arise when one party in the case challenges the scientific validity or reliability of the expert testimony the other side desires to use. This is a useful service that all scientific professions can provide the legal system. Before assessing a proposed expert's testimony and credentials, it is wise for you to look over the criteria the court suggested in the *Daubert* opinion as well as some examples of decisions in such matters. Because courts take a skeptical view of "new techniques" that have not been subject to peer review but appear to have been developed specifically for the case at hand, one should not fault an expert who does not use the most recently developed method but uses a previously existing method that has been generally regarded in the field as appropriate for

the particular problem. The issue is not whether you would have performed the same analysis the expert conducted but whether the analysis is appropriate and statistically sound. Indeed, Kadane (1990) conducted a Bayesian analysis of data arising in an equal employment and confirmed it with a frequentist method used in ►biostatistics that had been suggested for the problem by Gastwirth and Greenhouse (1987). He noted that it is reassuring when two approaches lead to the same inference. In my experience, this often occurs when data sets of moderate to large sample size are examined and one uses some common sense in interpreting any difference. (By common sense I mean that if one statistician analyzes a data set with test A and obtains a p-value of 0.04, i.e., a statistically significant one, but the other statistician uses another appropriate test B and obtains a p-value of 0.06, a so-called non-significant one, the results are really not meaningfully different.)

4. A "*Daubert*" hearing can be used to provide the judge with questions to ask an expert about the statistical methodology utilized. (This also gives the court's expert the opportunity to find the relevant portions of books and articles that can be shown the expert, thereby implementing the approach described in Comment 2 of section "►A More Informative Summary of Promotion Data: Hogan v. Pierce (31 F.E.P. 115 (D.D.C. 1983))".) This may be effective in demonstrating to a court that a non-statistician really does not have a reasonable understanding of some basic concepts such as power or the potential effect of violations of the assumptions underlying the methods used.
5. One task experts are asked to perform is to criticize or raise questions about the findings and methodology of the testimony given by the other party's expert. This is one place where is easy for one to become overly partisan and lose their scientific objectivity. This important problem is discussed by (Meier 1986). Before raising a criticism, one should ask whether it is important. Could it make a difference in either the conclusion or the weight given to it? In addition to checking that the assumptions underlying the analysis they are presenting are basically satisfied, one step an expert can carry out to protect their own statistical analyses from being unfairly criticized is to carry out a ►sensitivity analysis. Many methods for assessing whether an omitted variable could change an inference have been developed (Rosenbaum 2002) and van Belle (2002) has discussed the relative importance of violations of the assumptions underlying commonly used techniques.
6. While this entry focused on statistical testimony in civil cases, similar issues arise in the use of statistical evidence in criminal cases. The reader is referred to Aitken and Taroni (2004), Balding (2005) for the commonly used statistical methods used in this setting. Articles by a number of experts in both civil and criminal cases appear in Gastwirth (2000) provide additional perspectives on issues arising in the use of statistical evidence in the legal setting.

Acknowledgments

This entry was adapted from Gastwirth (2005). The author wishes to thank Prof. M. Lovic for his helpful suggestions.

About the Author

Professor Joseph L. Gastwirth is a Fellow of ASA (1970), IMS (1972), and AAS (1971), and an Elected member of ISI (1980). He was President of the Washington Statistical Society (1982–1983). He has served three times on the American Statistical Association's Law and Justice Statistics Committee and currently is its Chair. He has written over 150 articles concerning both the theory and application of statistics; especially in the legal setting. In 1985, he received a Guggenheim Fellowship, which led to his two-volume book *Statistical Reasoning in Law and Public Policy* (1988), and the Shiskin Award (1998) for Research in Economic Statistics for his development of statistical methods for measuring economic inequality and discrimination. He edited the book *Statistical Science in the Courtroom* (2000) and in 2002, his article with Dr. B. Freidlin using change-point methods to analyze data arising in equal employment cases shared the "Applications Paper of the Year" award of the American Statistical Association. He has served on the editorial boards of several major statistical journals and recently, he was appointed Editor of the journal, *Law, Probability and Risk*. On August 1, 2009, a workshop celebrating 45 years of statistical activity of Professor Gastwirth was organized at the George Washington University to "recognize his outstanding contributions to the development of nonparametric and robust methods and their use in genetic epidemiology, his pioneering research in statistical methods and measurement for the analysis of data arising in the areas of economic inequality, health disparities and equal employment, and in other legal applications".

Principal Component Analysis

Ian Jolliffe
Professor
University of Exeter, Exeter, UK

Introduction

Large or massive data sets are increasingly common and often include measurements on many variables. It is frequently possible to reduce the number of variables considerably while still retaining much of the information in the original data set. Principal component analysis (PCA) is probably the best known and most widely used dimension-reducing technique for doing this. Suppose we have n measurements on a vector $\mathbf{x}$ of p random variables, and we wish to reduce the dimension from p to q, where q is typically much smaller than p. PCA does this by finding linear combinations, $\mathbf{a}_1'\mathbf{x}, \mathbf{a}_2'\mathbf{x}, \ldots, \mathbf{a}_q'\mathbf{x}$, called *principal components*, that successively have maximum variance for the data, subject to being uncorrelated with previous $\mathbf{a}_k'\mathbf{x}$s. Solving this maximization problem, we find that the vectors $\mathbf{a}_1, \mathbf{a}_2, \ldots, \mathbf{a}_q$ are the eigenvectors of the covariance matrix, $\mathbf{S}$, of the data, corresponding to the q largest eigenvalues (see ►Eigenvalue, Eigenvector and Eigenspace). The eigenvalues give the variances of their respective principal components, and the ratio of the sum of the first q eigenvalues to the sum of the variances of all p original variables represents the proportion of the total variance in the original data set accounted for by the first q principal components. The familiar algebraic form of PCA was first presented by Hotelling (1933), though Pearson (1901) had earlier given a geometric derivation. The apparently simple idea actually has a number of subtleties, and a surprisingly large number of uses, and has a vast literature, including at least two comprehensive textbooks (Jackson 1991; Jolliffe 2002).

An Example

As an illustration we use an example that has been widely reported in the literature, and which is originally due to

Principal Component Analysis. Table 1 Principal Component Analysis Vectors of coefficients for the first two principal components for data from Yule et al. (1969)

Variable	a_1	a_2
x_1	0.34	0.39
x_2	0.34	0.37
x_3	0.35	0.10
x_4	0.30	0.24
x_5	0.34	0.32
x_6	0.27	−0.24
x_7	0.32	−0.27
x_8	0.30	−0.51
x_9	0.23	−0.22
x_{10}	0.36	−0.33

Yule et al. (1969). The data consist of scores, between 0 and 20, for 150 children aged $4^1/_2 - 6$ years from the Isle of Wight, on ten subtests of the Wechsler Pre-School and Primary Scale of Intelligence. Five of the tests were "verbal" tests and five were 'performance' tests. Table 1 gives the vectors $\mathbf{a}_1, \mathbf{a}_2$ that define the first two principal components for these data.

The first component is a linear combination of the ten scores with roughly equal weight (maximum 0.36, minimum 0.23) given to each score. It can be interpreted as a measure of the overall ability of a child to do well on the full battery of ten tests, and represents the major (linear) source of variability in the data. On its own it accounts for 48% of the original variability. The second component contrasts the first five scores (verbal tests) with the five scores on the performance tests. It accounts for a further 11% of the total variability. The form of this second component tells us that once we have accounted for overall ability, the next most important (linear) source of variability in the tests scores is between those children who do well on the verbal tests *relative to* the performance tests and those children whose test score profile has the opposite pattern.

Covariance or Correlation

Principal components successively maximize variance, and can be found from the eigenvalues/eigenvectors of a covariance matrix. Often a modification is adopted, in order to avoid two problems. If the p variables are measured in a mixture of units, then it is difficult to interpret the principal components. What is meant by a linear combination of weight, height and temperature, for example? Furthermore, if we measure temperature and weight in °F and pounds respectively, we may get completely *different principal components* from those obtained from the *same data* but using °C and kilograms. To avoid this arbitrariness, we standardize each variable to have zero mean and unit variance. Finding linear combinations of these standardized variables that successively maximize variance, subject to being uncorrelated with previous linear combinations, leads to principal components defined by the eigenvalues and eigenvectors of the correlation matrix, rather than the covariance matrix, of the original variables. When all variables are measured in the same units, covariance-based PCA may be appropriate, but even here they can be uninformative when a few variables have much larger variances than the remainder. In such cases the first few components are dominated by the high-variance variables and tell us little that could not have been deduced by inspection of the original variances. Circumstances exist where covariance-based PCA is of interest but most PCAs encountered in practice are correlation-based. Our example is a case where either approach could be used. The results given above are based on the correlation matrix but, because the variances of all 10 tests are similar, results from a covariance-based analysis would be little different.

How Many Components?

We have talked about q principal components accounting for most of the variation in the p variables? What is meant by "most" and, more generally, how do we decide how many components to keep? There is a large literature on this topic – see, for example, Jolliffe (2002), Chap. 6. Perhaps the simplest procedure is to set a threshold, say 80%, and stop when the first q components account for a percentage of total variation greater than this threshold. In our example the first two components accounted for only 59% of the variation. The threshold is often set higher than this – 70% to 90% are the usual sort of values, but it depends on the context of the data set and can be higher or lower. Other techniques are based on the values of the eigenvalues or on the differences between consecutive eigenvalues. Some of these simple ideas, as well as more sophisticated ones (Jolliffe 2002, Chap. 6) have been borrowed from factor analysis (see ▶Factor Analysis and Latent Variable Modelling). This is unfortunate because the different objectives of PCA and factor analysis (see below for more on this) mean that typically fewer dimensions should be retained in

factor analysis than in PCA, so the factor analysis rules are often inappropriate. It should also be noted that although it is usual to discard low-variance principal components, they can sometimes be useful in their own right, for example in finding ►outliers (Jolliffe 2002, Chap. 10) and in quality control (Jackson 1991).

Confusion with Factor Analysis

There is much confusion between principal component analysis and factor analysis, partly because some widely used software packages treat PCA as a special case of factor analysis, which it is not. There are several technical differences between PCA and factor analysis, but the most fundamental difference is that factor analysis explicitly specifies a model relating the observed variables to a smaller set of underlying unobservable factors. Although some authors express PCA in the framework of a model, its main application is as a descriptive, exploratory technique, with no thought of an underlying model. This descriptive nature means that distributional assumptions are unnecessary to apply PCA in its usual form. It can be used, although caution may be needed in interpretation, on discrete and even binary data, as well as continuous variables. One notable feature of factor analysis is that it is generally a two-stage procedure; having found an initial solution, it is rotated towards simple structure. This idea can be borrowed and used in PCA; having decided to keep q principal components, we may rotate within the q-dimensional subspace defined by the components in a way that makes the axes as easy as possible to interpret. This is one of number of techniques that attempt to simplify the results of PCA by post-processing them in some way, or by replacing PCA with a modified technique (Jolliffe 2002, Chap. 11).

Uses of Principal Component Analysis

There are many variations on the basic use of PCA as a dimension reducing technique whose results are used in a descriptive/exploratory manner – see Jackson (1991), Jolliffe (2002). PCA is often used a first step, reducing dimensionality before undertaking another technique, such as multiple regression, cluster analysis (see ►Cluster Analysis: An Introduction), discriminant analysis (see ►Discriminant Analysis: An Overview, and ►Discriminant Analysis: Issues and Problems) or independent component analysis.

Extensions to Principal Component Analysis

PCA has been extended in many ways. For example, one restriction of the technique is that it is linear. A number of non-linear versions have therefore been suggested. These include the Gifi approach to multivariate analysis. Another area in which many variations have been proposed is when the data are time series, so that there is dependence between observations as well as between variables (Jolliffe 2002, Chap. 12). There are many other extensions and modifications, and the list continues to grow.

Principles Underlying Econometric Estimators for Identifying Causal Effects

James J. Heckman
Winner of the Nobel Memorial Prize in Economic Sciences in 2000, Henry Schultz Distinguished Service Professor of Economics
The University of Chicago, Chicago, IL, USA
University College Dublin, Dublin, Ireland

This paper reviews the basic principles underlying the identification of conventional econometric evaluation estimators for causal effects and their recent extensions. Heckman (2008) discusses the econometric approach to causality and compares it to conventional statistical approaches. This paper considers alternative methods for identifying causal models.

The paper is in four parts. The first part presents a prototypical economic choice model that underlies econometric models of causal inference. It is a framework that is useful for analyzing and motivating the economic assumptions underlying alternative estimators. The second part discusses general identification assumptions for leading econometric estimators at an intuitive level. The third part elaborates the discussion of matching in the second part. Matching is widely used in applied work and makes strong informational assumptions about what analysts know relative to what the people they analyze know. The fourth part concludes.

A Prototypical Policy Evaluation Problem

Consider the following prototypical policy problem. Suppose a policy is proposed for adoption in a country. It has been tried in other countries and we know outcomes there. We also know outcomes in countries where it was not adopted. From the historical record, what can we conclude about the likely effectiveness of the policy in countries that have not implemented it?

To answer questions of this sort, economists build models of counterfactuals. Consider the following model. Let Y_0 be the outcome of a country (e.g., GDP) under a no-policy regime. Y_1 is the outcome if the policy is implemented. $Y_1 - Y_0$ is the "treatment effect" or causal effect of the policy. It may vary among countries. We observe characteristics X of various countries (e.g., level of democracy, level of population literacy, etc.). It is convenient to decompose Y_1 into its mean given X, $\mu_1(X)$ and deviation from mean U_1. One can make a similar decomposition for Y_0:

$$\begin{aligned} Y_1 &= \mu_1(X) + U_1 \\ Y_0 &= \mu_0(X) + U_0. \end{aligned} \tag{1}$$

Additive separability is not needed, but it is convenient to assume it, and I initially adopt it to simplify the exposition and establish a parallel regression notation that serves to link the statistical literature on treatment effects with the economic literature. (Formally, it involves no loss of generality if we define $U_1 = Y_1 - E(Y_1 \mid X)$ and $U_0 = U_0 - E(Y_0 \mid X)$.)

It may happen that controlling for the X, $Y_1 - Y_0$ is the same for all countries. This is the case of homogeneous treatment effects given X. More likely, countries vary in their responses to the policy even after controlling for X.

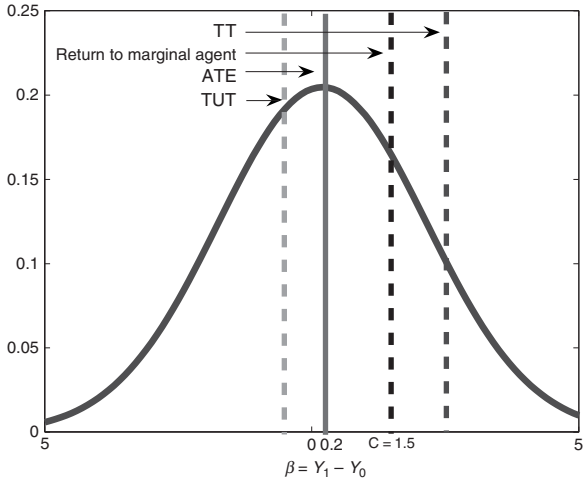
Figure 1 plots the distribution of $Y_1 - Y_0$ for a benchmark X. It also displays the various conventional treatment parameters. I use a special form of a "generalized Roy" model with constant cost C of adopting the policy (see Heckman and Vytlacil 2007a, for a discussion of this model). This is called the "extended Roy model." I use this model because it is simple and intuitive. (The precise parameterization of the extended Roy model used to generate the figure and the treatment effects is given at the base of Fig. 1.) The special case of homogeneity in $Y_1 - Y_0$ arises when the distribution collapses to its mean. It would be ideal if one could estimate the distribution of $Y_1 - Y_0$ given X and there is research that does this.

More often, economists focus on some mean of the distribution in the literature and use a regression framework to interpret the data. To turn (1) into a regression model, it is conventional to use the switching regression framework. (Statisticians sometimes attribute this representation to Rubin (1974, 1978), but it is due to Quandt (1958, 1972). It is implicit in the Roy (1951) model. See the discussion of this basic model of counterfactuals in Heckman and Vytlacil (2007a)). Define $D = 1$ if a country adopts a policy; $D = 0$ if it does not. Substituting (1) into this expression, and keeping all X implicit, one obtains

$$\begin{aligned} Y &= Y_0 + (Y_1 - Y_0)D \\ &= \mu_0 + (\mu_1 - \mu_0 + U_1 - U_0)D + U_0. \end{aligned} \tag{2}$$

This is the Roy-Quandt "switching regression" model. Using conventional regression notation,

$$Y = \alpha + \beta D + \varepsilon \tag{3}$$



TT = 2.666, TUT = –0.632
Return to Marginal Agent = $C = 1.5$
ATE = $\mu_1 - \mu_0 = \bar{\beta} = 0.2$

The Model

Outcomes	Choice Model
$Y_1 = \mu_1 + U_1 = \alpha + \bar{\beta} + U_1$ $Y_0 = \mu_0 + U_0 = \alpha + U_0$	$D = \begin{cases} 1 \text{ if } D^* > 0 \\ 0 \text{ if } D^* \leq 0 \end{cases}$
General Case	
$(U_1 \neq U_0) \not\perp\!\!\!\perp D$ ATE ≠ TT ≠ TUT	

The Researcher Observes (Y, D, C)

$Y = \alpha + \beta D + U_0$ where $\beta = Y_1 - Y_0$

Parameterization

$\alpha = 0.67 \quad (U_1, U_0) \sim N(\mathbf{0}, \Sigma) \quad D^* = Y_1 - Y_0 - C$

$\bar{\beta} = 0.2 \quad \Sigma = \begin{bmatrix} 1 & -0.9 \\ -0.9 & 1 \end{bmatrix} \quad C = 1.5$

Principles Underlying Econometric Estimators for Identifying Causal Effects. Fig. 1 Distribution of gains, the Roy economy (Heckman et al. 2006)

where $\alpha = \mu_0$, $\beta = (Y_1 - Y_0) = \mu_1 - \mu_0 + U_1 - U_0$ and $\varepsilon = U_0$. I will also use the notation that $\upsilon = U_1 - U_0$, letting $\bar{\beta} = \mu_1 - \mu_0$ and $\beta = \bar{\beta} + \upsilon$. Throughout this paper I use treatment effect and regression notation interchangeably. The coefficient on D is the treatment effect. The case where β is the same for every country is the case conventionally assumed. More elaborate versions assume that β depends on X ($\beta(X)$) and estimates interactions of D with X. The case where β varies even after accounting for X is called the "random coefficient" or "heterogenous treatment effect" case. The case where $\upsilon = U_1 - U_0$ depends on D is the case of essential heterogeneity analyzed by Heckman et al. (2006). This case arises when treatment choices depend at least in part on the idiosyncratic return to treatment. A great deal of attention has been focused on this case in recent decades and I develop the implications of this model in this paper.

An Index Model of Choice and Treatment Effects: Definitions and Unifying Principles

I now present the model of treatment effects developed in Heckman and Vytlacil (1999, 2001, 2005, 2007a,b) and Heckman et al. (2006), which relaxes the normality, separability and exogeneity assumptions invoked in the traditional economic selection models. It is rich enough to generate all of the treatment effects in the program evaluation literature as well as many other policy parameters. It does not require separability. It is a nonparametric generalized Roy model with testable restrictions that can be used to unify the treatment effect literature, identify different treatment effects, link the literature on treatment effects to the literature in structural econometrics and interpret the implicit economic assumptions underlying ▶instrumental variables, regression discontinuity design methods, control functions and matching methods.

Y is the measured outcome variable. It is produced from the switching regression model (2). Outcomes are general nonlinear, nonseparable functions of observables and unobservables:

$$Y_1 = \mu_1(X, U_1) \tag{4}$$

$$Y_0 = \mu_0(X, U_0). \tag{5}$$

Examples of models that can be written in this form include conventional latent variable models for discrete choice that are generated by a latent variable crossing a threshold: $Y_i = \mathbf{1}\left(Y_i^* \geq 0\right)$, where $Y_i^* = \mu_i(X) + U_i, i = 0, 1$. Notice that in the general case, $\mu_i(X, U_i) - E(Y_i \mid X) \neq U_i$, $i = 0, 1$.

The individual treatment effect associated with moving an otherwise identical person from "0" to "1" is $Y_1 - Y_0 = \Delta$ and is defined as the causal effect on Y of a *ceteris paribus* move from "0" to "1". To link this framework to the literature on economic choice models, I characterize the

decision rule for program participation by an index model:

$$D^* = \mu_D(Z) - V; \qquad D = 1 \quad \text{if} \quad D^* \geq 0; \qquad D = 0 \quad \text{otherwise}, \tag{6}$$

where, from the point of view of the econometrician, (Z, X) is observed and (U_1, U_0, V) is unobserved. The random variable V may be a function of (U_1, U_0). For example, in the original Roy Model, μ_1 and μ_0 are additively separable in U_1 and U_0 respectively, and $V = -[U_1 - U_0]$. In the original formulations of the generalized Roy model, outcome equations are separable and $V = -[U_1 - U_0 - U_C]$, where U_C arises from the cost function. Without loss of generality, I define Z so that it includes all of the elements of X as well as any additional variables unique to the choice equation.

I invoke the following assumptions that are weaker than those used in the conventional literature on structural econometrics or the recent literature on semiparametric selection models and at the same time can be used both to define and to identify different treatment parameters. (A much weaker set of conditions is required to define the parameters than is required to identify them. See Heckman and Vytlacil (2007b, Appendix B).) The assumptions are:

(A-1) (U_0, U_1, V) *are independent of* Z *conditional on* X *(Independence);*

(A-2) $\mu_D(Z)$ *is a nondegenerate random variable conditional on* X *(Rank Condition);*

(A-3) *The distribution of* V *is continuous; (Absolutely continuous with respect to Lebesgue measure.)*

(A-4) *The values of* $E|Y_1|$ *and* $E|Y_0|$ *are finite (Finite Means);*

(A-5) $0 < \Pr(D = 1 \mid X) < 1$.

(A-1) assumes that V is independent of Z given X and is used below to generate counterfactuals. For the definition of treatment effects one does not need either (A-1) or (A-2). The definitions of treatment effects and their unification do not require any elements of Z that are not elements of X or independence assumptions. However, an analysis of instrumental variables requires that Z contain at least one element not in X. Assumptions (A-1) or (A-2) justify application of instrumental variables methods and nonparametric selection or control function methods. Some parameters in the recent IV literature are defined by an instrument so I make assumptions about instruments up front, noting where they are not needed. Assumption (A-4) is needed to satisfy standard integration conditions. It guarantees that the mean treatment parameters are well defined. Assumption (A-5) is the assumption in the population of both a treatment and a control group for each X. Observe that there are no exogeneity requirements for X. This is in contrast with the assumptions commonly made in the conventional structural literature and the semiparametric selection literature (see, e.g., Powell 1994).

A counterfactual "no feedback" condition facilitates interpretability so that conditioning on X does not mask the effects of D. Letting X_d denote a value of X if D is set to d, a sufficient condition that rules out feedback from D to X is:

(A-6) *Let* X_0 *denote the counterfactual value of* X *that would be observed if* D *is set to* 0. X_1 *is defined analogously. Assume* $X_d = X$ *for* $d = 0, 1$. *(The* X_D *are invariant to counterfactual manipulations.)*

Condition (A-6) is not strictly required to formulate an evaluation model, but it enables an analyst who conditions on X to capture the "total" or "full effect" of D on Y (see Pearl 2000). This assumption imposes the requirement that X is an external variable determined outside the model and is not affected by counterfactual manipulations of D. However, the assumption allows for X to be freely correlated with U_1, U_0 and V so it can be endogenous.

In this notation, $P(Z)$ is the probability of receiving treatment given Z, or the "propensity score" $P(Z) \equiv \Pr(D = 1 \mid Z) = F_{V|X}(\mu_D(Z))$, where $F_{V|X}(\cdot)$ denotes the distribution of V conditional on X. (Throughout this paper, I will refer to the cumulative distribution function of a random vector A by $F_A(\cdot)$ and to the cumulative distribution function of a random vector A conditional on random vector B by $F_{A|B}(\cdot)$. I will write the cumulative distribution function of A conditional on $B = b$ by $F_{A|B}(\cdot \mid b)$.) I denote $P(Z)$ by P, suppressing the Z argument. I also work with U_D, a uniform random variable ($U_D \sim \text{Unif}[0,1]$) defined by $U_D = F_{V|X}(V)$. (This representation is valid whether or not (A-1) is true. However, (A-1) imposes restrictions on counterfactual choices. For example, if a change in government policy changes the distribution of Z by an external manipulation, under (A-1) the model can be used to generate the choice probability from $P(z)$ evaluated at the new arguments, i.e., the model is invariant with respect to the distribution Z.) The separability between V and $\mu_D(Z)$ or $D(Z)$ and U_D is conventional. It plays a crucial role in justifying instrumental variable estimators in the general models analyzed in this paper.

Vytlacil (2002) establishes that assumptions (A-1)–(A-5) for the model of Eqs. (2)–(6) are equivalent to the assumptions used to generate the LATE model of Imbens and Angrist (1994). Thus the nonparametric selection model for treatment effects developed by Heckman

and Vytlacil is implied by the assumptions of the Imbens and Angrist instrumental variable model for treatment effects. The Heckman and Vytlacil approach is more general and links the IV literature to the literature on economic choice models. The latent variable model is a version of the standard sample selection bias model. This weaves together two strands of the literature often thought to be distinct (see e.g., Angrist and Krueger 1999). Heckman et al. (2006) develop this parallelism in detail. (The model of Eqs. (4)–(6) and assumptions (A-1)–(A-5) impose two testable restrictions on the distribution of (Y, D, Z, X). First, it imposes an index sufficiency restriction: for any set $\mathcal{A}$ and for $j = 0, 1$,

$$\Pr(Y_j \in \mathcal{A} \mid X, Z, D = j) = \Pr(Y_j \in \mathcal{A} \mid X, P(Z), D = j).$$

Z (given X) enters the model only through the propensity score $P(Z)$ (the sets of $\mathcal{A}$ are assumed to be measurable). This restriction has empirical content when Z contains two or more variables not in X. Second, the model also imposes monotonicity in p for $E(YD \mid X = x, P = p)$ and $E(Y(1-D) \mid X = x, P = p)$. Heckman and Vytlacil (2005, Appendix A) develop this condition further, and show that it is testable.

Even though this model of treatment effects is not the most general possible model, it has testable implications and hence empirical content. It unites various literatures and produces a nonparametric version of the selection model, and links the treatment literature to economic choice theory.)

Definitions of Treatment Effects in the Two Outcome Model

The difficulty of observing the same individual in both treated and untreated states leads to the use of various population level treatment effects widely used in the biostatistics literature and often applied in economics. (Heckman et al. (1999) discuss panel data cases where it is possible to observe both Y_0 and Y_1 for the same person.) The most commonly invoked treatment effect is the Average Treatment Effect (ATE): $\Delta^{\text{ATE}}(x) \equiv E(\Delta \mid X = x)$ where $\Delta = Y_1 - Y_0$. This is the effect of assigning treatment randomly to everyone of type X assuming full compliance, and ignoring general equilibrium effects. (See, e.g., Imbens (2004).) The average impact of treatment on persons who actually take the treatment is Treatment on the Treated (TT): $\Delta^{\text{TT}}(x) \equiv E(\Delta \mid X = x, D = 1)$. This parameter can also be defined conditional on $P(Z)$: $\Delta^{\text{TT}}(x, p) \equiv E(\Delta \mid X = x, P(Z) = p, D = 1)$. (These two definitions of treatment on the treated are related by integrating out the conditioning p variable: $\Delta^{\text{TT}}(x) = \int_0^1 \Delta^{\text{TT}}(x, p) dF_{P(Z)|X,D}(p|x, 1)$ where $F_{P(Z)|X,D}(\cdot|x, 1)$ is the distribution of $P(Z)$ given $X = x$ and $D = 1$.)

The mean effect of treatment on those for whom $X = x$ and $U_D = u_D$, the Marginal Treatment Effect (MTE), plays a fundamental role in the analysis of the next subsection:

$$\Delta^{\text{MTE}}(x, u_D) \equiv E(\Delta \mid X = x, U_D = u_D). \tag{7}$$

This parameter is defined independently of any instrument. I separate the definition of parameters from their identification. The MTE is the expected effect of treatment conditional on observed characteristics X and conditional on U_D, the unobservables from the first stage decision rule. For u_D evaluation points close to zero, $\Delta^{\text{MTE}}(x, u_D)$ is the expected effect of treatment on individuals with the value of unobservables that make them most likely to participate in treatment and who would participate even if the mean scale utility $\mu_D(Z)$ is small. If U_D is large, $\mu_D(Z)$ would have to be large to induce people to participate.

One can also interpret $E(\Delta \mid X = x, U_D = u_D)$ as the mean gain in terms of $Y_1 - Y_0$ for persons with observed characteristics X who would be indifferent between treatment or not if they were randomly assigned a value of Z, say z, such that $\mu_D(z) = u_D$. When Y_1 and Y_0 are value outcomes, MTE is a mean willingness-to-pay measure. MTE is a choice-theoretic building block that unites the treatment effect, selection, matching and control function literatures.

A third interpretation is that MTE conditions on X and the residual defined by subtracting the expectation of D^* from D^*: $\tilde{U}_D = D^* - E(D^* \mid Z, X)$. This is a "replacement function" interpretation in the sense of Heckman and Robb (1985a) and Matzkin (2007), or "control function" interpretation in the sense of Blundell and Powell (2003). (These three interpretations are equivalent under separability in D^*, i.e., when (6) characterizes the choice equation, but lead to three different definitions of MTE when a more general nonseparable model is developed. See Heckman and Vytlacil (2007b).) The additive separability of Eq. 6 in terms of observables and unobservables plays a crucial role in the justification of instrumental variable methods.

The LATE parameter of Imbens and Angrist (1994) is a version of MTE. I define LATE independently of any instrument after first presenting the Imbens–Angrist definition. Define $D(z)$ as a counterfactual choice variable, with $D(z) = 1$ if D would have been chosen if Z had been set to z, and $D(z) = 0$ otherwise. Let $\mathcal{Z}(x)$ denote the support of the distribution of Z conditional on $X = x$. For any $(z, z') \in \mathcal{Z}(x) \times \mathcal{Z}(x)$ such that $P(z) > P(z')$, LATE is $E(\Delta \mid X = x, D(z) = 1, D(z') = 0) = E(Y_1 - Y_0 \mid X = x, D(z) = 1, D(z') = 0)$, the mean gain to persons who would be induced to switch from $D = 0$ to $D = 1$ if Z were

manipulated externally from z' to z. In an example of the returns to education, z' could be the base level of tuition and z a reduced tuition level. Using the latent index model, Heckman and Vytlacil (1999, 2005) show that LATE can be written as

$$\begin{aligned} E(Y_1 - Y_0 \mid X = x, D(z) = 1, D(z') = 0) \\ = E\left(Y_1 - Y_0 \mid X = x, u'_D < U_D < u_D\right) \\ = \Delta^{\text{LATE}}\left(x, u_D, u'_D\right) \end{aligned}$$

for $u_D = \Pr(D(z) = 1) = P(z)$, $u'_D = \Pr(D(z') = 1) = P(z')$, where assumption (A-1) implies that $\Pr(D(z) = 1) = \Pr(D = 1 \mid Z = z)$ and $\Pr(D(z') = 1) = \Pr(D = 1 \mid Z = z')$.

Imbens and Angrist define the LATE parameter as the probability limit of an estimator. Their analysis conflates issues of definition of parameters with issues of identification. The representation of LATE given here allows analysts to separate these two conceptually distinct matters and to define the LATE parameter more generally. One can in principle evaluate the right hand side of the preceding equation at any u_D, u'_D points in the unit interval and not only at points in the support of the distribution of the propensity score $P(Z)$ conditional on $X = x$ where it is identified. From assumptions (A-1), (A-3), and (A-4), $\Delta^{\text{LATE}}\left(x, u_D, u'_D\right)$ is continuous in u_D and u'_D and $\lim_{u'_D \uparrow u_D} \Delta^{\text{LATE}}\left(x, u_D, u'_D\right) = \Delta^{\text{MTE}}(x, u_D)$. (This follows from Lebesgue's theorem for the derivative of an integral and holds almost everywhere with respect to Lebesgue measure. The ideas of the marginal treatment effect and the limit form of LATE were first introduced in the context of a parametric normal generalized Roy model by Björklund and Moffitt (1987), and were analyzed more generally in Heckman (1997). Angrist et al. (2000) also define and develop a limit form of LATE.)

Heckman and Vytlacil (1999) use assumptions (A-1)–(A-5) and the latent index structure to develop the relationship between MTE and the various treatment effect parameters shown in the first three lines of Table 1a. They present the formal derivation of the parameters and associated weights and graphically illustrates the relationship between ATE and TT. All treatment parameters may be expressed as weighted averages of the MTE:

$$\begin{aligned} &\text{Treatment Parameter } (j) \\ &= \int \Delta^{\text{MTE}}(x, u_D)\, \omega_j(x, u_D)\, du_D \end{aligned}$$

where $\omega_j(x, u_D)$ is the weighting function for the MTE and the integral is defined over the full support of u_D. Except for the OLS weights, the weights in the table all integrate to one, although in some cases the weights for IV may be negative (Heckman et al. 2006).

In Table 1a, $\Delta^{\text{TT}}(x)$ is shown as a weighted average of Δ^{MTE}:

$$\Delta^{\text{TT}}(x) = \int_0^1 \Delta^{\text{MTE}}(x, u_D)\, \omega_{\text{TT}}(x, u_D)\, du_D,$$

where

$$\omega_{TT}(x, u_D) = \frac{1 - F_{P|X}(u_D \mid x)}{\int_0^1 \left(1 - F_{P|X}(t \mid x)\right) dt} = \frac{S_{P|X}(u_D \mid x)}{E(P(Z) \mid X = x)}, \tag{8}$$

and $S_{P|X}(u_D \mid x)$ is $\Pr(P(Z) > u_D \mid X = x)$ and $\omega_{\text{TT}}(x, u_D)$ is a weighted distribution. The parameter $\Delta^{\text{TT}}(x)$ oversamples $\Delta^{\text{MTE}}(x, u_D)$ for those individuals with low values of u_D that make them more likely to participate in the program being evaluated. Treatment on the untreated (TUT) is defined symmetrically with TT and oversamples those least likely to participate. The various weights are displayed in Table 1b. A central theme of the analysis of Heckman and Vytlacil is that under their assumptions all estimators and estimands can be written as weighted averages of MTE. This allows them to unify the treatment effect literature using a common functional MTE (u_D).

Observe that if $E(Y_1 - Y_0 \mid X = x, U_D = u_D) = E(Y_1 - Y_0 \mid X = x)$, so $\Delta = Y_1 - Y_0$ is mean independent of U_D given $X = x$, then $\Delta^{\text{MTE}} = \Delta^{\text{ATE}} = \Delta^{\text{TT}} = \Delta^{\text{LATE}}$. Therefore in cases where there is no heterogeneity in terms of unobservables in MTE (Δ constant conditional on $X = x$) or agents do not act on it so that U_D drops out of the conditioning set, marginal treatment effects are average treatment effects, so that all of the evaluation parameters are the same. Otherwise, they are different. Only in the case where the marginal treatment effect is the average treatment effect will the "effect" of treatment be uniquely defined.

Figure 2a plots weights for a parametric normal generalized Roy model generated from the parameters shown at the base of Fig. 2b. The model allows for costs to vary in the population and is more general than the extended Roy model used to construct Fig. 1. The weights for IV depicted in Fig. 2b are discussed in Heckman et al. (2006) and the weights for OLS are discussed in the next section. A high u_D is associated with higher cost, relative to return, and less likelihood of choosing $D = 1$. The decline of MTE in terms of higher values of u_D means that people with higher u_D have lower gross returns. TT overweights low values of u_D (i.e., it oversamples U_D that make it likely to have $D = 1$). ATE samples U_D uniformly. Treatment on the Untreated

Principles Underlying Econometric Estimators for Identifying Causal Effects. Table 1

(a) Treatment effects and estimands as weighted averages of the marginal treatment effect

$\text{ATE}(x) = E(Y_1 - Y_0 \mid X = x) = \int_0^1 \Delta^{\text{MTE}}(x, u_D)\, du_D$

$\text{TT}(x) = E(Y_1 - Y_0 \mid X = x, D = 1) = \int_0^1 \Delta^{\text{MTE}}(x, u_D)\, \omega_{\text{TT}}(x, u_D)\, du_D$

$\text{TUT}(x) = E(Y_1 - Y_0 \mid X = x, D = 0) = \int_0^1 \Delta^{\text{MTE}}(x, u_D)\, \omega_{\text{TUT}}(x, u_D)\, du_D$

Policy relevant treatment effect $(x) = E(Y_{a'} \mid X = x) - E(Y_a \mid X = x) = \int_0^1 \Delta^{\text{MTE}}(x, u_D)\, \omega_{\text{PRTE}}(x, u_D)\, du_D$ for two policies a and a' that affect the Z but not the X

$\text{IV}_J(x) = \int_0^1 \Delta^{\text{MTE}}(x, u_D)\, \omega_{\text{IV}}^J(x, u_D)\, du_D$, given instrument J

$\text{OLS}(x) = \int_0^1 \Delta^{\text{MTE}}(x, u_D)\, \omega_{\text{OLS}}(x, u_D)\, du_D$

(b) Weights (Heckman and Vytlacil 2005)

$$\omega_{\text{ATE}}(x, u_D) = 1$$

$$\omega_{\text{TT}}(x, u_D) = \left[\int_{u_D}^1 f(p \mid X = x) dp\right] \frac{1}{E(P \mid X = x)}$$

$$\omega_{\text{TUT}}(x, u_D) = \left[\int_0^{u_D} f(p \mid X = x)\, dp\right] \frac{1}{E((1 - P) \mid X = x)}$$

$$\omega_{\text{PRTE}}(x, u_D) = \left[\frac{F_{P_{a'},X}(u_D) - F_{P_a,X}(u_D)}{\Delta \bar{P}}\right]$$

$$\omega_{\text{IV}}^J(x, u_D) = \left[\int_{u_D}^1 (J(Z) - E(J(Z) \mid X = x)) \int f_{J,P|X}(j, t \mid X = x)\, dt\, dj\right] \frac{1}{\text{Cov}(J(Z), D \mid X = x)}$$

$$\omega_{\text{OLS}}(x, u_D) = 1 + \frac{E(U_1 \mid X = x, U_D = u_D)\, \omega_1(x, u_D) - E(U_0 \mid X = x, U_D = u_D)\, \omega_0(x, u_D)}{\Delta^{\text{MTE}}(x, u_D)}$$

$$\omega_1(x, u_D) = \left[\int_{u_D}^1 f(p \mid X = x)\, dp\right] \left[\frac{1}{E(P \mid X = x)}\right]$$

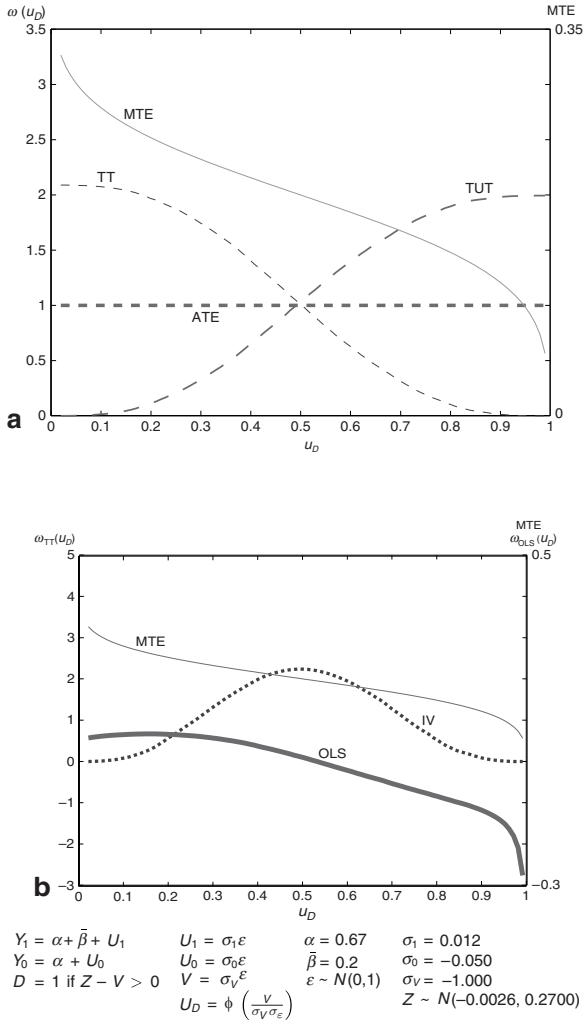
$$\omega_0(x, u_D) = \left[\int_0^{u_D} f(p \mid X = x)\, dp\right] \frac{1}{E((1 - P) \mid X = x)}$$

$(E(Y_1 - Y_0 \mid X = x, D = 0))$, or TUT, oversamples the values of U_D which make it unlikely to have $D = 1$.

Table 2 shows the treatment parameters produced from the different weighting schemes for the model used to generate the weights in Fig. 2a and 2b. Given the decline of the MTE in u_D, it is not surprising that TT>ATE>TUT. This is the generalized Roy version of the principle of diminishing returns. Those most likely to self select into the program benefit the most from it. The difference between TT and ATE is a sorting gain: $E(Y_1 - Y_0 \mid X, D = 1) - E(Y_1 - Y_0 \mid X)$, the average gain experienced by people who sort into treatment compared to what the average person would experience. Purposive selection on the basis of gains should lead to positive sorting gains of the kind found in the table. If there is negative sorting on the gains, then TUT ≥ ATE ≥ TT.

The Weights for a Generalized Roy Model

Heckman et al. (2006) show that all of the weights for treatment effects and IV estimators can be estimated over the available support. Since the MTE can be estimated by the method of Local Instrumental variables, we can form each treatment effect and each IV estimand as an integral to two estimable functions (subject to support). For the case of continuous Z, I plot the weights associated with the MTE for IV. This analysis draws on Heckman et al. (2006), who derive the weights. Figure 3 plots $E(Y \mid P(Z))$ and MTE for the extended Roy models generated by the parameters displayed at the base of the figure. In cases where $\beta \perp\!\!\!\perp D$, $\Delta^{\text{MTE}}(u_D)$ is constant in u_D. This is trivial when β is a constant. When β is random but selection into D does not depend on β, MTE is still flat. The more interesting case termed "essential heterogeneity" by



Principles Underlying Econometric Estimators for Identifying Causal Effects. Fig. 2(a) Weights for the marginal treatment effect for different parameters (Heckman and Vytlacil 2005) (**b**) Marginal treatment effect vs linear instrumental variables and ordinary least squares weights (Heckman and Vytlacil 2005)

Principles Underlying Econometric Estimators for Identifying Causal Effects. Table 2 Treatment parameters and estimands in the generalized Roy example

Treatment on the treated	0.2353
Treatment on the untreated	0.1574
Average treatment effect	0.2000
Sorting gain[a]	0.0353
Policy relevant treatment effect (PRTE)	0.1549
Selection bias[b]	−0.0628
Linear instrumental variables[c]	0.2013
Ordinary least squares	0.1725

[a] $TT - ATE = E(Y_1 - Y_0 \mid D = 1) - E(Y_1 - Y_0)$
[b] $OLS - TT = E(Y_0 \mid D = 1) - E(Y_0 \mid D = 0)$
[c] Using Propensity Score $P(Z)$ as the instrument.
Note: The model used to create Table 2 is the same as those used to create Fig. 2a and b. The PRTE is computed using a policy t characterized as follows:
If $Z > 0$ then $D = 1$ if $Z(1 + t) - V > 0$.
If $Z \leq t$ then $D = 1$ if $Z - V > 0$.
For this example t is set equal to 0.2.

Heckman and Vytlacil has $\beta \not\perp\!\!\!\perp D$. The left hand side (Fig. 3a) depicts $E(Y \mid P(Z))$ in the two cases. The first case makes $E(Y \mid P(Z))$ linear in $P(Z)$. The second case is nonlinear in $P(Z)$. This arises when $\beta \not\perp\!\!\!\perp D$. The derivative of $E(Y \mid P(Z))$ is presented in the right panel (Fig. 3b). It is a constant for the first case (flat MTE) but declining in $U_D = P(Z)$ for the case with selection on the gain. A simple test for linearity in $P(Z)$ in the outcome equation reveals whether or not the analyst is in cases I and II ($\beta \perp\!\!\!\perp D$) or case III ($\beta \not\perp\!\!\!\perp D$). (Recall that we keep the conditioning on X implicit.) These cases are the extended Roy counterparts to $E(Y \mid P(Z) = p)$ and MTE shown for the generalized Roy model in Figs. 4a and 4b.

MTE gives the mean marginal return for persons who have utility $P(Z) = u_D$. Thus, $P(Z) = u_D$ is the margin of indifference. Those with low u_D values have high returns. Those with high u_D values have low returns. Figure 3 highlights that in the general case MTE (and LATE) identify average returns for persons at the margin of indifference at different levels of the mean utility function ($P(Z)$).

Figure 5 plots MTE and LATE for different intervals of u_D using the model generating Fig. 3. LATE is the chord of $E(Y \mid P(Z))$ evaluated at different points. The relationship between LATE and MTE is depicted in the right panel (b) of Fig. 5. LATE is the integral under the MTE curve divided by the difference between the upper and lower limits.

Treatment parameters associated with the second case are plotted in Fig. 6. The MTE is the same as that presented in Fig. 3. ATE has the same value for all p. The effect of treatment on the treated for $P(Z) = p$, $\Delta^{TT}(p) = E(Y_1 - Y_0 \mid D = 1, P(Z) = p)$ declines in p (equivalently it declines in u_D). Treatment on the untreated given p, $\text{TUT}(p) = \Delta^{TUT}(p) = E(Y_1 - Y_0 \mid D = 0, P(Z) = p)$ also declines in p.

		$\mu_Z = (2, -2)$ and $\Sigma_Z = \begin{bmatrix} 9 & -2 \\ -2 & 9 \end{bmatrix}$
		$\gamma = (0.5, 0.5)$

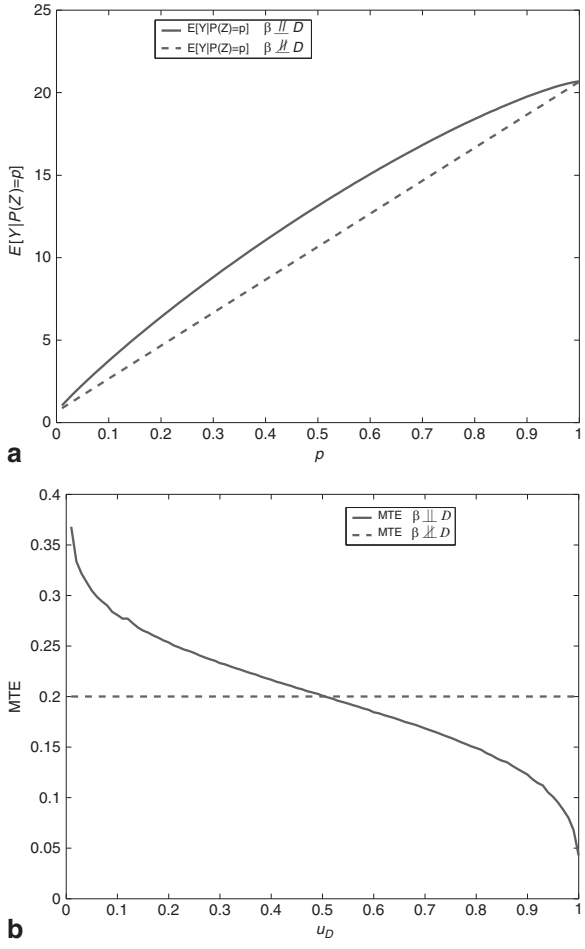
Principles Underlying Econometric Estimators for Identifying Causal Effects. Fig. 3 Conditional expectation of Y on $P(Z)$ and the marginal treatment effect (MTE) the extended Roy economy (Heckman et al. 2006)

$$LATE(p, p') = \frac{\Delta^{TT}(p')p' - \Delta^{TT}(p)p}{p' - p}, \qquad p' \neq p$$

$$MTE = \frac{\partial[\Delta^{TT}(p)p]}{\partial p}.$$

One can generate all of the treatment parameters from $\Delta^{TT}(p)$.

Matching on $P = p$ (which is equivalent to nonparametric regression given $P = p$) produces a biased estimator of $TT(p)$. Matching assumes a flat MTE (average return



Principles Underlying Econometric Estimators for Identifying Causal Effects. Fig. 4 (**a**) Plot of the $E(Y|P(Z) = p)$, (**b**) Plot of the identified marginal treatment effect from Fig. 2a (the derivative). Note: Parameters for the general heterogeneous case are the same as those used in Fig. 2a and 2b. For the homogeneous case we impose $U_1 = U_0$ ($\sigma_1 = \sigma_0 = 0.012$). (Heckman and Vytlacil 2005)

equals marginal return) as we develop below. Therefore it is systematically biased for $\Delta^{TT}(p)$ in a model with essential heterogeneity, where $\beta \not\perp\!\!\!\perp D$. Making observables alike makes the unobservables dissimilar. Holding p constant across treatment and control groups understates $TT(p)$ for low values of p and overstates it for high values of p. I develop this point further in section "►Matching", where I discuss the method of matching. First I present a unified approach that integrates all evaluation estimators in a common framework.

The Basic Principles Underlying the Identification of the Leading Econometric Evaluation Estimators

This section reviews the main principles underlying the evaluation estimators commonly used in the econometric literature. I assume two potential outcomes (Y_0, Y_1). $D = 1$ if Y_1 is observed, and $D = 0$ corresponds to Y_0 being observed. The observed outcome is

$$Y = DY_1 + (1 - D)Y_0. \tag{9}$$

The *evaluation problem* arises because for each person we observe either Y_0 or Y_1 but not both. Thus in general it is not possible to identify the individual level treatment effect $Y_1 - Y_0$ for any person. The typical solution to this problem is to reformulate the problem at the population level rather than at the individual level and to identify certain mean outcomes or quantile outcomes or various distributions of outcomes as described in Heckman and Vytlacil (2007a). For example, a commonly used approach focuses attention on average treatment effects, such as ATE = $E(Y_1 - Y_0)$.

If treatment is assigned or chosen on the basis of potential outcomes, so

$$(Y_0, Y_1) \not\perp\!\!\!\perp D,$$

where $\not\perp\!\!\!\perp$ denotes "is not independent" and "$\perp\!\!\!\perp$" denotes independent, we encounter the problem of selection bias. Suppose that we observe people in each treatment state $D = 0$ and $D = 1$. If $Y_j \not\perp\!\!\!\perp D$, then the observed Y_j will be selectively different from randomly assigned Y_j, $j = 0, 1$. Thus $E(Y_0 \mid D = 0) \neq E(Y_0)$ and $E(Y_1 \mid D = 1) \neq E(Y_1)$. Using unadjusted data to construct $E(Y_1 - Y_0)$ will produce one source of evaluation bias:

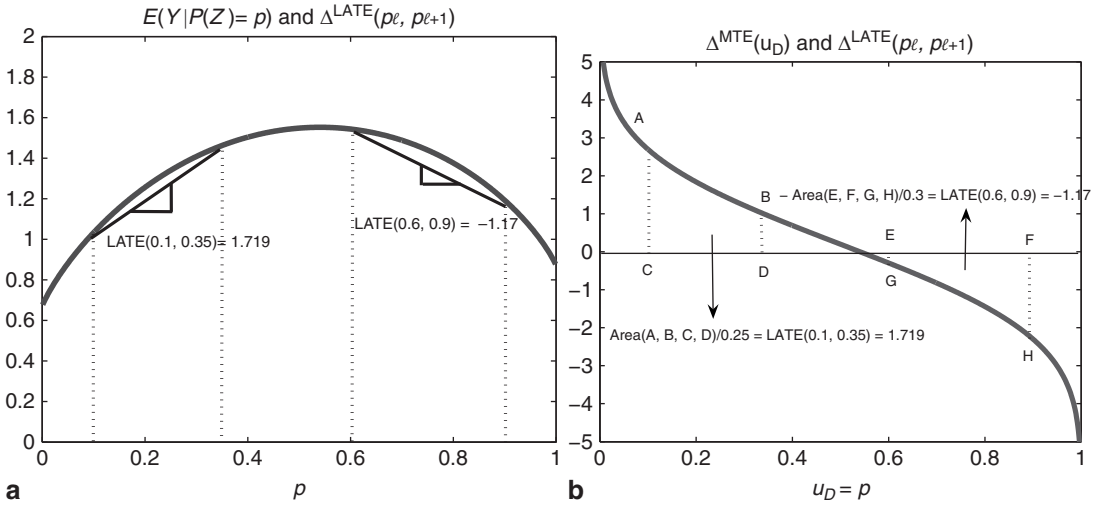
$$E(Y_1 \mid D = 1) - E(Y_0 \mid D = 0) \neq E(Y_1 - Y_0).$$

The selection problem underlies the evaluation problem. Many methods have been proposed to solve both problems.

The method with the greatest intuitive appeal, which is sometimes called the "gold standard" in evaluation analysis, is the method of random assignment. Nonexperimental methods can be organized by how they attempt to approximate what can be obtained by an ideal random assignment. If treatment is chosen at random with respect to (Y_0, Y_1), or if treatments are randomly assigned and there is full compliance with the treatment assignment,

(R-1) $(Y_0, Y_1) \perp\!\!\!\perp D$.

It is useful to distinguish several cases where (R-1) will be satisfied. The first is that agents (decision makers whose choices are being analyzed) pick outcomes that are random with respect to (Y_0, Y_1). Thus agents may not know



$$\Delta^{\text{LATE}}(p_\ell, p_{\ell+1}) = \frac{E(Y|P(Z) = p_{\ell+1}) - E(Y|P(Z) = p_\ell)}{p_{\ell+1} - p_\ell} = \frac{\int_{p_\ell}^{p_{\ell+1}} \Delta^{\text{MTE}}(u_D)du_D}{p_{\ell+1} - p_\ell}$$

$$\Delta^{\text{LATE}}(0.6, 0.9) = -1.17$$
$$\Delta^{\text{LATE}}(0.1, 0.35) = 1.719$$

Outcomes	Choice model
$Y_1 = \alpha + \bar{\beta} + U_1$	$D = \begin{cases} 1 \text{ if } D^* > 0 \\ 0 \text{ if } D^* \leq 0 \end{cases}$
$Y_0 = \alpha + U_0$	with $D^* = Y_1 - Y_0 - \gamma Z$

Parameterization

$$(U_1, U_0) \sim N(\mathbf{0}, \Sigma) \text{ and } Z \sim N(\mu_Z, \Sigma_Z)$$
$$\Sigma = \begin{bmatrix} 1 & -0.9 \\ -0.9 & 1 \end{bmatrix}, \ \mu_Z = (2, -2) \text{ and } \Sigma_Z = \begin{bmatrix} 9 & -2 \\ -2 & 9 \end{bmatrix}$$
$$\alpha = 0.67, \bar{\beta} = 0.2, \gamma = (0.5, 0.5)$$

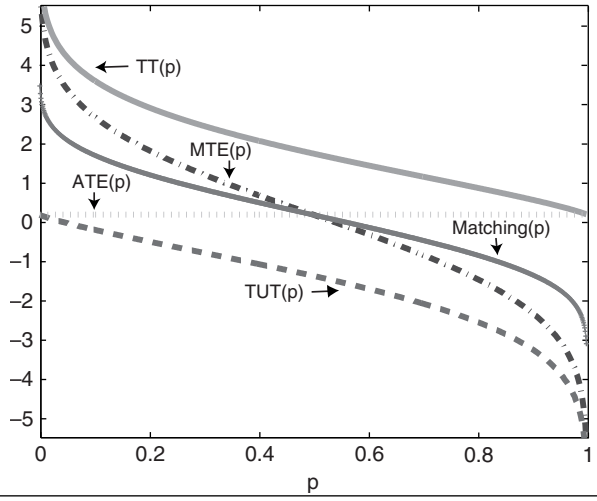
Principles Underlying Econometric Estimators for Identifying Causal Effects. Fig. 5 The local average treatment effect the extended Roy economy (Heckman et al. 2006)

(Y_0, Y_1) at the time they make their choices to participate in treatment or at least do not act on (Y_0, Y_1), so that $\Pr(D = 1 \mid X, Y_0, Y_1) = \Pr(D = 1 \mid X)$ for all X. Matching assumes a version of (R-1) conditional on matching variables X: $(Y_0, Y_1) \perp\!\!\!\perp D \mid X$.

A second case arises when individuals are randomly assigned to treatment status even if they would choose to self select into no-treatment status, and they comply with the randomization protocols. Let ξ be randomized assignment status. With full compliance, $\xi = 1$ implies that Y_1 is observed and $\xi = 0$ implies that Y_0 is observed. Then, under randomized assignment,

(R-2) $(Y_0, Y_1) \perp\!\!\!\perp \xi$,

even if in a regime of self-selection, $(Y_0, Y_1) \not\perp\!\!\!\perp D$. If ►randomization is performed conditional on X, we obtain $(Y_0, Y_1) \perp\!\!\!\perp \xi \mid X$.



Parameter	Definition	Under assumptions[a]
Marginal treatment effect	$E\left[Y_1 - Y_0 \mid D^* = 0, P(Z) = p\right]$	$\bar{\beta} + \sigma_{U_1 - U_0}\Phi^{-1}(1-p)$
Average treatment effect	$E\left[Y_1 - Y_0 \mid P(Z) = p\right]$	$\bar{\beta}$
Treatment on the treated	$E\left[Y_1 - Y_0 \mid D^* > 0, P(Z) = p\right]$	$\bar{\beta} + \sigma_{U_1 - U_0}\frac{\phi\left(\Phi^{-1}(1-p)\right)}{p}$
Treatment on the untreated	$E\left[Y_1 - Y_0 \mid D^* \leq 0, P(Z) = p\right]$	$\bar{\beta} - \sigma_{U_1 - U_0}\frac{\phi\left(\Phi^{-1}(1-p)\right)}{1-p}$
OLS/matching on $P(Z)$	$E\left[Y_1 \mid D^* > 0, P(Z) = p\right]$	$\bar{\beta} + \left(\frac{\sigma^2_{U_1} - \sigma_{U_1 U_0}}{\sqrt{\sigma_{U_1 - U_0}}}\right)\left(\frac{1-2p}{p(1-p)}\right)\phi\left(\Phi^{-1}(1-p)\right)$
	$-E\left[Y_0 \mid D^* \leq 0, P(Z) = p\right]$	

Principles Underlying Econometric Estimators for Identifying Causal Effects. Fig. 6 Treatment parameters and OLS/matching as a function of $P(Z) = p$. Note: $\Phi(\cdot)$ and $\phi(\cdot)$ represent the cdf and pdf of a standard normal distribution, respectively. $\Phi^{-1}(\cdot)$ represents the inverse of $\Phi(\cdot)$. [a] The model in this case is the same as the one presented below Fig. 5. (Heckman et al. 2006)

Let A denote actual treatment status. If the randomization has full compliance among participants, $\xi = 1 \Rightarrow A = 1$; $\xi = 0 \Rightarrow A = 0$. This is entirely consistent with a regime in which a person would choose $D = 1$ in the absence of randomization, but would have no treatment ($A = 0$) if suitably randomized, even though the agent might desire treatment.

If treatment status is chosen by self-selection, $D = 1 \Rightarrow A = 1$ and $D = 0 \Rightarrow A = 0$. If there is imperfect compliance with randomization, $\xi = 1 \nRightarrow A = 1$ because of agent choices. In general, $A = \xi D$ so that $A = 1$ only if $\xi = 1$ and $D = 1$. If treatment status is randomly assigned, either through randomization or randomized self-selection,

(R-3) $(Y_0, Y_1) \perp\!\!\!\perp A$.

This version of randomization can also be defined conditional on X. Under (R-1), (R-2), or (R-3), the average treatment effect (ATE) is the same as the marginal treatment effect of Björklund and Moffitt (1987) and Heckman and Vytlacil (1999, 2005, 2007a), and the parameters treatment on the treated (TT) ($E(Y_1 - Y_0 \mid D = 1)$) and treatment on the untreated (TUT) ($E(Y_1 - Y_0 \mid D = 0)$). (The marginal treatment effect is formally defined in the next section.) These parameters can be identified from population means:

$$\text{TT} = \text{MTE} = \text{TUT} = \text{ATE} = E(Y_1 - Y_0) = E(Y_1) - E(Y_0).$$

Forming averages over populations of persons who are treated ($A = 1$) or untreated ($A = 0$) suffices to identify this parameter. If there are conditioning variables X, we can define the mean treatment parameters for all X where (R-1) or (R-2) or (R-3) hold.

Observe that even with random assignment of treatment status and full compliance, one cannot, in general, identify the distribution of the treatment effects

$(Y_1 - Y_0)$, although one can identify the marginal distributions $F_1(Y_1 \mid A = 1, X = x) = F_1(Y_1 \mid X = x)$ and $F_0(Y_0 \mid A = 0, X = x) = F_0(Y_0 \mid X = x)$. One special assumption, common in the conventional econometrics literature, is that $Y_1 - Y_0 = \Delta(x)$, a constant given x. Since $\Delta(x)$ can be identified from $E(Y_1 \mid A = 1, X = x) - E(Y_0 \mid A = 0, X = x)$ because A is randomly allocated, in this special case the analyst can identify the joint distribution of (Y_0, Y_1). (Heckman (1992); Heckman et al. (1997).) This approach assumes that (Y_0, Y_1) have the same distribution up to a parameter Δ (Y_0 and Y_1 are perfectly dependent). One can make other assumptions about the dependence across ranks from perfect positive or negative ranking to independence. (Heckman et al. (1997).) The joint distribution of (Y_0, Y_1) or of $(Y_1 - Y_0)$ is not identified unless the analyst can pin down the dependence across (Y_0, Y_1). Thus, even with data from a randomized trial one cannot, without further assumptions, identify the proportion of people who benefit from treatment in the sense of gross gain ($\Pr(Y_1 \geq Y_0)$). This problem plagues all evaluation methods. Abbring and Heckman (2007) discuss methods for identifying joint distributions of outcomes. (See also Aakvik et al. (2005); Carneiro et al. (2001, 2003); and Cunha et al. (2005).)

Assumption (R-1) is very strong. In many cases, it is thought that there is *selection bias* with respect to Y_0, Y_1, so persons who select into status 1 or 0 are selectively different from randomly sampled persons in the population. The assumption most commonly made to circumvent problems with (R-1) is that even though D is not random with respect to potential outcomes, the analyst has access to control variables X that effectively produce a randomization of D with respect to (Y_0, Y_1) given X. This is the method of matching, which is based on the following conditional independence assumption:

(M-1) $\quad (Y_0, Y_1) \perp\!\!\!\perp D \mid X.$

Conditioning on X randomizes D with respect to (Y_0, Y_1). (M-1) assumes that any selective sampling of (Y_0, Y_1) can be adjusted by conditioning on observed variables. (R-1) and (M-1) are different assumptions and neither implies the other. In a linear equations model, assumption (M-1) that D is independent from (Y_0, Y_1) given X justifies application of ▶least squares on D to eliminate selection bias in mean outcome parameters. For means, matching is just nonparametric regression. (Barnow et al. (1980) present one application of matching in a regression setting.) In order to be able to compare X-comparable people in the treatment regime one must assume

(M-2) $\quad 0 < \Pr(D = 1 \mid X = x) < 1.$

Assumptions (M-1) and (M-2) justify matching. Assumption (M-2) is required for *any* evaluation estimator that compares treated and untreated persons. It is produced by random assignment if the randomization is conducted for all $X = x$ and there is full compliance.

Observe that from (M-1) and (M-2), it is possible to identify $F_1(Y_1 \mid X = x)$ from the observed data $F_1(Y_1 \mid D = 1, X = x)$ since we observe the left hand side of

$$F_1(Y_1 \mid D = 1, X = x) = F_1(Y_1 \mid X = x) = F_1(Y_1 \mid D = 0, X = x).$$

The first equality is a consequence of conditional independence assumption (M-1). The second equality comes from (M-1) and (M-2). By a similar argument, we observe the left hand side of

$$F_0(Y_0 \mid D = 0, X = x) = F_0(Y_0 \mid X = x) = F_0(Y_0 \mid D = 1, X = x),$$

and the equalities are a consequence of (M-1) and (M-2). Since the pair of outcomes (Y_0, Y_1) is not identified for anyone, as in the case of data from randomized trials, the joint distributions of (Y_0, Y_1) given X or of $Y_1 - Y_0$ given X are not identified without further information. This is a problem that plagues all selection estimators.

From the data on Y_1 given X and $D = 1$ and the data on Y_0 given X and $D = 0$, since $E(Y_1 \mid D = 1, X = x) = E(Y_1 \mid X = x) = E(Y_1 \mid D = 0, X = x)$ and $E(Y_0 \mid D = 0, X = x) = E(Y_0 \mid X = x) = E(Y_0 \mid D = 1, X = x)$ we obtain

$$E(Y_1 - Y_0 \mid X = x) = E(Y_1 - Y_0 \mid D = 1, X = x) = E(Y_1 - Y_0 \mid D = 0, X = x).$$

Effectively, we have a randomization for the subset of the support of X satisfying (M-2).

At values of X that fail to satisfy (M-2), there is no variation in D given X. One can define the residual variation in D not accounted for by X as

$$\mathcal{E}(x) = D - E(D \mid X = x) = D - \Pr(D = 1 \mid X = x).$$

If the variance of $\mathcal{E}(x)$ is zero, it is not possible to construct contrasts in outcomes by treatment status for those X values and (M-2) is violated. To see the consequences of this violation in a regression setting, use $Y = Y_0 + D(Y_1 - Y_0)$ and take conditional expectations, under (M-1), to obtain

$$E(Y \mid X, D) = E(Y_0 \mid X) + D[E(Y_1 - Y_0 \mid X)].$$

This follows because $E(Y \mid X, D) = E(Y_0 \mid X, D) + DE(Y_1 - Y_0 \mid X, D)$ but from (M-1), $E(Y_0 \mid X, D) = E(Y_0 \mid X)$ and $E(Y_1 - Y_0 \mid X, D) = E(Y_1 - Y_0 \mid X)$. If $Var(\mathcal{E}(x)) > 0$

for all x in the support of X, one can use nonparametric least squares to identify $E(Y_1 - Y_0 \mid X = x)$ =ATE(x) by regressing Y on D and X. The function identified from the coefficient on D is the average treatment effect. (Under the conditional independence assumption (M-1), it is also the effect of treatment on the treated $E(Y_1 - Y_0 \mid X, D = 1)$ and the marginal treatment effect formally defined in the next section.) If $Var(\mathcal{E}(x)) = 0$, ATE(x) is not identified at that x value because there is no variation in D that is not fully explained by X. A special case of matching is linear least squares where one can write

$$Y_0 = X\alpha + U \qquad Y_1 = X\alpha + \beta + U,$$

$U_0 = U_1 = U$ and hence under (M-1),

$$E(Y \mid X, D) = X\alpha + \beta D.$$

If D is perfectly predictable by X, one cannot identify β because of a multicollinearity problem (see ▶Multicollinearity). (M-2) rules out perfect collinearity. (Clearly (M-1) and (M-2) are sufficient but not necessary conditions. For the special case of OLS, as a consequence of the assumed linearity in the functional form of the estimating equation, we achieve identification of β if $Cov(X, U) = 0$, $Cov(D, U) = 0$ and (D, X) are not perfectly collinear. These conditions are much weaker than (M-1) and (M-2) and can be satisfied if (M-1) and (M-2) are only identified in a subset of the support of X.) Matching is a nonparametric version of least squares that does not impose functional form assumptions on outcome equations, and that imposes support condition (M-2).

Conventional econometric choice models make a distinction between variables that appear in outcome equations (X) and variables that appear in choice equations (Z). The same variables may be in (X) and (Z) but more typically, there are some variables not in common. For example, the instrumental variable estimator is based on variables that are not in X but that are in Z. Matching makes no distinction between the X and the Z. (Heckman et al. (1998) distinguish X and Z in matching. They consider a case where conditioning on X may lead to failure of (M-1) and (M-2) but conditioning on (X, Z) satisfies a suitably modified version of this condition.) It does not rely on exclusion restrictions. The conditioning variables used to achieve conditional independence can in principle be a set of variables Q distinct from the X variables (covariates for outcomes) or the Z variables (covariates for choices). I use X solely to simplify the notation. The key identifying assumption is the assumed existence of a random variable X with the properties satisfying (M-1) and (M-2).

Conditioning on a larger vector (X augmented with additional variables) or a smaller vector (X with some components removed) may or may not produce suitably modified versions of (M-1) and (M-2). Without invoking further assumptions there is no objective principle for determining what conditioning variables produce (M-1).

Assumption (M-1) is strong. Many economists do not have enough faith in their data to invoke it. Assumption (M-2) is testable and requires no act of faith. To justify (M-1), it is necessary to appeal to the quality of the data.

Using economic theory can help guide the choice of an evaluation estimator. A crucial distinction is the one between the information available to the analyst and the information available to the agent whose outcomes are being studied. Assumptions made about these information sets drive the properties of econometric estimators. Analysts using matching make strong informational assumptions in terms of the data available to them. In fact, all econometric estimators make assumptions about the presence or absence of informational asymmetries, and I exposit them in this paper.

To analyze the informational assumptions invoked in matching, and other econometric evaluation strategies, it is helpful to introduce five distinct information sets and establish some relationships among them. (See also the discussion in Barros (1987), Heckman and Navarro (2004), and Gerfin and Lechner (2002).) (1) An information set $\sigma(I_R)$ with an associated random variable that satisfies conditional independence (M-1) is defined as a *relevant* information set; (2) The minimal information set $\sigma(I_R)$ with associated random variable needed to satisfy conditional independence (M-1), the *minimal relevant* information set; (3) The information set $\sigma(I_A)$ available to the agent at the time decisions to participate are made; (4) The information available to the economist, $\sigma(I_{E^*})$; and (5) The information $\sigma(I_E)$ used by the economist in conducting an empirical analysis. I will denote the random variables generated by these sets as $I_{R^*}, I_R, I_A, I_{E^*}, I_E$, respectively. (I start with a primitive probability space (Ω, σ, P) with associated random variables I. I assume minimal σ-algebras and assume that the random variables I are measurable with respect to these σ-algebras. Obviously, strictly monotonic or affine transformations of the I preserve the information and can substitute for the I.)

Definition 1 *Define $\sigma(I_{R^*})$ as a relevant information set if the information set is generated by the random variable I_{R^*}, possibly vector valued, and satisfies condition (M-1), so*

$$(Y_0, Y_1) \perp\!\!\!\perp D \mid I_{R^*}.$$

Definition 2 *Define $\sigma(I_R)$ as a minimal relevant information set if it is the intersection of all sets $\sigma(I_{R^*})$ and satisfies $(Y_0, Y_1) \perp\!\!\!\perp D \mid I_R$. The associated random variable I_R is a minimum amount of information that guarantees that condition (M-1) is satisfied. There may be no such set.* (Observe that the intersection of all sets $\sigma(I_{R^*})$ may be empty and hence may not be characterized by a (possibly vector valued) random variable I_R that guarantees $(Y_1, Y_2) \perp\!\!\!\perp D \mid I_R$. If the information sets that produce conditional independence are nested, then the intersection of all sets $\sigma(I_{R^*})$ producing conditional independence is well defined and has an associated random variable I_R with the required property, although it may not be unique (e.g., strictly monotonic transformations and affine transformations of I_R also preserve the property). In the more general case of non-nested information sets with the required property, it is possible that no uniquely defined minimal relevant set exists. Among collections of nested sets that possess the required property, there is a minimal set defined by intersection but there may be multiple minimal sets corresponding to each collection.)

If one defines the relevant information set as one that produces conditional independence, it may not be unique. If the set $\sigma(I_{R^*})$ satisfies the conditional independence condition, then the set $\sigma(I_{R^*}, Q)$ such that $Q \perp\!\!\!\perp (Y_0, Y_1) \mid I_{R^*}$ would also guarantee conditional independence. For this reason, I define the relevant information set to be minimal, that is, to be the intersection of all relevant sets that still produce conditional independence between (Y_0, Y_1) and D. However, no minimal set may exist.

Definition 3 *The agent's information set, $\sigma(I_A)$, is defined by the information I_A used by the agent when choosing among treatments. Accordingly, call I_A the agent's information.*

By the agent I mean the person making the treatment decision not necessarily the person whose outcomes are being studied (e.g., the agent may be the parent; the person being studied may be a child).

Definition 4 *The econometrician's full information set, $\sigma(I_{E^*})$, is defined as all of the information available to the econometrician, I_{E^*}.*

Definition 5 *The econometrician's information set, $\sigma(I_E)$, is defined by the information used by the econometrician when analyzing the agent's choice of treatment, I_E, in conducting an analysis.*

For the case where a unique minimal relevant information set exists, only three restrictions are implied by the structure of these sets: $\sigma(I_R) \subseteq \sigma(I_{R^*})$, $\sigma(I_R) \subseteq \sigma(I_A)$, and $\sigma(I_E) \subseteq \sigma(I_{E^*})$. (This formulation assumes that the agent makes the treatment decision. The extension to the case where the decision maker and the agent are distinct is straightforward. The requirement $\sigma(I_R) \subseteq \sigma(I_{R^*})$ is satisfied by nested sets.) I have already discussed the first restriction. The second restriction requires that the minimal relevant information set must be part of the information the agent uses when deciding which treatment to take or assign. It is the information in $\sigma(I_A)$ that gives rise to the selection problem which in turn gives rise to the evaluation problem.

The third restriction requires that the information used by the econometrician must be part of the information that the agent observes. Aside from these orderings, the econometrician's information set may be different from the agent's or the relevant information set. The econometrician may know something the agent doesn't know, for typically he is observing events after the decision is made. At the same time, there may be private information known to the agent but not the econometrician. Matching assumption (M-1) implies that $\sigma(I_R) \subseteq \sigma(I_E)$, so that the econometrician uses at least the minimal relevant information set, but of course he or she may use more. However, using more information is not guaranteed to produce a model with conditional independence property (M-1) satisfied for the augmented model. Thus an analyst can "overdo" it. Heckman and Navarro (2004) and Abbring and Heckman (2007) present examples of the consequences of the asymmetry in agent and analyst information sets.

The possibility of asymmetry in information between the agent making participation decisions and the observing economist creates the potential for a major identification problem that is ruled out by assumption (M-1). The methods of control functions and instrumental variables estimators (and closely related regression discontinuity design methods) address this problem but in different ways. Accounting for this possibility is a more conservative approach to the selection problem than the one taken by advocates of ▶least squares, or its nonparametric counterpart, matching. Those advocates assume that they know the X that produces a relevant information set. Heckman and Navarro (2004) show the biases that can result in matching when standard econometric model selection criteria are applied to pick the X that are used to satisfy (M-1). Conditional independence condition (M-1) cannot be tested without maintaining other assumptions. (These assumptions may or may not be testable. The required "exogeneity" conditions are discussed in Heckman and Navarro (2004). Thus randomization of assignment of treatment status might be used to test (M-1) but this requires that there be full compliance and that the

randomization be valid (no anticipation effects or general equilibrium effects).) Choice of the appropriate conditioning variables is a problem that plagues *all* econometric estimators.

The methods of control functions, replacement functions, proxy variables, and instrumental variables all recognize the possibility of asymmetry in information between the agent being studied and the econometrician and recognize that even after conditioning on X (variables in the outcome equation) and Z (variables affecting treatment choices, which may include the X), analysts may fail to satisfy conditional independence condition (M-1). (The term and concept of control function is due to Heckman and Robb (1985a,b, 1986a,b). See Blundell and Powell (2003) (who call the Heckman and Robb replacement functions control functions). A more recent nomenclature is "control variate." Matzkin (2007) provides a comprehensive discussion of identification principles for econometric estimators.) These methods postulate the existence of some unobservables θ, which may be vector valued, with the property that

(U-1) $(Y_0, Y_1) \perp\!\!\!\perp D \mid X, Z, \theta,$

but allow for the possibility that

(U-2) $(Y_0, Y_1) \not\perp\!\!\!\perp D \mid X, Z.$

In the event (U-2) holds, these approaches model the relationships of the unobservable θ with Y_1, Y_0 and D in various ways. The content in the control function principle is to specify the exact nature of the dependence on the relationship between observables and unobservables in a nontrivial fashion that is consistent with economic theory. Heckman and Navarro present examples of models that satisfy (U-1) but not (U-2).

The early literature focused on mean outcomes conditional on covariates (Heckman and Robb 1985a, b, 1986a, b) and assumes a weaker version of (U-1) based on conditional mean independence rather than full conditional independence. More recent work analyzes distributions of outcomes (e.g., Aakvik et al. 2005; Carneiro et al. 2001, 2003). This work is reviewed in Abbring and Heckman (2007).

The normal Roy selection model makes distributional assumptions and identifies the joint distribution of outcomes. A large literature surveyed by Matzkin (2007) makes alternative assumptions to satisfy (U-1) in nonparametric settings. Replacement functions (Heckman and Robb 1985a) are methods that proxy θ. They substitute out for θ using observables. (This is the "control variate" of Blundell and Powell (2003). Heckman and Robb (1985a) and Olley and Pakes (1996) use a similar idea. Matzkin (2007) discusses replacement functions.) Aakvik et al. (1999, 2005), Carneiro et al. (2001, 2003), Cunha et al. (2005), and Cunha et al. (2006, 2010) develop methods that integrate out θ from the model assuming $\theta \perp\!\!\!\perp (X, Z)$, or invoking weaker mean independence assumptions, and assuming access to proxy measurements for θ. They also consider methods for estimating the distributions of treatment effects. These are discussed in Abbring and Heckman (2007).

The normal selection model produces partial identification of a generalized Roy model and full identification of a Roy model under separability and normality. It models the conditional expectation of U_0 and U_1 given X, Z, D. In terms of (U-1), it models the conditional mean dependence of Y_0, Y_1 on D and θ given X and Z. Powell (1994) and Matzkin (2007) survey methods for producing semiparametric versions of these models. Heckman and Vytlacil (2007a, Appendix B) or the appendix of Heckman and Navarro (2007) present a prototypical identification proof for a general selection model that implements (U-1) by estimating the distribution of θ, assuming $\theta \perp\!\!\!\perp (X, Z)$, and invoking support conditions on (X, Z).

Central to both the selection approach and the instrumental variable approach for a model with heterogenous responses is the probability of selection. This is an integral part of the Roy model previously discussed. Let Z denote variables in the choice equation. Fixing Z at different values (denoted z), I define $D(z)$ as an indicator function that is "1" when treatment is selected at the fixed value of z and that is "0" otherwise. In terms of a separable index model $U_D = \mu_D(Z) - V$, for a fixed value of z,

$$D(z) = \mathbf{1}[\mu_D(z) \geq V]$$

where $Z \perp\!\!\!\perp V \mid X$. Thus fixing $Z = z$, values of z do not affect the realizations of V for any value of X. An alternative way of representing the independence between Z and V given X due to Imbens and Angrist (1994), writes that $D(z) \perp\!\!\!\perp Z$ for all $z \in \mathcal{Z}$, where $\mathcal{Z}$ is the support of Z. The Imbens and Angrist independence condition for IV is

$$\{D(z)\}_{z \in \mathcal{Z}} \perp\!\!\!\perp Z \mid X.$$

Thus the probabilities that $D(z) = 1, z \in \mathcal{Z}$ are not affected by the occurrence of Z. Vytlacil (2002) establishes the equivalence of these two formulations under general conditions. (See Heckman and Vytlacil (2007b) for a discussion of these conditions.)

The method of instrumental variables (IV) postulates that

(IV-1) $\left(Y_0, Y_1, \{D(z)\}_{z \in \mathcal{Z}}\right) \perp\!\!\!\perp Z \mid X.$ (*Independence*)

One consequence of this assumption is that $E(D \mid Z) = P(Z)$, the propensity score, is random with respect to potential outcomes. Thus $(Y_0, Y_1) \perp\!\!\!\perp P(Z) \mid X$. So are all other functions of Z given X. The method of instrumental variables also assumes that

(IV-2) $E(D \mid X, Z) = P(X, Z)$ *is a nondegenerate function of* Z *given* X. (*Rank Condition*)

Alternatively, one can write that $Var(E(D \mid X, Z)) \neq Var(E(D \mid X))$.

Comparing (IV-1) to (M-1) in the method of instrumental variables, Z is independent of (Y_0, Y_1) given X whereas in matching D is independent of (Y_0, Y_1) given X. So in (IV-1), Z plays the role of D in matching condition (M-1). Comparing (IV-2) with (M-2), in the method of IV the choice probability $\Pr(D = 1 \mid X, Z)$ is assumed to vary with Z conditional on X, whereas in matching, D varies conditional on X. Unlike the method of control functions, no explicit model of the relationship between D and (Y_0, Y_1) is required in applying IV.

(IV-2) is a rank condition and can be empirically verified. (IV-1) is not testable as it involves assumptions about counterfactuals. In a conventional common coefficient regression model

$$Y = \alpha + \beta D + U,$$

where β is a constant and where I allow for $Cov(D, U) \neq 0$, (IV-1) and (IV-2) identify β. $\left(\beta = \frac{Cov(Z,Y)}{Cov(Z,D)}.\right)$ When β varies in the population and is correlated with D, additional assumptions must be invoked for IV to identify interpretable parameters. Heckman et al. (2006) and Heckman and Vytlacil (2007b) discuss these conditions.

Assumptions (IV-1) and (IV-2), with additional assumptions in the case where β varies in the population which I discuss in this paper, can be used to identify mean treatment parameters. Replacing Y_1 with $\mathbf{1}(Y_1 \leq t)$ and Y_0 with $\mathbf{1}(Y_0 \leq t)$, where t is a constant, the IV approach allows us to identify marginal distributions $F_1(y_1 \mid X)$ or $F_0(y_0 \mid X)$.

In matching, the variation in D that arises after conditioning on X provides the source of randomness that switches people across treatment status. Nature is assumed to provide an experimental manipulation conditional on X that replaces the randomization assumed in (R-1)–(R-3). When D is perfectly predictable by X, there is no variation in it conditional on X, and the randomization assumed to be given by nature in the matching model breaks down. Heuristically, matching assumes a residual $\mathcal{E}(X) = D - E(D \mid X)$ that is nondegenerate and is one manifestation of the randomness that causes persons to switch status. (It is heuristically illuminating, but technically incorrect to replace $\mathcal{E}(X)$ with D in (R-1) or R in (R-2) or T in (R-3). In general $\mathcal{E}(X)$ is not independent of X even if it is mean independent.)

In the IV method, it is the choice probability $E(D \mid X, Z) = P(X, Z)$ that is random with respect to (Y_0, Y_1), not components of D not predictable by (X, Z). Variation in Z for a fixed X provides the required variation in D that switches treatment status and still produces the required conditional independence:

$$(Y_0, Y_1) \perp\!\!\!\perp P(X, Z) \mid X.$$

Variation in $P(X, Z)$ produces variations in D that switch treatment status. Components of variation in D not predictable by (X, Z) do not produce the required independence. Instead, the predicted component provides the required independence. It is just the opposite in matching. Versions of the method of control functions use measurements to proxy θ in (U-1) and (U-2) and remove spurious dependence that gives rise to selection problems. These are called replacement functions (see Heckman and Robb 1985a) or control variates (see Blundell and Powell 2003).

The methods of replacement functions and proxy variables all start from characterizations (U-1) and (U-2). θ is not observed and (Y_0, Y_1) are not observed directly but Y is observed:

$$Y = DY_1 + (1 - D) Y_0.$$

Missing variables θ produce selection bias which creates a problem with using observational data to evaluate social programs. From (U-1), if one conditions on θ, condition (M-1) for matching would be satisfied, and hence one could identify the parameters and distributions that can be identified if the conditions required for matching are satisfied.

The most direct approach to controlling for θ is to assume access to a function $\tau(X, Z, Q)$ that perfectly proxies θ:

$$\theta = \tau(X, Z, Q). \tag{10}$$

This approach based on a perfect proxy is called the method of replacement functions by Heckman and Robb (1985a). In (U-1), one can substitute for θ in terms of observables (X, Z, Q). Then

$$(Y_0, Y_1) \perp\!\!\!\perp D \mid X, Z, Q.$$

It is possible to condition nonparametrically on (X, Z, Q) and without having to know the exact functional form of τ. θ can be a vector and τ can be a vector of functions. This method has been used in the economics of education for decades (see the references in Heckman and Robb 1985a). If θ is ability and τ is a test score, it is sometimes assumed

that the test score is a perfect proxy (or replacement function) for θ and that one can enter it into the regressions of earnings on schooling to escape the problem of ability bias (typically assuming a linear relationship between τ and θ). (Thus if $\tau = \alpha_0 + \alpha_1 X + \alpha_2 Q + \alpha_3 Z + \theta$, one can write

$$\theta = \tau - \alpha_0 - \alpha_1 X - \alpha_2 Q - \alpha_3 Z,$$

and use this as the proxy function. Controlling for T, X, Q, Z controls for θ. Notice that one does not need to know the coefficients $(\alpha_0, \alpha_1, \alpha_2, \alpha_3)$ to implement the method, one can condition on X, Q, Z.) Heckman and Robb (1985a) discuss the literature that uses replacement functions in this way. Olley and Pakes (1996) apply this method and consider nonparametric identification of the τ function. Matzkin (2007) provides a rigorous proof of identification for this approach in a general nonparametric setting.

The method of replacement functions assumes that (10) is a perfect proxy. In many applications, this assumption is far too strong. More often, θ is measured with error. This produces a factor model or measurement error model (Aigner et al. 1984). Matzkin (2007) surveys this method. One can represent the factor model in a general way by a system of equations:

$$Y_j = g_j(X, Z, Q, \theta, \varepsilon_j), \quad j = 1, \ldots, J. \tag{11}$$

A linear factor model separable in the unobservables writes

$$Y_j = g_j(X, Z, Q) + \alpha_j \theta + \varepsilon_j, \quad j = 1, \ldots, J, \tag{12}$$

where

$$(X, Z, Q) \perp\!\!\!\perp (\theta, \varepsilon_j), \varepsilon_j \perp\!\!\!\perp \theta, \quad j = 1, \ldots, J, \tag{13}$$

and the ε_j are mutually independent. Observe that under (11) and (12), Y_j controlling for X, Z, Q only imperfectly proxies θ because of the presence of ε_j. θ is called a factor, α_j factor loadings and the ε_j "uniquenesses" (see e.g., Aigner 1985).

A large literature, reviewed in Abbring and Heckman (2007) and Matzkin (2007) shows how to establish identification of econometric models under factor structure assumptions. Cunha et al. (2010), Schennach (2004) and Hu and Schennach (2008) establish identification in nonlinear models of the form (11). (Cunha et al. (2006, 2010) apply and extend this approach to a dynamic factor setting where the θ_t are time dependent.) The key to identification is multiple, but imperfect (because of ε_j), measurements on θ from the Y_j, $j = 1, \ldots, J$ and X, Z, Q, and possibly other measurement systems that depend on θ. Carneiro et al. (2003), Cunha et al. (2005, 2006) and Cunha and Heckman (2007, 2008) apply and develop these methods. Under assumption (13), they show how to nonparametrically identify the econometric model and the distributions of the unobservables $F_\Theta(\theta)$ and $F_{\xi_j}(\varepsilon_j)$. In the context of classical simultaneous equations models, identification is secured by using covariance restrictions across equations exploiting the low dimensionality of vector θ compared to the high dimensional vector of (imperfect) measurements on it. The recent literature (Cunha et al. 2003; Cunha et al. 2010; Hu and Schennach 2008) extends the linear model to a nonlinear setting.

The recent econometric literature applies in special cases the idea of the control function principle introduced in Heckman and Robb (1985a). This principle, versions of which can be traced back to Telser (1964), partitions θ in (U-1) into two or more components, $\theta = (\theta_1, \theta_2)$, where only one component of θ is the source of bias. Thus it is assumed that (U-1) is true, and (U-1)′ is also true:

$$\text{(U-1)}' \quad (Y_0, Y_1) \perp\!\!\!\perp D \mid X, Z, \theta_1,$$

and (U-2) holds. For example, in a normal selection model with additive separability, one can break U_1, the error term associated with Y_1, into two components:

$$U_1 = E(U_1 \mid V) + \varepsilon,$$

where V plays the role of θ_1 and is associated with the choice equation. Under normality, ε is independent of $E(U_1 \mid V)$. Further,

$$E(U_1 \mid V) = \frac{Cov(U_1, V)}{Var(V)} V, \tag{14}$$

assuming $E(U_1) = 0$ and $E(V) = 0$. Heckman and Robb (1985a) show how to construct a control function in the context of the choice model

$$D = \mathbf{1}[\mu_D(Z) > V].$$

Controlling for V controls for the component of θ_1 in (U-1)′ that gives rise to the spurious dependence. The Blundell and Powell (2003, 2004) application of the control function principle assumes functional form (14) but assumes that V can be perfectly proxied by a first stage equation. Thus they use a replacement function in their first stage. Their method does not work when one can only condition on D rather than on $D^* = \mu_D(Z) - V$ instead of directly measuring it. (Imbens and Newey (2002) extend their approach. See the discussion in Matzkin (2007).) In the sample selection model, it is not necessary to identify V. As developed in Heckman and Robb (1985a) and

Heckman and Vytlacil (2007a, b), under additive separability for the outcome equation for Y_1, one can write

$$E(Y_1 \mid X, Z, D = 1) = \mu_1(X) + \underbrace{E(U_1 \mid \mu_D(Z) > V)}_{\text{control function}},$$

so the analyst "expects out" rather than solve out the effect of the component of V on U_1 and thus control for selection bias under the maintained assumptions. In terms of the propensity score, under the conditions specified in Heckman and Vytlacil (2007a), one may write the preceding expression in terms of $P(Z)$:

$$E(Y_1 \mid X, Z, D = 1) = \mu_1(X) + K_1(P(Z)),$$

where $K_1(P(Z)) = E(U_1 \mid X, Z, D = 1)$. It is not literally necessary to know V or be able to estimate it. The Blundell and Powell (2003, 2004) application of the control function principle assumes that the analyst can condition on and estimate V.

The Blundell and Powell method and the method of Imbens and Newey (2002) build heavily on (14) and implicitly make strong distributional and functional form assumptions that are not intrinsic to the method of control functions. As just noted, their method uses a replacement function to obtain $E(U_1 \mid V)$ in the first step of their procedures. The general control function method does not require a replacement function approach. The literature has begun to distinguish between the more general control function approach and the *control variate* approach that uses a first stage replacement function.

Matzkin (2003) develops the method of unobservable instruments which is a version of the replacement function approach applied to ▶nonlinear models. Her unobservable instruments play the role of covariance restrictions used to identify classical simultaneous equations models (see Fisher, 1966). Her approach is distinct from and therefore complementary with linear factor models. Instead of assuming $(X, Z, Q) \perp\!\!\!\perp (\theta, \varepsilon_j)$, she assumes in a two equation system that $(\theta, \varepsilon_1) \perp\!\!\!\perp Y_2 \mid Y_1, X, Z$. See Matzkin (2007).

I do not discuss panel data methods in this paper. The most commonly used panel data method is difference-in-differences as discussed in Heckman and Robb (1985a), Blundell et al. (1998), Heckman et al. (1999), and Bertrand et al. (2004), to cite only a few of the key papers. Most of the estimators I have discussed can be adapted to a panel data setting. Heckman et al. (1998) develop difference-in-differences matching estimators. Abadie (2002) extends this work. (There is related work by Athey and Imbens (2006), which exposits the Heckman et al. (1998) difference-in-differences matching estimator.) Separability between errors and observables is a key feature of the panel data approach in its standard application. Altonji and Matzkin (2005) and Matzkin (2003) present analyses of nonseparable panel data methods. Regression discontinuity estimators, which are versions of IV estimators, are discussed by Heckman and Vytlacil (2007b).

Table 3 summarizes some of the main lessons of this section. I stress that the stated conditions are necessary conditions. There are many versions of the IV and control functions principle and extensions of these ideas which refine these basic postulates. See Heckman and Vytlacil (2007b). Matzkin (2007) is an additional reference on sources of identification in econometric models.

I next introduce the generalized Roy model and the concept of the marginal treatment effect which helps to link the econometric literature to the statistical literature. The Roy model also provides a framework for thinking about the difference in information between the agents and the statistician.

Matching

The method of matching is widely-used in statistics. It is based on strong assumptions which often make its application to economic data questionable. Because of its popularity, I single it out for attention. The method of matching assumes selection of treatment based on potential outcomes

$$(Y_0, Y_1) \not\perp\!\!\!\perp D,$$

so $\Pr(D = 1 \mid Y_0, Y_1)$ depends on Y_0, Y_1. It assumes access to variables Q such that conditioning on Q removes the dependence:

$$(Y_0, Y_1) \perp\!\!\!\perp D \mid Q. \qquad \text{(Q-1)}$$

Thus,

$$\Pr(D = 1 \mid Q, Y_0, Y_1) = \Pr(D = 1 \mid Q).$$

Comparisons between treated and untreated can be made at all points in the support of Q such that

$$0 < \Pr(D = 1 \mid Q) < 1. \qquad \text{(Q-2)}$$

The method does not explicitly model choices of treatment or the subjective evaluations of participants, nor is there any distinction between the variables in the outcome equations (X) and the variables in the choice equations (Z) that is central to the IV method and the method of control functions. In principle, condition (Q-1) can be satisfied using a set of variables Q distinct from all or some of the components of X and Z. The conditioning variables do not have to be exogenous.

Principles Underlying Econometric Estimators for Identifying Causal Effects. Table 3 Identifying assumptions under commonly used methods

	Identifying assumptions	Identifies marginal distributions?	Exclusion condition needed?
Random assignment	$(Y_0, Y_1) \perp\!\!\!\perp \xi, \xi = 1 \Longrightarrow A = 1, \xi = 0 \Longrightarrow A = 0$ (full compliance) Alternatively, if self-selection is random with with respect to outcomes, $(Y_0, Y_1) \perp\!\!\!\perp D$. Assignment can be conditional on X.	Yes	No
Matching	$(Y_0, Y_1) \not\perp\!\!\!\perp D$, but $(Y_0, Y_1) \perp\!\!\!\perp D \mid X$, $0 < \Pr(D = 1 \mid X) < 1$ for all X So D conditional on X is a nondegenerate random variable	Yes	No
Control functions and extensions	$(Y_0, Y_1) \not\perp\!\!\!\perp D \mid X, Z$, but $(Y_1, Y_0) \perp\!\!\!\perp D \mid X, Z, \theta$. The method models dependence induced by θ or else proxies θ (replacement function) Version (i) Replacement functions (substitute out θ by observables) (Blundell and Powell, 2003; Heckman and Robb, 1985b; Olley and Pakes, 1996). Factor models Carneiro et al., (2003) allow for measurement error in the proxies. Version (ii) Integrate out θ assuming $\theta \perp\!\!\!\perp (X, Z)$ (Aakvik et al., 2005; Carneiro et al., 2003) Version (iii) For separable models for mean response expect θ conditional on X, Z, D as in standard selection models (control functions in the same sense of Heckman and Robb).	Yes	Yes (for semiparametric models)
IV	$(Y_0, Y_1) \not\perp\!\!\!\perp D \mid X, Z$, but $(Y_1, Y_0) \perp\!\!\!\perp Z \mid X$, $\Pr(D = 1 \mid Z)$ is a nondegenerate function of Z	Yes	Yes

(Y_0, Y_1) are potential outcomes that depend on X

$$D = \begin{cases} 1 \text{ if assigned (or choose) status 1} \\ 0 \text{ otherwise} \end{cases}$$

Z are determinants of D, θ is a vector of unobservables

For random assignments, A is a vector of actual treatment status. $A = 1$ if treated; $A = 0$ if not.

$\xi = 1$ if a person is randomized to treatment status; $\xi = 0$ otherwise (Heckman and Vytlacil 2007b)

From condition (Q-1) one recovers the distributions of Y_0 and Y_1 given Q – $\Pr(Y_0 \le y_0 \mid Q = q) = F_0(y_0 \mid Q = q)$ and $\Pr(Y_1 \le y_1 \mid Q = q) = F_1(y_1 \mid Q = q)$ – but not the joint distribution $F_{0,1}(y_0, y_1 \mid Q = q)$, because the analyst does not observe the same persons in the treated and untreated states. This is a standard evaluation problem common to all econometric estimators. Methods for determining which variables belong in Q rely on untested exogeneity assumptions which we discuss in this section.

OLS is a special case of matching that focuses on the identification of conditional means. In OLS linear functional forms are maintained as exact representations or valid approximations. Considering a common coefficient model, OLS writes

$$Y = \pi Q + D\alpha + U, \tag{Q-3}$$

where α is the treatment effect and

$$E(U \mid Q, D) = 0. \tag{Q-4}$$

The assumption is made that the variance-covariance matrix of (Q, D) is of full rank:

$$Var(Q, D) \text{ full rank.} \tag{Q-5}$$

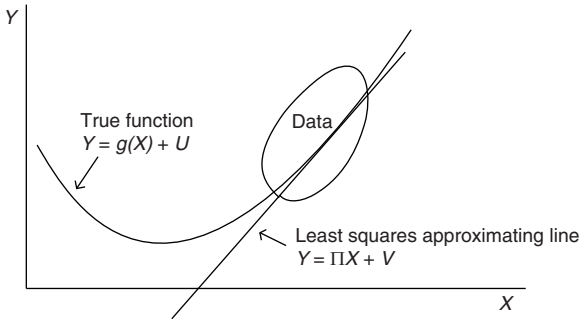
Under these conditions, one can identify α even though D and U are dependent: $D \not\perp\!\!\!\perp U$. Controlling for the observable Q eliminates any spurious mean dependence between D and U: $E(U \mid D) \neq 0$ but $E(U \mid D, Q) = 0$. (Q-3) is the linear regression counterpart to (Q-1). (Q-5) is the linear regression counterpart to (Q-2). Failure of (Q-5) would mean that using a nonparametric estimator one might perfectly predict D given Q, and that $\Pr(D = 1 \mid Q = q) = 1$ or 0. (This condition might be met only at certain values of $Q = q$. For certain parameterizations (e.g., the linear probability model), one may obtain predicted probabilities outside the unit interval.)

Matching can be implemented as a nonparametric method. When this is done, the procedure does not require specification of the functional form of the outcome equations. It enforces the requirement that (Q-2) be satisfied by estimating functions pointwise in the support of Q. Assume that $Q = (X, Z)$ and that X and Z are the same except where otherwise noted. Thus I invoke assumptions (M-1) and (M-2) presented in section "►The Basic Principles Underlying the Identification of the Leading Econometric Evaluation Estimators", even though in principle one can use a more general conditioning set.

Assumptions (M-1) and (M-2) or (Q-1) and (Q-2) rule out the possibility that after conditioning on X (or Q), agents possess more information about their choices than econometricians, and that the unobserved information helps to predict the potential outcomes. Put another way, the method allows for potential outcomes to affect choices but only through the observed variables, Q, that predict outcomes. This is the reason why Heckman and Robb (1985a, 1986b) call the method selection on observables.

Heckman and Vytlacil (2007b) establish the following points. (1) Matching assumptions (M-1) and (M-2) generically imply a flat MTE in u_D, i.e., they assume that $E(Y_1 - Y_0 \mid X = x, U_D = u_D)$ does not depend on u_D. Thus the unobservables central to the Roy model and its extensions and the unobservables central to the modern IV literature are assumed to be absent once the analyst conditions on X. (M-1) implies that all mean treatment parameters are the same. (2) Even if one weakens (M-1) and (M-2) to mean independence instead of full independence, generically the MTE is flat in u_D under the assumptions of the nonparametric generalized Roy model developed in section "►An Index Model of Choice and Treatment Effects: Definitions and Unifying Principles", so again all mean treatment parameters are the same. (3) IV and matching make distinct identifying assumptions even though they both invoke conditional independence assumptions. (4) Comparing matching with IV and control function (sample selection) methods, matching assumes that conditioning on observables eliminates the dependence between (Y_0, Y_1) and D. The control function principle models the dependence. (5) Heckman and Navarro (2004) and Heckman and Vytlacil (2007b) demonstrate that if the assumptions of the method of matching are violated, the method can produce substantially biased estimators of the parameters of interest. (6) Standard methods for selecting the conditioning variables used in matching assume exogeneity. Violations of the exogeneity assumption can produce biased estimators.

Nonparametric versions of matching embodying (M-2) avoid the problem of making inferences outside the support of the data. This problem is implicit in any application of least squares. Figure 7 shows the support problem that can arise in linear least squares when the linearity of the regression is used to extrapolate estimates determined in one empirical support to new supports. Careful attention to support problems is a virtue of any nonparametric method, including, but not unique to, nonparametric matching. Heckman, Ichimura, Smith, and Todd (1998)



Principles Underlying Econometric Estimators for Identifying Causal Effects. Fig. 7 The least squares extrapolation problem avoided by using nonparametric regression or matching (Heckman and Vytlacil 2007b)

show that the bias from neglecting the problem of limited support can be substantial. See also the discussion in Heckman, LaLonde, and Smith (1999).

Summary

This paper exposits the basic economic model of causality and compares it to models in statistics. It exposits the key identifying assumptions of commonly used econometric estimators for causal inference. The emphasis is on the economic content of these assumptions. I discuss how matching makes strong assumption about the information available to economist/statistician.

Prior Bayes: Rubin's View of Statistics

Herman Rubin
Purdue University, West Lafayette, IN, USA

Introduction

What is statistics? The common way of looking at it is a collection of methods, somehow or other produced, and one should use one of those methods for a given set of data. The typical user who has little more than this comes to a statistician asking for THE answer, as if the data are sufficient to get this without knowing the problem.

No; the first thing is to formulate the problem. One cannot do better than to assume that there is an unknown state of nature, that there is a probability distribution of observations given a state of nature, a set of possible actions, and that each action in each state of nature has (possibly random) consequences.

Following the von Neumann–Morgenstern (1944) axioms for utility, in 1947 (see Rubin 1987a) I was able to show that if one has a self-consistent evaluation of actions in each state of nature, the utility function for an unknown state of nature has to be an integral of the utilities for the states of nature. Another way of looking at this in the discrete case is that one assigns a weight to each result in each state of nature, and should choose the action which produces the best sum; this generalizes to the best value of the integral. This is the prior Bayes approach.

Let us simplify to the usual Bayes model; it can be generalized to include more, and in fact, must be for the infinite parametric (usually called non-parametric) problems encountered.

So the quantity to be minimized is

$$\int \int L(\omega, q(x))d\mu(x|\omega)d\xi(\omega).$$

If this integral is finite, and if, for example, L is positive, the integration can be interchanged and the result written as

$$\int \int L(\omega, q(x))d\phi(\omega|x)dm(x),$$

and if the properties of q for different x are unrestricted, one can (hopefully) use the usual Bayes proceduce of minimizing the inner integral.

But this can require a huge amount of computing power, possibly even exceeding the capacity of the universe,and sufficient assurance that one has a sufficiently good approximation to the loss-prior combination. One use this latter because it is only the product of L and ξ which is relevant. One can try to approximate, but posterior robustness results are hard, and often impossible, to come by.

On the other hand, the prior Bayes approach can show what is and what is not important, and can, in many cases, provide methods which are not much worse than full Bayes methods, or at least the approximations made. One might question how this can be shown, considering that the full Bayes procedure cannot be calculated; however, a smaller problem with one which can be calculated might be shown to come close. Also, one can get procedures which are good with considerable uncertainty about the prior distribution of the parameter.

Results and Examples

Some early approaches, some by those not believing in the Bayes approach, were the empirical Bayes results of Robbins and his followers. Empirical Bayes extends much farther now, and it is in the spirit of prior Bayes, as the performance of the procedures is what is considered. There is a large literature on this, and I will not go into it in any great detail.

Suppose we consider the case of the usual test of a point null, when the distribution is normal. If we assume the prior is symmetric, we need only consider procedures which accept if the mean is close enough to the null, and reject otherwise. If we assume that the prior gives a point mass at the null, and is otherwise given by a smooth density, the prior Bayes risk is

$$\xi(\{0\})P(|X > c|0) + \int Q(\omega)h(\omega)P(|X| \le c|\omega)d\omega,$$

where Q is the loss of incorrect acceptance.

This shows that the tails of the prior distribution are essentially irrelevant if the variance is at all small, so the prior probability of the null is NOT an important consideration. Only the ratio of the probability of the null to the density at the null of the alternative is important. This shows that the large-sample results of Rubin and Sethuraman (1965) can be a good approximation for moderate, or even small, samples. It also shows how the "p-value" should change with the sample size. An expository paper is in preparation.

If the null is not a point null, this is still a good approximation if the width of the null is smaller than the standard deviation of the observations; if it is not, the problem is much harder, and the form of the loss-prior combination under the null becomes of considerable importance. Again, the prior Bayes approach shows where the problem lies, in the behavior of the loss-prior combination near the division point between accepptance and rejection. In "standard" units, a substantial part of the parameter space may be involved.

For another example, consider the problem of estimating an infinite dimensional normal mean with the covariance matrix a multiple of the identity, or the similar problem of estimating a spectral density function. The first problem was considereed by Rubin (1987b), and was corrrected in Hui Xu's thesis in 2008. If one assumes the prior mean square of the kth mean, or the corresponding Fourier coefficient, is non-increasing, an empirical Bayes type result can be obtained, and can be shown to be asymptotically optimal in the class of "simple" procedures, which are the ones currently being used with more stringent assumptions, and which are generally not as good. The results are good even if the precise form is not known, while picking a kernel is much more restrictive and generally not even asymptotically optimal.

For the latter problem, obtaining a reasonable prior seems to be extremely difficult, but the simple procedures obtained are likely to be rather good even if one is found. The positive definiteness of the Toeplitz matrix of the covariances is a difficult condition to work with.

I see a major set of applications to non-parametric problems, properly called infinite parametric, problems such as density estimation, testing with infinite dimensional alternatives, etc. With a large number of dimensions, the classical approach does not work well, and the only "simple Bayesian" approaches use priors which look highly constrained to me.

About the Author

"Professor Rubin has contributed in deep and original ways to statistical theory and philosophy. The statistical community has been vastly enriched by his contributions through his own research and through his influence, direct or indirect on the research and thinking of others." Erich Marchard and William Strawdeman, *A festschrift for Herman Rubin*, A. DasGupta (ed.), p. 21. "He is well known for his broad ranging mathematical research interests and for fundamental contributions in Bayesian decision theory, in set theory, in estimations for simultaneous equations, in probability and in asymptotic statistics." Mary Ellen Block, Ibid. p. 408. Professor Rubin is a Fellow of the IMS, and a Fellow of the AAAS (American Association for the Advancement of Science).

Probabilistic Network Models

Ove Frank
Professor Emeritus
Stockholm University, Stockholm, Sweden

A network on vertex set V is represented by a function y on the set V^2 of ordered vertex pairs. The function can be univariate or multivariate and its variables can be numerical or categorical. A graph G with vertex set V and edge set E in V^2 is represented by a binary function $y = \{(u, v, y_{uv}) : (u, v) \in V^2\}$ where y_{uv} indicates whether $(u, v) \in E$. If $V = \{1, \ldots, N\}$ and vertices are ordered according to their labels, y can be given as an N by N adjacency matrix $y = (y_{uv})$. Simple undirected graphs have $y_{uv} = y_{vu}$ and $y_{vv} = 0$ for all u and v. Colored graphs have a categorical variable y with the categories labeled by colors. Graphs with more general variables y are called valued graphs or networks. If Y is a random variable with outcomes y representing networks in a specified family of networks, the probability distribution induced on this family is a probabilistic network model and Y is a representation of a random network.

Simple random graphs are defined with uniform distributions or Bernoulli distributions. Uniform models assign

equal probabilities to all graphs in a specified finite family of graphs, such as all graphs of order N and size M, or all connected graphs of order N, or all trees of order N. Bernoulli graphs (Bernoulli digraphs) have edge indicators that are independent Bernoulli variables for all unordered (ordered) vertex pairs. There is an extensive literature on such random graphs, especially on the simplest Bernoulli (p) graph, which has a common edge probability p for all vertex pairs. An extension of a fixed graph G to a Bernoulli (G, α, β) graph is a Bernoulli graph that is obtained by independently removing edges in G with probability α and independently inserting edges in the complement of G with probability β. Such models have been applied to study reliability problems in communication networks. Attempts to model the web have recently contributed to an interest in random graph models with specified degree distributions and random graph processes for very large dynamically changing graphs.

The literature on social networks describes models for finite random digraphs on $V = \{1, \ldots, N\}$ in which dyads (Y_{uv}, Y_{vu}) for $u < v$ are independent and have probabilities that depend on parameters governing in- and out-edges of each vertex and mutual edges of each vertex pair. Special cases of such models with independent dyads are obtained by assuming homogeneity for the parameters of different vertices or different groups of vertices. Extensions to models with dependent dyads include Markov graphs that allow dependence between incident dyads. Other extensions are log-linear models that assume that the log-likelihood function is a linear function of specified network statistics chosen to reflect various properties of interest in the network.

Statistical analysis of network data comprise exploratory tools for selecting appropriate probabilistic network models as well as confirmatory tools for estimating and testing various models. Many of these tools use computer intensive methods.

Applications of probabilistic network models appear in many different areas in which relationships between the units studied are essential for an understanding of their properties and characteristics. The social and behavioral sciences have contributed to the development of many network models for the study of social interaction, friendship, dominance, co-operation and competition. There are applications to criminal networks and co-offending, communication and transportation networks, vaccination programs in epidemiology, information retrieval and organizational systems, particle systems in physics, biometric cell systems. Random graphs and random fields are also theoretically developed in computer science, mathematics, and statistics. There is an exciting interplay between model development and new applications in a variety of important areas.

Many references to the literature on graphs, random graphs, and random networks are provided by the following sources.

Probability on Compact Lie Groups

David Applebaum
Professor, Head
University of Sheffield, Sheffield, UK

Introduction

Probability on groups enables us to study the interaction between chance and symmetry. In this article I'll focus on the case where symmetry is generated by continuous groups, specifically compact Lie groups. This class contains many examples such as the n-torus, special orthogonal groups $SO(n)$ and special unitary groups $SU(n)$ which are important in physics and engineering applications. It is also a very good context to demonstrate the key role played by non-commutative harmonic analysis via group representations. The classic treatise (Heyer 1977) by Heyer gives a systematic mathematical introduction to this topic while

Diaconis (1988) presents a wealth of concrete examples in both probability and statistics.

For motivation, let ρ be a probability measure on the real line. Its characteristic function $\widehat{\rho}$ is the Fourier transform $\widehat{\rho}(u) = \int_{\mathbb{R}} e^{iux}\rho(dx)$ and $\widehat{\rho}$ uniquely determines ρ. Note that the mappings $x \to e^{iux}$ are the irreducible unitary representations of $\mathbb{R}$.

Now let G be a compact Lie group and ρ be a probability measure defined on G. The group law of G will be written multiplicatively. If we are given a probability space $(\Omega, \mathcal{F}, P)$ then ρ might be the law of a G-valued random variable defined on Ω. The *convolution* of two such measures ρ_1 and ρ_2 is the unique probability measure $\rho_1 * \rho_2$ on G such that

$$\int_G f(\sigma)(\rho_1 * \rho_2)(d\sigma) = \int_G \int_G f(\sigma\tau)\rho_1(d\sigma)\rho_2(d\tau),$$

for all continuous functions f defined on G. If X_1 and X_2 are independent G-valued random variables with laws ρ_1 and ρ_2 (respectively), then $\rho_1 * \rho_2$ is the law of X_1X_2.

Characteristic Functions

Let $\widehat{G}$ be the set of all irreducible unitary representations of G. Since G is compact, $\widehat{G}$ is countable. For each $\pi \in \widehat{G}, \sigma \in G, \pi(\sigma)$ is a unitary (square) matrix acting on a finite dimensional complex inner product space V_π having dimension d_π. Every group has the trivial representation δ acting on $\mathbb{C}$ by $\delta(\sigma) = 1$ for all $\sigma \in G$. The *characteristic function* of the probability measure ρ is the matrix-valued function $\widehat{\rho}$ on $\widehat{G}$ defined uniquely by

$$\langle u, \widehat{\rho}(\pi)v\rangle = \int_G \langle u, \pi(\tau)v\rangle\rho(d\tau),$$

for all $u, v \in V_\pi$. $\widehat{\rho}$ has a number of desirable properties (Siebert 1981). It determines ρ uniquely and for all $\pi \in \widehat{G}$:

$$\widehat{\rho_1 * \rho_2}(\pi) = \widehat{\rho}_1(\pi)\widehat{\rho}_2(\pi).$$

In particular $\widehat{\delta} = 1$.

Lo and Ng (1988) considered a family of matrices $(C_\pi, \pi \in \widehat{G})$ and asked when there is a probability measure ρ on G such that $C_\pi = \widehat{\rho}(\pi)$. They found a necessary and sufficient condition to be that $C_\delta = 1$ and that the following non-negativity condition holds: for all families of matrices $(B_\pi, \pi \in \widehat{G})$ where B_π acts on V_π and for which $\sum_{\pi\in S_\pi} d_\pi \mathrm{tr}(\pi(\sigma)B_\pi) \geq 0$ for all $\sigma \in G$ and all finite subsets S_π of V_π we must have $\sum_{\pi\in S_\pi} d_\pi \mathrm{tr}(\pi(\sigma)C_\pi B_\pi) \geq 0$.

Densities

Every compact group has a bi-invariant finite Haar measure which plays the role of Lebesgue measure on $\mathbb{R}^d$ and which is unique up to multiplication by a positive real number. It is convenient to normalise this measure (so it has total mass 1) and denote it by $d\tau$ inside integrals of functions of τ. We say that a probability measure ρ has a *density* f if $\rho(A) = \int_A f(\tau)d\tau$ for all Borel sets A in G. To investigate existence of densities we need the *Peter–Weyl theorem* that the set of functions $\left\{d_\pi^{\frac{1}{2}}\pi_{ij}; 1 \leq i, j \leq d_\pi, \pi \in \widehat{G}\right\}$ are a complete orthonormal basis for $L^2(G, \mathbb{C})$. So any $f \in L^2(G, \mathbb{C})$ can be written

$$f(\sigma) = \sum_{\pi\in\widehat{G}} d_\pi \mathrm{tr}(\pi(\sigma)\widehat{f}(\pi)), \tag{1}$$

where $\widehat{f}(\pi) = \int_G f(\tau)\pi(\tau^{-1})d\tau$ is the Fourier transform. In Applebaum (2008) it was shown that ρ has a square-integrable density f (which then has an expansion as in (1)) if and only if $\sum_{\pi\in\widehat{G}} d_\pi \mathrm{tr}(\widehat{\rho}(\pi)\widehat{\rho}(\pi)^*) < \infty$ where * is the usual matrix adjoint. A sufficient condition for ρ to have a continuous density is that $\sum_{\pi\in\widehat{G}} d_\pi^{\frac{3}{2}} |\mathrm{tr}(\widehat{\rho}(\pi)\widehat{\rho}(\pi)^*)|^{\frac{1}{2}} < \infty$ in which case the series on the right hand side of (0.1) converges absolutely and uniformly (see Proposition 6.6.1 on pp. 117–118 of Faraut [2008]).

Conjugate Invariant Probabilities

Many interesting examples of probability measures are conjugate invariant, i.e., $\rho(\sigma A\sigma^{-1}) = \rho(A)$ for all $\sigma \in G$. In this case there exists $c_\pi \in \mathbb{C}$ such that $\widehat{\rho}(\pi) = c_\pi I_\pi$ where I_π is the identity matrix in V_π (Said et al. 2010). If a density exists it takes the form $f(\sigma) = \sum_{\pi\in\widehat{G}} d_\pi \overline{c_\pi}\chi_\pi(\sigma)$, where $\chi_\pi(\sigma) = \mathrm{tr}(\pi(\sigma))$ is the group character.

Example 1 *Gauss Measure.* Here $c_\pi = e^{\sigma^2\kappa_\pi}$ where $\kappa_\pi \leq 0$ is the eigenvalue of the group Laplacian corresponding to the Casimir operator $\kappa_\pi I_\pi$ on V_π and $\sigma > 0$. For example if $G = SU(2)$ then it can be parametrized by the Euler angles ψ, ϕ and θ, $\widehat{G} = \mathbb{Z}_+$, $\kappa_m = -m(m+2)$ and we have a continuous density depending only on $0 \leq \theta \leq \frac{\pi}{2}$:

$$f(\theta) = \sum_{m=0}^{\infty} (m+1)e^{-\sigma^2 m(m+2)} \frac{\sin((m+1)\theta)}{\sin(\theta)}.$$

Example 2 *Laplace Distribution.* This is a generalization of the double exponential distribution on $\mathbb{R}$ (with equal parameters). In this case $c_\pi = (1 - \beta^2\kappa_\pi)^{-1}$ where $\beta > 0$ and κ_π is as above.

Infinite Divisibility

A probability measure ρ on G is *infinitely divisible* if for each $n \in \mathbb{N}$ there exists a probability measure $\rho^{\frac{1}{n}}$ on G such that the nth convolution power $\left(\rho^{\frac{1}{n}}\right)^{*n} = \rho$. Equivalently $\widehat{\rho}(\pi) = \widehat{\rho^{\frac{1}{n}}}(\pi)^n$ for all $\pi \in \widehat{G}$. If G is connected as well as compact any such ρ can be realised as μ_1 in

a weakly continuous convolution semigroup of probability measures $(\mu_t, t \geq 0)$. For a general Lie group, such an *embedding* may not be possible and the investigation of this question has generated much research over more than 30 years (McCrudden 1998). The structure of convolution semigroups has been intensely analyzed. These give the laws of group-valued ►*Lévy processes*, i.e., processes with stationary and independent increments (Liao 2004). In particular there is a Lévy–Khintchine type formula (originally due to G.A.Hunt) which classifies these in terms of the structure of the infinitesimal generator of the associated Markov semigroup that acts on the space of continuous functions. One of the most important examples is Brownian motion (see ►Brownian Motion and Diffusions) and this has a Gaussian distribution. Another important example is the *compound Poisson process* (see ►Poisson Processes)

$$Y(t) = X_1 X_2 \cdots X_{N(t)} \tag{2}$$

where $(X_n, n \in \mathbb{N})$ is a sequence of i.i.d. random variables having common law ν (say) and $(N(t), t \geq 0)$ is an independent Poisson process of intensity $\lambda > 0$. In this case $\mu_t = \sum_{n=0}^{\infty} e^{-\lambda t} \frac{(\lambda t)^n}{n!} \nu^{*n}$. Note that μ_t does not have a density and it is conjugate invariant if ν is.

Applications

There is intense interest among statisticians and engineers in the *deconvolution problem* on groups. The problem is to estimate the signal density f_X from the observed density f_Y when the former is corrupted by independent noise having density f_ϵ, so the model is $Y = X\epsilon$ and the inverse problem is to untangle $f_Y = f_X * f_\epsilon$. Inverting the characteristic function enables the construction of non-parametric estimators for f_X and optimal rates of convergence are known for these when f_ϵ has certain smoothness properties (Kim and Richards 2001; Koo and Kim 2008). In Said et al. (2010) the authors consider the problem of *decompounding*, i.e., to obtain non-parametric estimates of the density of X_1 in (2) based on i.i.d. observations of a noisy version of Y: $Z(t) = \epsilon Y(t)$, where ϵ is independent of $Y(t)$. This is applied to multiple scattering of waves from complex media by working with the group $SO(3)$ which acts as rotations on the sphere.

About the Author

David Applebaum is Professor of Probability and Statistics and is currently Head of the Department of Probability and Statistics, University of Sheffield UK. He has published over 60 research papers and is the author of two books, *Probability and Information* (second edition), Cambridge University Press (1996, 2008) and *Lévy Processes and Stochastic Calculus* (second edition), Cambridge University Press (2004, 2009). He is joint managing editor of the *Tbilsi Mathematical Journal* and associate editor for *Bernoulli*, *Methodology and Computing in Applied Probability*, *Journal of Stochastic Analysis and Applications* and *Communications on Stochastic Analysis*. He is a member of the Atlantis Press Advisory Board for Probability and Statistics Studies.

Probability Theory: An Outline

Tamás Rudas
Professor, Head of Department of Statistics, Faculty of Social Sciences
Eötvös Loránd University, Budapest, Hungary

Sources of Uncertainty in Statistics

Statistics is often defined as the science of the methods of data collection and analysis, but from a somewhat more

conceptual perspective, statistics is also the science of methods dealing with uncertainty. The sources of uncertainty in statistics may be divided into two groups. Uncertainty associated with the data one has and uncertainty associated with respect to the mechanism which produced the data. These kinds of uncertainty are often interrelated in practice, yet it is useful to distinguish them.

Uncertainties in Data

One may distinguish two main sources of uncertainty with respect to data. One is related to measurement error, the other to sampling error.

Measurement error is the difference between the actual measurement obtained and the true value of what was measured. This applies to both cases when a numerical measurement taken (typical in the physical, biological, medical, psychological sciences) but also to qualitative observations when subjects are classified (typical in the social and behavioral sciences), except that in the latter case, instead of the numerical value of the error, its lack or presence is considered. In the former case, it is often observed that the errors are approximately distributed as normal, even if very precise and expensive measuring instruments are used. In the latter case, the existence of measurement error, that is misclassification, is often attributed to self-reflection of the human beings observed. In both situations, the lack of understanding of the precise mechanisms behind measurement errors suggest applying a stochastic model assuming that the result of the measurement is the sum of the true value plus a random error.

Sampling error stems from the uncertainty of how our results would differ, if a sample that is different from the actual one were observed. It is usually associated with the entire sample (and not with the individual observations) and is measured as the difference between the estimates obtained from the actual sample, and the census value that could be obtained if the same data collection methods were applied to the entire population. The census value may or may not be equal to the true population parameter of interest. For example, if the measurement error is assumed to be constant, then the census value differs from the population value by this quantity. Usually, the likely size of the sampling error is characterized by the standard deviation (standard error) of the estimates. Under many common random sampling schemes, the distribution of the estimates is normal, and the choice of the standard error, as a characteristic quantity, is well justified.

Uncertainties in Modeling

While uncertainties associated with the data seem to be inherent characteristics, uncertainties related to modeling are more determined by our choice of models, which depends very often on the existing knowledge regarding the research problem at hand. The most common assumption is that the quantity of interest has a specified, though unknown to the researcher, distribution, that may or may not be assumed to belong to some parametric family of distributions. A further possible choice, gaining increasing popularity during the recent decades, is that the distribution of interest belongs to a parametric family, though not with a specified parameter value, rather characterized by a probability distribution (the prior distribution) on the possible parameter values. The former view is adopted in frequentist statistics and the latter view is the Bayesian approach to statistics.

To model uncertainty, frequentist statistics uses frequentist or classical probability theory, while ▶Bayesian statistics often relies on a subjective concept of probability.

Classical and Frequentist Probability

Historically, there are two sources of modern probability theory. One is the theory of gambling, where the main goal was to determine how probable certain outcomes were in a game of chance. These problems could be appropriately handled under the assumptions that all possible outcomes of an experiment (rolling a die, for example) are equally likely and probabilities could be determined as the ratio of the number of outcomes with a certain characteristic, to the total number of outcomes. This interpretation of probability is called classical probability. Questions related to gambling also made important contributions to developing the concepts of Boolean algebra (the algebra of events associated with an experiment), conditional probability and infinite sequences of random variables (which play an important role in the frequentist interpretation of probability see below). The other source of modern probability theory is the analysis of errors associated with a measurement. This led, among others, to the understanding of the central role played by the normal distribution.

It is remarkable, that the main concepts and results of these two apparently very different fields, all may be based on one set of axioms, proposed by Kolmogorov and given in the next section.

The Kolmogorov Axioms

The axioms, summarizing the concepts developed within the classical and frequentist approaches, apply to experiments that may be repeated infinitely many times, where all circumstances of the experiment are supposed to remain constant. An experiment may be identified with its possible outcomes. Certain subsets of outcomes are called events, with he assumption that no outcome (the impossible event) and all the outcomes (the certain event) are

events and countable unions or intersections of events are also events. This means that the set of events associated with an experiment form a sigma-field. Then the Kolmogorov axioms (basic assumptions that are accepted to be true) are the following:

For any event A, its probability

$$P(A) \geq 0$$

For the certain event Ω

$$P(\Omega) = 1$$

For a series $A_i, i = 1, 2, \ldots$ of pairwise disjoint events

$$\Sigma_{i=1,2,\ldots} P(A_i) = P(\Sigma_{i=1,2,\ldots} A_i)$$

The heuristic interpretation is that the probability of an event manifests itself via the relative frequency of this event over long series of repetitions of the experiment. This is why this approach to probability is often called frequentist probability. Indeed, the axioms are true for relative frequencies instead of probabilities.

The Laws of Large Numbers

The link between the heuristic notion of probability and the mathematical theory of probability is established by the result that if $f_n(A)$ denotes the frequency of event A after n repetitions of an experiment, then

$$f_n(A)/n \to P(A),$$

where the convergence $\to$ may be given various interpretations. More generally, if X is a random variable (that is, such a function that $X \in I$ is an event for every interval I), then for the average of n independent observations of X, $\overline{X}_n$,

$$\overline{X}_n \to E(X),$$

where $E(X)$ is the expected value of X. Here, convergence is in probability (weak law) or almost surely (strong law) (See also ►Laws of Large Numbers).

The Central Limit Theorem

This fundamental result explains why the normal distribution plays such a central role of statistics. Many of the statistics are sample averages and for their asymptotic distributions the following result holds. If $V(X)$ denotes the variance of X, then the asymptotic distribution of

$$\frac{\overline{X}_n - E(X)}{\sqrt{V(X)/n}}$$

is standard normal (see also ►Central Limit Theorems).

Subjective Probability

This interpretation of the concept of probability associates it with the strength of trust or belief that a person has in the occurrence of an event. Such beliefs manifest themselves, for example, in betting preferences: out of two events, a rational person would have a betting preference for the one with which he/she associates a larger subjective probability. A fundamental difference between frequentist and subjective probability is that the latter may also be applied to experiments and events that may not be repeated many times. Of course, the subjective probabilities of different individuals may be drastically different from each other and it has been demonstrated repeatedly that the subjective probabilities an individual associates with different events, may not be logically consistent. Bayesian statistics sometimes employs the elicitation of such subjective probabilities to construct a prior distribution.

About the Author

Professor Rudas was the Founding Dean of the Faculty of Social Sciences, Eötvös Loránd University, from 2003 to 2009. He is also an Affiliate Professor in the Department of Statistics, University of Washington, Seattle, and a Recurrent Visiting Professor in the Central European University, Budapest. He is Vice President, European Association of Methodology, 2008–. Professor Rudas has been awarded the Erdei Prize of the Hungarian Sociological Association for the application of statistical methods in sociology (1988), and the Golden Memorial Medal of the Eötvös Loránd University (2009).

Probability, History of

Jordi Vallverdú
Universitat Autònoma de Barcelona, Barcelona, Spain

Five thousand years ago dice were invented in India (David 1998). This fact implies that their users had at least a common sense approach to the idea of probability. Those dice were not the contemporary cubical standard dice, but fruit stones or animal bones (Dandoy 2006). They must surely have been used for fun and gambling as well as for fortune-telling practices. The worries about the future and the absurd idea that the world was causally guided by supernatural forces led those people to a belief in the explanatory power of rolling dice.

In fact, cosmogonical answers were the first attempt to explain in a causal way the existence of things and beings. The Greek creation myth involved a game of dice between Zeus, Poseidon, and Hades. Also in the classic Hindu book *Mahabharata* (section "Sabha-parva"), we can find the use of dice for gambling. But in both cases there is no theory regarding probability in dice, just their use "for fun."

Later, and beyond myths, Aristotle was the strongest defender of the causal and empirical approach to reality (*Physics*, II, 4–6) although he considered the possibility of chance, especially the problem of the game of dice (*On Heavens*, II, 292a30) and probabilities implied in it. These ideas had nothing to do with those about atomistic chance by Leucippus and Democritus nor Lucrecius' controversial *clinamen*'s theory. Hald (1988) affirms the existence of probabilistic rather than mathematical thought in Classical Antiquity; we can accept that some authors (like Aristotle) were worried about the idea of chance (as well as about the primordial emptiness and other types of conceptual *cul-de-sac*), but they made no formal analysis of it. Later, we can find traces of interest in the moral aspects of gambling with dice in Talmudic (*Babylonian Talmud, Book* 8*: Tract Sanhedrin, chapter* III*, Mishnas* I *to* III) and Rabbinical texts, and we know that in 960, Bishop Wibolf of Cambrai calculated 56 diverse ways of playing with three dice. *De Vetula*, a Latin poem from the thirteenth century, tells us of 216 possibilities. But the first occurrence of combinatorics per se arose from Chinese interest in future prediction through the 64 hexagrams of the *I Ching* (previously eight trigrams derived from four binary combinations of two elemental forces, *yin* and *yang*).

In 1494 Luca Paccioli defined the basic principles of algebra and multiplication tables up to 60 × 60 in his book *Summa de arithmetica, geometria, proportioni e proportionalita*. He posed the first serious statistical problem of two men playing a game called "balla," which is to end when one of them has won six rounds. However, when they stop playing *A* has only won five rounds and *B* three. How should they divide the wager? It would be another 200 years before this problem was solved.

In 1545 Girolamo Cardano wrote the books *Ars magna* (the great art) and *Liber de ludo aleae* (the book on games of chance). This was the first attempt to use mathematics to describe statistics and probability, and accurately described the probabilities of throwing various numbers with dice. Galileo expanded on this by calculating probabilities using two dice. At the same time the quantification of all aspects of daily life (art, music, time, space) between the years 1250 and 1600 made possible the numerical analysis of nature and, consequently, the discovery of the distribution of events and their rules (Crosby 1996).

It was finally Blaise Pascal who refined the theories of statistics and, with Pierre de Fermat, solved the "balla" problem of Paccioli (Devlin 2008). All these paved the way for modern statistics, which essentially began with the use of actuarial tables to determine insurance for merchant ships (Hacking 1984, 1990). Pascal was also the first to apply probability studies to the theory of decision (see his *Pensées*, 233), curiously, in the field of religious decisions. It is in this historical moment that the Latin term "probabilis" acquires its actual meaning, evolving from "worthy of approbation" to "numerical assessment of likelihood on a determined scale" (Moussy 2005).

In 1662, Antoine Arnauld and Pierre Nicole published the influential *La logique ou l'art de penser*, where we can find statistical probabilities. Games and their statistical roots worried people like Cardano, Pascal, Fermat, and Huygens (Weatherford 1982), although all of them were immersed in a strict mechanistic paradigm. Huygens is considered the first scientist interested in scientific probability, and in 1657 he published *De ratiotiniis in aleae ludo*. In 1708 Pierre Raymond de Montmort published his *Essay d'Analyse sur les Jeux de Hazard*, probably the first comprehensive text on probability theory. It was the next step after Pascal's work on combinatorics and its application to the solution of problems on games of chance. Later, De Moivre wrote the influential *De mensura sortis* (1711), and 78 years later, Laplace published

his *Philosophical Essay About Probability*. In the 1730s, Daniel Bernoulli (Jacob Bernoulli's nephew) developed the idea of utility as the mathematical combination of the quantity and perception of risk. Gottfried Leibniz at the beginning of the eighteenth century argued in several of his writings against the idea of chance, defending deterministic theories. According to him, chance was not part of the true nature of reality but the result of our incomplete knowledge. In this sense, probability is the estimation of facts that could be completely known and predicted, not the basic nature of things. Even morality was guided by natural laws, as Immanuel Kant argued in his *Foundations of the Metaphysics of Morals* (1785).

In 1763 an influential paper written by the Reverend Thomas Bayes was published posthumously. Richard Price, who was a friend of his, worked on the results of his efforts to find the solution to the problem of computing a distribution for the parameter of a ▶binomial distribution: *An Essay towards solving a Problem in the Doctrine of Chances*. Proposition 9 in the essay represented the main result of Bayes. Degrees of belief are therein considered as a basis for statistical practice. In a nutshell, Bayes proposed a theorem in which "probability" is defined as an index of subjective confidence, at the same time taking into account the relationships that exist within an array of simple and conditional probabilities. ▶Bayes' theorem is a tool for assessing how probable evidence can make a given hypothesis (Swinburne 2005). So, we can revise predictions in the light of relevant evidence and make a Bayesian inference, based on the assignment of some a priori distribution of a parameter under investigation (Stigler 1990). The classical formula of Bayes' rule is:

$$P(A|B) = \frac{P(B|A)P(A)}{P(B)},$$

where our *posterior* belief $P(A|B)$ is calculated by multiplying our *prior* belief $P(A)$ by the *likelihood* $P(B|A)$ that B will occur if A is true. This classical version of Bayesianism had a long history, beginning with Bayes and continuing through Laplace to Jeffreys, Keynes, and Carnap in the twentieth century. Later, in the 1930s, a new type of Bayesianism appeared, the "subjective Bayesianism" of Ramsey and De Finetti (Ramsey 1931; de Finetti 1937; Savage 1954).

At the end of the nineteenth century, a lot of things were changing in the scientific and philosophical arena. The end of the idea of "causality" and the conflicts about observation lay at the heart of the debate. Gödel attacked Hilbert's axiomatic approach to mathematics and Bertrand Russell, as clever as ever, told us: "The law of causality (. . .) is a relic of a bygone age, surviving, like the monarchy, only because it is erroneously supposed to do no harm (. . .) The principle "same cause, same effect," which philosophers imagine to be vital to science, is therefore utterly otiose" (Suppes 1970, p. 5). Nevertheless, scientists like Einstein were reluctant to accept the loss of determinism in favor of a purely random Universe; Einstein's words "God does not play dice" are the example of the difficulty of considering the whole world as a world of probabilities, with no inner intentionality, nor moral direction. On the other hand, scientists like Monod (*Chance and Necessity*, 1970) accepted this situation. In both cases, there is a deep consideration of the role of probability and chance in the construction of the philosophical and scientific meaning about reality.

In the 1920s there arose from theworks of Fisher (1922) and Neyman and Pearson (1928) the *classic* statistical paradigm: frequentism. They use the relative frequency concept, that is, you must perform one experiment many times and measure the proportion where you get a positive result. This proportion, if you perform the experiment enough times, is the probability. If Neyman and Pearson wrote their first joint paper and presented their approach as *one among alternatives*, Fisher, with his null hypothesis testing, gave a different message: his statistics was the formal solution of the problem of inductive inference (Gigerenzer 1990, p. 228).

From then on, these two main schools, Bayesian and Frequentist, were fighting each other to demonstrate that theirs was the superior and only valid approach (Vallverdú 2008).

Finally, with the advent of the information era and all the (super)computer scientific simulations, Bayesianism has again achieved a higher status inside the community of experts on probability. Bayesian inference also allows intelligent and real-time monitoring of computational clusters, and its application in belief networks has proved to be a good technique for diagnosis, forecasting, and decision analysis tasks. This fact has contributed to the increasing application of parallel techniques for large Bayesian networks in expert systems (automated causal discovery, AI…) (Korb and Nicholson 2003).

Probit Analysis

Tiberiu Postelnicu
Professor Emeritus
Romanian Academy, Bucharest, Romania

Introduction

The idea of probit analysis was originally published in *Science* by Chester Ittner Bliss (1899–1979) in 1934. He was primarily concerned with finding an effective pesticide to control insects that fed on grape leaves. By plotting the response of the insects to various concentrations of pesticides, he could visually see that each pesticide affected the insects at different concentrations, but he did not have a statistical method to compare this difference. The most logical approach would be to fit a regression of the response versus the concentration or dose and compare between the different pesticides. The relationship of response to dose was sigmoid in nature and at that time regression was only used on linear data. Therefore, Bliss developed the idea of transforming the sigmoid dose–response curve to a straight line. When biological responses are plotted against their causal stimuli (or their logarithms) they often form a

sigmoid curve. Sigmoid relationships can be linearized by transformations such as logit, probit, and angular. For most systems the probit (normal sigmoid) and logit (logistic sigmoid) give the most closely fitting result. Logistic methods are useful in epidemiology, but in biological assay work, probit analysis is preferred. David Finney, from the University of Edinburgh, took Bliss' idea and wrote a book entitled *Probit Analysis* in 1947, and since this year it is still the preferred statistical method in understanding dose–response relationships.

Probit

In probability theory and statistics, the *probit function* is the inverse cumulative distribution function (CDF), or *quantile function* associated with the standard normal distribution. It has applications in exploratory statistical graphics and specialized regression modeling of binary response variables. For the standard normal distribution, the CDF is commonly denoted $\Phi(z)$, which is a continuous, monotone-increasing sigmoid function whose domain is the real line and range is $(0,1)$. The probit function gives the inverse computation, generating a value of an $N(0,1)$ random variable, associated with specified cumulative probability. Formally, the probit function is the inverse of $\Phi(z)$, denoted $\Phi^{-1}(p)$. In general, we have $\Phi(\text{probit}(p)) = p$ and $\text{probit}(\Phi(z)) = z$. Bliss proposed transforming the percentage into "*probability unit*" (or "*probit*") and included a table to aid researchers to convert their kill percentages to his probit, which they could then plot against the logarithm of the dose and thereby, it was hoped, obtain a more or less straight line. Such a probit model is still important in toxicology, as well as in other fields. It should be observed that probit methodology, including numerical optimization for fitting of probit functions, was introduced before widespread availability of electronic computing and, therefore, it was convenient to have probits uniformly positive.

Related Topics

The probit function is useful in statistical analysis for diagnosing deviation from normality, according to the method of Q–Q plotting. If a set of data is actually a sample of a normal distribution, a plot of the values against their probit scores will be approximately linear. Specific deviation from normality such as asymmetry, heavy tails, or bimodality can be diagnosed based on the detection of specific deviations from linearity. While the $Q-Q$ plot can be used for comparison with any distribution family (not only the normal), the normal Q–Q plot is a relatively standard exploratory data analysis procedure because the assumption of normality is often a starting point for analysis.

The normal distribution CDF and its inverse are not available in closed form, and computation requires careful use of numerical procedures. However, the functions are widely available in software for statistics and probability modeling, and also in spreadsheets. In computing environments where numerical implementations of the inverse error function are available, the probit function may be obtained as $\text{probit}(p) = \sqrt{2}\text{erf}^{-1}(2p-1)$. An example is MATLAB, where an "erfinv" function is available and the language MATHEMATICA implements "InverseErf." Other environments directly implement the probit function in the R programming language.

Closely related to the probit function is the *logit function* using the "odds" $p/(1-p)$, where p is the proportional response, i.e., r out of n responded, so there is $p = r/n$ and $\text{logit}(p) = \text{log odds} = \log(p/(1-p))$. Analogously to the probit model, it is possible to assume that such a quantity is related linearly to a set of predictors, resulting in the logit model, the basis in particular of logistic regression model (see ►Logistic Regression), the most prevalent form of regression analysis for binary response data. In current statistical practice, probit and logit regression models are often handled as cases of the generalized linear model (see ►Generalized Linear Models).

Probit Model

In statistics and related fields, a *probit model* is a specification for a binary response model that employs a probit link function. This model is most often estimated using the standard maximum likelihood procedure; such an estimation is called *probit regression*. A fast method for computing maximum likelihood estimates for probit models was proposed by Ronald Fisher in an Appendix to the article of Bliss in 1935.

Probit analysis is a method of analyzing the relationship between a stimulus (dose) and the quantal (all or nothing) response. Quantitative responses are almost always preferred, but in many situations they are not practical. In these cases, it is only possible to determine if a certain response has occurred. In a typical quantal response experiment, groups of animals are given different doses of a drug. The percent dying at each dose level is recorded. These data may then be analyzed using probit analysis. StatPlus includes two different methods of probit analysis, but the Finney method is the most important and useful. The probit model assumes that the percent response is related to the log dose as the cumulative normal distribution, that is, the log doses may be used as variables to read the percent dying from the cumulative normal. Using the

normal distribution, rather than other probability distributions, influences the predicted response rate at the high and low ends of possible doses, but has little influence near the middle. Much of the comparison of different drugs is done using response rates of 50%. The probit model may be expressed mathematically as follows:

$$P = a + b(\log(\text{Dose})),$$

where P is five plus the inverse normal transform of the response rate (called the probit). The five is added to reduce the possibility of negative probits, a situation that caused confusion when solving the problem by hand.

Suppose the response variable Y is *binary*, that is, it can have only two possible outcomes, which we will denote as 1 and 0. For example, Y may represent presence/absence of a certain condition, success/failure of some device, and answer yes/no on a survey. We also have a vector of regression X, which are assumed to influence the outcome Y. Specifically, we assume that the model takes the form

$$P[Y = 1|X] = \Phi(X'\beta),$$

where P is the probability and Φ is the probit function – the CDF of the standard normal distribution. The parameters β are typically estimated by maximum likelihood. For more complex probit analysis, such as the calculation of relative potencies from several related dose–response curves, consider nonlinear optimization software or specialist dose–response analysis software. The latter is a FORTRAN routine written by David Finney and Ian Craigie from Edinburgh University Computing Center. MLP or GENSTAT can be used for a more general nonlinear model fitting. We must take into account that the standard probit analysis is designed to handle only quantal responses with binomial error distributions. Quantal data, such as the number of subjects responding versus the total number of subjects tested, usually have binomial error distributions. We should not use continuous data, such as percent maximal response, with probit analysis as these data are likely to require regression methods that assume a different error distribution.

Applications

Probit analysis is used to analyze many kinds of dose–response or binomial response experiments in a variety of fields. It is commonly used in toxicology to determine the relative toxicity of chemicals to living organisms. This is done by testing the response of an organism under various concentrations of each of the chemicals in question and then comparing the concentrations at which one encounters a response. The response is always binomial and the relationship between the response and the various concentrations is always sigmoid. Probit analysis acts as a transformation from sigmoid to linear and then runs a regression on the relationship. Once the regression is run, we can use the output of the probit analysis to compare the amount of chemical required to create the same response in each of the various chemicals. There are many points used to compare the differing toxicities of chemicals, but the LC50 (liquids) or LD50 (solids) are the most widely used outcomes of the modern dose–response experiments. The LC50/LD50 represent the concentration (LC50) or dose (LD50) at which 50% of the population responds. It is possible to use probit analysis with various methods such as statistical packages SPSS, SAS, R, or S, but it is good to see the history of the methodology to get a thorough understanding of the material. We must take care that probit analysis assumes that the relationship between number responding (non-percent response) and concentration is normally distributed; if not, logit is preferred.

The properties of the estimates given by probit analysis have been studied also by Ola Hertzberg (1974). The up-and-down technique is the best known among staircase methods for estimating the parameters in quantal response curves (QRC). Some small sample properties of probit analysis are considered and in the estimate distribution the medians are used as a measure of location.

About the Author

Tiberiu Postelnicu (born on June 15, 1930, Campina), received his Ph.D. in Mathematics, University of Bucharest, in 1957. He was Head of Department of Biostatistics, Carol Davila University of Medicine and Pharmacy, Bucharest, and Department of Biometrics, Centre of Mathematical Statistics of the Romanian Academy, Bucharest. He is a member of the International Statistical Institute, Biometric Society, Bernoulli Society for Mathematical Statistics and Probability, Italian Society for Statistics, and the New York Academy of Science. Dr. Postelnicu was a member of the editorial boards of the *Biometrical Journal* and *Journal for Statistical Planning and Inference*. He was awarded the Gheorghe Lazar Prize for Mathematics, Romanian Academy (1972). Currently, Professor Postelnicu is President of the Commission for Biometrics of the Romanian Academy.

Promoting, Fostering and Development of Statistics in Developing Countries

Noël H. Fonton[1], Norbert Hounkonnou[2]
[1]Professor, Head of Centre of Biostatistics and Director Laboratory of Modeling of Biological Phenomena University of Abomey-Calavi, Cotonou, Benin Republic
[2]Professor, Chairman of International Chair of Mathematical Physics and Applications (ICMPA UNESCO Chair) Cotonou, Benin Republic

Statistical methods are universal and hence their applicability depends neither on geographical area nor on a people's culture. Promoting and increasing the use of statistics in developing countries can help to find solutions to the needs of their citizens. Developing countries are confronted with endemic poverty that requires implementable solutions for alleviating suffering. Such poverty is a signal call to the world to meet fundamental human needs—food, adequate shelter, access to education and healthcare, protection from violence, and freedom. Statistics and statistical tools, the matching between hypothesis, data collection, and statistical method, are necessary as development strategies in the developing counties are formulated to address these needs.

First, a reliable basis for the implementation of strategies against poverty and achievement of the Millennium Development Goals require good statistics, an essential element of good governance. Therefore, important indicators to inform and monitor development policies are often derived from household surveys, which have become a dominant form of data collection in developing countries. Such surveys are an important source of socioeconomic data. Azouvi (2001) has proposed a low-cost statistical program in four areas: statistical coordination, national accounts, economic and social conjuncture, and dissemination. To increase awareness that good statistics are important for achieving better development results, the Marrakech Action Plan for Statistics (MPS) was developed in 2004. This global plan for improving development statistics was agreed upon at a second round-table for best managing development results (World Bank, 2004). The idea is that better data are needed for better results in order to improve development statistics. One indicator to ensure the application of this MPS is the full participation of developing countries in the 2010 census round. Additionally, funds allocated by the World Bank from the Development Grant Facility and technical assistance from national universities are critical.

Second, national capacity-building in statistics is very limited. Even in developed countries, secondary school students, together with their teachers, rarely see the applicability and the challenge of statistical thinking (Boland, 2002). This situation exists to a greater degree in the university training systems of many developing countries. It is suggested that statistical programs should be reviewed and executed by statisticians and examples of a local nature should be used. This is possible with sufficient number of statisticians in various fields. According to Lo (2009), there are 5 to 10 holders of doctoral degrees in statistics per country, with higher numbers in some countries. There is a low number of statisticians in developing countries due to the lack of master's degree programs in statistics. In sub-Saharan, French-speaking African countries, the "Statistiques pour l'Afrique Francophone et Applications au vivant" (STAFAV) project is being implemented in three parts: a network for master's training in applied statistics at Cotonou (Benin), Saint-Louis (Senegal), and Yaounde (Cameroon); some PhD candidates jointly supervised by scientists from African universities and French universities; and the development of statistical research through an African Network of Mathematical Statistics and Applications (RASMA). STAFAV constitutes a good means for increasing statistical capacity in

developing countries. With the launch of the Statistical Pan African Society (SPAS), more visibility for research and the use of statistics and probability may be achieved via the African Visibility Program in Statistics and Probability. This society is an antidote to the very isolated work of statistics researchers and allows researchers to share experiences and scientific work.

Third, statistics are a tool for solving the problems of developing countries, but the development of research activities is a challenge. Many of these countries are located in tropical areas; therefore, there are major differences between them and other countries due to high biological variability and the probability distribution of the studied phenomena is frequently misunderstood. Control of biological variability requires wide use of probability theory. Because of the disparate populations and subpopulations in the experimental data, the use of one probability distribution should be called into question. Lacking sophisticated statistical methods, development of statistical methods of mix-distributions becomes a challenge. Economic loss, agriculture, water policies, and health (malaria, HIV/AIDS, and recently H1N1) are the major areas for research programs in which statistics have a major role to play. Development of statistical research programs directed at the well-being of local people is necessary.

The sustainability of statistical development is another important issue in the field. Graduate statisticians, when returning to their native countries, often do not have facilities for continuing education, documentation, or statistics software packages. To foster statistics in developing countries, national statistics institutes, universities, and research centers need to increase funds allocated for subscribing to statistical journals, mainly online, and software, with a staff properly trained on those fields. Statisticians must be offered opportunities to attend annual conferences and to do research and/or professional training in a statistical institute outside of their countries.

Contributions of statisticians from developed countries, working or teaching in developing countries, are welcome. Specifically, they can join research teams in developing countries, share experiences with them, help acquire funding, and teach.

Properties of Estimators

Paul H. Garthwaite
Professor of Statistics
The Open University, Milton Keynes, UK

Estimation is a primary task of statistics and estimators play many roles. Interval estimators, such as confidence intervals or prediction intervals, aim to give a range of plausible values for an unknown quantity. Density estimators aim to approximate a probability distribution. These and other varied roles of estimators are discussed in other sections. Here attention is restricted to point estimation, where the aim is to calculate from data a single value that is a good estimate of an unknown parameter.

We will denote the unknown parameter by θ, which is assumed to be a scalar. In the standard situation there is a statistic T whose value, t, is determined by sample data. T is a random variable and it is referred to as a (point) estimator of θ if t is an estimate of θ. Usually there will be a variety of possible estimators so criteria are needed to separate good estimators from poor ones. There are a number of desirable properties which we would like estimators to possess, though a property will not necessarily identify a unique "best" estimator and rarely will there be an estimator that has all the properties mentioned here. Also, caution must be exercised in using the properties as a reasonable property will occasionally lead to an estimator that is unreasonable.

One property that is generally useful is unbiasedness. T is an unbiased estimator of θ if, for any θ, $E(T) = \theta$. Thus T is unbiased if, on average, it tends neither to be bigger nor smaller than the quantity it estimates, regardless of

the actual value of the quantity. The bias of T is defined to be $E(T) - \theta$. Obviously a parameter can have more than one unbiased estimator. For example, if θ is the mean of a symmetric distribution from which a random sample is taken, then T is an unbiased estimator if it is the mean, median or mid-range of the sample. It is also the case that sometimes a unique unbiased estimator is not sensible. For example, Cox and Hinkley (1974, p. 253) show that if a single observation is taken from a geometric distribution with parameter θ, then there is only one unbiased estimator and its estimate of θ is either 1 (if the observation's value is 1) or 0 (if the observation's value is greater than 1). In most circumstances these are not good estimates.

It is desirable, almost by definition, that the estimate t should be close to θ. Hence the quality of an estimator might be judged by its expected absolute error, $E(|T - \theta|)$, or its mean squared error, $E[(T - \theta)^2]$. The latter is used far more commonly, partly because of its relationship to the mean and variance of T:

$$\text{mean squared error} = \text{variance} + (\text{bias})^2. \qquad (1)$$

If the aim is to find an estimator with small mean squared error (MSE), clearly unbiasedness is desirable, as then the last term in Eq. (1) vanishes. However, unbiasedness is not essential and trading a small amount of bias for a large reduction in variance will reduce the MSE. Perhaps the best known biased estimators are the regression coefficients given by ridge regression (see ►Ridge and Surrogate Ridge Regressions), which handles multicollinearities in a regression problem by allowing a small amount of bias in the coefficient estimates, thereby reducing the variance of the estimates.

It may seem natural to try to find estimators which minimize MSE, but this is often difficult to do. Moreover, given any estimator, there is usually some value of θ for which that estimator's MSE is greater than the MSE of some other estimator. Hence the existence of an estimator with a *uniformly* minimum MSE is generally in doubt. For example, consider the trivial and rather stupid estimator that ignores the data and chooses some constant θ_0 as the estimator of θ. Should θ actually equal θ_0, then this estimator has an MSE of 0 and other estimators will seldom match it. Thus other estimators will not have a uniformly smaller MSE than this trivial estimator.

Restricting attention to unbiased estimators solves many of the difficulties of working with MSE. The task of minimizing MSE reduces to that of minimizing variance and substantial theory has been developed about minimum variance unbiased estimators (MVUEs). This includes two well-known results, the *Cramér–Rao lower bound* and the ►*Rao–Blackwell theorem.* The Cramér–Rao lower bound is I_θ^{-1}, where I_θ is the Fisher information about θ. (I_θ is determined from the likelihood for θ.) Subject to certain regularity conditions, the Cramér–Rao lower bound is a lower bound to the variance of any unbiased estimator of θ.

A benefit of the Cramér–Rao lower bound is that it provides a numerical scale-free measure for judging an estimator: the *efficiency* of an unbiased estimator is defined as the ratio of the Cramér–Rao lower bound to the variance of the estimator. Also, an unbiased estimator is said to have the property of being efficient if its variance equals the Cramér–Rao lower bound. Efficient estimators are not uncommon. For example, the sample mean is an efficient estimator of the population mean when sampling is from a normal distribution or a Poisson distribution, and there are many others. By definition, only an MVUE might be efficient.

Sufficiency is a property of a statistic that can lead to good estimators. A statistic S (which may be a vector) is sufficient for θ if it captures all the information about θ that the data contain. For example, the sample variance is sufficient for the population variance when data are a random sample from a normal distribution – hence to make inferences about the population variance we only need to know the sample variance and not the individual data values. The definition of sufficiency is a little more transparent in ►Bayesian statistics than in classical statistics (though the definitions are equivalent). In the Bayesian approach, S is sufficient for θ if the distribution of θ, given the value of S, is the same as θ's distribution given all the data. i.e. $g(\theta \mid S) = g(\theta \mid \text{data})$, where $g(\,.\,)$ is the p.d.f. of θ. In the classical definition (where θ cannot be considered to have a distribution), S is sufficient for θ if the conditional distribution of the data, given the value of S, does not depend on θ. A sufficient statistic may contain much superfluous information along with the information about θ, so the concept of a *minimal sufficient statistic* is also useful. A statistic is minimal sufficient if it can be expressed as a function of every other sufficient statistic.

The Rao–Blackwell theorem shows the importance of sufficient statistics when seeking unbiased estimators with small variance. It states that if $\widehat{\theta}$ is an unbiased estimator of θ and S is a sufficient statistic, then

1. $T_S = E(\widehat{\theta} \mid S)$ is a function of S alone and is an unbiased estimator of θ.
2. $\text{Var}(T_S) \le \text{var}(\widehat{\theta})$.

The theorem means that we can try to improve on any unbiased estimator by taking its expectation conditional on a sufficient statistic – the resulting estimator will also be unbiased and its variance will be smaller than, or equal

to, the variance of the original estimator. Stronger results hold if a minimal sufficient statistic is also *complete*: S is complete if $E[h(S)]$ cannot equal 0 for all θ unless $h(S) \equiv 0$ almost everywhere (where h is any function). If S is complete there is at most one function of S that is an unbiased estimator of θ. Suppose now, that S is a complete minimal sufficient statistic for θ. An important result is that if $h(S)$ is an unbiased estimator of θ, then $h(S)$ is an MVUE for θ, if an MVUE exists. The consequence is that, when searching for an MVUE, attention can be confined to functions of a complete sufficient statistic.

Turning to asymptotic properties, suppose that data consist of a ►simple random sample of size n and consider the behavior of an estimator T as $n \to \infty$. An almost essential property is that the estimator should be consistent: T is a consistent estimator of θ if T converges to θ in probability as $n \to \infty$. Consistency implies that, as the sample size increases, any bias in T tends to 0 and the variance of T also tends to 0.

Two useful properties that do not relate directly to the accuracy of an estimator are ►*asymptotic normality* and *invariance*. When sample sizes are large, confidence intervals and hypothesis tests are often based on the assumption that the distribution of an estimator is approximately normal. Hence asymptotic normality is a useful property in an estimator, especially if approximate normality holds quite well for modest sample sizes. Invariance of estimators relates to the method of forming them. It is the notion that if we take a transformation of a parameter, then ideally its estimator should transform in the same way. For example, let $\phi = g(\theta)$, where ϕ is a one-to-one function of θ. Then if a method of forming estimators gives t_1 and t_2 as estimates of ϕ and θ, invariance would imply that t_1 necessarily equalled $g(t_2)$. Maximum likelihood estimators are invariant.

We have assumed that the unknown parameter (θ) is a scalar. Concepts such as unbiasedness, sufficiency, consistency, invariance and asymptotic normality extend very naturally to the case where the unknown parameter is a vector. If θ is a vector but an estimate of just one of its components is required, then a vector-form of the Cramer–Rao lower bound yields a minimum variance for any unbiased estimator of the component. Simultaneous estimation of more than one component, however, raises new challenges unless estimating each component separately and combining the estimates is optimal.

While a search for MVUEs has been a focus of one area of statistics, other branches of statistics want different properties in estimators. Robust methods want point estimators that are comparatively insensitive to a few aberrant observations or the odd outlier. Nonparametric methods want to estimate a population mean or variance, say, without making strong assumptions about the population distribution. These branches of statistics do not place paramount importance on unbiasedness or minimal variance, but they nevertheless typically seek estimators with low bias and small variance – it is just that their estimators must also satisfy other requirements. In contrast, Bayesian statistics uses a markedly different framework for choosing estimators. In its basic form the parameters of the sampling model are given a prior distribution, while a loss function specifies the penalty for inaccuracy in estimating a parameter. The task is then to select an estimator or decision rule that will minimize the expected loss, so minimizing expected loss is the property of dominant importance.

Many other sections of this encyclopedia also consider point estimators and point estimation methods. These include sections on nonparametrics, robust estimation, Bayesian methods and decision theory. The focus in this section has been the classical properties of point estimators. Deeper discussion of this topic and proofs of results are given in most advanced textbooks on statistical inference or theoretical statistics, such as Bickel and Doksum (2000), Cox and Hinkley (1974), Garthwaite et al. (2002), and Lehmann and Casella (1998).

About the Author

Paul Garthwaite is Professor of Statistics at the Open University, UK, where he was Head of the Department of Statistics from 2001–2004 and again in 2006. He worked for twenty years in the University of Aberdeen and has held visiting positions at universities in New York State, Minnesota, Brisbane and Sydney. In 1983 he was awarded the L J Savage Prize, a prize now under the auspices of the International Society for Bayesian Analysis. He has published 80 journal papers and is co-author of two books, *Statistical Inference* (Oxford University Press, 2002) and *Uncertain Judgements: Eliciting Expert' Probabilities* (Willey, 2006).

A common problem in statistics, and especially in sample surveys, is how to estimate the proportion p $(= 1 - q)$ of people with a given characteristic (e.g., being left-handed) in a population of known size N. If there are M left-handed people in the population, then $p = M/N$. The usual method of estimating p is to take a ►simple random sample (SRS), that is, a random sample without replacement, of size n and count the number of left-handed people, x, in the sample. If the sample is representative, then p can be estimated by the sample proportion $\hat{p} = x/n$. To make inferences about p we need to use the probability distribution of x, namely the Hypergeometric distribution (see ►Hypergeometric Distribution and Its Application in Statistics), a distribution that is difficult to use. From this distribution we can get the mean and variance of x and hence of $\hat{p}$, namely

$$\mu_{\hat{p}} = p \quad \text{and} \quad \sigma^2_{\hat{p}} = r\frac{pq}{n},$$

where $r = (N - n)/(N - 1) \approx 1 - f$, and f is the sampling fraction n/N, which can be ignored if it is less that 0.1 (or better 0.05). Fortunately, for sufficiently large N, M and n, x and $\hat{p}$ are approximately normal so that $z = (\hat{p} - p)/\sigma_{\hat{p}}$ has an approximate standard normal distribution (with mean 0 and variance 1). This approximation will still hold if we replace p by $\hat{p}$ in the denominator of $\sigma_{\hat{p}}$ to get $\hat{\sigma}_{\hat{p}}$ giving us an approximate 95% confidence interval $\hat{p} \pm 1.96\hat{\sigma}_{\hat{p}}$.

Inverse sampling can also be used to estimate p, especially when the characteristic is rare. Random sampling is continued until x units of the given characteristic are selected, n now being random, and Haldane in 1945 gave the estimate $\hat{p}_I = (x - 1)/(n - 1)$. This has variance estimate $\hat{\sigma}^2_{\hat{p}_I} = r_I(\hat{p}_I\hat{q}_I)/(n - 2)$, where $r_I = 1 - (n - 1)/N$ for without replacement and $r_I = 1$ for with replacement, and an approximate 95% confidence interval for p is $\hat{p}_I \pm 1.96\hat{\sigma}_{\hat{p}_I}$ (Salehi and Seber 2001).

Another application of this theory is in the case where M consists of a known number of marked animals released into a population of unknown size, but with f known to be sufficiently small so that we can set $r = 1$. The confidence interval for p can then be rearranged to give a confidence interval for N. This simple idea has lead to a very large literature on capture-recapture (Seber 2002).

Returning to our example relating to left-handed people, when we choose the first person from the population, the probability of getting a left-handed person will be p so that the terms "probability" and "proportion" tend to be used interchangeably in the literature, although they are distinct concepts. They can be brought even closer together if sampling is with replacement for then the probability of getting a left-handed person at each selection remains at p and x now has a ►Binomial distribution, as we have n independent trials with probability of "success" being p. The above formulas for means and variances and confidence interval are still the same except that r is now exactly 1. This is not surprising as we expect sampling with replacement to be a good approximation for sampling without replacement when a small proportion of a population is sampled. Confidence intervals for the Binomial distribution have been studied for many years and a variety of approximations and modifications have been considered, for example, Newcombe (1998a). "Exact" confidence intervals, usually referred to as the Clopper–Pearson intervals, can also be computed using the so-called "tail" probabilities of the binomial distribution, which are related to a ►Beta distribution (cf. Agresti and Coull 1998). We can also use the above theory to test null hypotheses like H_0: $p = p_0$, though such hypotheses apply more to probabilities than proportions.

When it comes to comparing two proportions, there are three different experimental situations that need to be considered. Our example for explaining these relates to voting preferences. Suppose we wish to compare the proportions, say p_i $(i = 1, 2)$, of people voting for a particular candidate in two separate areas and we do so by taking an SRS of size n_i in each area and computing $\hat{p}_i$ for each area. In comparing the areas we will be interested in estimating $\theta = p_1 - p_2$ using $\hat{\theta} = \hat{p}_1 - \hat{p}_2$. As the two estimates are statistically independent, and assuming f can be neglected for each sample, we have

$$\sigma^2_{\hat{\theta}} = \frac{p_1q_1}{n_1} + \frac{p_1q_2}{n_2},$$

which we can estimate by replacing each p_i by its estimate. Assuming the normal approximation is valid for each sample, we have the usual approximate 95% confidence interval $\hat{\theta} \pm 1.96\hat{\sigma}_{\hat{\theta}}$ for θ. This theory also applies to comparing two Binomial probabilities and, as with a single probability, a number of methods have been proposed (see Newcombe 1998b). Several procedures for testing the null hypothesis H_0: $\theta = 0$ are available including an "exact" test due to Fisher and an approximate Chi-square test with or without a correction for continuity.

A second situation is when we have a single population and the p_is now refer to two different candidates. The estimates $\hat{p}_i$ $(i = 1, 2)$ are no longer independent and we now find, from Scott and Seber (1983), that

$$\sigma^2_{\hat{\theta}} = \frac{1}{n}[p_1 + p_2 - (p_1 - p_2)^2],$$

where n is the sample size. Once again we can replace the unknown p_i by their estimates and, assuming f can be ignored, we can obtain an approximate confidence interval for θ, as before.

A third situation occurs when two proportions from the same populations overlap in some way. Suppose we carry out a sample survey ▶questionnaire of n questions that have answers "Yes" and "No." Considering the first two questions, Q_1 and Q_2, let p_{11} be the proportion of people who say "Yes" to both questions, p_{12} the proportion who say "Yes" to Q_1 and "No" to Q_2, p_{21} the proportion who say "No" to Q_1 and "Yes" to Q_2, and p_{22} the proportion who say "No" to both questions. Then $p_1 = p_{11}+p_{12}$ is the proportion saying "Yes " to Q_1 and $p_2 = p_{11} + p_{21}$ the proportion saying "Yes" to Q_2. We want to estimate $\theta = p_1 - p_2$, as before. If x_{ij} are observed in the category with probability p_{ij} and $x_1 = x_{11} + x_{12}$ and $x_2 = x_{11} + x_{21}$, then, from Wild and Seber (1993),

$$\sigma^2_{\hat{\theta}} = \frac{1}{n}[p_{12} + p_{21} - (p_{12} - p_{21})^2].$$

To estimate the above variance, we would replace each p_{ij} by its estimate $\hat{p}_{ij}$. In many surveys though, only x_1 and x_2 are recorded so that the only parameters we can estimate are the p_i using $\hat{p}_i = x_i/n$. However, we can use these estimates in the following bounds

$$\frac{1}{n}d(1-d) \le \sigma^2_{\hat{\theta}} \le \frac{1}{n}[min(p_1 + p_2, q_1 + q_2) - (p_1 - p_2)^2],$$

where $d = |p_{12} - p_{21}| = |p_1 - p_2|$. Further comments about constructing confidence intervals, testing hypotheses, and dealing with non-responses to the questions are given in the above paper.

For an elementary discussion of some of the above ideas see Wild and Seber (2000).

Psychiatry, Statistics in

Graham Dunn
Professor of Biomedical Statistics and Head of the Health Methodology Research Group
University of Manchester, Manchester, UK

Why "Statistics in Psychiatry"? What makes statistics in psychiatry a particularly interesting intellectual challenge? Why is it not merely a sub-discipline of ▶medical statistics such as the application of statistics in rheumatology or statistics in cardiology? It is in the nature of mental illness and of mental health. Mental illness extends beyond

medicine into the realms of the social and behavioral sciences. Similarly, statistics in psychiatry owes as much, or more, to developments in social and behavioral statistics as it does to medical statistics. Statisticians in this area typically user a much wider variety of multivariate statistical methods than do medical statisticians elsewhere. Scientific psychiatry has always taken the problems of measurement much more seriously than appears to be the case in other clinical specialties. This is partly due to the fact that the measurement problems in psychiatry are obviously rather complex, but partly also because the other clinical fields appear to have been a bit backward by comparison. It is also an academic discipline where, at its best, there is fruitful interplay between the ideas typical of the 'medical model' of disease and those coming from the psychometric traditions of, say, educationalists and personality theorists.

"Mental diseases have both psychological, sociological and biological aspects and their study requires a combination of the approaches of the psychologist, the sociologist and the biologist, using the last word rather than physician since the latter must be all three. In *each* of these aspects statistical reasoning plays a part, whether it be in the future planning of hospitals, the classification of the various forms of such illnesses, the study of causation or the evaluation of methods of treatment." (Moran 1969 – my italics)

"The etiology of mental illness inevitably involves complex and inadequately understood interactions between social stressors and genetically and socially determined vulnerabilities – the whole area being overlaid by a thick carpet of measurement and misclassification errors." (Dunn 2000)

Do the varieties of mental illness fall into discrete, theoretically justified, diagnostic categories? Or are the boundaries entirely pragmatic and artificial? Should we be considering dimensions (matters of degree) or categories? Is the borderline between bipolar depression and schizophrenia, for example, real or entirely arbitrary? The same question even applies to the existence of mental illness itself. What distinguishes illness from social deviance and eccentricity? Establishing the validity and utility of psychiatric diagnoses has been, and still is, a major application of statistical thinking involving a whole range of complex multivariate methods (factor analysis being one of the most prominent). Once psychiatrists have created a diagnostic system they also need to be able to demonstrate its reliability. They need to be confident that psychiatrists will consistently allocate patients with a particular profile of symptoms to the same diagnostic group. They need to know that the category "schizophrenia" means the same thing and is used in the same way by all scientific psychiatrists, whether they work in the USA, China or Uganda. Here, again, statistical methods (kappa coefficients, for example) hold the centre stage.

The development of rating scales and the evaluation of the associated measurement errors form the central core of statistics in psychiatry. It is the problem of measurement that makes psychiatry stand apart from the other medical specialties. Scientific studies in all forms of medicine (including psychiatry) need to take account of confounding and selection effects. Demonstration of treatment efficacy for mental illness, like treatment efficacy elsewhere in medicine, always needs the well-designed controlled randomized trial. But measurement and measurement error make psychiatry stand out. Here, the statistician's world has long been populated by latent variable models of all sorts – finite mixture and latent class models, factor analysis and item response models and, of course, structural equations models (SEM) allowing one to investigate associations and - with luck and careful design - causal links between these latent variables.

About the Author

Graham Dunn has been Professor of Biomedical Statistics and Head of the Biostatistics Group at the University of Manchester since 1996. Before that he was Head of the Department of Biostatistics and Computing at the Institute of Psychiatry. Graham's research is primarily focussed on the design and analysis of randomised trials of complex interventions, specialising on the evaluation of cognitive behavioural and other psychological approaches to the treatment of psychosis, depression and other mental health problems. Of particular interest is the design and analysis of multi-centre explanatory trials from which it is possible to test for and estimate the effects of mediation and moderation, and for the effects of dose (sessions attended) and the quality of the therapy provided (including therapist effects). He also has interests in the design and analysis of measurement reliability studies. A key methodological component of both of these fields of applied research is the development and implementation of econometric methods such as the use of instrumental variables. He is author or co-author of seven statistics books, including *Statistical Evaluation of Measurement Errors* (Wiley, 2nd edition 2004), *Statistics in Psychiatry* (Hodder Arnold, 2000) and (with Brian Everitt) *Applied Multivariate Data Analysis* (Wiley, 2nd edition 2001).

Psychological Testing Theory

Vesna Buško
Associate Professor, Faculty of Humanities and Social Sciences
University of Zagreb, Zagreb, Croatia

Testing and assessment of individual differences have been a critical part of the professional work of scientists and practitioners in psychology and related disciplines. It is generally acknowledged that psychological tests, along with the existing conceptualizations of measurements of human potential, are among the most valuable contributions of the behavioral sciences to society. Testing practice is for many reasons an extremely sensitive issue, and is not only a professional but also a public issue. As the decisions based on test results and their interpretations often entail important individual and societal consequences, psychological testing has been the target of substantial public attention and long-standing criticism (AERA, APA, and NCME 2006).

The theory of psychological tests and measurement, or, as typically referred to, test theory or psychometric theory, offers a general framework and a set of techniques for evaluating the development and use of psychological tests. Due to their latent nature, the majority of psychological constructs are typically measured indirectly, i.e., by observing behavior on appropriate tasks or responses to test items. Different test theories have been proposed to provide rationales for behaviorally based measurement.

Classical test theory (CTT) has been the foundation of psychological test development since the turn of the twentieth century (Lord and Novick 1968). It comprises a number of psychometric models and techniques intended to estimate theoretical parameters, including the description of different psychometric properties, such as the derivation of reliability estimates and ways to assess the validity of use of test. This knowledge is crucial if we are to make sound inferences and interpretations from the test scores.

The central notion of CTT is that any observed test score (X) can be decomposed into two additive components: a *true score* (T) and a random *measurement error* term (e). Different models of CTT have been proposed, each defined by specific sets of assumptions that determine the circumstances under which the model may be reasonably applied. Some assumptions are associated with properties of measurement error as random discrepancies between true and observed test scores, whereas others include variations of the assumption that the two tests measure the same attribute. The latter assumption is essential for deducing test reliability, i.e., the ratio of true score variance to observed score variance, from the discrepancy between two measurements of the same attribute in the same person.

CTT and its applications have been criticized for various weaknesses, such as population dependence of its parameters, focus on a single undifferentiated random error, or arbitrary definition of test score variables. Generalizability theory (see Brennan 2001) was developed as an extension of the classical test theory approach, providing a framework for estimating the effects of multiple sources of error or other factors determining test scores. Another generalization of CTT has been put forward within the formulation of the Latent State-Trait Theory (see Steyer 2003). Formal definitions of states and traits have been introduced, and models allowing the separation of persons, situations, and/or interaction effects from measurement error components of the test scores are presented.

A more recent development in psychometric theory, item response theory (IRT), emerged to address some of the limitations of the classical test theory (Embretson and Reise 1999). The core assumption of IRT is that the probability of a person's expected response to an item is the joint function of that person's ability, or her/his position on the latent trait, and one or more parameters characterizing the item. The response probability is presented in the form of an item characteristic curve as a function of the latent trait.

Despite the controversies and criticisms surrounding CTT, and the important advances and challenges in the field of IRT, both classical and modern test theories appear today to be widely used and are complementary in designing and evaluating psychological and educational tests.

Psychology, Statistics in

Joseph S. Rossi
Professor, Director of Research at the Cancer Prevention Research Center
University of Rhode Island, Kingston, RI, USA

The use of quantitative methods in psychology is present essentially at its beginning as an independent discipline, and many of the early developers of statistical methods, such as Galton, Pearson, and Yule, are generally considered by psychologists as among the major contributors to the development of psychology itself. In addition, many early psychologists made major contributions to the development of statistical methods, often in the context of psychometric measurement theory and multivariate methods (e.g., Spearman, Thurstone). Among the techniques that psychologists developed or helped to develop during the early part of the twentieth century are the correlation coefficient, the chi-square test, regression analysis, factor analysis (see ►Factor Analysis and Latent Variable Modelling), ►principal components analysis, and various multivariate procedures. The use of the ►analysis of variance (ANOVA) in psychology did not begin until about 1940 and quickly became widespread.

During the decades of the 1940s and 1950s, a kind of schism arose among psychologists, with experimental psychologists favoring the use of ANOVA techniques and psychologists interested in measurement and individual differences favoring correlation and regression techniques, culminating in Cronbach's famous declaration concerning the "two disciplines" of scientific psychology. That these procedures were both aspects of the general linear model (see ►General Linear Models) and essentially equivalent mathematically did not become widely known among psychologists until about 1968. A similar sort of schism with respect to models of statistical inference has been resolved with a kind of hybrid model that accommodates both the Fisher and Neyman-Pearson approaches, although in this case, most researchers in psychology are completely unaware that such a schism ever existed, and that the models of statistical decision-making espoused in their textbooks and in common everyday use represent a combination of views thought completely antithetical by their original proponents. Bayesian approaches, while not unknown in psychology, remain vastly underutilized.

Statistical methods currently in common use in psychology include: Pearson product-moment correlation coefficient, chi-square test (see ►Chi-Square Tests), *t* test, univariate and multivariate analysis of variance (see ►Analysis of Variance and ►Multivariate Analysis of Variance (MANOVA)) and covariance with associated follow-up procedures (e.g., Tukey test), multiple regression, factor analysis (see ►Factor Analysis and Latent Variable Modelling) and ►principal components analysis, discriminant function analysis, path analysis, and structural equation modeling (see ►Structural Equation Models). Psychologists have been instrumental in the continued development and refinement of many of these procedures, particularly for measurement oriented procedures, such as item response theory, and structural equation modeling techniques, including confirmatory factor analysis, latent growth curve modeling, multiple group structural invariance modeling, and models to detect mediation and moderation effects. There is considerable emphasis on group level data analysis using parametric statistical procedures and the assumptions of univariate and multivariate normality. The use of nonparametric procedures, once fairly common, has declined substantially in recent decades. The use of more modern nonparametric techniques and robust methods is almost unknown among applied researchers.

The Null Hypothesis Significance Testing Controversy

Common to many of the procedures in use in psychology is an emphasis on null hypothesis significance testing (NHST) and concomitant reliance on statistical test *p* values for assessing the merit of scientific hypotheses. Considering its still dominant position, the use of the NHST paradigm in psychology and related disciplines has been subject to numerous criticisms over a surprisingly long period of time, starting at least 70 years ago. Until recently, these criticisms have not gained much traction. Common objections raised against the NHST paradigm include the following:

- The null is not a meaningful hypothesis and is essentially always false.

- Rejection of the null hypothesis provides only weak support for the alternative hypothesis.
- Failure to reject the null hypothesis does not mean that the null can be accepted, so that null results are inconclusive.
- Significance test p values are misleading in that they depend largely on sample size and consequently do not indicate the magnitude or importance of the obtained effect.
- The obtained p value is unrelated to, but frequently confused with both the study alpha (α) level and $1 - \alpha$.
- Reliance on p values has led to an overemphasis on the type I error rate and to the neglect of the type II error rate.
- Statistical significance is not the same as scientific or practical significance.
- The NHST approach encourages an emphasis on point estimates of parameter values rather than confidence intervals.
- The use of the $p < 0.05$ criterion for ►statistical significance is arbitrary and has led to dichotomous decision making with regard to the acceptance/rejection of study hypotheses. This has resulted in the phenomenon of "publication bias," which is the tendency for studies that report statistical significance to be published while those that do not are not published, despite the overall quality or merit of the research.
- The dichotomous decision making approach inherent to the NHST paradigm has seriously compromised the ability of researchers to accumulate data and evidence across studies. This has hindered the development of theories in many areas of psychology, since a few negative results tend to be accorded more weight than numerous positive results.

The extent and seriousness of these criticisms has led some to suggest an outright ban on the use of significance testing in psychology. Once inconceivable, this position is receiving serious consideration in numerous journal articles in the most prestigious journals in psychology, has been discussed by recent working groups and task forces on quantitative methods and reporting standards in psychology, and is even the subject of one recent book. Even among those not willing to discard significance testing entirely, there is widespread agreement on a number of alternative approaches that would reduce reliance on p values. These include the use of confidence intervals, effect size indices, ►power analysis, and ►meta-analysis. Confidence intervals (see ►Confidence Interval) provide useful information beyond that supplied by point estimates of parameters and p values. In psychology, the most frequently used has been the 95% confidence interval. Despite its simplicity, confidence intervals are still not widely used and reported or even that well understood by many applied researchers. For example, some recent studies have indicated that even when error bars are shown on graphs, it is not at all clear if authors intended to show standard deviations, standard errors, or confidence intervals.

Measures of effect size have been recommended as supplements to or even as substitutes for reporting p values. These provide a more direct index of the magnitude of study results and are not directly influenced by study sample size. Measures of effect size fall into two broad categories. The most common historically are measures of the proportion of shared variance between two (or more) variables, such as r^2 and R^2. These indices have a long history of use in research employing correlational and regression methods, particularly within the tradition of individual differences research. Within the tradition of experimental psychology, comparable measures have been available for many years but have not seen widespread use until relatively recently. Most commonly used for the t test and ANOVA are η^2 and ω^2, which index the proportion of variance in the dependent variable that is accounted for by the independent variable. Again, under the general linear model (see ►General Linear Models), these indices are essentially equivalent mathematically and retain their separate identities primarily for historical purposes. Multivariate analogs exist but are not well known and not often used.

A second and more recent approach to measuring the magnitude of study outcomes independent of p values is represented by standardized measures of effect size. These were developed by Cohen as early as 1960 but have not seen widespread use until relatively recently. While he developed a wide range of such indices designed to cover numerous study designs and statistical methods, by far the most widely known and used is Cohen's d. An advantage of d is its simplicity:

$$d = (M_1 - M_2)/s_p$$

where M_1 and M_2 represent the means of two independent groups and s_p is the pooled within-groups standard deviation. It is also easily related to proportion of variance measures:

$$\eta^2 = d^2/(d^2 + 4).$$

A disadvantage of d is that is it applicable only to the comparison of two groups. A generalized version applicable to the ANOVA F test is Cohen's f. However, this measure is much less well-known and not often utilized. As a guide to use and interpretation, Cohen developed a simple rubric

for categorizing the magnitudes of effect sizes. For *d*, small, medium, and large effect sizes are defined as 0.20, 0.50, and 0.80, respectively. The equivalent magnitudes for proportion of variance accounted for are 0.01, 0.06, and 0.14, respectively. Cohen recognized these definitions as arbitrary, but subsequent research suggests they hold up well across a broad range of research areas in the "softer" areas of psychology.

Although methods for aggregating data across independent studies have been in use for more than 100 years, a more formal and systematic approach did not begin to take shape until 1976 with the independent work of Rosenthal and Glass, who coined the term meta-analysis. While very controversial at first, and to a lesser extent still, the technique caught on rapidly as an efficient way to summarize quantitatively the results of a large number of studies, thus overcoming the heavy reliance on *p* values used in the more traditional narrative literature review. In principle any outcome measure can be employed; however, in practice meta-analysis relies heavily on the use of effect sizes as the common metric integrated across studies. Many studies employ the Pearson correlation coefficient *r* for this purpose, although Cohen's *d* is without question the most frequently used, primarily due to its simplicity and easy applicability to a wide range of focused two-group comparisons characteristic of many studies in psychology (e.g., control vs treatment, men vs women). It is probably fair to say that the rise of meta-analysis over the past 20–30 years has greatly facilitated and popularized the concept of the effect size in psychology. As a consequence, a great deal of work has been conducted on *d* to investigate its properties as a statistical estimator. This has resulted in substantial advances in meta-analysis as a statistical procedure. Most early meta-analyses employed simple two-group comparisons of effect size across studies using a fixed effects model approach (often implicitly). Most recent applications have emphasized a regression model approach in which numerous study-level variables are quantified and used as predictors of effect size (e.g., subject characteristics, study setting, measures and methods used, study design quality, funding source, publication status and date, author characteristics, etc.). Fixed effects models still predominate, but there is growing recognition that random (or mixed) effects models may be more appropriate in many cases. A considerable array of follow-on procedures have been developed as aids in the interpretation of meta-analysis results (e.g., effect size heterogeneity test *Q*, funnel and forest plots, assessment of publication bias, fail-safe number, power analysis, etc.). When done well, meta-analysis not only summarizes the literature, it identifies gaps and provides clear suggestions for future research.

Current Trends and Future Directions

Quantitative specialists in psychology continue to work on methods and design in a number of areas. These include data descriptive and exploratory procedures and alternatives to parametric methods, such as ▶exploratory data analysis and cluster analysis (see ▶Cluster Analysis: An Introduction), robust methods, and computer-intensive methods. Work focusing on design includes alternatives to randomized designs, methods for field experiments and quasi-experimental designs, and the use of fractional ANOVA designs. Structural equation modeling continues to receive a lot of attention, including work on latent growth curve modeling, latent transition analysis, intensive longitudinal modeling, invariance modeling, multiple group models, multilevel models, hierarchical linear modeling, and models to detect mediation and moderation effects.

Missing data analysis and multiple imputation methods (see ▶Multiple Imputation), especially for longitudinal designs, is also receiving considerable emphasis. The increased interest in longitudinal approaches has not been limited to group designs. The single subject/idiographic approach, also known as the person-specific paradigm, has been the focus of much recent work. This approach focuses on change over time at the individual level, exemplified by time series analysis, intensive longitudinal modeling, dynamic factor analysis, and dynamic cluster analysis.

Psychologists also continue to conduct a great deal of work on meta-analysis and integrative data analysis, particularly on random effects and hierarchical model approaches, as well as on investigations of the properties of various effect size indices as statistical estimators and the application and development of effect size indices for a wider range of study designs. Increased use of meta-analysis by applied researchers is encouraging the use of alternatives to null hypothesis testing, including the specification of non-zero null hypotheses, and the use of alternative hypotheses that predict the magnitude of the expected effect sizes.

About the Author

Joseph S. Rossi, Ph.D., is Professor and Director of the Behavioral Science Ph.D. program in the Department of Psychology, and Director of Research at the Cancer Prevention Research Center, at the University of Rhode Island. He has been principal investigator or co-investigator on more than 50 grants and has published more than 150 papers and chapters. In 1996, the American Psychological Society and the Institute for Scientific Information listed Dr. Rossi 5th in author impact (citations/paper) and 12th in number of citations (*APS Observer*, January

1996, pp. 14–18). In 2006, he was named one of the most highly cited researchers in the world in the fields of Psychology/Psychiatry by Thomson Reuters (http://isihighlycited.com/). He won the University of Rhode Island's Scholarly Excellence Award in 2003, was elected to membership in the Society of Multivariate Experimental Psychology in 1995, and is a fellow of Division 5 of the American Psychological Association. Dr. Rossi is one of the principal developers of the transtheoretical model of health behavior change. His areas of interest include quantitative psychology, health promotion and disease prevention, and expert system development for health behavior change. Dr. Rossi is a member of the University of Rhode Island's Institutional Review Board.

Public Opinion Polls

Christopher Wlezien
Professor of Political Sciences
Temple University, Philadelphia, PA, USA

A public opinion poll is a survey of the views of a sample of people. It is what we use to measure public opinion in the modern day. This was not always true, of course, as nonrandom "straw polls" have been in regular use at least since the early nineteenth century. We thus had information even back then about what the public thought and wanted, though it was not very reliable. The development of probability sampling, and its application by George Gallup, Archibald Crossley, and Elmo Roper, changed things in important ways, as we now had more reliable information about public opinion (see Geer 1996). The explosion of survey data since that time has fueled the growth in research on attitudes and opinion and behavior that continues today.

There are various forms of probability sampling. In simple random sampling respondents are selected purely at random from the population. This is the most basic form of probability sampling and does a good job representing

the population particularly as the sample size increases and sampling error declines. In stratified random sampling, the population is divided into strata, e.g., racial or ethnic groups, and respondents are selected randomly from within the strata. This approach helps reduce sampling error across groups, which can result from simple random sampling. Traditionally, most survey organizations have relied on ▶cluster sampling. Here the population is divided into geographic clusters, and the survey researcher draws a sample of these clusters and then samples randomly from within them. This is particularly useful when respondents are geographically disbursed. Survey organizations using any of these methods traditionally have relied on face-to-face interviews.

The technology of public opinion polling has changed quite dramatically over time. The invention of random digit dialing (RDD) had an especially significant impact, as interviewing could be done over the telephone based on lists of randomly-generated phone numbers. The more recent introduction of internet polling is having a similar impact. These developments have clear and increasing advantages in cost and speed, and have made it much easier to conduct polls. Witness the growth in the number of pre-election trial-heat polls in presidential election years in the United States (US) (Wlezien and Erikson 2002). Consider also that National Annenberg Election Survey (NAES) conducted over 100,000 telephone interviews during the 2000 presidential election campaign, with similar numbers in 2004 and 2008. In the same election years Knowledge Networks' conducted repeated interviews with 29,000 individuals via the internet. Similar developments can be seen in other countries, including Canada and the United Kingdom. These numbers would be almost inconceivable using face-to-face interviews.

The developments also come with disadvantages. To begin with, there is coverage error. Not everyone has a telephone, and the number relying solely on a cell phone – which poses special challenges for telephone surveys – is growing. Fewer have access to the internet and we cannot randomly e-mail them (note that this precludes calculations of sampling error, and thus confidence intervals. Internet polls do have a number of advantages for scholarly research, however (Clarke et al. 2008)). Even among those we can reach, nonresponse is a problem. The issue here is that respondents who select out of surveys may not be representative of the population. Survey organizations and scholars have long relied on weighting devices to address coverage and nonresponse error (besides sampling error and coverage and nonresponse error, all polls are subject to measurement error, which reflects flaws in the survey instrument itself, including question wording, order, interviewer training and other things. For a treatment of the different forms of survey error, see Weissberg (2005)). In recent years more complicated approaches have begun to be used, including "propensity scores" (see, e.g., Terhanian 2008).

A recent analysis of polling methods in the 2008 US presidential election campaign suggested that the survey mode had little effect on poll estimates (AAPOR 2009). The extent to which the weighting fixes used by survey organizations succeed is the subject of ongoing research – see, e.g., work on internet polls by Malhotra and Krosnick (2007) and Sanders et al. (2007). It is of special importance given the appeal of internet surveys owing to the speed with which they can be conducted and their comparatively low cost.

Despite the difficulties, polls have performed very well. Pre-election polls have proved very accurate at predicting the final vote, particularly at the end of the campaign (Traugott 2005). They also predict well earlier on, though it is not an identity relation, e.g., in US presidential elections, early leads tend to decline by Election Day (Wlezien and Erikson 2002). Pre-election polls in recent election years have provided more information about the election outcome than highly-touted election prediction markets (Erikson and Wlezien 2008). Polls also tell quite a lot about public opinion (see, e.g., Stimson 1991; Page and Shapiro 1992; Erikson and Tedin 2009). Policymakers now have reliable information about the preferences of those with a stake in the policies they make. It also appears to make a difference to what they actually do (Geer 1996).

Acknowledgments

I thank my colleague Michael G. Hagen for very helpful comments.

About the Author

Dr. Christopher Wlezien is Professor, Department of Political Science, Temple University, Philadelphia. While at Oxford University, he co-founded the Spring School in Quantitative Methods for Social Research. He is an elected member of the International Statistical Institute (2006), and holds or has held visiting positions at Columbia University, the European University Institute, Institute Empresa, Juan March Institute, McGill University, L'Institut d'Etudes Politiques de Paris, and the University of Manchester. He has authored or co-authored many papers and books, including *Degrees of Democracy* (Cambridge, 2010), in which he develops and tests a thermostatic model of public opinion and policy. Currently, he is founding co-editor of the *Journal of Elections, Public Opinion and Parties* and Associate editor of *Public Opinion Quarterly*.

P–Values

Raymond Hubbard
Thomas F. Sheehan Distinguished Professor of Marketing
Drake University, Des Moines, IA, USA

The origin of the *p*-value is credited to Karl Pearson (1900), who introduced it in connection with his chi-square test (see ►Chi-Square Tests). However, it was Sir Ronald Fisher who popularized significance tests and *p*-values in the multiple editions of his hugely influential books *Statistical Methods for Research Workers* and *The Design of Experiments*, first published in 1925 and 1935, respectively. Fisher used divergencies in the data to reject the null hypothesis by calculating the probability of the data on a true null hypothesis, or $\Pr(x|H_0)$. More formally, $p = \Pr(T(X) \geq T(x)|H_0)$. The *p*-value is the probability of getting a test statistic $T(X)$ larger than or equal to the observed result, $T(x)$, as well as more extreme ones, assuming a true null hypothesis, H_0, of no effect or relationship. Thus, the *p*-value is an index of the (im)plausibility of the actual observations (together with more extreme, unobserved ones) if the null is true, and is a random variable whose distribution is uniform over the interval $[0,1]$.

The reasoning is that if the data are viewed as being rare or extremely unlikely under H_0, this constitutes *inductive evidence* against the null hypothesis. Fisher (1966, p. 13) immortalized a *p*-value of 0.05 for rejecting the null: "It is usual and convenient for experimenters to take 5 per cent. as a standard level of significance, in the sense that they are prepared to ignore all results which fail to reach this standard." Consequently, values like $p < 0.01$, $p < 0.001$, and so on, are said to furnish even stronger evidence against H_0. So Fisher considered *p*-values to play an important epistemological role (Hubbard and Bayarri 2003).

Moreover, Fisher (1959, p. 43) saw the *p*-value as an *objective* measure for judging the (im)plausibility of H_0:

> "…the feeling induced by a test of significance has an objective basis in that the probability statement on which it is based is a fact communicable to and verifiable by other rational minds. The level of significance in such cases fulfils the conditions of a measure of the rational grounds for the disbelief [in the null hypothesis] it engenders."

Researchers across the world have enthusiastically adopted *p*-values as a "scientific" and "objective" criterion for certifying knowledge claims.

Unfortunately, the *p*-value is neither an objective nor very useful measure of evidence in statistical significance testing (see Hubbard and Lindsay 2008, and the references therein). In particular, *p*-values exaggerate the evidence against H_0. Because of this, the validity of much published research with comparatively small (including 0.05) *p*-values must be called into question.

Of great concern, though obviously no fault of the index itself, members of the research community insist on investing *p*-values with capabilities they do not possess (for critiques of this, see, among others, Carver 1978; Nickerson 2000). Some common misconceptions regarding the *p*-value are that it denotes an objective measure of:

- The probability of the null hypothesis being true
- The probability (in the sense of $1 - p$) of the alternative hypothesis being true
- The probability (again, in the sense of $1 - p$) that the results will replicate
- The magnitude of an effect
- The substantive or practical significance of a result
- The Type I error rate
- The generalizability of a result

Despite its ubiquity, the *p*-value is of very limited use. Indeed, I agree with Nelder's (1999, p. 261) assertion that the most important task in developing a helpful statistical science is "to demolish the *P*-value culture."

P-Values, Combining of

Dinis Pestana
Professor, Faculty of Sciences
Universidade de Lisboa, DEIO, and CEAUL – Centro de Estatística e Aplicações da Universidade de Lisboa, Lisboa, Portugal

Let us assume that the *p*-values p_k are known for testing H_{0k} versus H_{Ak}, $k = 1, \ldots, n$, in n independent studies on some common issue, and our aim is to achieve a decision on the overall question H_0^*: all the H_{0k} are true *versus* H_A^*: some of the H_{Ak} are true. As there are many different ways in which H_0^* can be false, selecting an appropriate test is in general unfeasible. On the other hand, combining the available p_k's so that $T(p_1, \ldots, p_n)$ is the observed value of a random variable whose sampling distribution under H_0^* is known is a simple issue, since under H_0^*, $\boldsymbol{p}$ is the observed value of a random sample $\boldsymbol{P} = (P_1, \ldots P_n)$ from a $Uniform(0,1)$ population. In fact, several different sensible combined testing procedures are often used.

A rational combined procedure should of course be *monotone*, in the sense that if one set of *p*-values $\boldsymbol{p} = (p_1, \ldots, p_n)$ leads to rejection of the overall null hypothesis H_0^*, any set of componentwise smaller *p*-values $\boldsymbol{p}' = (p_1', \ldots, p_n')$, $p_k' \leq p_k$, $k = 1, \ldots, n$, must also reject H_0^*.

Tippett (1931) used the fact that $P_{1:n} = \min\{P_1, \ldots, P_n\} \underset{|_{H_0^*}}{\sim} Beta(1,n)$ to reject H_0^* if the minimum observed p-value $p_{1:n} < 1-(1-\alpha)^{1/n}$. This *Tippett's minimum method* is a special case of *Wilkinson's method* (Wilkinson, 1951), advising rejection of H_0^* when some low rank order statistic $p_{k:n} < c$; as $P_{k:n} \sim Beta(k, n+1-k)$, to reject H_0^* at level α the cut-of-point c is the solution of $\int_0^c u^{k-1}(1-u)^{n-k}\mathrm{d}u = \alpha\, B(k, n+1-k)$.

The exact distribution of $\overline{P}_n = \frac{1}{n}\sum_{k=1}^n P_k$ is cumbersome, but for large n an approximation based on the central limit theorem (see ▶Central Limit Theorems) can be used to perform an overall test on H_0^* vs. H_A^*. On the other hand, the probability density function of the ▶geometric mean $G_n = \left(\prod_{k=1}^n P_k\right)^{\frac{1}{n}}$ of n independent uniform random variables is readily computed, $f_{G_n}(x) = \dfrac{n\,(-n\,x\,\ln\,x)^{n-1}}{\Gamma(n)}\mathrm{I}_{(0,1)}(x)$, leading to a more powerful test; see, however, the discussion below on publication bias.

Another way of constructing combined p-values is to use additive properties of simple functions of uniform random variables. Fisher (1932) used the fact that $P_k \sim Uniform(0,1) \Longrightarrow -2\ln P_k \sim \chi^2_2$, and therefore, $-2\sum_{k=1}^n \ln P_k \underset{|_{H_0^*}}{\sim} \chi^2_{2n}$. Then H_0^* is rejected at the significance level α if the $-2\sum_{k=1}^n \ln p_k > \chi^2_{2n,1-\alpha}$. Stouffer et al. (1949) used as test statistic $\sum_{k=1}^n \dfrac{\Phi^{-1}(P_k)}{\sqrt{n}} \underset{|_{H_0^*}}{\sim} Gaussian(0,1)$, where Φ^{-1} denotes the inverse of the distribution function of the standard Gaussian, rejecting H_0^* at level α if $\left|\sum_{k=1}^n \frac{\Phi^{-1}(P_k)}{\sqrt{n}}\right| > z_{1-\alpha}$.

Another simple transformation of uniform random variables P_k is the logit transformation, $\ln\frac{P_k}{1-P_k} \sim Logistic(0,1)$. As $\sum_{k=1}^n \dfrac{\ln\frac{P_k}{1-P_k}}{\sqrt{n\,\frac{\pi^2(5n+2)}{3(5n+4)}}} \approx t_{5n+4}$, reject H_0^* at the significance level α if $-\sum_{k=1}^n \dfrac{\ln\frac{p_k}{1-p_k}}{\sqrt{n\,\frac{\pi^2(5n+2)}{3(5n+4}}} > t_{5n+4,1-\alpha}$.

Birnbaum (1954) has shown that every monotone combined test procedure is *admissible*, i.e., provides a most powerful test against some alternative hypothesis for combining some collection of tests, and is therefore optimal for some combined testing situation whose goal is to harmonize eventually conflicting evidence, or to pool inconclusive evidence. In the context of social sciences Mosteller and Bush (1954) recommend Stouffer's method, but Littel and Folks (1971, 1973) have shown that under mild conditions Fisher's method is optimal for combining independent tests.

As in many other techniques used in ▶meta-analysis, publication bias can easily lead to erroneous conclusions. In fact, the set of available p-values comes only from studies considered worth publishing because the observed p-values were small, seeming to point out significant results. Thus the assumption that the p_k's are observations from independent $Uniform(0,1)$ random variables is questionable, since in general they are in fact a set of low order statistics, given that p-values greater than 0.05 have not been recorded. For instance, $\mathbb{E}\left(G_n^k\right) = \left(\frac{1}{1+\frac{k}{n}}\right)^n \underset{n\to\infty}{\longrightarrow} \mathrm{e}^{-k}$, and in particular $\mathbb{E}\left(G_n\right) = \left(\frac{n}{n+1}\right)^n \underset{n\to\infty}{\downarrow} \frac{1}{\mathrm{e}} \approx 0.3679$, the standard deviation decreases to zero, the skewness steadily decreases after a maximum 0.2645 for $n = 5$, and the kurtosis increases from -0.8541 (for $n = 2$) towards 0. Whenever $p_{n:n}$ falls below the critical rejection point, this test will lead to the rejection of H_0^*, but $p_{n:n}$ smaller than the critical point (for $n \geq 14$, the expected value of G_n is greater than 0.36 and the standard deviation is smaller than 0.1) is what should be expected as a consequence of publication bias.

Another important issue: H_A^* states that some of the H_{Ak} are true, and so a meta-decision on H_0^* implicitly assumes that some of the P_k may have non-uniform distribution, cf. Hartung et al. (2008, pp. 81–84) and Kulinskaya et al. (2008, pp. 117–119), and references therein, on the promising concepts of generalized and of random p-values. Gomes et al. (2009) investigated the effect of augmenting the available set of p-values with uniform and with non uniform pseudo-p-values, using results such as: Let X_{m_1} and X_{m_2} be independent random variables, X_m denoting a random variable with probability density function $f_m(x) = \left(mx + \frac{2-m}{2}\right)\mathrm{I}_{(0,1)}(x)$, $m \in [-2,2]$, i.e., a convex mixture of uniform and $Beta(1,2)$ (if $m \in [-2,0)$), thus favoring pseudo-p-values near 0 the sharper the slope is, the slope $m = 0$ corresponding to standard uniform, or of uniform and $Beta(2,1)$ (if $m \in (0,2]$), in this case favoring the occurrence of p-values near 1. Then $\min\left(\frac{X_{m_1}}{X_{m_2}}, \frac{1-X_{m_1}}{1-X_{m_2}}\right)$ is a member of the same family – more precisely $X_{\frac{m_1 m_2}{6}}$. In particular, if either $m_1 = 0$ or $m_2 = 0$, then $\min\left(\frac{X_{m_1}}{X_{m_2}}, \frac{1-X_{m_1}}{1-X_{m_2}}\right)$ can be used to generate a new set of uniform random variables, which moreover are independent of the ones used to generate them.

Extensive simulation, namely with computationally augmented samples of p-values (Gomes et al. 2009;

Brilhante et al. 2010) led to the conclusion that in what concerns decreasing power, and increasing number of unreported cases needed to reverse the overall conclusion of a meta-analysis, the methods of combining *p*-values rank as follows:

1. Arithmetic mean
2. ►Geometric mean
3. Chi-square transformation (Fisher's method)
4. Logistic transformation
5. Gaussian transformation (Stouffer's method)
6. Selected order statistics (Wilkinson's method)
7. Minimum (Tippett's method)

About the Author

Professor Dinis Pestana has been President of the Department of Statistics and Operations Research, University of Lisbon, for two consecutive terms (1986–1989), President of the Faculty of Sciences of Lisbon extension in Madeira (1985–1988) before the University of Madeira has been founded, President of the Center of Statistics and Applications, Lisbon University, for three consecutive terms (1981–1987). He supervised the Ph. D. studies of many students that played a leading role in the development of Statistics at the Portuguese universities, and is co-author of 40 papers published in international journals or as chapters of books, and many other papers, namely explaining Statistics to the layman. He launched the annual meetings of the Portuguese Statistical Society, and had a leading role on the local organization of international events, such as the 2001 European Meeting of Statisticians in Funchal.

Pyramid Schemes

Robert T. Smythe
Professor
Oregon State University, Corvallis, OR, USA

A pyramid scheme is a business model in which payment is made primarily for enrolling other people into the scheme. Some schemes involve a legitimate business venture, but in others no product or services are delivered. A typical pyramid scheme combines a plausible business opportunity (such as a dealership) with a recruiting operation that promises substantial rewards. A recruited individual makes an initial payment, and can earn money by recruiting others who also make a payment; the recruiter receives part of these receipts, and a cut of future payments as the new recruits go on to recruit others. In reality, because of the geometrical progression of (hypothetical) recruits, few participants in a pyramid scheme will be able to recruit enough others to recover their initial investment, let alone make a profit, because the pool of potential recruits is rapidly exhausted.

Although they are illegal in many countries, pyramid schemes have existed for over a century. As recently as November 2008, riots broke out in several towns in Colombia after the collapse of several pyramid schemes, and in 2006 Ireland launched a website to better educate consumers to pyramid fraud after a series of schemes were perpetrated in Cork and Galway.

Perhaps the best-known type of pyramid scheme is a *chain letter*, which often does not involve even a fictitious product. A chain letter may contain k names; purchasers of the letter invest \$2x, with \$$x$ paid to the name at the top of the letter and \$$x$ to the seller of the letter. The purchaser deletes the name at the top of the list, adds his own at the bottom, and sells the letter to new recruits. The promoter's pitch is that if the purchaser, and each subsequent recruit for k−1 stages, sells just two letters, there will be 2^{k-1} people selling 2^k letters featuring the purchaser's name at the top of the list, so that the participant would net $\$2^k x$ from the venture. Many variants of this basic "get rich quick" scheme have been, and continue to be, promoted.

A structure that can be used to model many pyramid schemes is that of recursive trees. A tree with n vertices labeled $1, 2, \ldots, n$ is a *recursive tree* if node 1 is distinguished as the *root*, and for each j with $2 \le j \le n$, the labels of the vertices in the unique path from the root to node j form an increasing sequence. The special case of *random* or *uniform* recursive trees, in which all trees in the set of trees of given order n are equally probable, has been extensively analyzed (cf. Smythe and Mahmoud (1994), for example); however, most pyramid schemes or chain letters in practice have restrictions making their probability models non-uniform. The number of places where the next node may join the tree is then a random variable, unlike the uniform case. This complicates the analysis considerably (and may account for the relative sparsity of mathematical analysis of the properties of pyramid schemes).

Bhattacharya and Gastwirth (1983) analyze a chain letter scheme allowing reentry, in which each purchaser may sell only two letters, unless he purchases a new letter to re-enter the chain. In terms of recursive trees, this means that a node of the tree is *saturated* once it has two offspring nodes, and no further nodes can attach to it. It is further assumed that at each stage, participants who have not yet sold two letters all have an equal chance to make the next sale, i.e., all unsaturated nodes of the recursive tree have an equal chance of being the "parent" of the next node to be added. If L_n denotes the number of leaves of the recursive tree (nodes with no offspring) at stage n under this growth rule, L_n/n corresponds to the proportion of "shutouts" (those receiving no revenue) in this chain letter scheme. The analysis of Bhattacharya and Gastwirth sets up a nonhomogeneous Markov chain model and derives a diffusion approximation for large n. They find that L_n/n converges to 0.382 in this model and that the (centered and scaled) number of shutouts has a normally distributed limit. Mahmoud (1994) considers the height h_n of the tree of order n in this same "random pyramid" scheme and show that it converges with probability 1 to 3.98912; the proof involves embedding the discrete-time growth process of the pyramid in a continuous time birth-and-death process. Mahmoud notes that a similar analysis could be carried out for schemes permitting the sale of m letters, provided that the probabilistic behavior of the total number of shutouts could be derived (as it was in the binary case by Bhattacharya and Gastwirth).

Gastwirth (1977) and Gastwirth and Bhattacharya (1984) analyze another variant of pyramid schemes, known as a quota scheme. This places a limit on the maximum number of participants, so that the scheme corresponds to a recursive tree of some fixed size n. This scheme derives from a case in a Connecticut court (Naruk 1975) in which people bought dealerships in a "Golden Book of Values," then were paid to recruit other dealers. In this scheme, each participant receives a commission from all of his descendants; thus for the jth participant, the size of the branch of the tree rooted at j determines his profit. If S_j denotes the size of this branch, and j/n converges to a limit θ, Gastwirth and Bhattacharya showed that the distribution of S_j converges to the geometric law

$$P(S_j = i+1) = \theta(1-\theta)^i \quad \text{for } i = 0, 1, 2, \ldots$$

(It was later shown (Mahmoud and Smythe (1991)) that if j is fixed, the limiting distribution of S_j/n is $Beta(1, j-1)$.) Calculations made by Gastwirth and Bhattacharya show that, for example, when n is fixed at 270, the 135th entry has probability only about 0.15 of recruiting two or more new entrants, and probability 0.03 of three or more recruits. Gastwirth (1977) shows that for large n, the expected proportion of all participants who are able to recruit at least r persons is 2^{-r}.

Other variants of pyramid schemes include the "8-Ball Model" and the "2-Up System" (http://www.mathmotivation.com/money/pyramid-scheme.html). In the eight-Ball model, the participant again recruits two new entrants, but does not receive any payment until two further levels have been successfully recruited. Thus a person at any level in the scheme would theoretically receive $2^3 = 8$ times his "participation fee," providing incentive to help those in lower levels succeed. In the two-Up scheme, the income from a participant's first two recruits goes to the individual who recruited the participant; if the participant succeeds in recruiting three or more new entrants, the income received from these goes to the participant, along with the income from the first two sales made by each subsequent recruit. This scheme creates considerable incentive to pursue the potentially lucrative third recruit. For both of these schemes, it is easily calculated that when the pool of prospective recruits is exhausted, the majority of the participants in the scheme end up losing money.

About the Author

Robert Smythe is Professor of Statistics at Oregon State University. He was Chair of the Department of Statistics for ten years and previously chaired the Department of Statistics at George Washington University for eight years. He has written in many areas of probability and statistics, and is a Fellow of the American Statistical Association and a Fellow of the Institute for Mathematical Statistics.

Q

Quantitative Risk Management

Paul Embrechts
Professor of Mathematics
ETH Zurich, Zurich, Switzerland

Introduction

Quantitative Risk Management (QRM for short) is a relatively new field of mathematical research on the scientific firmament. As a field of science, QRM concentrates on the axiomatisation, the measurement and the analysis of risk in a rather broad context. Examples range from the construction of dykes, over the development of new medical compounds to the calculation of risk capital for insurance companies and banks. The quantification of risk and the societal challenges concerning "living with risks" are well known to all; how high do we need to build a sea dyke in order to protect a geographic area and its inhabitants, or what are prudent regulatory guidelines in order to safeguard a stable financial system? It is immediately clear that an overview of the field is out of the question, the various acronyms encountered stand proof of this: besides QRM, ERM (Enterprise-wide Risk Management), GRM (Global RM), IRM (Integrative RM), and no doubt others. A broad overview of the various faces of RM can for instance be obtained from (Melnick and Everitt 2008). In this paper we will restrict to a rather specific, though important interpretation, that of McNeil et al. (2005); the latter is mainly derived from the field of banking and insurance, though the concepts, techniques and tools are much more widely applicable. First of all, we will look at risk as related to randomness or uncertainty. As such, the main tools discussed in McNeil et al. (2005) concern the field of stochastics: probability theory, statistics and the theory of stochastic processes. I am very well aware that this restriction is a shortcoming but so be it. It suffices to stress over and over again that in any application of importance and substance, it pays for the quantitative risk modeller to show a fair amount of humbleness. Also, that same modeller must realise that such "real problems" only can be solved in an interdisciplinary context, and that the quantitative analyst (often referred to as "quant" in the world of banking) should be very well aware of the (often disturbing) importance of the qualitative, the irrational, the human factor. Having said all that, in the following paragraphs we concentrate only on the quantitative, stochastic side of risk, hence referred to as QRM, and this as summarised in McNeil et al. (2005). Examples will mainly come from the banking world.

The Basic Set-Up: Risk Measures

The first question one needs to consider is whether risk is to be measured in a dynamic way (as a process in time) or in a static, one-period way, say. For reason of space, we concentrate on the latter. Hence risk is modelled initially by a real-valued random variable (rv) X defined on some probability space $(\Omega, \mathcal{F}, P)$

$$X : (\Omega, \mathcal{F}, P) \to \mathbb{R}\,.$$

The distributional properties of X are captured by its distribution function (df) F_X, or F for short,

$$F_X(x) = P(X \le x)\,, \quad \overline{F}_X(x) = P(X > x)\,.$$

For notational convenience, we shall only concentrate on the upper tail $\overline{F} = 1 - F$ of the df F. A risk measure $\mathcal{R}$ now maps the rv X (in our case the df F_X) onto a real number $\mathcal{R}(X)$ satisfying certain axiomatic properties: in applications to finance, these are referred to as the axioms of *coherence* (see Artzner et al. 1999):

(C1) (homogeneity) $\forall \lambda > 0 : \mathcal{R}(\lambda X) = \lambda \mathcal{R}(X)$
(C2) (translation invariance) $\forall a \in \mathcal{R} : \mathcal{R}(X + a) = \mathcal{R}(X) + a$
(C3) (subadditivity) $\mathcal{R}(X_1 + X_2) \le \mathcal{R}(X_1) + \mathcal{R}(X_2)$
(C4) (monotonicity) $X_1 \le X_2 \Rightarrow \mathcal{R}(X_1) \le \mathcal{R}(X_2)$.

A risk measure $\mathcal{R}$ satisfying (C1–C4) is called a coherent risk measure. Especially (C3) is disputed (it is related to the notions of diversification and risk aggregation) and indeed several alternative axioms have been proposed; see for instance Föllmer and Schied (2004). The key questions to be asked for any axiomatic system are:

(Q1) Construct examples satisfying (C1–C4);
(Q2) Do risk measures used in practice satisfy (C1–C4), and
(Q3) How can such risk measures be estimated.

Miodrag Lovric (ed.), *International Encyclopedia of Statistical Science*, DOI 10.1007/978-3-642-04898-2,

Concerning (Q1) one can show that any coherent risk measure is a so called generalized scenario measure; see McNeil et al. (2005, p.244). A commonly used risk measure in the world of banking regulation is the so-called Value-at-Risk measure $\mathrm{VaR}_\alpha(X)$ for $\alpha \in (0,1)$, typically $\alpha \in \{0.99, 0.995, 0.999, 0.9997\}$, i.e., α is close to 1,

$$\mathrm{VaR}_\alpha(X) = F_X^{\leftarrow}(\alpha)$$

where $F_X^{\leftarrow}$ stands for the (generalized) inverse, or quantile function of F_X; see McNeil et al. (2005, p. 38). In general, VaR is *not* coherent. A consequence is that $P(X > \mathrm{VaR}_\alpha(X)) = 1 - \alpha$. It is coherent for so-called elliptical dfs like the multivariate normal or the multivariate Student-t, but coherence (in particular (C3)) typically fails for either very skew, very heavy-tailed (infinite mean models) or multivariate dfs exhibiting a very special dependence structure; see McNeil et al. (2005 pp. 241, 242). A widely used risk measure that is coherent is the so-called Expected Shortfall.

$$\mathrm{ES}_\alpha(X) = E(X \mid X > \mathrm{VaR}_\alpha(x))$$

which for continuous dfs F_X is coherent; see McNeil et al. (2005, p. 243). A very readable paper on this topic is Acerbi and Tasche (2002). An obvious weakness of VaR, as compared to ES, is that it only contains a *frequency* estimate ("once every ...") whereas ES yields *severity* information ("what if ...").

Multivariate Models

So far, I have mainly looked at one-dimensional risk rvs (though in (C3) the two-dimensional distribution of the vector $(X_1, X_2)'$ plays a crucial role). QRM therefore devotes a considerable amount of effort to determining useful models for d-dimensional risk vectors $\mathbf{X} = (X_1, \ldots, X_d)'$. In the case of continuous rvs, key models are:

(M1) The multivariate normal $N_d(\boldsymbol{\mu}, \Sigma)$;
(M2) The multivariate Student-t $t_{\nu,d}(\Sigma)$;
(M3) The class of generalised hyperbolic dfs, and
(M4) The class of elliptical dfs.

The latter class (M4) is a particularly useful one. It is defined (in a slightly restricted form) as follows: suppose $\mathbf{Z} \sim N_d(\mathbf{0}, I_d)$, hence the components $Z_1, \ldots, Z_d$ of $\mathbf{Z}$ are iid $N(0,1)$ and $\boldsymbol{\mu} \in \mathbb{R}^d$, $\mathbb{A}$ is a $d \times d$ matrix, then

$$\mathbf{X} = \boldsymbol{\mu} + \mathbb{A}\mathbf{Z}$$

is called *elliptical*. From a RM point of view, these dfs exhibit several very nice properties, for instance, VaR is coherent in this class; see McNeil et al. (2005, p. 242). Also, linear combinations of the components $X_1 \ldots, X_d$ are of the same type; see McNeil et al. (2005, p. 95). An interesting discussion relevant for applications to finance is to be found in Bingham and Kiesel (2002). As already stated, the world of elliptical models is fully understood (and very well behaved) when it comes to risk management. An interesting research topic concerns "how do such nice properties change if one moves away from ellipticality?"

A final model construction we need to mention here is the so-called *copula* construction; see McNeil et al. (2005) (Chap. 5). A copula is a df C on $[0,1]^d$ with uniform marginals. Suppose now that we are given marginal dfs $F_1, \ldots, F_d$, then the following construction always leads to a valid d-dimensional df with marginals $F_1, \ldots, F_d$:

$$\text{(M5)} \quad F(x_1, \ldots, x_d) = C(F_1(x_1), \ldots, F_d(x_d)).$$

Reading (M5) from left to right yields, for a given df F, at least one copula C such that (M5) holds; whenever the F_i's are continuous, then C (or better C_F) is unique. This is the content of Sklar's Theorem; see for instance McNeil et al. (2005, p. 186), or Nelsen (2007) and Joe (1997). This leads for instance to widely used models like the Gauss- (or normal-) copula or the t-copula. In the former case, F corresponds to a multivariate normal distribution (see ▶Multivariate Normal Distributions), whereas in the latter case F stands for a multivariate t. In (M5) we can inject any copula function on the right-hand side leading to numerous families like the Clayton, Gumbel, Frank, Archimedean, ... copulas. All with their specific properties which may make them useful for specific QRM applications. Since their appearance on the QRM scene in the late 1990s, ▶copulas have attracted a considerable amount of interest; the reader should consult Embrechts (2009) for details on their use and which basic papers to read for a start.

Statistical Estimation

Given a problem where risk has to be estimated, the whole of statistics may enter. However, as many of the risk measures used (like VaR_α and ES_α) concern rare or extreme events, α is close to 1, it is natural that Extreme Value Theory (EVT) plays an important role. Numerous textbooks of a varying degree of complexity yield an introduction to EVT; see for instance McNeil et al. (2005, Chap. 7), Embrechts et al. (1997), Coles (2001) and the references therein. Many other statistical techniques enter at this stage, in particular such fields as rare event estimation/simulation and resampling techniques are very useful here. Just to show that EVT quickly links to further relevant QRM questions, consider the following

$$\lambda_u = \lim_{\alpha \uparrow 1} P(X_2 > \mathrm{VaR}_\alpha(X_2) \mid X_1 > \mathrm{VaR}_\alpha(X_1)),$$

the so-called (upper) asymptotic dependence measure. This number (given that the limit exists, and this is indeed a condition) yields so-called spillover or contagion information from a high loss on X_1 to X_2. It turns out that λ_u *only* depends on the copula of the joint df of X_1 and X_2. Also, for the Gaussian copula model with correlation $\rho < 1$, $\lambda_u = 0$; this mathematically explains why the Gaussian copula model never yields sufficient joint extremal events. The latter issue played a role in the credit crisis starting in 2007 where such models were used to price and hedge complicated credit derivatives; see Li (2001). For the t-copula, $\lambda_u > 0$, hence such a model would allow for joint extremes. At this point, one could combine multivariate EVT with questions of risk aggregation and diversification in QRM, a topic of considerable methodological as well as practical importance; see for instance Embrechts et al. (2009) for a first impression.

An Example: Operational Risk

In order to end with a brief example showing how some of the above may be applied, consider the so-called class of Operational Risk (OR): "OR is defined as the risk of loss resulting from inadequate or failed internal processes, people and systems or from external events. This definition includes legal risk, but excludes strategic and reputational risk." See McNeil et al. (2005, Chap. 10) and Panjer (2006). The so-called Basel II regulatory guidelines for larger international banks require the estimation of risk capital for OR based on a 1-year, 99.9% VaR, i.e., a 1 in 1,000 year event. Internal OR data is typically aggregated over a number d (often 8) of business lines each yielding their OR loss rvs $X_1, \ldots, X_d$ and the corresponding (estimated) risk measures $\mathrm{VaR}_{0.999}(X_1), \ldots, \mathrm{VaR}_{0.999}(X_2)$. At a next step one adds these numbers yielding

$$\mathrm{VaR}_{0.999}^{\mathrm{sum}} = \sum_{i=1}^{d} \mathrm{VaR}_{0.999}(X_i).$$

The bank in question then has the possibility to bring a so–called diversification factor $\delta \in [0,1]$ into account so that the resulting risk capital becomes

$$\mathrm{RC}(\mathrm{OR}) = (1-\delta)\mathrm{VaR}_{0.999}^{\mathrm{sum}}.$$

Of course, non-coherence would yield $\delta < 0$! As such one sees that several of the topics very briefly touched upon enter immediately, and this in a very fundamental way. See the above references for further reading on this topic.

Conclusion

It is clear that the above paragraphs only give a tiny view on the new, emerging field of QRM. A good (quantitative) risk manager has to be master of several trades, including being an excellent communicator. The literature on the field is exploding. The handbook McNeil et al. (2005) is definitely an excellent start on the topic from a more mathematical point of view. The references given no doubt will help in digging deeper and hopefully also yield a much broader view of this fast evolving field.

About the Author

Paul Embrechts is Professor of Mathematics at the ETH Zurich specialising in actuarial mathematics and quantitative risk management. Previous academic positions include the Universities of Leuven, Limburg and London (Imperial College). Dr. Embrechts has held visiting professorships at the University of Strasbourg, ESSEC Paris, the Scuola Normale in Pisa (Cattedra Galileiana), the London School of Economics (Centennial Professor of Finance), the University of Vienna, Paris 1 (Panthéon-Sorbonne), the National University of Singapore and has an Honorary Doctorate from the University of Waterloo. He is an Elected Fellow of the Institute of Mathematical Statistics, Actuary-SAA, Honorary Fellow of the Institute and the Faculty of Actuaries, Corresponding Member of the Italian Institute of Actuaries, Member Honoris Causa of the Belgian Institute of Actuaries and is on the editorial board of numerous scientific journals. He belongs to various national and international research and academic advisory committees. He co-authored the influential books *Modelling of Extremal Events for Insurance and Finance* (Springer, 1997) and *Quantitative Risk Management: Concepts, Techniques and Tools* (Princeton UP, 2005). Dr. Embrechts consults on issues in quantitative risk management for financial institutions, insurance companies and international regulatory authorities.

Questionnaire

Jasna Horvat
Professor, Faculty of Economics in Osijek
J.J. Strossmayer University, Osijek, Croatia

A questionnaire is a helpful tool for collecting a wide range of information from a large number of respondents. The questionnaire was invented by Sir Francis Galton in about 1870. Containing structured groups of questions, it can be used to examine the general characteristics of a population, to compare attitudes of different groups, and to test theories. Questionnaires are any written instruments that present respondents with a series of questions or statements to which they are to react, either by writing out their answers or selecting from among existing answers (Brown 2001). It is important to emphasize that the process of developing a questionnaire involves several steps, starting with problem definition and ending with analysis and interpretation.

A questionnaire should be organized so as to be easy to conduct, fill in, and respond to. It should start with a general introduction to a topic, followed by questions from the least sensitive to the most sensitive. Its structure must in no way influence the responses. A frequently used technique when going from general to specific topics is called the *funnel approach*, as it begins with broader (more general) questions and then asks narrower (more specific) questions, reflecting the shape of a funnel (Grover and Vriens 2006). A questionnaire should ask the "right questions" (by careful use of wording and language) in such a way as to make it easily understandable to the respondent.

There are a great number of questionnaire types. Churchill (2006) classified questionnaires by the method of administration, describing the following types: *personal* (face-to-face conversation between the interviewer and the respondent), *telephone* (the conversation with respondents occurs over the telephone), and *mail questionnaire* (mailing the questionnaire to designated respondents with a covering letter). With the advent of computers and their increasing usage in research processes, the development of different forms of questionnaires adapted to CADAC (Computer Assisted Data Collection) methods has taken place. In other words, every CADAC method requires a different design and logic of the questionnaire (Table 1).

In recent years, there have been publications covering tested measurement instruments that allow researchers to use the most appropriate questionnaire for the defined research problem. Manuals such as *The Handbook of Marketing Scales* or *The Marketing Scale Handbook of Scaling Procedures: Issues and Application* provide invaluable assistance when creating questionnaires. Such handbooks provide an insight into all the new uses of previously developed scales in consumer behavior and advertising, presented along with a description, the origin of the scale, reliability, validity, and other useful information.

Information on respondents collected by a questionnaire is divided into factual, behavioral, and attitudinal information (Dörnyei 2003). This assumption is expanded by *knowledge questions*, the group of information intended to measure respondents' knowledge about a topic.

Factual questions. These query basic information about the respondents, demographic questions (gender, age. . .), and other background information relevant for the interpretation of the questionnaire results (level of education, socioeconomic status, religion, workplace. . .).

Behavioral questions. These are used to investigate current and past behaviors of respondents (lifestyles, habits, and actions).

Attitudinal questions. These depend on the topical problems under investigation and include information about attitudes, opinions, beliefs, interests, and values.

Questionnaire. Table 1 Specific question computer assisted form (de Leeuw and Nicholls II 1996)

Face-to-face questionnaire	CAPI	Computer Assisted Personal Interviewing
Telephone questionnaire	CATI	Computer Assisted Telephone Interviewing
Self-administered questionnaire	CASI	Computer Assisted Self Interviewing
	CSAQ	Computerized Self-Administered Questionnaire
Questionnaire where interviewer is present	CASI of CASIIP	Computer Assisted Self-Interviewing With Interviewer Present
	CASI-V	Question Text On Screen: Visual
	CASI-A	Text On Screen And On Audio
Mail questionnaire	DBM	Disk By Mail
	EMS	Electronic Mail Survey
Panel research questionnaire	CAPAR	Computer Assisted Panel Research
	Teleinterview	Electronic Diaries
Various questionnaires (no interviewer)	TDE	Touchtone Data Entry
	VR	Voice Recognition
	ASR	Automatic Speech Recognition

Knowledge questions. These are used to assess what respondents know about a particular topic, as the level of knowledge.

Forms of questions. Questions are basically divided into closed-ended questions (respondents choose from a set of predetermined answers) and open-ended questions (respondents can answer in their own words).

Closed-ended questions have to be exhaustive and mutually exclusive. They include multiple choice, yes-no answers, and questions with a numerical rating scale (e.g., 1 – strongly disagree, 5 – strongly agree). Closed-ended questionnaires are suitable for processing massive quantities of data, they are easier to answer, and it takes less time to respond to more questions. Respondents pick out answers without any possibility of intervention and need to understand both questions and answers.

Open-ended questions are appropriate in an exploratory phase of research or to obtain specific comments or answers that cannot be expressed as a numerical code. The answers are more difficult to tabulate and analyze, but provide more information and uncover the respondents' knowledge without being reminded. Eventually the answers must be adjusted (open categories are transformed into closed ones) to allow for statistical analysis, but this process is costly, time consuming, and subject to error.

Advantages of questionnaires are primarily in their low costs and relatively quick collection of data from a large portion of a group (particularly compared to face-to-face interviews). The data collected with questionnaires are easy to analyze. Data entry and tabulation can be simply done with various computer software packages. The most popular questionnaires are conducted by large organizations such as the European Commission (Eurobarometer) and UNESCO among others, who regularly publish their research and make it publicly accessible.

Disadvantages of questionnaires. Questionnaires are standardized forms of data collecting, so it is not possible to explain any points in the questions that participants might misinterpret. If researchers inadvertently omit a question, it is not usually possible to go back to respondents, especially if they are anonymous. Open-ended questions can generate large amounts of data that can take a long time to process and analyze.

Sometimes questionnaires can seem impersonal and respondents have even been known to ignore certain questions, particularly if they are not interested in the topic. Another drawback is a potentially low response rate, which can dramatically decrease the confidence in the results. For example, perhaps more responses would be received from participants having a strong opinion on the subject matter and are thereby motivated to respond, while less would be received from potential participants who are indifferent to the topic. The results would not necessarily be accurately representative if applied to the wider

population. Additionally, the results would be less reliable if some questions were misunderstood.

Queueing Theory

U. Narayan Bhat
Professor Emeritus
Southern Methodist University, Dallas, TX, USA

Queueing is essential to manage congestion in traffic of any type in the modern technological world. This does not mean it is a new phenomenon. More than one hundred years ago, recognizing its importance to telephone traffic, Danish mathematician A.K. Erlang (1909) showed for the first time how probability theory can be used to provide a mathematical model for telephone conversations. From then on, slowly in the first 3 decades, moderately in the next 3 decades, and tremendously in the last 4 decades, the probabilistic approach to modeling queueing phenomena when it is appropriate has grown and contributed significantly to the technological progress. For a historical perspective of the growth of queueing theory see Chapter 1 of Bhat (2008).

Queueing theory describes probabilistically and mathematically the interaction between the arrival process of customers and the service provided to them in order to manage the system in an efficient manner. The term customer is used in a generic sense representing a unit, human or otherwise, demanding service. The unit providing service is known as the server. Some examples of a queueing system are: a communication system with voice and data traffic demanding transmission; a manufacturing system with several work stations; patients arriving at a doctor's office; vehicles requiring service; and so on.

Since the arrival process and service are random phenomena we start with a probabilistic model (also known as a stochastic model) of a queueing system. If we analyze such models using mathematical techniques we can derive its properties that can be used in understanding its behavior and managing it for its efficient use.

In order to build a probabilistic model, first we describe the arrival process (called the input process) using probability distributions. For example, the arrival of customers could be in a Poisson process (see ►Poisson Processes) i.e., the number of customers arriving in a set period of time has a Poisson distribution. Its parameter, say λ, gives the mean number of customers arriving during a unit time. The known distribution now identifies the arrival process. The amount of service provided by the facility is represented by a random variable since it could be random. The distribution of the random variable identifies the service process. When we talk about service we have to take into consideration the mode of service such as service provided with several servers, service provided in a network of servers, etc. Also we must include factors such as queue discipline (e.g., first come, first served (FCFS), also known as first in, first out (FIFO); last come, first served (LCFS or LIFO); group service; priority service; etc.). Another factor that complicates the model is the system capacity, which may be finite or infinite.

Because of the multitude of factors involved in a queueing system, we use a three or four element symbolic representation in discussing various types of systems. The basic structure of the representation is to use symbols or numbers for the three elements: input/service/number of servers. When the system capacity is finite an additional element is added. The commonly used symbols for distributions are: M for Poisson or exponential, E_k

for Erlangian with k phases (gamma distribution with an integer scale parameter k), D for deterministic, and G for a general (also GI for general independent) or an unspecified distribution. Thus $M/G/1$ represents a Poisson arrival, general service, and a single server system, and $M/G/1/N$ has the same description as above with a capacity restriction of N customers in the system.

When the arrival process is represented by a random variable with an index parameter t, define $A(t)$ as the number of customers arriving and $D(t)$ the number of customers leaving the system during a time period $(0, t)$. Let the number of customers in the system at time t be $Q(t)$. Then $Q(t) = A(t) - D(t)$. In order to manage the system efficiently one has to understand how the process $Q(t)$ behaves over time. Note that all $A(t), D(t)$, and $Q(t)$ are stochastic processes (which are sequences of random variables indexed by the time parameter t.) Since the total number of customers leaving the system at t is dependent on the number customers arriving during that time, the mode of their arrival (e.g., there may be time periods with no customers in the system, commonly called idle periods), the service mechanism, queue discipline (when some customers get preferred treatment) and other factors that affect the operation of the system (e.g., service breakdowns), to analyze $Q(t)$, all these factors need to be taken into account in the model.

In the analysis of a queueing system the stochastic process $W(t)$ representing the waiting time of a customer to get served, and the random variable, say B, representing the busy period (the amount of time the system is continuously busy at a stretch) are also used. The objective of the analysis is to get the distributional properties of the stochastic processes $Q(t)$ and $W(t)$ and the random variable B for use in decision making. Analyzing stochastic processes in finite time t often becomes very complex. When the constituent elements such as arrival and service are not time-dependent we can derive the distributions of the limit random variables $Q = \lim_{t\to\infty} Q(t)$ and $W = \lim_{t\to\infty} W(t)$ when they exist. The ratio arrival/service rate is commonly known as the traffic intensity of the queueing system (say ρ). The property $\rho < 1$ is generally the requirement for the existence of the limit distributions of the stochastic processes $Q(t)$ and $W(t)$, when they are time-independent. The behavioral performance measures of interest in a queueing system are transition probability distributions of $Q(t)$ and $W(t)$, probability distributions of Q, W and B, and their means and variances.

In addition to the behavioral problems of underlying stochastic processes mentioned above, we are also interested in inference problems such as estimation and tests of hypotheses regarding basic parameters and performance measures, and optimization problems for assistance in decision making. An introduction to these topics and the necessary references may be found in Bhat (2008).

In order to provide an illustration of the behavioral analysis of a queueing system we consider below a system with Poisson arrivals, exponential service, and single server, symbolically known as an $M/M/1$ queue. This is the simplest and the most used system in applications. As systems include more complicated features more advanced techniques will need to be employed to analyze the corresponding stochastic models.

Let customers arrive in a Poisson process with rate λ. This means that the number $A(t)$ of the customers arriving in $(0, t)$ has a Poisson distribution

$$P[A(t) = j] = e^{-\lambda t}\frac{(\lambda t)^j}{j!},\ j = 0, 1, 2, \ldots$$

It also means that the interarrival times have an exponential distribution with probability density $a(x) = \lambda e^{-\lambda x}$ $(x > 0)$. We assume the service times to have an exponential distribution with probability density $b(x) = \mu e^{-\mu x}$ $(x > 0)$. With these assumptions we have $E[\text{inter-arrival time}] = (1/\lambda) = 1/\text{arrival rate}$ and $E[\text{service time}] = (1/\mu) = 1/\text{service rate}$. The ratio of arrival rate to service rate is the traffic intensity $\rho = \lambda/\mu$. Note that we have assumed the processes to be time-independent.

Let $Q(t)$ be the number of customers in the system at time t and its transition probability distribution be defined as

$$P_{ij}(t) = P[Q(t) = j | Q(0) = i]$$

because of the Poisson arrival process and the exponential service distribution, $Q(t)$ can be modeled as a birth and death process (a class of stochastic processes with major properties (a) probability of more than one state change during an infinitesimal interval of time is close to zero; (b) the rate of change in a unit time is constant and (c) changes occurring in non-overlapping intervals of time are independent of each other) governed by the following difference-differential equations.

$$\begin{aligned} P'_{i0}(t) &= -\lambda P_{i0}(t) + \mu P_{i1}(t) \\ P'_{in}(t) &= -(\lambda + \mu)P_{in}(t) + \lambda P_{i,n-1}(t) \\ &\quad + \mu P_{i,n+1}(t) \quad n = 1, 2, \ldots \end{aligned}$$

with $P_{in}(0) = 1$ when $n = i$ and $= 0$ otherwise. Solving these equations to obtain $P_{in}(t)$ is not very simple. Readers may refer to Gross et al. (2008) and its earlier editions for their solutions.

When $\rho < 1$, the limit $\lim_{t\to\infty} P_{ij}(t) = p_j$ exists and is independent of the initial state i. It can be obtained easily from the following equations that result by letting $t \to \infty$ in the above set of difference-differential equations.

$$\lambda p_0 = \mu p_1$$
$$(\lambda + \mu)p_n = \lambda p_{n-1} + \mu p_{n+1} \quad n = 1, 2, \ldots$$

along with $\sum_{n=0}^{\infty} p_n = 1$. We get $p_0 = 1 - \rho$, $p_n = (1 - \rho)\rho^n (n = 0, 1, 2, \ldots)$. The mean $E(Q)$ and variance $V(Q)$ of this distribution can be obtained as $E(Q) = \rho/(1 - \rho)$ and $V(Q) = \rho/(1 - \rho)^2$.

The waiting time of an arriving customer, when the queue discipline is FCFS, is the total amount of time required to serve the customers who are already in the system and this total time has an Erlangian distribution. Let us denote it as T_q (we use T as the random variable representing the total time the customer is in the system, also known as total workload.) Accordingly we get

$$P[T_q \le t] = 1 - \rho e^{-\mu(1-\rho)t}$$
$$E[T_q] = \rho/\mu(1 - \rho) \text{ and } E[T] = 1/\mu(1 - \rho).$$

Let $E(Q) = L$ and $E[T] = W$. Looking at the above results we can see that $L = \lambda W$ showing how L and W are related in this system. This property is known as Little's Law and it holds in more complex systems under certain general conditions. Another property is the exponential nature of the limiting waiting time distribution shown above which holds in more general queueing systems as well.

The derivation of the distribution of the busy period B is more complicated even in this simple system. We may refer the reader to Gross et al. (2008) for its derivation.

The literature on queueing theory is vast and it is impossible to cover all facets of the analysis of queueing systems using various modeling and sophisticated mathematical techniques in a short article in an encyclopedia. The following references and bibliographies given in them provide the basic understanding of the subject at two levels: Bhat (2008) for those who have a background only in probability and statistics and Gross and Harris (1998) or Gross et al. (2008) for those who have some background in stochastic processes.

About the Author

Professor Bhat retired in May 2005 after serving as SMU's dean of research and graduate studies and professor of statistical science and operations research in Dedman College of Humanities and Sciences at SMU. He joined the SMU faculty in 1969. He received his Ph.D. degree from the University of Western Australia. In addition to teaching, he has served in numerous administrative roles, including chair of several academic departments, vice provost and dean of graduate studies, associate dean for academic affairs and dean ad interim of Dedman College, as well as associate dean of the School of Engineering. Dr. Bhat received the SMU Trustees' Distinguished Service Award in May 2004. He was associate editor for following journals: *Operations Research* (1970–1975), *Management Science* (1969–1974), *OPSEARCH* (1968–1974), and *Queueing Systems: Theory And Applications* (1985–2000). He was President, Omega Rho, The International Honor Society (1994–1996). He has authored and co-authored six books, in addition to technical papers, the latest book being *Introduction to queueing theory: Modeling and Analysis in Applications*, published by Birkhauser in 2008.

[2]Heidelberg, Germany
[3]Brigham and Women's Hospital, Boston, MA, USA

R is a widely used open source language for scientific computing and visualization. It is based on the S language (S: An Interactive Environment for Data Analysis and Graphics, R. A. Becker and J. M. Chambers, Wadsworth, 1984), but with a few paradigms adopted from the Lisp family of languages.

R began its life in 1992, when Ross Ihaka and Robert Gentleman started a project that ultimately evolved into what it is now. In the early days, their main goal was to develop something that was like S, but which had clearer underlying semantics. Around the same time, other major changes were taking place: the world wide web was quickly gaining steam, and a new open source operating system named Linux (with major components from the GNU project) was becoming a popular tool for academic researchers. With these advances, it made sense to make the software more widely available, and hence it needed a name. In part to reflect its heritage, and in part to reflect their contributions, Ross and Robert chose to call it R. At this time, R was still primitive and had restricted capabilities, but a number of other scientists realized its potential, and shortly after its release the R-core group was formed. The activities and hard work of this group of contributors was what really made the breakthrough, and due to their efforts, R quickly become more stable, reliable and forward looking.

R is now under constant development by a team of approximately 20 individuals (essentially members of R-core) and has a fairly consistent 6 month release cycle. The core language is extended through add-on packages which can be obtained and installed in a local version of R, thereby customizing it to a user's interests. These packages are perhaps one of the main advantages of R, since a wide variety of statistical, computational and visualization methods are available. These add-on packages are often written by experts in the methodology, and that has served well to ensure the high quality of the outputs. However, users should realize that the availability of packages on sites such as cran.r-project.org or www.bioconductor.org does not imply any endorsement of their scientific quality except perhaps by their authors. Textbooks, the mailing list archives, and the scientific publications that sometimes accompany a package are good places for users to derive a judgment on packages' suitability for their needs.

R has served to bring scientific computing into many peoples hands. Many statisticians world-wide use R for their teaching and research. R has become widely used in many other fields as well, physics, chemistry, sociology, and notably biology. It is used in a wide variety of industries, Google, Microsoft, various pharmaceutical companies, banks and many investment houses. Its flexibility and the ability to relatively easily code new algorithms is likely to be one of the reasons that R has seen such wide-spread adoption. While reliable estimates of the number of users are hard to obtain increases in download traffic, in frequency of posting to the email help list suggest that the user base is continuing to grow quite rapidly.

R has made scientific computing easier for many sophisticated users and it has also brought in people who are new to the field. Balancing the diverse needs of the community is a particular problem. Discussions on the mailing lists can range from the very philosophical (often surrounding variants of object oriented programming) to the somewhat simpler (but often repeated) bug report that R's numerical capabilities are questionable. For all classes of new users it may be helpful to realize that R has a long history, the actual numerical code used for most of the applications is more than 10 years old and much of it is even older. Large parts of that code have been widely tested for years and it is somewhat unlikely that it fails to perform as intended in any really obvious way (as one person put it, you may be new to R, but R is not new). The fact that R has a long history (somewhat longer than that of Java, for example) means that changes to the way that functions work (even when we know that the original version

Miodrag Lovric (ed.), *International Encyclopedia of Statistical Science*, DOI 10.1007/978-3-642-04898-2,

was not optimal) are not likely to happen – there is simply too much code and too many users invested in the way it currently works and one must have very good reasons to modify code.

New users of R, or any other programming language, that want to do scientific programming should be conversant with the basics of computer arithmetic. To quote from "The Elements of Programming Style" by Kernighan and Plauger: 10.0 times 0.1 is hardly ever 1.0. The issue is one of representing a real number in the allocated memory of a computer, this can only be done exactly for a small subset of all numbers and for all others some rounding is needed. Interested readers should consult a good book on numerical computing and David Goldberg (1991), "What Every Computer Scientist Should Know About Floating-Point Arithmetic," ACM Computing Surveys, 23/1, 5–48, which is available online at: http://docs.sun.com/source/806-3568/ncg_goldberg.html.

As noted above the R language is largely based on the S language that was developed at Bell Laboratories by John Chambers and colleagues during the 1970s and 1980s. While a major goal was providing an interactive environment for performing statistical, and more generally scientific, computing there were other motivations for their work. One of the guiding philosophies of John's work was the notion that scientists needed to use computers to solve problems, and that if the computing environment was suitably conducive they would gradually evolve into being programmers. The main reason is that while there are many commonalities between problems, there is always some need for additional programming and the tweaking of inputs or outputs. Thus, one hopes that the language will actually help to develop the next generation of computational experts by converting some set of its users into programmers. It is worth emphasizing again, that the benefits of having a scientist conversant with, and invested in a method typically means that the method will provide the correct outputs. There is potential for the implementation to be sub-optimal, but that can generally be overcome if the method gets adopted for wide-spread use.

In his book, Algorithms + Data Structures = Programs, N. Wirth describes the fundamental notion that computer programs rely on both a set of algorithms and a set of data structures. R contains a very rich set of algorithms, but of equal importance is the ability of the user to create and use data structures that are appropriate to the problem at hand. R has a very rich and extensible collection of data structures and well designed data structures can greatly simplify many programming problems. Common examples are specific data structures do hold dates and data structures to hold time series objects. Both of these specialized containers are widely used and their use greatly simplifies many programming problems. Specialized methods can be written to deal with the specific implementations and users are then free to worry about other problems (and not converting month–day–year representations into something numeric).

In our work in computational biology we found that the complexity of most experiments was very high and the users were typically spending a great deal of their time doing very basic data management. A very typical example comes from the analysis of microarrays on some set of samples. The arrays provide us with a very large (generally 10s of thousands) of measurements one genes for each sample and at the same time we would have a separate set of data describing the characteristics of the sample. Most users would then spend some time arranging that the order of the columns in the microarray data was the same as that of the rows in the sample characteristic data (somewhat peculiarly microarray data are stored with samples as columns, while most other statistical data is stored with the samples as rows). That is fine until subsets are needed or one decides to do a permutation test (see ►Permutation Tests) for some hypothesis. At that point, depending on whether samples or genes are being permuted different operations are needed. This task is both tedious and has the potential to be done incorrectly in ways that are hard to detect. The rather simple expedient of defining a new data structure that contains both arrays, and where subsetting is defined and implemented to work appropriately greatly simplifies the analysts job and has the additional effect of making it much more likely that the right answer is obtained.

This observation leads us to another arena in which R is taking an important role: that of reproducibility in scientific computing. This issue arises often due to the fact that the analysis of any reasonably large and complex data set is error prone. The chance that mistakes are made, steps omitted increases as the number of people involved in the analysis grows and as the number of software tools increases. A dynamic document is a document that consists of both text and computer code. In greatly simplified terms the document is processed and the computer code is evaluated. An output document is created where each block of computer code is replaced with its output. Typically the computer code is used to produce the figures and tables that are needed for the final document. The final document can then be submitted as a paper to a journal or as an internal report within a group or company. The advantage of the approach is that anyone with access to the raw document and the data can reproduce the document and more importantly they can understand how every figure and table was produced.

Radon–Nikodým Theorem

Takis Konstantopoulos[1], Zurab Zerakidze[2], Grigol Sokhadze[2]
[1]Professor
Heriot-Watt University, Edinburgh, UK
[2]Professor
Javakhishvili Tbilisi State University, Tbilisi, Georgia

The theorem is concerned with the existence of density (derivative) of one measure with respect to another. Let $(\Omega, \mathscr{F})$ be a measurable space, i.e., a set Ω together with a σ-algebra $\mathscr{F}$ of subsets of Ω. Suppose that ν, μ are two σ-finite positive measures on $(\Omega, \mathscr{F})$ such that ν is absolutely continuous (denoted by $\nu \ll \mu$) with respect to μ, i.e., if $\mu(A) = 0$ for some $A \in \mathscr{F}$ then $\nu(A) = 0$. The Radon–Nikodým theorem states that these exists a μ-integrable function $f : \Omega \to \mathbb{R}_+$ such that

$$\nu(A) = \int_A f(\omega)\mu(d\omega), \quad A \in \mathscr{F}.$$

Moreover, f is μ-a.e. unique, in the sense that if f' also satisfies the above then the μ-measure of the points ω such that $f(\omega) \neq f'(\omega)$ equals zero. The function f is called Radon–Nikodým derivative of μ with respect to ν and this is often denoted by

$$f(\omega) = \frac{d\nu}{d\mu}(\omega).$$

The standard proof is as follows. First, assume that $\mu(\Omega) < \infty$. Denote by G the class of all non-negative μ-integrable functions g such that

$$\int_A g(\omega)\mu(d\omega) \le \nu(A), \quad A \in \mathscr{F}.$$

Let c be the supremum of the set numbers $\{\int_\Omega g d\mu : g \in G\}$, and choose a sequence g_n of elements of G such that $\lim_{n\to\infty} \int_\Omega g_n d\mu = \int_\Omega g d\mu$. Observe that if g', g'' are elements of G then so is their maximum $\max(g', g'')$. This observation, together with the monotone convergence theorem, allows us to conclude that $f = \sup_n g_n$ is also a member of G and $\int_\Omega f d\mu = c$. This shows that $\int_A f d\mu \le \nu(A)$ for all $A \in \mathscr{F}$. To show that the difference is actually zero we need to use the Hahn decomposition of a signed measure. Details can be found in Kallenberg (2002, pp. 28–30). The general case for a σ-finite μ follows easily by taking an increasing sequence Ω_n with $\mu(\Omega_n) < \infty$ and $\cup_n \Omega_n = \Omega$, and by applying the previous construction to each Ω_n.

The theorem was proved by Johann Radon (1913) in 1913 for the case $\Omega = \mathbb{R}^n$ and generalized by Otton Nikodým (1930) in 1930 in its present form. The Radon–Nikodým derivative possesses the following properties:

1. Linearity: $\frac{d(c_1\nu_1 + c_2\nu_2)}{2\mu} = c_1\frac{d\nu_1}{d\mu} + c_2\frac{d\nu_2}{d\mu}$, $c_1, c_2 \in \mathbb{R}$.
2. Change of measure: If $\nu \ll \mu$ and g is a ν-integrable function then $\int_\Omega g d\nu = \int_\Omega g\frac{d\nu}{d\mu}d\mu$.
3. Chain rule: If $\lambda \ll \nu \ll \nu$ then $\frac{d\lambda}{d\mu} = \frac{d\lambda}{d\nu}\frac{d\nu}{d\mu}$.
4. Inverse rule: If $\nu \ll \mu$ and $\mu \ll \nu$ then $\frac{d\nu}{d\mu} = \left(\frac{d\mu}{d\nu}\right)^{-1}$.

It is worth noting that a more general statement holds, known as *Lebesgue decomposition*: Let ν, μ be σ-finite measures on $(\Omega, \mathscr{F})$. Then there exists a unique measure $\nu_a \ll \mu$ and a unique measure $\nu_s \perp \mu$ (singular with respect to μ) such that $\nu = \nu_a + \nu_s$.

Also note that the σ-finiteness condition cannot be dropped. For example, if $\Omega = \mathbb{R}$, $\mathscr{F}$ the σ-algebra of Borel sets, μ the counting measure and ν the Lebesgue measure, we certainly have $\nu \ll \mu$ but a density of ν with respect to μ does not exist.

The Radon–Nikodým theorem has numerous applications in many areas of modern mathematics. We mention a few below.

1. Conditional expectation. Let $(\Omega, \mathscr{F}, P)$ be a probability space, X a non-negative random variable with $EX = \int_\Omega X dP < \infty$, and $\mathscr{G}$ a sub-σ-algebra of $\mathscr{F}$. The notion of conditional expectation $E(X|\mathscr{G})$ of X given $\mathscr{G}$ was introduced by A.N. Kolmogorov (1933) in 1933 by means of the Radon–Nikodým derivative as follows. Consider the measure $\nu(A) = \int_A X dP$, $A \in \mathscr{G}$. Clearly, $\nu \ll P$ on $\mathscr{G}$. According to the Radon–Nikodým theorem there is a $\mathscr{G}$-measurable function $E(X|\mathscr{G})$ which satisfies the relation

$$\int_A E(X|\mathscr{G})dP = \int_A X dP, \quad A \in \mathscr{G}.$$

More generally, we define $E(X|\mathscr{G}) = E(X^+|\mathscr{G}) - E(X^-|\mathscr{G})$. For further information see Konstantopoulos (2009).

2. ►Martingales. If P, Q are two probability measures on the same measurable space $(\Omega, \mathscr{F})$ such that $Q \ll P$ then, for any sub-σ-algebra $\mathscr{G} \subset \mathscr{F}$ we have $Q \ll P$ on $(\Omega, \mathscr{G})$. If we denote by $\left(\frac{dQ}{dP}\right)_{\mathscr{F}}$ and $\left(\frac{dQ}{dP}\right)_{\mathscr{G}}$ the two Radon–Nikodým derivatives we have the consistency property $E\left[\left(\frac{dQ}{dP}\right)_{\mathscr{F}}|\mathscr{G}\right] = \left(\frac{dQ}{dP}\right)_{\mathscr{G}}$.

In fact, if $\mathscr{F}_n$ is an increasing sequence of sub-σ-algebras generating $\mathscr{F}$, then $E\left[\left(\frac{dQ}{dP}\right)_{\mathscr{F}}|\mathscr{F}_n\right]$ is a uniformly integrable martingale (Williams 1989) whose limit (a.s. and in L_1) equals $\left(\frac{dQ}{dP}\right)_{\mathscr{F}}$.

3. Kullback–Leibler divergence and Hellinger distance. In Theoretical Statistics, the notion of ▶*Kullback–Leibler divergence* was introduced by Solomon Kullback and Richard Leibler (1951) in 1951. This is a generalization of the notion of ▶entropy for two distributions. If μ and ν are two probability measures on the same space with $\nu \ll \mu$, the Kullback–Leibler divergence or distance

$$Q(\nu \parallel \mu) = -\int_\Omega \log\left(\frac{d\nu}{d\mu}\right) d\mu$$

measures the relative variability of ν with respect to μ. The quantity is always non-negative (owing to the convexity of $-\log$ and Jensen's inequality) but not symmetric. The Kulback–Leibler divergence is used in Information Theory (Cover and Thomas 1991) to define the mutual information between two random variables.

The *Hellinger distance* $H(\mu,\nu)$ between two probability measures μ and ν which are absolutely continuous to a third probability measure λ is defined by

$$H^2(\mu,\nu) = \frac{1}{2}\int_\Omega \left(\sqrt{\frac{d\mu}{d\lambda}} - \sqrt{\frac{d\nu}{d\lambda}}\right)^2 d\lambda$$

and we have $H^2(\mu,\nu) \le Q(\nu \parallel \mu)$.

4. Densities on $\mathbb{R}^n$. Let f, g be densities of two probability measures P, Q, respectively, on $\mathbb{R}^n$. Then $Q \ll P$ if and only if there are versions of f and g such that $\{x : f(x) > 0\} \subset \{x : g(x) > 0\}$. In this case, $\frac{dQ}{dP}(x) = \frac{g(x)}{f(x)}$. For example, if P is the law of n i.i.d. standard normal random variables $(\xi_1,\dots,\xi_n)$, and if Q is the law of $(\xi_1+\mu_1,\dots,\xi_n+\mu_n)$, for some constants $\mu_1,\dots,\mu_n$, then $\frac{dQ}{dP}(x_1,\dots,x_n) = \exp\sum_{j=1}^n\left(\mu_j x_j - \frac{1}{2}\mu_j^2\right)$.

5. The Radon–Nikodým derivative between two Brownian motions. This is an infinite-dimensional generalisation of the previous example. Define the probability measure $P_{T,\mu}$, on the space Ω of continuous functions $\omega : [0,T] \to \mathbb{R}$, to be the law of a Brownian motion (see ▶Brownian Motion and Diffusions) with drift μ and unit variance. We have $P_{T,\mu} \ll P_{T,0}$ and $\frac{dP_{T,\mu}}{dP_{T,0}}(\omega) = e^{\mu\omega(T)-\frac{1}{2}\mu^2 T}$. Moreover, the consistency (martingale) property $E_{T,0}\left[\frac{dP_{T,\mu}}{dP_{T,0}}|\mathscr{F}_t\right] = \frac{dP_{t,\mu}}{dP_{t,0}}$, $t \le T$, holds. Here $\mathscr{F}_t$ is the σ-algebra generated by $(\omega(s), s \le t)$. A further generalisation of this is the *Cameron–Martin–Girsanov theorem* (Cameron and Martin 1944). Let (X_t) be a measurable $(\mathscr{F}_t)$-adapted process such that $Z_t := \exp\left\{\int_0^t X_s dW_s - \frac{1}{2}\int_0^t X_s^2 ds\right\}$ is defined and is a martingale. Define Q on $(\Omega,\mathscr{F}_T)$ by $\frac{dQ}{dP_{T,0}} = Z_T$. Then the law of the process $\left(W_t - \int_0^t X_s ds, 0 \le t \le T\right)$ on $(\Omega,\mathscr{F}_T,Q)$ is again $P_{T,0}$. More general results on the absolute convergence of Gaussian measures and the calculation of a density function are studied, e.g., by Feldman (1958), Ibragimov and Rozanov (1970), Zerakidze (1969) and Yadrenko (1980). Results on diffusions and general processes appear, e.g., in Liptser and Shiryaev (1974), Gikhman and Skorokhod (1971–1975). Smooth measures were studied by Bell (1991), Daletskii and Sokhadze (1988), Bogachev (2008), Kulik and Pilipenko (2000), among others.

6. The Radon–Nikodým derivative between two ▶Poisson processes. Let P_λ be the law of a rate-λ homogeneous Poisson process on a bounded measurable set $S \subset \mathbb{R}^n$ with Lebesgue measure $|S|$. The P_λ is a probability measure on the space Ω of integer-valued random measures with no multiple points. For any $0 < \lambda, \mu < \infty$ we have that $P_\lambda \ll P_\mu$ with Radon–Nikodým derivative

$$\frac{dP_\lambda}{dP_\mu}(\omega) = \left(\frac{\lambda}{\mu}\right)^{\omega(S)} \cdot e^{-(\lambda-\mu)|S|}.$$

To see this, it is sufficient to show that for any bounded measurable $f : \Omega \to \mathbb{R}$ we have $E_\lambda[\exp\int_S f(x)\omega(dx)] = E_\mu\left[\left(\frac{\lambda}{\mu}\right)^{\omega(S)} \cdot e^{-(\lambda-\mu)|S|} \cdot \exp\int_S f(x)\omega(dx)\right]$, something that is easily verifiable by means of the Poisson characteristic functional $E_\lambda[\exp\int_S f(x)\omega(dx)] = \exp\lambda\int_S(e^{f(x)} - 1)dx$. Note that if $\widehat{P}_\lambda$ is the image of P_λ on $\mathbb{Z}_+$ under the mapping $\omega \mapsto \omega(S)$ then the formula above says that $\frac{dP_\lambda}{dP_\mu}(\omega) = \frac{d\widehat{P}_\lambda}{d\widehat{P}_\mu}(\omega(S))$. We also note that if S is not bounded, e.g., if $S = \mathbb{R}^n$, the above fails to hold because $P_\lambda \perp P_\mu$ if $\lambda \ne \mu$.

7. The Radon–Nikodým derivative between two Markov jump processes. Consider a Markov jump process in a countable state space S with transition rates $q_{x,y}$ such that $q(x) := -q(x,x) = \sum_y q_{x,y} < \infty$ for all $x \in S$, and initial distribution μ. Let Q be the matrix with entries $q_{x,y}$. In other words, Q and μ define a probability measure $P_{\mu,Q}$ on the space Ω of right-continuous piecewise-constant functions $\omega : [0,T] \to S$. We only consider finite time horizon T. We change μ, Q to $\widetilde{\mu}, \widetilde{Q}$ in a way that $\mu \ll \widetilde{\mu}$ and $q_{x,y} = 0$ whenever $\widetilde{q}_{x,y} = 0$. Then $P_{\mu,Q} \ll P_{\widetilde{\mu},\widetilde{Q}}$ and

$$\frac{dP_{\mu,Q}}{dP_{\widetilde{\mu},\widetilde{Q}}}(\omega) = \frac{\mu(\omega(0))}{\widetilde{\mu}(\omega(0))}\exp\left\{-\int_0^T (q(\omega(s)) - \widetilde{q}(\omega(s)))ds\right\} \cdot \prod_{x\ne y}\left(\frac{q_{x,y}}{\widetilde{q}_{x,y}}\right)^{N_T(\omega,x,y)},$$

where $N_T(\omega, x, y)$ is the total number of points $s \le T$ such that $\omega(s-) = x, \omega(s) = y$.

8. The Esscher transform. Let $(X_t, t \ge 0)$ be a Lévy process (see ►Lévy Processes), i.e. a stochastic process with values in $\mathbb{R}$ which is continuous in probability and has stationary-independent increments. Assume that the Laplace exponent $\psi(\beta) = \log E \exp(\beta X_1)$ is defined for β belonging to a non-trivial interval. Let $Z_t^\beta := \exp\{\beta X_t - \psi(\beta)t\}$ and define a new measure P^β via the Radon–Nikodým derivative $\frac{dP^\beta}{dP}\big|_{\mathscr{F}_t} = Z_t^\beta$, where $\mathscr{F}_t = \sigma(X_s, s \le t)$. This derivative is known as the *Esscher transform* and leads to a natural generalisation of the Cameron–Martin–Girsanov theorem: The process (X_t) is still a Lévy process under P^β. See Kyprianou (2006) for its use in Fluctuation Theory.

9. Palm probability. Let $(\Omega, \mathscr{F}, P)$ be a probability space and $M : (\Omega \times \mathbb{R}^d) \to \mathbb{R}_+$ be measurable in the first argument and a locally finite probability measure in the second. We call such an M a random measure on $\mathbb{R}^d$. Assume that $\lambda(B) = EM(B)$ is a locally finite measure. Define the Campbell measure $C(A, B) = E[\mathbf{1}_A M(B)]$, $A \in \mathscr{F}, B \in \mathscr{B}$, where $\mathscr{B}$ is the class of Borel sets on $\mathbb{R}^d$, and observe that $C(A, \cdot) \ll \lambda$ for each $A \in \mathscr{F}$. The Radon–Nikodým derivative $P^x(A) = \frac{dC(A,\cdot)}{d\lambda}(x)$ has a version which is a probability measure on $(\Omega, \mathscr{F})$ and is called *Palm probability*. If M is a simple point process (see ►Point Processes), i.e. $M(\omega, \cdot)$ takes values in $\mathbb{Z}_+$ such that $M(\omega, \{x\}) \in \{0, 1\}$, for all x and ω, then $P^x(A)$ gives the probability of A given that M places a unit mass at the point x. The concept is most useful for stationary random measures (Kallenberg 2002).

About the Authors

Takis Konstantopoulos is Professor of Probability in the School of Mathematical and Computer Sciences, Heriot-Watt University, Edinburgh. He is also a member of the Maxwell Institute for Mathematical Sciences. He received a BSc from the National Technical University of Athens, Greece and a M.Sc. and Ph.D. (1989) from the University of California, Berkeley, USA. He has held a charge de recherche position in INRIA, Sophia Antipolis, France. He has served as a faculty member in the University of Texas at Austin in Electrical Engineering and in Mathematics. He has been Professor of Mathematics (2002–2005) at the University of Patras Greece where he also served as Director of the Probability and Statistics division. His research interests include stochastic processes, limit theorems, stochastic networks, applied probability and pure mathematics. He is advisor of the Centre for Education in Sciences (Patras, Greece). He is an organizer of an international program on "stochastic processes in communication sciences" at the Newton Institute for Mathematical Sciences, Cambridge, UK, January–July 2010.

Professor Zerakidze was Head of the Higher Mathematics department of Gori State University. He was also Head of a Mathematical Society of Gori region (2005–2007). He has been awarded with the Order of Honour by the President of Georgia (March 17th 2000). His work "The divisible family of measures" was included in the Big Russian Encyclopedia in the section "Probability and the mathematical statistics" page 533, Moscow, 1999.

Professor Grigol Sokhadze received his Ph.D. in Mathematics in 1992. He has (co-)authored about 100 papers in probability and statistics.

Random Coefficient Models

Nicholas T. Longford
Universitat Pompeu Fabra, Barcelona, Spain

Independence of the observations is a key assumption of many standard statistical methods, such as ▶analysis of variance (ANOVA) and ordinary regression, and some of its extensions. Common examples of data structures that do not fit into such a framework arise in longitudinal analysis, in which observations are made on subjects at subject-specific sequences of time points, and in studies that involve subjects (units) ocurring naturally in clusters, such as individuals within families, schoolchildren within classrooms, employees within companies, and the like. The assumption of independence of the observations is not tenable, because observations within a cluster are likely to be more similar than observations in general. Such similarity can be conveniently represented by a positive correlation (dependence).

This section describes an adaptation of the ordinary regression for clustered observations. Such observations require two indices, one for elements within clusters, $i = 1, \ldots, n_j$, and another for clusters, $j = 1, \ldots, m$. Thus, we have $n = n_1 + \cdots + n_m$ elementary units and m clusters. The ordinary regression model

$$y_{ij} = \mathbf{x}_{ij}\boldsymbol{\beta} + \varepsilon_{ij}, \tag{1}$$

with the usual assumptions of normality, independence and equal variance (homoscedasticity) of the deviations $\varepsilon_{ij}, \varepsilon_{ij} \sim \mathcal{N}(0, \sigma^2)$, i.i.d., implies that the regressions within the clusters j have a common vector of coefficients $\boldsymbol{\beta}$. This restriction can be relaxed by allowing the regressions to differ in their intercepts. A practical way of defining such a model is by the equation

$$y_{ij} = \mathbf{x}_{ij}\boldsymbol{\beta} + \delta_j + \varepsilon_{ij}, \tag{2}$$

where δ_j is a random sample from a centred normal distribution, $\delta_j \sim \mathcal{N}\left(0, \sigma_B^2\right)$, i.i.d., independent from the ε's. With this model, the within-cluster regressions are parallel; their intercepts are $\beta_0 + \delta_j$, but the coefficients on all the other variables in $\mathbf{x}$ are common to the clusters. A more appealing interpretation of the model is that observations in a cluster are correlated,

$$\operatorname{cor}\left(y_{i_1,j}, y_{i_2,j}\right) = \frac{\sigma_B^2}{\sigma^2 + \sigma_B^2},$$

because they share the same deviation δ_j. Further relaxation of how the within-cluster regressions differ is attained by allowing some (or all) the regression slopes to be specific to the clusters. We select a set of variables in $\mathbf{x}$, denoted by $\mathbf{z}$, and assume that the regressions with respect to these variables differ across the clusters, but are constant with respect to the remaining variables;

$$y_{ij} = \mathbf{x}_{ij}\boldsymbol{\beta} + \mathbf{z}_{ij}\boldsymbol{\delta}_j + \varepsilon_{ij}, \tag{3}$$

where $\boldsymbol{\delta}_j$ is a random sample from a multivariate normal distribution (see ▶Multivariate Normal Distributions) $\mathcal{N}(\mathbf{0}, \boldsymbol{\Sigma}_B)$, independent from the ε's. We say that the variables in $\mathbf{z}$ are associated with (cluster-level) variation. The variance of an observation y_{ij}, without conditioning on the cluster j, is

$$\operatorname{var}\left(y_{ij}\right) = \sigma^2 + \mathbf{x}_{ij}\boldsymbol{\Sigma}_B\mathbf{x}_{ij}^{\top}.$$

We refer to σ^2 and $\mathbf{z}_{ij}\boldsymbol{\Sigma}_B\mathbf{z}_{ij}^{\top}$ as the *variance components* (at the elementary and cluster levels, respectively). The principle of invariance with respect to linear transformations of $\mathbf{z}$ implies that the intercept should always be included in $\mathbf{z}$, unless $\mathbf{z}$ is empty, as in the model in (1). The function $V(\mathbf{z}) = \mathbf{z}\boldsymbol{\Sigma}_B\mathbf{z}^{\top}$, over the feasible values of $\mathbf{z}$, defines the *pattern* of variation, and it can be described by its behaviour (local minima, points of inflection, and the like). By way of an example, suppose $\mathbf{z}$ contains the intercept and a single variable z. Denote the variances in $\boldsymbol{\Sigma}_B$ by σ_0^2 and σ_z^2, and the covariance by σ_{0z}. Then

$$V(\mathbf{z}) = \sigma_0^2 + 2z\sigma_{0z} + z^2\sigma_z^2, \tag{4}$$

and this quadratic function has a unique minimum at $z^* = -\sigma_{0z}/\sigma_z^2$, unless $\sigma_z^2 = 0$, in which case we revert to the model in (2) in which $V(\mathbf{z})$ is constant.

The model in (3) is fitted by maximum likelihood (ML) which maximizes the log-likelihood function

$$l\left(\boldsymbol{\beta}, \sigma^2, \boldsymbol{\Sigma}_B\right) = -\frac{1}{2}\sum_{j=1}^{m}\Big[\log\left\{\det\left(\mathbf{V}_j\right)\right\} + \left(\mathbf{y}_j - \mathbf{X}_j\boldsymbol{\beta}\right)^{\top}\mathbf{V}_j^{-1}\left(\mathbf{y}_j - \mathbf{X}_j\boldsymbol{\beta}\right)\Big],$$

in which $\mathbf{V}_j$ is the variance matrix of the observations in cluster j, $\mathbf{y}_j$ the vector of the outcomes for the observations in cluster j, and $\mathbf{X}_j$ the corresponding regression design matrix formed by vertical stacking of the rows $\mathbf{x}_{ij}$, $i = 1, \ldots, n_j$. The variation design matrices $\mathbf{Z}_j, j = 1, \ldots, m$, are defined similarly; with them, $\mathbf{V}_j = \sigma^2\mathbf{I}_{n_j} + \mathbf{Z}_j\boldsymbol{\Sigma}_B\mathbf{Z}_j^{\top}$, where $\mathbf{I}_{n_j}$ is the $n_j \times n_j$ identity matrix. For ML solutions, see Longford (1993) and Goldstein (2000). These and other algorithms are implemented in most standard statistical packages.

►Model selection entails two tasks, selecting a set of variables to form $\mathbf{x}$ and selecting its subset to form $\mathbf{z}$. The variables in $\mathbf{x}$ can be defined for elements or clusters; the latter can be defined as being constant within clusters. Inclusion of cluster-level variables in $\mathbf{z}$ does not have an interpretation in terms of varying regression coefficients, so associating them with variation is in most contexts not meaningful. However, the identity in (4) and its generalisations for $\boldsymbol{\Sigma}_B$ with more than two rows and columns indicate that $\mathbf{z}$ can be used for modelling variance heterogeneity. The likelihood ratio test statistic and various information criteria can be used for selecting among alternative models, so long as one is a submodel of the other; that is, the variables in both $\mathbf{x}$ and $\mathbf{z}$ of one model are subsets of (or coincide with) their counterparts in the other model.

Random coefficients can be applied to a range of models much wider than ordinary regression. In principle, we can conceive any *basis model*, characterized by a vector of parameters, which applies to every cluster. A subset of these parameters is constant across the clusters and the remainder varies according to a model for cluster-level variation. The latter model need not be a multivariate normal distribution, although suitable alternatives to it are difficult to identify. The basis model itself can be complex, such as a random coefficient model itself. This gives rise to three- or, generally, *multilevel models*, in which elements are clustered within two-level units, these units in three-level units, and so on. Generalized linear mixed models have ►generalized linear models (McCullagh and Nelder 1989) as their basis.

Random coefficient models are well suited for analysing surveys in which clusters arise naturally as a consequence of the organisation (design) of the survey and the way the studied population is structured. They can be applied also in settings in which multiple observations are made on subjects, as in longitudinal studies (Molenberghs and Verbeke 2000). In some settings it is contentious as to whether the clusters should be regarded as fixed or random. When they are assumed to be random the (random coefficient) models are often more parsimonious than their fixed-effects (ANCOVA) models, because the number of parameters involved does not depend on the number of clusters.

Random Field

Mikhail P. Moklyachuk
Professor
Kyiv National Taras Shevchenko University, Kyiv, Ukraine

Random field $X(t)$ on $D \subset \mathbb{R}^n$ (i.e., $t \in D \subset \mathbb{R}^n$) is a function whose values are random variables for any $t \in D$. The dimension of the coordinate is usually in the range from one to four, but any $n > 0$ is possible. A one-dimensional

random field is usually called a stochastic process. The term "random field" is used to stress that the dimension of the coordinate is higher than one. Random fields in two and three dimensions are encountered in a wide range of sciences and especially in the earth sciences, such as hydrology, agriculture, and geology. Random fields where t is a position in space-time are studied in turbulence theory and in meteorology.

Random field $X(t)$ is described by its finite-dimensional (cumulative) distributions

$$F_{t_1,\ldots,t_k}(x_1,\ldots,x_k) = P\{X(t_1) < x_1,\ldots,X(t_k) < x_k\}, k = 1,2\ldots$$

The cumulative distribution functions are by definition left-continuous and nondecreasing. Two requirements on the finite-dimensional distributions must be satisfied. The symmetry condition

$$F_{t_1,\ldots,t_k}(x_1,\ldots,x_k) = F_{t_{\pi 1},\ldots,t_{\pi k}}(x_{\pi 1},\ldots,x_{\pi k}),$$

where π is a permutation of the index set $\{1,\ldots,k\}$. The compatibility condition

$$F_{t_1,\ldots,t_{k-1}}(x_1,\ldots,x_{k-1}) = F_{t_1,\ldots,t_k}(x_1,\ldots,x_{k-1},\infty).$$

Kolmogorov Existence Theorem states: If a system of finite-dimensional distributions $F_{t_1,\ldots,t_k}(x_1,\ldots,x_k)$, $k = 1,2\ldots$, satisfies the symmetry and compatibility conditions, then there exists on some probability space a random field $X(t)$, $t \in D$, having $F_{t_1,\ldots,t_k}(x_1,\ldots,x_k)$, $k = 1,2\ldots$, as its finite-dimensional distributions.

The expectation (mean value) of a random field is by definition the Stieltjes integral

$$m(t) = EX(t) = \int_{\mathbb{R}^1} x dF_t(x).$$

The (auto-)covariance function is also expressed as the Stieltjes integral

$$B(t,s) = E(X(t)X(s)) - m(t)m(s) = \iint_{\mathbb{R}^2} xy dF_{t,s}(x,y) - m(t)m(s),$$

whereas the variance is $\sigma^2(t) = B(t,t)$.

Gaussian random fields play an important role due to several reasons: the specification of their finite-dimensional distributions is simple, they are reasonable models for many natural phenomena, and their estimation and inference are simple.

A Gaussian random field is a random field where all the finite-dimensional distributions are ▶multivariate normal distributions. Since multivariate normal distributions are completely specified by expectations and covariances, it suffices to specify $m(t)$ and $B(t,s)$ in such a way that the symmetry condition and the compatibility condition hold true. The expectation can be arbitrarily chosen, but the covariance function must be positive-definite to ensure the existence of all finite-dimensional distributions.

Wiener sheet (*Brownian sheet*) is a Gaussian random field $W(t)$, $t = (t_1,t_2) \in \mathbb{R}^2_+$ with $EW(t) = 0$ and correlation function $B(t,s) = E(X(t)X(s)) = \min\{s_1,t_1\}\min\{s_2,t_2\}$. Analogously, the n-parametric Wiener process is a Gaussian random field $W(t)$, $t \in \mathbb{R}^n_+$ with $EW(t) = 0$ and correlation function $B(t,s) = \prod_{i=1}^n \min(s_i,t_i)$. The multiparametric Wiener process $W(t)$ has independent homogeneous increments. A generalized derivative of the multiparametric Wiener process $W(t)$ is the *Gaussian white noise process* on $\mathbb{R}^n_+$ (Chung and Walsh 2005).

Poisson random fields are also reasonable models for many natural phenomena. A Poisson random field is an integer-valued (point) random field where the (random) amount of points that belong to a bounded set from the range of values of the field has a Poisson distribution and the random amounts of points that belong to nonoverlapping sets are mutually independent (Kerstan et al. 1974).

Markov random field $X(t)$, $t \in D \subset \mathbb{R}^n$, is a random function that has the Markov property with respect to a fixed system of ordered triples (S_1,Γ,S_2) of nonoverlapping subsets from the domain of definition D. The Markov property means that for any measurable set B from the range of values of the function $X(t)$ and every $t_0 \in S_2$, the following equality holds true:

$$P\{X(t_0) \in B | X(t), t \in S_1 \cup \Gamma\} = P\{X(t_0) \in B | X(t), t \in \Gamma\}.$$

This means that the future S_2 does not depend on the past S_1 when the present Γ is given. Let, for example, $D = \mathbb{R}^n$, $\{\Gamma\}$ be a family of all spheres in $\mathbb{R}^n$, S_1 be the interior of Γ, and S_2 be the exterior of Γ. A homogeneous and isotropic Gaussian random field $X(t)$, $t \in \mathbb{R}^n$, has the Markov property with respect to the ordered triples (S_1,Γ,S_2) if and only if $X(t) = \xi$, where ξ is a random variable. Nontrivial examples of homogeneous and isotropic Markov random fields can be constructed when considering the generalized random fields. Markov random fields are completely described in the class of homogeneous Gaussian random fields on $\mathbb{Z}^n$, in the class of multidimensional homogeneous generalized Gaussian random fields on the space $\mathbb{C}_0^\infty(\mathbb{R}^m)$ and the class of multidimensional homogeneous and isotropic generalized Gaussian random fields (Glimm and Jaffe 1981; Rozanov 1982; Yadrenko 1983).

Gibbs random fields form a class of random fields that have extensive applications in solutions of problems in statistical physics. The distribution functions of these

fields are determined by Gibbs distribution (Malyshev and Minlos 1985).

Homogeneous random field in the strict sense is a real-valued random function $X(t)$, $t \in \mathbb{R}^n$ (or $t \in \mathbb{Z}^n$), where all its finite-dimensional distributions are invariant under arbitrary translations, that is,

$$F_{t_1+s,\ldots,t_k+s}(x_1,\ldots,x_k) = F_{t_1,\ldots,t_k}(x_1,\ldots,x_k)\ \forall s \in \mathbb{R}^n.$$

Homogeneous random field in the wide sense is a real-valued random function $X(t)$, $t \in \mathbb{R}^n$ ($t \in \mathbb{Z}^n$), $E|X(t)|^2 < +\infty$, where $EX(t) = m = \text{const.}$ and the correlation function $EX(t)X(s) = B(t-s)$ depends on the difference $t-s$ of coordinates of points t and s.

Homogeneous random field $X(t)$, $t \in \mathbb{R}^n$, $EX(t) = 0$, $E|X(t)|^2 < +\infty$, and its correlation function $B(t) = EX(t+s)X(s)$ admit the spectral representations

$$X(t) = \int \cdots \int \exp\left\{\sum_{k=1}^{n} t_k\lambda_k\right\} Z(d\lambda),$$

$$B(t) = \int \cdots \int \exp\left\{\sum_{k=1}^{n} t_k\lambda_k\right\} F(d\lambda),$$

where $F(d\lambda)$ is a measure on the Borel σ-algebra B_n of sets from $\mathbb{R}^n$, and $Z(d\lambda)$ is an orthogonal random measure on B_n such that $EZ(S_1)Z(S_2) = F(S_1 \cap S_2)$. The integration range is $\mathbb{R}^n$ in the case of continuous time random field $X(t)$, $t \in \mathbb{R}^n$, and $[-\pi,\pi]^n$ in the case of discrete time random field $X(t)$, $t \in \mathbb{Z}^n$. In the case where the spectral representation of the correlation function is of the form

$$B(t) = \int \cdots \int \exp\left\{\sum_{k=1}^{n} t_k\lambda_k\right\} f(\lambda)d\lambda,$$

the function $f(\lambda)$ is called the spectral density of the field $X(t)$. Based on these spectral representations we can prove, for example, the *law of large numbers* for random field $X(t)$:

The mean square limit

$$\lim_{N\to\infty} \frac{1}{(2N+1)^n} \sum_{|t_i|\le N, i=1,\ldots,n} X(t) = Z\{0\}.$$

This limit is equal to $EX(t) = 0$ if and only if $E|Z\{0\}|^2 = F\{0\}$. In the case where $F\{0\} = 0$ and

$$\int_{-\pi}^{\pi} \cdots \int_{-\pi}^{\pi} \prod_{i=1}^{n} \log\left|\log\frac{1}{|\lambda_i|}\right| F(d\lambda) < +\infty,$$

the *strong law of large numbers* holds true for the random field $X(t)$.

Isotropic random field is a real-valued random function $X(t)$, $t \in \mathbb{R}^n$, $E|X(t)|^2 < +\infty$, where the expectation and the correlation function have properties $EX(t) = EX(gt)$ and $EX(t)X(s) = EX(gt)X(gs)$ for all rotations g around the origin of coordinates. An isotropic random field $X(t)$ admits the decomposition

$$X(t) = \sum_{m=0}^{\infty} \sum_{l=1}^{h(m,n)} X_m^l(r) S_m^l(\theta_1,\theta_2,\ldots,\theta_{n-2},\varphi),$$

where $(r,\theta_1,\theta_2,\ldots,\theta_{n-2},\varphi)$ are spherical coordinates of the point $t \in \mathbb{R}^n$, $S_m^l(\theta_1,\theta_2,\ldots,\theta_{n-2},\varphi)$ are spherical harmonics of the degree m, $h(m,n)$ is the amount of such harmonics, $X_m^l(r)$ are uncorrelated stochastic processes such that $EX_m^l(r)X_{m_1}^{l_1}(s) = b_m(r,s)\delta_m^{m_1}\delta_l^{l_1}$, where δ_i^j is the Kronecker symbol, $b_m(r,s)$ is a sequence of positive definite kernels such that $\sum_{m=0}^{\infty} h(m,n)b_m(r,s) < +\infty$, $b_m(0,s) = 0, m \ne 0$.

Isotropic random field $X(t)$, $t \in \mathbb{R}^2$, on the plane admits the decomposition

$$X(r,\varphi) = \sum_{m=0}^{\infty} \left\{X_m^1(r)\cos(m\varphi) + X_m^2(r)\sin(m\varphi)\right\}.$$

The class of isotropic random fields includes homogeneous and isotropic random fields, multiparametric Brownian motion processes (see ▶Brownian Motion and Diffusions).

Homogeneous and isotropic random field is a real-valued random function $X(t)$, $t \in \mathbb{R}^n$, $E|X(t)|^2 < +\infty$, where the expectation $EX(t) = c = \text{const.}$ and the correlation function $EX(t)X(s) = B(|t-s|)$ depends on the distance $|t-s|$ between points t and s. Homogeneous and isotropic random field $X(t)$ and its correlation function $B(r)$ admit the spectral representations (Rozanov 1982; Yadrenko 1983; Yaglom 1987)

$$X(t) = c_n \sum_{m=0}^{\infty} \sum_{l=1}^{h(m,n)} S_m^l(\theta_1,\theta_2,\ldots,\theta_{n-2},\varphi) \int_0^{\infty} \frac{J_{m+(n-2)/2}(r\lambda)}{(r\lambda)^{(n-2)/2}} Z_m^l(d\lambda),$$

$$B(r) = \int_0^{\infty} Y_n(r\lambda)d\Phi(\lambda),$$

where

$$Y_n(x) = 2^{(n-2)/2}\Gamma\left(\frac{n}{2}\right)\frac{J_{(n-2)/2}(x)}{x^{(n-2)/2}}$$

is a spherical Bessel function, $\Phi(\lambda)$ is a bounded nondecreasing function called the spectral function of the field $X(t)$, $Z_m^l(d\lambda)$ are random measures with orthogonal values such that $EZ_m^l(S_1)Z_{m_1}^{l_1}(S_2) = \delta_m^{m_1}\delta_l^{l_1}\Phi(S_1 \cap S_2)$, $c_n^2 = 2^{n-1}\Gamma(n/2)\pi^{n/2}$.

Homogeneous and isotropic random field $X(t), t \in \mathbb{R}^2$, on the plane admits the spectral representation

$$X(t,\varphi) = \sum_{m=0}^{\infty} \cos(m\varphi) Y_m(r\lambda) Z_m^1(d\lambda) + \sum_{m=1}^{\infty} \sin(m\varphi) Y_m(r\lambda) Z_m^2(d\lambda).$$

These spectral decompositions of random fields form a power tool for the solution of statistical problems for random fields such as extrapolation, interpolation, filtering, and estimation of parameters of the distribution (Yadrenko 1983; Yaglom 1987a, b).

About the Author

Dr. Mikhail P. Moklyachuk is a Professor of the Department of Probability Theory, Statistics and Actuarial Mathematics, Kyiv National Taras Shevchenko University, Ukraine. He is the author and coauthor of more than 100 papers and six books, including *Robust estimates for functionals of stochastic processes* (Kyiv University Press, 2008). Professor Moklyachuk has received the Taras Shevchenko prize (Kyiv University best textbook award, 1999) for the textbook *Variational Calculus. Extremum Problems*. He is the editor of the Cooperation Unit of Zentralblatt MATH (Zentralblatt fuer Mathematik/Mathematics Abstracts), coeditor of *Current Index to Statistics*, and member of the editorial board, *Theory of Probability and Mathematical Statistics*.

Random Matrix Theory

Jack W. Silverstein
Professor
North Carolina State University, Raleigh, NC, USA

Random matrix theory (RMT) originated from the investigation of energy levels of a large number of particles in quantum mechanics. Many laws were discovered by numerical study in mathematical physics. In the late 1950s, E. P. Wigner formulated the problem in terms of the empirical distribution of a random matrix (Wigner 1955, 1958), which began the investigation into the semicircular law of Gaussian matrices. Since then, RMT has formed an active branch in modern probability theory.

Basic Concepts

Let $\mathbf{A}$ be an $n \times n$ matrix with eigenvalues $\lambda_1, \cdots, \lambda_n$. If all λ_js are real, then we can construct a 1-dimensional empirical distribution function

$$F^{\mathbf{A}}(x) = \frac{1}{n} \sum_{j=1}^{n} I(\lambda_j \le x),$$

otherwise, we may construct a 2-dimensional empirical distribution function by the real and imaginary parts of λ_j, i.e.

$$F^{\mathbf{A}}(x,y) = \frac{1}{n} \sum_{j=1}^{n} I(\Re(\lambda_j) \le x; \Im(\lambda_j) \le y).$$

Then, $F^{\mathbf{A}}$ is called the *empirical spectral distribution* (ESD) of $\mathbf{A}$. The main task of RMT is to investigate limiting properties of $F^{\mathbf{A}}$ in the case where $\mathbf{A}$ is random and the order n tends to infinity. If there is a limit distribution F, then the limit is called the *limiting spectral distribution* (LSD) of the sequence of the $\mathbf{A}$. Interesting problems include finding the explicit forms of the LSD if it exists and to investigate its properties.

There are two methods used in determining limiting properties of $F^{\mathbf{A}}$ (Bai 1999). One is the *method of moments*, using the fact that the moments of $F^{\mathbf{A}}$ are the scaled traces

of powers of **A**. The other is using *Stieltjes transforms*, defined for any distribution function F as

$$m(z) = \int \frac{1}{x - z} dF(x),$$

for $z \in \mathbb{C}$.

Contrary to the progress made on the eigenvalues of large dimensional random matrices, very few results have been obtained on the limiting properties of the eigenmatrix (i.e., the matrix of the standardized eigenvectors of **A**). Due to its importance in the application to statistics and applied areas, investigation on eigenmatrices is becoming more active.

Limiting Spectral Distributions

1. **Semicircular Law** A Wigner matrix is defined as a Hermitian (symmetric if real) matrix $\mathbf{W} = (w_{ij})_{n\times n}$ whose entries above or on the diagonal are independent. Then the ESD of $n^{-1/2}\mathbf{W}$ tends to the semicircular law with density

$$p(x) = \frac{1}{2\pi}\sqrt{4 - x^2} I(|x| < 2),$$

if $\mathrm{E}w_{ij} = 0$, $\mathrm{E}|w_{ij}|^2 = 1$ and for any $\delta > 0$,

$$\frac{1}{n^2}\sum_{ij} \mathrm{E}\left|w_{ij}^2\right| I\left(|w_{ij}| \geq \delta\sqrt{n}\right) \to 0.$$

2. **Marčenko–Pastur Law** Let $\mathbf{X} = (x_{ij})_{p\times n}$ whose entries are independent random variables with mean zero and variance 1. If $p/n \to y \in (0, \infty)$ and for any $\delta > 0$,

$$\frac{1}{np}\sum_{ij} \mathrm{E}\left|x_{ij}^2\right| I\left(|x_{ij}| \geq \delta\sqrt{n}\right) \to 0.$$

Then the ESD of $\mathbf{S}_n = \frac{1}{n}\mathbf{X}\mathbf{X}^*$ (so-called sample covariance matrix) tends to the Marčenko–Pastur law with density

$$\frac{1}{2\pi xy}\sqrt{(b - x)(x - a)} I(a < x < b)$$

where $a = (1 - \sqrt{y})^2$ and $b = (1 + \sqrt{y})^2$. Furthermore, if $y > 1$, the LSD has a point mass $1 - 1/y$ at the origin.

3. **LSD of Products of Random Matrices** Let $\mathbf{T}$ $(p \times p)$ be a Hermitian matrix with LSD H (a probability distribution function) and $\mathbf{S}_n$, p/n satisfy the conditions in item (2). Then the ESD of $\mathbf{S}_n\mathbf{T}$ exists and the Stieltjes transform $m(z)$ is the unique solution on the upper complex plane to the equation

$$m = \int \frac{1}{t(1 - y - yzm) - z} dH(t),$$

where z is complex with positive imaginary part.

Extreme Eigenvalues and Spectrum Separation

Limits of extreme eigenvalues of large random matrices is one of the important topics. In many cases, under the assumption of finite fourth moment, the extreme eigenvalues almost surely tend to the respective boundaries of the LSD. For the product $\mathbf{S}_n\mathbf{T}$, if the support of the LSD is disconnected, then, under certain conditions, it is proved that there are no eigenvalues among the gaps and the numbers on each side are exactly the same of eigenvalues of $\mathbf{T}$, on the corresponding sides of the interval which determines the gap of the LSD (Bai and Silverstein 1999).

Further deeper investigation into extreme eigenvalues is the Tracy–Widom Law which says that $n^{2/3}$ times the difference of the extreme eigenvalues and the corresponding boundary points tends to the so-called Tracy–Widom law (Tracy and Widom 1994).

Convergence Rates of Empirical Spectral Distributions

Convergence rates of ESDs of large dimensional random matrices to their corresponding LSDs are important for application of spectral theory of large dimensional matrix. Bai inequality is the basic mathematical tool to establish the convergence rates (Bai 1993a,b). The currently known best rates are that $O(n^{-1/2})$ for the expected ESDs for Wigner matrix and for sample covariance matrix, and $O_p(n^{-2/5})$ and $O_{a.s.}(n^{-2/5+\eta})$ for their ESDs.

The exact rates are still far from known.

CLT of LSS

If $\lambda_1, \ldots, \lambda_n$ are the eigenvalues of the random matrix **A** and f is a function defined on the space of the eigenvalues, then the LSS (linear spectral statistic) for the random matrix is defined by

$$\frac{1}{n}\sum_{k=1}^{n} f(\lambda_k) = \int f(x) dF^{\mathbf{A}}(x).$$

To investigate the limiting distribution of the LSS, we define $X_n(f) = n\left(\int f(x) d\left(F^{\mathbf{A}}(x) - F(x)\right)\right)$.

Under certain conditions, the normalized LSS, $X_n(f)$, is proved to tend to a normal distribution for the Wigner matrix, the product $\mathbf{S}_n\mathbf{T}$, as well as for the multivariate F-matrix, with asymptotic means and variances explicitly expressed by the Stieltjes transforms of the LSDs (Bai and Yao 2005; Bai and Silverstein 2004; Zheng 2010).

These theorems have been found to have important applications to multivariate analysis and many other areas.

Limiting Properties of Eigenvectors

Work in this area has been primarily done on the matrices in item (2) with **X** containing real entries (Silverstein

1979, 1984, 1990). Write $\mathbf{S}_n = \mathbf{O}\Lambda\mathbf{O}^*$, its spectral decomposition. When the entries of $\mathbf{X}$ are Gaussian, then $\mathbf{S}_n$ is the standard Wishart matrix, with $\mathbf{O}$ Haar-distributed in the group of $p \times p$ orthogonal matrices. The question is to compare the distribution of $\mathbf{O}$ when the entries of $\mathbf{X}$ are not Gaussian to Haar measure when p is large. This has been pursued when $\mathbf{X}$ is made up of iid random variables, by comparing the distribution of $\mathbf{y} = \mathbf{O}^*\mathbf{x}$, where $\mathbf{x}$ is a unit p-dimensional vector, to the uniform distribution on the unit sphere in $\mathbb{R}^p$. A stochastic process is defined in terms of the entries of $\mathbf{y}$, which converges weakly to Brownian bridge in the Wishart case. A necessary condition for this process to behave the same way for non Gaussian entries has been shown to be $\mathrm{E}\left(x_{11}^4\right) = 3$, matching the fourth moment of a standardized Gaussian (Silverstein 1984). For certain choices of $\mathbf{x}$ and for symmetrically distributed x_{11}, weak convergence to Brownian bridge has been shown in Silverstein (1990).

About the Author

Professor Silverstein was named IMS Fellow for "seminal contributions to the theory and application of random matrices" (2007). He has (co-)authored over 50 publications, including the book *Spectral Analysis of Large Dimensional Random Matrices* (with Z.D. Bai, 2nd edition, Springer, New York, 2009).

Random Permutations and Partition Models

Peter McCullagh
John D. MacArthur Distinguished Service Professor
University of Chicago, Chicago, IL, USA

Set Partitions

For $n \geq 1$, a partition B of the finite set $[n] = \{1, \ldots, n\}$ is

- A collection $B = \{b_1, \ldots\}$ of disjoint non-empty subsets, called blocks, whose union is $[n]$
- An equivalence relation or Boolean function $B\colon [n] \times [n] \to \{0,1\}$ that is reflexive, symmetric and transitive
- A symmetric Boolean matrix such that $B_{ij} = 1$ if i, j belong to the same block

These equivalent representations are not distinguished in the notation, so B is a set of subsets, a matrix, a Boolean function, or a subset of $[n]\times[n]$, as the context demands. In practice, a partition is sometimes written in an abbreviated form, such as $B = 2|13$ for a partition of $[3]$. In this notation, the five partitions of $[3]$ are

$$123, \quad 12|3, \quad 13|2, \quad 23|1, \quad 1|2|3.$$

The blocks are unordered, so $2|13$ is the same partition as $13|2$ and $2|31$.

A partition B is a sub-partition of B^* if each block of B is a subset of some block of B^* or, equivalently, if $B_{ij} = 1$ implies $B^*_{ij} = 1$. This relationship is a partial order denoted by $B \leq B^*$, which can be interpreted as $B \subset B^*$ if each partition is regarded as a subset of $[n]^2$. The partition lattice $\mathcal{E}_n$ is the set of partitions of $[n]$ with this partial order. To each pair of partitions B, B' there corresponds a greatest lower bound $B \wedge B'$, which is the set intersection or Hadamard component-wise matrix product. The least upper bound

$B \vee B'$ is the least element that is greater than both, the transitive completion of $B \cup B'$. The least element of $\mathcal{E}_n$ is the partition $\mathbf{0}_n$ with n singleton blocks, and the greatest element is the single-block partition denoted by $\mathbf{1}_n$.

A permutation $\sigma\colon [n] \to [n]$ induces an action $B \mapsto B^\sigma$ by composition such that $B^\sigma(i,j) = B(\sigma(i), \sigma(j))$. In matrix notation, $B^\sigma = \sigma B \sigma^{-1}$, so the action by conjugation permutes both the rows and columns of B in the same way. The block sizes are preserved and are maximally invariant under conjugation. In this way, the 15 partitions of $[4]$ may be grouped into five orbits or equivalence classes as follows:

$$1234, \quad 123|4\,[4], \quad 12|34\,[3], \quad 12|3|4\,[6], \quad 1|2|3|4.$$

Thus, for example, 12|34 is the representative element for one orbit, which also includes 13|24 and 14|23.

The symbol $\#B$ applied to a set denotes the number of elements, so $\#B$ is the number of blocks, and $\#b$ is the size of block $b \in B$. If $\mathcal{E}_n$ is the set of equivalence relations on $[n]$, or the set of partitions of $[n]$, the first few values of $\#\mathcal{E}_n$ are 1, 2, 5, 15, 52, called Bell numbers. More generally, $\#\mathcal{E}_n$ is the nth moment of the unit Poisson distribution whose exponential generating function is $\exp(e^t - 1)$. In the discussion of explicit probability models on $\mathcal{E}_n$, it is helpful to use the ascending and descending factorial symbols

$$\alpha^{\uparrow r} = \alpha(\alpha+1)\cdots(\alpha+r-1) = \Gamma(r+\alpha)/\Gamma(\alpha)$$
$$k^{\downarrow r} = k(k-1)\cdots(k-r+1)$$

for integer $r \geq 0$. Note that $k^{\downarrow r} = 0$ for positive integers $r > k$. By convention $\alpha^{\uparrow 0} = 1$.

Partition Model

The term *partition model* refers to a probability distribution, or family of probability distributions, on the set $\mathcal{E}_n$ of partitions of $[n]$. In some cases, the probability is concentrated on the the subset $\mathcal{E}_n^k \subset \mathcal{E}_n$ of partitions having k or fewer blocks. A distribution on $\mathcal{E}_n$ such that $p_n(B) = p_n(\sigma B \sigma^{-1})$ for every permutation $\sigma\colon [n] \to [n]$ is said to be finitely exchangeable. Equivalently, p_n is exchangeable if $p_n(B)$ depends only on the block sizes of B.

Historically, the most important examples are Dirichlet-multinomial random partitions generated for fixed k in three steps as follows.

- First generate the random probability vector $\pi = (\pi_1, \ldots, \pi_k)$ from the Dirichlet distribution with parameter $(\theta_1, \ldots, \theta_k)$.
- Given π, the sequence $Y_1, \ldots, Y_n, \ldots$ is independent and identically distributed, each component taking values in $\{1, \ldots, k\}$ with probability π. Each sequence of length n in which the value r occurs $n_r \geq 0$ times has probability
$$\frac{\Gamma(\theta_\cdot)\prod_{j=1}^k \theta_j^{\uparrow n_j}}{\Gamma(n+\theta_\cdot)},$$
where $\theta_\cdot = \sum \theta_j$.
- Now forget the labels $1, \ldots, k$ and consider only the partition B generated by the sequence Y, i.e., $B_{ij} = 1$ if $Y_i = Y_j$. The distribution is exchangeable, but an explicit simple formula is available only for the uniform case $\theta_j = \lambda/k$, which is now assumed. The number of sequences generating the same partition B is $k^{\downarrow \#B}$, and these have equal probability in the uniform case. Consequently, the induced partition has probability
$$p_{nk}(B,\lambda) = k^{\downarrow \#B}\frac{\Gamma(\lambda)\prod_{b\in B}(\lambda/k)^{\uparrow \#b}}{\Gamma(n+\lambda)}, \qquad (1)$$
called the uniform Dirichlet-multinomial partition distribution. The factor $k^{\downarrow \#B}$ ensures that partitions having more than k blocks have zero probability.

In the limit as $k \to \infty$, the uniform Dirichlet-multinomial partition becomes

$$p_n(B,\lambda) = \frac{\lambda^{\#B}\prod_{b\in B}\Gamma(\#b)}{\lambda^{\uparrow n}}. \qquad (2)$$

This is the celebrated Ewens distribution, or Ewens sampling formula, which arises in population genetics as the partition generated by allele type in a population evolving according to the Fisher–Wright model by random mutation with no selective advantage of allele types (Ewens 1972). The preceding derivation, a version of which can be found in Chap. 3 of Kingman (1980), goes back to Watterson (1974). The Ewens partition is the same as the partition generated by a sequence drawn according to the Blackwell-McQueen urn scheme (Blackwell and MacQueen 1973).

Although the derivation makes sense only if k is a positve integer, the distribution (1) is well defined for negative values $-\lambda < k < 0$. For a discussion of this and the connection with GEM distributions and Poisson-Dirichlet distributions, see Pitman (2006, Sect. 3.2).

Partition Processes and Partition Structures

Deletion of element n from the set $[n]$, or deletion of the last row and column from $B \in \mathcal{E}_n$, determines a map $D_n\colon \mathcal{E}_n \to \mathcal{E}_{n-1}$, a projection from the larger to the smaller lattice. These deletion maps make the sets $\{\mathcal{E}_1, \mathcal{E}_2, \ldots\}$ into a projective system

$$\cdots \mathcal{E}_{n+1} \xrightarrow{D_{n+1}} \mathcal{E}_n \xrightarrow{D_n} \mathcal{E}_{n-1} \cdots$$

A family $p = (p_1, p_2, \ldots)$ in which p_n is a probability distribution on $\mathcal{E}_n$ is said to be mutually consistent, or

Kolmogorov-consistent, if each p_{n-1} is the marginal distribution obtained from p_n under deletion of element n from the set $[n]$. In other words, $p_{n-1}(A) = p_n\left(D_n^{-1}A\right)$ for $A \subset \mathcal{E}_{n-1}$. Kolmogorov consistency guarantees the existence of a random partition of the natural numbers whose finite restrictions are distributed as p_n. The partition is infinitely exchangeable if each p_n is finitely exchangeable. Some authors, for example Kingman (1980), refer to p as *a partition structure*.

An exchangeable partition process may be generated from an exchangeable sequence $Y_1, Y_2, \ldots$ by the transformation $B_{ij} = 1$ if $Y_i = Y_j$ and zero otherwise. The Dirichlet-multinomial and the Ewens processes are generated in this way. Kingman's (1978) paintbox construction shows that every exchangeable partition process may be generated from an exchangeable sequence in this manner.

Let B be an infinitely exchangeable partition, $B[n] \sim p_n$, let B^* be a fixed partition in $\mathcal{E}_n$, and suppose that the event $B[n] \leq B^*$ occurs. Then $B[n]$ lies in the lattice interval $[\mathbf{0}_n, B^*]$, which means that $B[n] = B[b_1]|B[b_2]|\ldots$ is the concatenation of partitions of the blocks $b \in B^*$. For each block $b \in B^*$, the restriction $B[b]$ is distributed as $p_{\#b}$, so it is natural to ask whether, and under what conditions, the blocks of B^* are partitioned independently given $B[n] \leq B^*$. Conditional independence implies that

$$p_n(B \,|\, B[n] \leq B^*) = \prod_{b \in B^*} p_{\#b}(B[b]), \tag{3}$$

which is a type of non-interference or lack-of-memory property not dissimilar to that of the exponential distribution on the real line. It is straightforward to check that the condition is satisfied by (2) but not by (1). Aldous (1996) shows that conditional independence uniquely characterizes the Ewens family.

Chinese Restaurant Process

A partition process is a random partition $B \sim p$ of a countably infinite set $\{u_1, u_2, \ldots\}$, and the restriction $B[n]$ of B to $\{u_1, \ldots, u_n\}$ is distributed as p_n. The conditional distribution of $B[n+1]$ given $B[n]$ is determined by the probabilities assigned to those events in $\mathcal{E}_{n+1}$ that are consistent with $B[n]$, i.e. the events $u_{n+1} \mapsto b$ for $b \in B$ and $b = \emptyset$. For the uniform Dirichlet-multinomial model (1), these are

$$\mathrm{pr}(u_{n+1} \mapsto b \,|\, B[n] = B) = \begin{cases} (\#b + \lambda/k)/(n+\lambda) & b \in B \\ \lambda(1 - \#B/k)/(n+\lambda) & b = \emptyset. \end{cases} \tag{4}$$

In the limit as $k \to \infty$, we obtain

$$\mathrm{pr}(u_{n+1} \mapsto b \,|\, B[n] = B) = \begin{cases} \#b/(n+\lambda) & b \in B \\ \lambda/(n+\lambda) & b = \emptyset, \end{cases} \tag{5}$$

which is the conditional probability for the Ewens process.

To each partition process p there corresponds a sequential description called the Chinese restaurant process, in which $B[n]$ is the arrangement of the first n customers at $\#B$ tables. The placement of the next customer is determined by the conditional distribution $p_{n+1}(B[n+1] \,|\, B[n])$. For the Ewens process, the customer chooses a new table with probability $\lambda/(n+\lambda)$ or one of the occupied tables with probability proportional to the number of occupants. The term, due to Pitman, Dubins and Aldous, is used primarily in connection with the Ewens and Dirichlet-multinomial models.

Exchangeable Random Permutations

Beginning with the uniform distribution on permutations of $[n]$, the exponential family with canonical parameter $\theta = \log(\lambda)$ and canonical statistic $\#\sigma$ equal to the number of cycles is

$$p_n(\sigma) = \lambda^{\#\sigma}/\lambda^{\uparrow n}.$$

The Stirling number of the first kind, $S_{n,k}$, is the number of permutations of $[n]$ having exactly k cycles, for which $\lambda^{\uparrow n} = \sum_{k=1}^{n} S_{n,k}\lambda^k$ is the generating function. The cycles of the permutation determine a partition of $[n]$ whose distribution is (2), and a partition of the integer n whose distribution is (6). From the cumulant function

$$\log(\lambda^{\uparrow n}) = \sum_{j=0}^{n-1} \log(j+\lambda)$$

it follows that $\#\sigma = X_0 + \cdots + X_{n-1}$ is the sum of independent Bernoulli variables with parameter $E(X_j) = \lambda/(\lambda+j)$, which is evident also from the Chinese restaurant representation. For large n, the number of cycles is roughly Poisson with parameter $\lambda \log(n)$, implying that $\hat{\lambda} \simeq \#\sigma/\log(n)$ is a consistent estimate as $n \to \infty$, but practically inconsistent.

A minor modification of the Chinese restaurant process also generates a random permutation by keeping track of the cyclic arrangement of customers at tables. After n customers are seated, the next customer chooses a table with probability (4) or (5), as determined by the partition process. If the table is occupied, the new arrival sits to the left of one customer selected uniformly at random from the table occupants. The random permutation thus generated is $j \mapsto \sigma(j)$ from j to the left neighbour $\sigma(j)$.

Provided that the partition process is consistent and exchangeable, the distributions p_n on permutations of $[n]$ are exchangeable and mutually consistent under the projection $\Pi_n \to \Pi_{n-1}$ on permutations in which element n is deleted from the cyclic representation (Pitman 2006, Sect. 3.1). In this way, every infinitely exchangeable random partition also determines an infinitely exchangeable random permutation $\sigma: \mathbb{N} \to \mathbb{N}$ of the natural numbers. Distributional exchangeability in this context is not to be confused with uniformity on Π_n.

On the Number of Unseen Species

A partition of the set $[n]$ is a set of blocks, and the block sizes determine a partition of the integer n. For example, the partition 15|23|4 of the set $[5]$ is associated with the integer partition 2 + 2 + 1, one singleton and two doubletons. An integer partition $m = (m_1, \ldots, m_n)$ is a list of multiplicities, also written as $m = 1^{m_1} 2^{m_2} \cdots n^{m_n}$, such that $\sum j m_j = n$. The number of blocks, usually called the number of parts of the integer partition, is the sum of the multiplicities $m_\cdot = \sum m_j$.

Each integer partition is a group orbit in $\mathcal{E}_n$ induced by the action of the symmetric group on the set $[n]$. The multiplicity vector m contains all the information about block sizes, but there is a subtle transfer of emphasis from block sizes to the multiplicities of the parts.

By definition, an exchangeable distribution on set partitions is a function only of the block sizes, so $p_n(B) = q_n(m)$, where m is the integer partition corresponding to B. Since there are

$$\frac{n!}{\prod_{j=1}^{n} (j!)^{m_j} m_j!}$$

set partitions B corresponding to a given integer partition m, to each exchangeable distribution p_n on set partitions there corresponds a marginal distribution

$$q_n(m) \frac{n!}{\prod_{j=1}^{n} (j!)^{m_j} m_j!}$$

on integer partitions. For example, the Ewens distribution on integer partitions is

$$\frac{\lambda^{m_\cdot} \Gamma(\lambda) \prod \Gamma(j)^{m_j}}{\Gamma(n+\lambda)} \times \frac{n!}{\prod_{j=1}^{n} (j!)^{m_j} m_j!} = \frac{\lambda^{m_\cdot} n! \, \Gamma(\lambda)}{\Gamma(n+\lambda) \prod_j j^{m_j} m_j!}. \tag{6}$$

This version leads naturally to an alternative description as follows. Let $M = M_1, \ldots, M_n$ be independent Poisson random variables with mean $E(M_j) = \lambda \theta^j / j$ for some positive number θ. Then $\sum j M_j$ is sufficient for θ, and the conditional distribution $\mathrm{pr}\left(M = m \,\middle|\, \sum_{j=1}^{n} j M_j = n\right)$ is the Ewens integer-partition distribution with parameter λ. This representation leads naturally to a simple method of estimation and testing, using Poisson log-linear models with model formula $1 + j$ and offset $-\log(j)$ for response vectors that are integer partitions.

The problem of estimating the number of unseen species was first tackled in a paper by Fisher (1943), using an approach that appears to be entirely unrelated to partition processes. Specimens from species i occur as a Poisson process (see ▶Poisson Processes) with rate ρ_i, the rates for distinct species being independent and identically distributed gamma random variables. The number $N_i \geq 0$ of occurrences of species i in an interval of length t is a negative binomial random variable

$$\mathrm{pr}(N_i = x) = (1-\theta)^{\nu} \theta^x \frac{\Gamma(\nu + x)}{x! \, \Gamma(\nu)}. \tag{7}$$

In this setting, $\theta = t/(1+t)$ is a monotone function of the sampling time, whereas $\nu > 0$ is a fixed number independent of t. Specimen counts for distinct species are independent and identically distributed random variables with parameters $\nu > 0$ and $0 < \theta < 1$.

The probability that no specimens from species i occur in the sample is $(1-\theta)^{\nu}$, the same for every species. Most species are unlikely to be observed if either θ is small, i.e., the time interval is short, or ν is small.

Let M_x be the number of species occurring $x \geq 0$ times, so that $M_\cdot$ is the unknown total number of species of which $M_\cdot - M_0$ are observed. The approach followed by Fisher is to estimate the parameters θ, ν by conditioning on the number of species observed and regarding the observed multiplicities M_x for $x \geq 1$ as multinomial with parameter vector proportional to the negative binomial frequencies (7). For Fisher's entomological examples, this approach pointed to $\nu = 0$, consistent with the Ewens distribution (6), and indicating that the data are consistent with the number of species being infinite. Fisher's approach using a model indexed by species is less direct for ecological purposes than a process indexed by specimens. Nonetheless, subsequent analyses by Good and Toulmin (1956), Holgate (1969) and Efron and Thisted (1976) showed how Fisher's model can be used to make predictions about the likely number of new species in a subsequent temporal extension of the original sample. This amounts to a version of the Chinese restaurant process.

At this point, it is worth clarifying the connection between Fisher's negative binomial formulation and the Ewens partition formulation. The relation between them is the same as the relation between binomial and negative binomial sampling schemes for a Bernoulli process: they are not equivalent, but they are complementary. The partition formulation is an exchangeable process indexed by *specimens*: it gives the distribution of species numbers in a

sample consisting of a fixed number of *specimens*. Fisher's version is also an exchangeable process, in fact an iid process, but this process is indexed by *species*: it gives the distribution of the sample composition for a fixed set of *species* observed over a finite period. In either case, the conditional distribution given a sample containing k species and n specimens is the distribution induced from the uniform distribution on the set of $S_{n,k}$ permutations having k cycles. For the sorts of ecological or literary applications considered by Good and Toulmin (1956) or Efron and Thisted (1976), the partition process indexed by specimens is much more direct than one indexed by species.

Fisher's finding that the multiplicities decay as $E(M_j) \propto \theta^j/j$, proportional to the frequencies in the log-series distribution, is a property of many processes describing population structure, either social structure or genetic structure. It occurs in Kendall's (1975) model for family sizes as measured by surname frequencies. One explanation for universality lies in the nature of the transition rates for Kendall's process, a discussion of which can be found in Sect. 2.4 of Kelly (1978).

Equivariant Partition Models

A family $p_n(\sigma;\theta)$ of distributions on permutations indexed by a parameter matrix θ, is said to be equivariant under the induced action of the symmetric group if $p_n(\sigma;\theta) = p_n(g\sigma g^{-1}; g\theta g^{-1})$ for all σ, θ, and for each group element $g\colon [n] \to [n]$. By definition, the parameter space is closed under conjugation: $\theta \in \Theta$ implies $g\theta g^{-1} \in \Theta$. The same definition applies to partition models. Unlike exchangeability, equivariance is not a property of a distribution, but a property of the family. In this setting, the family associated with $[n]$ is not necessarily the same as the family of marginal distributions induced by deletion from $[n+1]$.

Exponential family models play a major role in both theoretical and applied work, so it is natural to begin with such a family of distributions on permutations of the matrix-exponential type

$$p_n(\sigma;\theta) = \alpha^{\#\sigma} \exp(\mathrm{tr}(\sigma\theta))/M_\alpha(\theta),$$

where $\alpha > 0$ and $\mathrm{tr}(\sigma\theta) = \sum_{j=1}^n \theta_{\sigma(j),j}$ is the trace of the ordinary matrix product. The normalizing constant is the α-permanent

$$M_\alpha(\theta) = \mathrm{per}_\alpha(K) = \sum_\sigma \alpha^{\#\sigma} \prod_{j=1}^n K_{\sigma(j),j}$$

where $K_{ij} = \exp(\theta_{ij})$ is the component-wise exponential matrix. This family of distributions on permutations is equivariant.

The limit of the α-permanent as $\alpha \to 0$ gives the sum of cyclic permutations

$$\mathrm{cyp}(K) = \lim_{\alpha\to 0} \alpha^{-1} \mathrm{per}_\alpha(K) = \sum_{\sigma:\#\sigma=1} \prod_{j=1}^n K_{\sigma(j),j},$$

giving an alternative expression for the α-permanent

$$\mathrm{per}_\alpha(K) = \sum_{B\in\mathcal{E}_n} \alpha^{\#B} \prod_{b\in B} \mathrm{cyp}(K[b])$$

as a sum over partitions. The induced marginal distribution (10) on partitions is of the product-partition type recommended by Hartigan (1990), and is also equivariant. Note that the matrix θ and its transpose determine the same distribution on partitions, but they do not usually determine the same distribution on permutations.

The α-permanent has a less obvious convolution property that helps to explain why this function might be expected to occur in partition models:

$$\sum_{b\subset[n]} \mathrm{per}_\alpha(K[b])\,\mathrm{per}_{\alpha'}(K[\bar{b}]) = \mathrm{per}_{\alpha+\alpha'}(K). \qquad (8)$$

The sum extends over all 2^n subsets of $[n]$, and $\bar{b}$ is the complement of b in $[n]$. A derivation can be found in section 2.4 of McCullagh and Møller (2006). If B is a partition of $[n]$, the symbol $K \cdot B = B \cdot K$ denotes the Hadamard component-wise matrix product for which

$$\mathrm{per}_\alpha(K \cdot B) = \prod_{b\in B} \mathrm{per}_\alpha(K[b])$$

is the product over the blocks of B of α-permanents restricted to the blocks. Thus the function $B \mapsto \mathrm{per}_\alpha(K\cdot B)$ is of the product-partition type.

With α, K as parameters, we may define a family of probability distributions on $\mathcal{E}_n^k$, i.e., partitions of $[n]$ having k or fewer blocks, as follows:

$$p_{nk}(B) = k^{\downarrow\#B}\,\mathrm{per}_{\alpha/k}(K\cdot B)/\mathrm{per}_\alpha(K). \qquad (9)$$

The fact that (9) is a probability distribution on $\mathcal{E}_n$ follows from the convolution property of permanents. The limit as $k \to \infty$

$$p_n(B) = \alpha^{\#B} \prod_{b\in B} \mathrm{cyp}(K[b])/\mathrm{per}_\alpha(K), \qquad (10)$$

is a product-partition model satisfying the conditional independence property (3). For $K = \mathbf{1}_n$, the $n \times n$ matrix whose elements are all one, $\mathrm{per}_\alpha(\mathbf{1}_n) = \alpha^{\uparrow n}$ is the ascending factorial function. Thus the uniform Dirichlet-multinomial model (1) and the Ewens model (2) are both obtained by setting $\theta = 0$.

Leaf-Labelled Trees

Kingman's $[n]$-coalescent is a non-decreasing, $\mathcal{E}_n$-valued Markov process (see ▶Markov Processes) (B_t) in continuous-time starting from the partition $B_0 = \mathbf{0}_n$ with n singleton blocks at time zero. The coalescence intensity is one for each pair of blocks regardless of size, so each coalescence event unites two blocks chosen uniformly at random from the set of pairs. Consequently, the first coalescence occurs after a random time T_n exponentially distributed with rate $\rho(n) = n(n-1)/2$ and mean $1/\rho(n)$. After k coalescences, the partition consists of $n-k$ blocks, and the waiting time T_k for the next subsequent coalescence is exponential with rate $\rho(n-k)$. The time to complete coalescence is the sum of independent exponentials $T = T_n + T_{n-1} + \cdots + T_2$, which is a random variable with mean $2-2/n$ and variance increasing from 1 at $n = 2$ to a little less than 1.16 as $n \to \infty$. In the context of the Fisher–Wright model, the coalescent describes the genealogical relationships among a sample of individuals, and T is the time to the most recent common ancestor of the sample.

The $[n]$-coalescent is exchangeable for each n, but the property that makes it interesting mathematically, statistically and genetically is its consistency under selection or sub-sampling (Kingman 1982). If we denote by p_n the distribution on $[n]$-trees implied by the specific Markovian model described above, it can be shown that the embedded tree obtained by deleting element n from the sample $[n]$ is not only Markovian but also distributed as p_{n-1}, i.e., the same coalescent rule applied to the subset $[n-1]$. This property is mathematically essential for genealogical trees because the occurrence or non-occurrence of individual n in the sample does not affect the genealogical relationships among the remainder.

A fragmentation $[n]$-tree is a non-increasing $\mathcal{E}_n$-valued Markov process starting from the trivial partition $B_0 = \mathbf{1}_n$ with one block of size n at time $t = 0$. The simplest of these are the consistent binary Gibbs fragmentation trees studied by Aldous (1996), Bertoin (2001, 2006) and McCullagh et al. (2008). The first split into two branches occurs at a random time T_n exponentially distributed with parameter $\rho(n)$. Subsequently, each branch fragments independently according to the same family of distributions with parameter $\rho(\#b)$ for branch b, which is a Markovian conditional independence property analogous to (3). Consistency and conditional independence put severe limitations on both the splitting distribution and the rate function $\rho(n)$, so the entire class is essentially one-dimensional.

A rooted leaf-labelled tree T is also a non-negative symmetric matrix. The interpretation of T_{ij} as the distance from the root to the junction at which leaves i, j occur on disjoint branches implies the inequality $T_{ij} \geq \min(T_{ik}, T_{jk})$ for all $i, j, k \in [n]$. The set of $[n]$-trees is a subset of the positive definite symmetric matrices, not a manifold, but a finite union of manifolds of dimension $2n-1$, or n if the diagonal elements are constrained to be equal. Like partitions, rooted trees form a projective system within the positive definite matrices. A fragmentation tree is an infinitely exchangeable random tree, which is also a special type of infinitely exchangeable random matrix.

Cluster Processes and Classification Models

A $\mathcal{R}^d$-valued cluster process is a pair (Y, B) in which $Y = (Y_1, \ldots)$ is an $\mathcal{R}^d$-valued random sequence and B is a random partition of $\mathbb{N}$. The process is said to be exchangeable if, for each finite sample $[n] \subset \mathbb{N}$, the restricted process $(Y[n], B[n])$ is invariant under permutation $\sigma: [n] \to [n]$ of sample elements.

The Gauss–Ewens process is the simplest non-trivial example for which the distribution for a sample $[n]$ is as follows. First fix the parameter values $\lambda > 0$, and Σ^0, Σ^1 both positive definite of order d. In the first step B has the Ewens distribution on $\mathcal{E}_n$ with parameter λ. Conditionally on B, Y is a zero-mean Gaussian matrix of order $n \times d$ with covariance matrix

$$\operatorname{cov}(Y_{ir}, Y_{js} \mid B) = \delta_{ij}\Sigma^0_{rs} + B_{ij}\Sigma^1_{rs},$$

where δ_{ij} is the Kronecker symbol. A scatterplot color-coded by blocks of the Y values in $\mathcal{R}^2$ shows that the points tend to be clustered, the degree of clustering being governed by the ratio of between to within-cluster variances.

For an equivalent construction we may proceed using a version of the Chinese restaurant process in which tables are numbered in order of occupancy, and $t(i)$ is number of the table at which customer i is seated. In addition, $\epsilon_1, \ldots$ and $\eta_1, \ldots$ are independent Gaussian sequences with independent components $\epsilon_i \sim N_d(0, \Sigma^0)$, and $\eta_i \sim N_d(0, \Sigma^1)$. The sequence t determines B, and the value for individual i is a vector $Y_i = \eta_{t(i)} + \epsilon_i$ in $\mathcal{R}^d$, or $Y_i = \mu + \eta_{t(i)} + \epsilon_i$ if a constant non-zero mean vector is included.

Despite the lack of class labels, cluster processes lend themselves naturally to prediction and classification, also called supervised learning. The description that follows is taken from McCullagh and Yang (2006) but, with minor modifications, the same description applies equally to more complicated non-linear versions associated with generalized linear mixed models (Blei et al. 2003). Given the observation $(Y[n], B[n])$ for the 'training sample' $[n]$, together with the feature vector Y_{n+1} for specimen u_{n+1}, the conditional distribution of $B[n+1]$ is determined by

those events $u_{n+1} \mapsto b$ for $b \in B$ and $b = \emptyset$ that are compatible with the observation. The assignment of a positive probability to the event that the new specimen belongs to a previously unobserved class seems highly desirable, even logically necessary, in many applications.

If the classes are tree-structured with two levels, we may generate a sub-partition $B' \leq B$ whose conditional distribution given B is Ewens restricted to the interval $[\mathbf{0}_n, B]$, with parameter λ'. This sub-partition has the effect of splitting each main clusters randomly into sub-clusters. For the sample $[n]$, let $t'(i)$ be the number of the sub-cluster in which individual i occurs. Given B, B', the Gauss-Ewens two-level tree process is a sum of three independent Gaussian processes $Y_i = \eta_{t(i)} + \eta'_{t'(i)} + \epsilon_i$ for which the conditional distributions may be computed as before. In this situation, however, events that are compatible with the observation $B[n], B'[n]$ are of three types as follows:

$$u_{n+1} \mapsto b' \in B'[n], \quad u_{n+1} \mapsto \emptyset \subset b \in B[n], \quad u_{n+1} \mapsto \emptyset.$$

In all, there are $\#B' + \#B + 1$ disjoint events for which the conditional distribution given $B[n], B'[n], Y[n+1]$ must be computed. An event of the second type is one in which the new specimen belongs to the major class $b \in B$, but not to any of the sub-types previously observed for this class.

Further Applications of Partition Models

Exchangeable partition models are used to construct nontrivial, exchangeable processes suitable for cluster analysis and density estimation. See Frayley and Raftery (2002) for a review. Here, cluster analysis means cluster detection and cluster counting in the absence of covariate or relational information about the units. In the computer-science literature, cluster detection is also called unsupervised learning. The simplest of these models is the marginal Gauss–Ewens process in which only the sequence Y is observed. The conditional distribution $p_n(B \mid Y)$ on $\mathcal{E}_n$ is the posterior distribution on clusterings or partitions of $[n]$, and $E(B \mid Y)$ is the one-dimensional marginal distribution on pairs of units. In estimating the number of clusters, it is important to distinguish between the sample number $\#B[n]$, which is necessarily finite, and the population number $\#B[\mathbb{N}]$, which could be infinite (McCullagh and Yang 2008).

Exchangeable partition models are also used to provide a Bayesian solution to the multiple comparisons problem. The key idea is to associate with each partition B of $[k]$ a subspace $V_B \subset \mathcal{R}^k$ equal to the span of the columns of B. Thus, V_B consists of vectors x such that $x_r = x_s$ if $B_{rs} = 1$. For a treatment factor having k levels $\tau_1, \ldots, \tau_k$, the Gauss–Ewens prior distribution on R^k puts positive mass on the subspaces V_B for each $B \in \mathcal{E}_k$. Likewise, the posterior distribution also puts positive probability on these subspaces, which enables us to compute in a coherent way the posterior probability $\mathrm{pr}(\tau \in V_B)$ or the marginal posterior probability $\mathrm{pr}(\tau_r = \tau_s \mid y)$. For details, see (Gopalan and Berry 1998).

Random Variable

Czesław Stępniak
Professor
Maria Curie-Skłodowska University, Lublin, Poland
University of Rzeszów, Rzeszów, Poland

Random variable (r.v.) is a real function defined on the set of outcomes. It reduces the set-theoretical problems in probability to some simpler ones in real analysis. R.v. 's are indispensable in probability computing.

Motivation

Formal definition of a r.v. is a consequence of some practical and logical needs. Let us start from a measure-theoretic frame $(\Omega, \mathcal{A}, P)$, where Ω is the set of outcomes, $\mathcal{A}$ is a σ-algebra of subsets of Ω, serving as random events, and P is a normalized measure on the space $(\Omega, \mathcal{A})$, called probability. Any real function $f = f(\omega)$ transforms the initial probability system $(\Omega, \mathcal{A}, P)$ onto some induced system $(\Omega_f, \mathcal{A}_f, P_f)$, where Ω_f is the image of Ω by f, $\mathcal{A}_f$ is the σ-algebra of of subsets B on Ω_f induced by f, while P_f is a probability measure on $(\Omega_f, \mathcal{A}_f)$ defined by

$$P_f(B) = P(\{\omega : f(\omega) \in B\}). \tag{1}$$

For practical reasons we require that the family $\mathcal{A}_f$ includes all intervals $(a; b >$, i.e., that $\mathcal{A}_f \supseteq \mathcal{B}$, where $\mathcal{B}$ means the family of Borel sets in the real line. On the other hand the right side of (1) is well defined, if and only if, $\{\omega : f(\omega) \in B\} \in \mathcal{A}$. Since $\mathcal{A}_f$ is σ-algebra generated by the intervals, the last condition may be expressed in a more readable form

$$\{\omega : f(\omega) \le c\} \in \mathcal{A} \text{ for any } c \in R. \tag{2}$$

Formal Definition

Any real function defined on the (measurable) space $(\Omega, \mathcal{A})$ satisfying the condition (2) is said to be a random variable on $(\Omega, \mathcal{A})$. Traditionally, random variables are denoted by capital letters $X(\omega), Y(\omega), Z(\omega)$, or simply X, Y, Z. The following exmple shows that not every function of outcome is a random variable.

Example 1 Let us set $\Omega = \{1,2,3,4,5\}$, $\mathcal{A} = \{\varnothing, \{1,3,5\}, \{2,4\}, \Omega\}$ and

$$f(\omega) = \begin{cases} 0, & \text{if } \omega \le 2 \\ 1, & \text{if } \omega > 2. \end{cases}$$

By setting in (2) $c = 1$ we get $\{\omega : f(\omega) < 1\} = \{1,2\} \notin \mathcal{A}$. Thus f is not random variable on the space $(\Omega, \mathcal{A})$.

The probability measure $P_X(B) = P(\{\omega : X(\omega) \in B\})$ for $B \in \mathcal{B}$ is said to be distribution of the r.v. X. This expression has mainly theoretical sense, because the Borel sets are abstractive objects. More practical in use is so called *cumulative distribution function (c.d.f)* F defined by $F(\alpha) = P(\{\omega : X(\omega) \le \alpha\})$.

Example 2 (Two-Dice Game). Here the set of outcomes may be presented in the form $\Omega = \{(i,j) : i,j = 1,2,3,4,5,6\}$, the family of random events $\mathcal{A}$ may be defined as the family of all subsets of Ω, while $X(\omega)$, for any $\omega = (i,j)$ may be defined as $i + j$. Such a r.v. takes the possible values from 2 to 12 with probabilities

$$P_X(k) = \begin{cases} \frac{k-1}{36} & \text{if} \quad k \le 7 \\ \frac{12-k+1}{36} & \text{if} \quad k > 7, \end{cases}$$

while the values of c.d.f. $F_X = F_X(\alpha)$ are collected in the Table 1.

It is worth to add that if $X = X(\omega)$ is a random variable and f is a Borel function, i.e., a real function of a real variable such that $\{x : f(x) \le c\} \in \mathcal{B}$ for all $c \in R$ then the composition $f[X(\omega)]$ is also random variable.

Random Variable. Table 1 Values of c.d.f. $F_X = F_X(\alpha)$ in example 2

Interval for α	$(-\infty, 2)$	$<2,3)$	$<3,4)$	$<4,5)$	$<5,6)$	$<6,7)$
$F_X(\alpha)$	0	$\frac{1}{36}$	$\frac{3}{36}$	$\frac{6}{36}$	$\frac{10}{36}$	$\frac{15}{36}$
Interval for α	$<7,8)$	$<8,9)$	$<9,10)$	$<10,11)$	$<11,12)$	$<12,+\infty)$
$F_X(\alpha)$	$\frac{21}{36}$	$\frac{26}{36}$	$\frac{30}{36}$	$\frac{33}{36}$	$\frac{35}{36}$	1

Classification of r.v. 's

It is well known that any c.d.f. F is continuous, perhaps outside a countable set on the real line. For practical purposes we distinguish two classes of random variables. A r.v. is

1. *Discrete,* if its c.d.f is constant in all intervals designed by the points of its discontinuity
2. *Continuous,* if there exists a nonnegative integrable function f on R, called *density,* such that $F(\alpha) = \int_{-\infty}^{+\infty} f(x)dx$ for all $\alpha \in R$.

This classification is fully justified by two different analytical tools used in presentation and calculation of the r.v.'s. Distribution of a discrete r.v. X taking values x_i for some $i \in I$ is given by *probability mass function* $p_i = P(X = x_i)$ and its expectation is calculated by the formula $Ex = \sum_i x_i p_i$. Distribution of a continuous r.v. X is usually given by its *density function* f, while its expectation is calculated by the formula $Ex = \int_{-\infty}^{+\infty} xf(x)dx$.

About the Author

Professor Czesław Stępniak was formerly working at Agricultural University in Lublin, Poland (1972–2001) and heading Department of Statistics and Econometrics, Maria Curie-Skłodowska University in Lublin, Poland (2003–2009). During academic year 1987–1988 he was visiting Mathematical Sciences Institute of Cornell University, Ithaca, NY, as a senior scientist. Jointly with E. Torgersen, C. F. J. Wu and H. Heyer, Czesław Stępniak laid mathematical foundation to comparison of statistical experiments. He was also a recipient of two awards from Ministry of Science and Education in Poland "for a series of papers." Professor Stępniak authored more than 50 articles in peer-reviewed journals. He has two descendents Marek Niezgoda and Zdzisław Otachel.

Random Walk

Rabi Bhattacharya
Professor of Mathematics
The University of Arizona, Tucson, AZ, USA

The simple random walk $\{S_n : n = 0, 1, \ldots\}$, starting at an integer x, is a stochastic process on the integers, given by $S_0 = x$, $S_n = x + X_1 + \ldots + X_n (n \geq 1)$, where $X_n, n \geq 1$, is an independent Bernoulli sequence: $P(X_n = 1) = p$, $P(X_n = -1) = 1 - p = q$, $0 < p < 1$. In the case, $p = q = 1/2$, it is called the *simple symmetric random walk*, while if $p \neq 1/2$, it is *asymmetric*. By the binomial theorem, $P(S_n = y \mid S_0 = 0) = C^n_{\frac{(n+y)}{2}} p^{(n+y)/2} q^{(n-y)/2}$, if y and n are of the same parity, i.e., if either both are odd or both are even. Otherwise, $P(S_n = y \mid S_0 = 0) = 0$. Here $= C^n_m = n!/(m!(n-m)!)$.

For $c \leq x \leq d$ integers, the probability $\pi(x)$ that a simple random walk, starting at x, reaches c before d satisfies the equation

$$\pi(x) = p\pi(x+1) + q\pi(x-1) \quad \text{for } c < x < d,\ \pi(c) = 1,\ \pi(d) = 0, \qquad (1)$$

as shown by conditioning on the first step X_1. For the symmetric walk, the solution of this equation is $\pi(x) = (d-x)/(d-c)$. Since $\pi(x) \to 1$ as $d \to \infty$, the symmetric walk will reach the state c, starting from any state $x > c$, with probability one. By symmetry, it will reach every state with probability one. Iterating this argument one sees that, with probability one, the symmetric random walk visits every state infinitely often. That is, the walk is *recurrent*. For the asymmetric walk, the solution to (1) is $\pi(x) = (1 - (p/q)^{d-x})/(1 - (p/q)^{d-c})$. If $p < 1/2$, then the limit of this is 1 as $d \to \infty$ and, with probability one,

the random walk will visit c, starting from $x > c$. On the other hand, if $p > 1/2$, then $\pi(x) \to (q/p)^{x-c} < 1$, as $d \to \infty$. The probability of ever reaching d, starting from $x < d$ is obtained by symmetry as 1 if $p > 1/2$ and $(p/q)^{d-x}$ if $p < 1/2$. The asymmetric simple random walk is thus *transient*. Indeed, it follows from the strong law of large numbers (*SLLN*) that if $p > 1/2$, then $S_n \to \infty$ with probability one as $n \to \infty$; and $S_n \to -\infty$, with probability one, if $p < 1/2$. For these and other properties of the random walk, such as those described below, see Feller (1968, Chap. 3), Bhattacharya and Waymire (2009, Chap. 1), or Durrett (1995, Chap. 3). For additional information, refer to Billingsley (1968), and Spitzer (1964).

For computation of various probabilities associated with a simple random walk, the following result proved by D. Andre in 1887 is very useful: Consider the polygonal path of the random walk joining successive points (j, S_j), $(j+1, S_{j+1})$ $(j = 0, 1, \ldots, n-1)$ by line segments. Let $y > 0$. Then (a) the set of paths from $(0,0)$ to $(n, y-1)$ (n and $y-1$ of the same parity) which touch or cross the level y, is in one-one correspondence with (b) the set of all paths from $(0,0)$ to $(n, y+1)$ (*Reflection principle*). To prove this, let τ be the first time a path of the type (a) touches the level y prior to time n. Then replace the segment of the path from (τ, y) to $(n, y-1)$ by its mirror reflection about the level y. This gives a path of the type (b). Conversely, given any path of the type (b), reflect about y the segment of the path from (τ, y) to $(n, y+1)$. This gives a path of the type (a). Here is an application of this principle.

Example 1 (First passage time distribution of a simple random walk). Let y be a positive integer, and $F_{n,y}$ the event that the random walk, starting at zero, reaches y for the first time at time n, i.e., $F_{n,y} = \{S_j \neq y$, for $0 \le j < n, S_n = y\}$, n and y of the same parity. Altogether there are $C^n_{\frac{n+y}{2}}$ paths from $(0,0)$ to (n,y), each having probability $p^{(n+y)/2} q^{(n-y)/2}$. Of these, the number which cross or touch the level y prior to time n and for which $S_{n-1} = y-1$ is, by the reflection principle, $C^{n-1}_{\frac{n+y}{2}}$. Also the number for which $S_{n-1} = y+1$ is $C^{n-1}_{\frac{n+y}{2}}$. Subtracting these two from the number $C^n_{\frac{n+y}{2}}$ of all paths, one obtains, for all $y \neq 0$ (treating the case $y < 0$ by symmetry),

$$\begin{aligned} P(F_{n,y}) &= \left(C^n_{\frac{n+y}{2}} - 2C^{n-1}_{\frac{n+y}{2}}\right) p^{(n+y)/2} q^{(n-y)/2} \\ &= (|y|/n) C^n_{\frac{n+y}{2}} p^{(n+y)/2} q^{(n-y)/2} \qquad (2) \\ &\quad (n = |y|, |y|+2, |y|+4, \ldots). \end{aligned}$$

One may also consider the simple symmetric random walk $S_0 = x$, $S_n = x + X_1 + \ldots + X_n$ $(n \ge 1)$, in dimension $d \ge 1$, as a stochastic process on the d-dimensional lattice Z^d, with $X_n (n \ge 1)$ i.i.d. random vectors, taking values $\pm e_j (j = 1, \ldots, d)$, each with probability $1/2d$. Here e_j is the vector whose j-th coordinate is 1 and the remaining $d-1$ coordinates are zero. It was proved by G. Polya in 1921 that this walk is recurrent in dimensions 1,2, and transient in higher dimensions.

De Moivre (1756) obtained the normal approximation to the binomial probability $P(S_n = y \mid S_0 = 0)$, as a combinatorial result. The full potential of this was realized by Laplace (1812) who formulated and derived the far reaching central limit theorem (*CLT*, see ▶Central Limit Theorems). Apparently, Gauss knew about the normal distribution as early as 1794, and assuming this as the distribution of errors of measurement, he obtained his famous method of ▶least squares. Hence the name Gaussian distribution is often used for the normal distribution. The final version of the *CLT* for a *general random walk* $S_n = X_1 + \ldots + X_n$ $(n \ge 1)$, where X_n are arbitrary independent identically distributed (*i.i.d.*) random variables with mean zero and finite variance $\sigma^2 > 0$, was obtained by Lévy (1925): $n^{-1/2}(X_1 + \ldots + X_n)$ converges in distribution to the normal distribution $N(0, \sigma^2)$ with mean zero and variance σ^2, as $n \to \infty$. In physical terms, this result says the following: if time and length are rescaled so that in one unit of rescaled time there are a large number n of i.i.d. displacements of small rescaled lengths of order $1/\sqrt{n}$, then the random walk displacements over a period of time t will appear as Gaussian with mean zero and variance $t\sigma^2$, the increments over disjoint intervals being independent. That such a Gaussian process exists with continuous sample paths was proved rigorously by N.Wiener in 1923. This process is called the *Brownian motion*, following its implicit use by A. Einstein in 1905–1906 to describe the kinetic motion of colloidal molecules in a liquid, experimentally observed earlier by the botanist R. Brown. Interestingly, even before Einstein, Bachelier (1900) described the random movements of stocks by this Gaussian process. The statement that the rescaled random walk $S_n(n = 0, 1, 2, \ldots)$ converges in distribution to Brownian motion (see ▶Brownian Motion and Diffusions) was proved rigorously by M. Donsker in 1951, and this result is known as the functional central limit theorem (*FCLT*). Both the *CLT* and the *FCLT* extend to arbitrary dimensions d.

As consequences of the *FCLT*, one can derive many asymptotic results for the simple symmetric random walk given by the corresponding result for the limiting Brownian motion. Conversely, by evaluating combinatorially some probability associated with the random walk, one may derive the corresponding probability for the Brownian motion. A Brownian motion with variance parameter $\sigma^2 = 1$ is called a standard Brownian motion, and denoted $\{B_t : t \ge 0\}$ below.

Example 2 (Boundary hitting probability of Brownian motion). Let $c \le x \le d$ be arbitrary reals. Then, using the corresponding result for the scaled ▶random walk, one obtains

$$P(\{B_t : t \ge 0\} \text{ reaches c before } d \mid B_0 = x) = (d-x)/(d-c). \quad (3)$$

Example 3 (Arcsine law). Let U denote the amount of time in $[0,1]$ the Brownian motion spends above zero, i.e., U = Lebesgue measure of the set $\{t : 0 \le t \le 1 : B_t > 0\}$, given $B_0 = 0$. Consider the polygonal path of the simple symmetric random walk $S_j(j = 0,1,\ldots n)$, starting at zero. By combinatorial arguments, such as the reflection principle, one can calculate exactly the proportion of times the polygonal path lies above zero and, by the *FCLT*, this yields

$$P(U \le x) = (2/\pi) sin^{-1}\sqrt{x}\ (0 \le x \le 1). \quad (4)$$

Randomization

Cristiano Ferraz
Associate Professor
Federal University of Pernambuco, Recife, Brazil

Randomization is prescribed in several statistical procedures for reasons related not only to the assurance of scientific objectivity. Randomization, in essence, may be defined as a physical mechanism to assign probabilities to events. In probability sampling, such events are related to the selection of samples from finite populations. Samples are selected according to randomization processes that

guarantee selection probabilities for any specific sample. As a consequence, it also guarantees inclusion probabilities (of first and higher orders) for any element of the population. When a simple random sampling design (without replacement) is employed, for instance, any sample A, of size n from a population $\mathcal{U}$, of size N ($n < N$) have the same probability of been selected, and its inclusion probability of first order corresponds to the sample fraction, n/N. Restrictions imposed on the randomization lead to different sample designs (e.g., systematic sampling, Bernoulli sampling, Poisson sampling, and stratified sampling) and are responsible for their statistical properties. Similarly, in comparative experiments, the events are related to the assignment of treatments to experimental units. In experiments following the randomization principle, treatments are randomly assigned to available experimental units. This means such an assignment follows a specific randomization protocol. If, for instance, the protocol implies each group of size r from a total $n = tr$ available experimental units have the same probability of receiving a given treatment, the experiment is been conducted to compare t treatments according to a completely randomized design (with r genuine replicates). Once again, restrictions in the randomization lead to different designs (e.g., randomized complete block designs, Latin square designs, and split-plot designs).

Statistical methods of sampling and design of experiments rely on randomization to make valid design-based inferences. In both cases, inferences are supported by real reference distributions, induced by randomization. Its major role may be evident from appropriately derived linear models. A linear model for data from a ▶simple random sample, for instance, may be derived as follows. Let y_i be defined as the ith observation of a variable of interest Y under a simple random sample selection scheme (such as the traditional drawing of n balls, one at a time, without replacement, from an urn with N balls labeled from 1 to N). Hence, y_i can assume any value Y_k (the value of Y associated to element $k \in \mathcal{U}$). Let also be the following indicator variable defined:

$$\delta_{ik} = \begin{cases} 1, & \text{if } y_i = Y_k \\ 0, & \text{if } y_i \neq Y_k \end{cases}$$

Now, it is possible to write

$$y_i = \sum_{k \in \mathcal{U}} \delta_{ik} Y_k. \tag{1}$$

Let Y_k be rewritten as $\mu + (Y_k - \mu)$, with $\mu = \frac{\sum_{k \in \mathcal{U}} Y_k}{N}$. Then, (1) may be rewritten as

$$y_i = \sum_{k \in \mathcal{U}} \delta_{ik} [\mu + (Y_k - \mu)] = \mu + \sum_{k \in \mathcal{U}} \delta_{ik} (Y_k - \mu). \tag{2}$$

Define $\omega_i = \sum_{k \in \mathcal{U}} \delta_{ik} (Y_k - \mu)$ and (2) may be written as

$$y_i = \mu + \omega_i. \tag{3}$$

Expression (3) is the simplest linear model. According to this model, the ith observation of a variable of interest Y, observed on a simple random sample, may be regarded as the population mean (μ) plus a random term (ω_i) with statistical properties implied by the randomization scheme. For example, the description of "balls withdrawn from an urn" scheme allows one to write

$$P(\delta_{ik} = 1) = \frac{1}{N}, \text{ for any } k \in \mathcal{U};$$
$$P(\delta_{ik} = 1, \delta_{i'k'} = 1) = 0 \text{ for } k \neq k'; \text{ and,}$$
$$P(\delta_{ik} = 1, \delta_{i'k'} = 1) = \frac{1}{N(N-1)}, \text{ for } i \neq i' \text{ and } k \neq k'.$$

Therefore, the following properties hold:

$$E(\omega_i) = E\left(\sum_{k \in \mathcal{U}} \delta_{ik} (Y_k - \mu)\right) = \frac{1}{N} \sum_{k \in \mathcal{U}} (Y_k - \mu) = 0; \tag{4}$$

$$V(\omega_i) = E(\omega_i^2) = \sum_{k \in \mathcal{U}} \sum_{k' \in \mathcal{U}} (Y_k - \mu)(Y_{k'} - \mu) E(\delta_{ik} \delta_{ik'})$$
$$= \frac{1}{N} \sum_{k \in \mathcal{U}} (Y_k - \mu)^2 = \frac{(N-1)}{N} \sigma^2 \tag{5}$$

where $\sigma^2 = \frac{\sum_{k \in \mathcal{U}} (Y_k - \mu)^2}{N-1}$. It can also be shown that

$$Cov(\omega_i, \omega_{i'}) = -\frac{\sigma^2}{N} \tag{6}$$

Clearly, properties (4), (5), and (6) are consequences of the randomization process. They are not assumptions. Based on them, estimators such as the sample mean can be evaluated and proved unbiased with variances given as stated in many sampling books.

The ideas related to the role of randomization in scientific investigation were originally proposed by Fisher (1925, 1937). Since then, the relevance of the subject motivated works by several authors. Only few of them are referenced here as suggestions for further reading by limitation of space. Hinkelmann and Kempthorne (1994), for instance, explore the role of randomization in designed experiments by deriving linear models and examining in

depth the properties of the induced reference distributions. Särndal et al. (1992) emphasize the fundamental ideas of probability sampling giving attention to unbiased estimation. Finally, Tillé (2006) describes a series of computational algorithms (randomization protocols) to select samples according to the probabilistic method.

Randomization Tests

Eugene S. Edgington
Professor Emeritus
University of Calgary, Calgary, AB, Canada

A randomization test is a permutation test (see ►Permutation Tests) that is based on randomization (random assignment), where the test is carried out in the following way. A test statistic (such as a difference between means) is computed for the experimental data (measurements or observations). Then the data are repeatedly divided or rearranged in a manner consistent with what the random assignment procedure would have produced if the treatments had no differential effect. The test statistic is computed for each of the resulting data permutations. Those data permutations, including the one for the experimental results, constitute the reference set for determining significance. The proportion of data permutations in the reference set having test statistic values greater than or equal to (or for certain test statistics, less than or equal to) the value for the experimental results is the *p*-value (significance or probability value). Determining significance on the basis of a distribution of test statistics generated by permuting the data is characteristic of all permutation tests; it is when the basis for permuting the data is random assignment (not random sampling) that a permutation test is called a randomization test.

The null hypothesis for a randomization test is that the measurement for each experimental unit (e.g., a subject or a plot of land) is the same under one assignment to treatments as under any alternative assignment. Thus, under the null hypothesis, assignment of experimental units to treatments randomly divides the measurements among the treatments. Each data permutation in the reference set represents the results that, if the null hypothesis is true, would have been obtained for a particular assignment. A randomization test is valid for any kind of sample, no matter how the sample is selected. This is an extremely important property because the use of non-random samples is common in experimentation, and parametric statistical tables (e.g., *t* and *F* tables) are not valid for such samples.

The validity of parametric statistical tables depends on random samples, and the invalidity of application to non-random samples is widely recognized. The random sampling assumption underlying the parametric significance tables is that of a sampling procedure that gives all possible samples of *n* individuals within a specified population

the same probability of being drawn. Arguments regarding the "representativeness" of a non-randomly selected sample are irrelevant to the question of its randomness: a random sample is random because of the sampling procedure used to select it, not because of the composition of the sample. Thus random selection is necessary to ensure that samples are random.

It must be stressed that violation of the random sampling assumption invalidates parametric statistical tables not just for the occasional experiment but for virtually all experiments involving statistical tests. A person conducting a poll may be able to enumerate the population to be sampled and select a random sample by a lottery procedure, but an experimenter would not have enough time, money, or information to take a random sample of the population of the world in order to make statistical inferences about people in general. Not many experiments in biology, education, medicine, psychology, or any other field use randomly selected subjects, and those that do usually concern populations so specific as to be of little interest. For instance, when human subjects for psychological experiments are selected randomly, often they are drawn from a population of students who attend a certain university, are enrolled in a particular class, and are willing to serve as subjects. Biologists and others performing experiments on animals generally do not even pretend to take random samples although they commonly use standard hypothesis testing procedures designed to test null hypotheses about populations. These well-known facts are mentioned here as a reminder of the rareness of random samples in experimentation and of the specificity of the populations on those occasions when random samples are taken.

In most experimentation the concept of population comes into the statistical analysis because it is traditional to discuss the results of a statistical test in terms of inferences about populations, not because the experimenter has sampled randomly some population to which he wishes to generalize. The population of interest to the experiment is likely to be one that cannot be sampled randomly. Random sampling by a lottery procedure, a table of random numbers, or any other device requires sampling a finite population, but experiments of a basic nature are not designed to find out something about a particular finite existing population. For example, with either animals or human subjects the intention is to draw inferences applicable to individuals already dead and individuals not yet born, as well as those who are alive at the present time. If we were concerned only with an existing population, we would have extremely biological laws because every minute some individuals are born and some die, producing a continual change in the existing population. Thus the population of interest in most experiments is not one about which statistical inferences can be made because it cannot be sampled randomly.

A number of desirable properties of randomization tests are a function of their intelligibility. A knowledge of calculus or other aspects of "advanced mathematics" is unnecessary for an experimenter to develop a new randomization test, using only his statistical knowledge of finite statistics involving combinations and permutations. The way in which random assignment is carried out in an experiment permits an experimenter to see whether the method of permuting the data is valid for that experiment for either simple or complex randomization tests. Neither the producer nor the consumer of randomization tests needs to rely on unknown authorities to justify their decision regarding the validity of a randomization test – or of its invalidity. For professors who enjoy making their students think instead of memorize, teaching randomization tests is enjoyable, and the pleasure of reasoning at a level that permits a student to develop new statistical tests that are custom-made to fit a new type of experimental design can appeal to ingenuity of many students.

Rank Transformations

W. J. Conover
Horn Professor of Statistics
Texas Tech University, Lubbock, TX, USA

Statistics

The Science of Statistics is concerned with the analysis of data. This analysis may be as simple as presenting a graph, or finding an average. In more complex analyzes a statistical model may be assumed, and inferences may be made concerning the more general characteristics of the population of data from which a sample of data was obtained.

Parametric Versus Nonparametric

If the statistical model involves assumptions regarding the distribution of probabilities that govern the population of data then the resulting statistical methods are usually called "parametric." If the statistical model involves assumptions, but not assumptions regarding the distribution of probabilities governing the population, then the resulting statistical methods are usually called "nonparametric" or "distribution-free." Many of the best nonparametric methods involve the ranks of the data rather than the data itself. By ranks of the data it is meant that the smallest observation in the data set is given rank 1, the second smallest is given rank 2, and so forth.

Rank Transformation

Parametric methods usually have some optimum property for the parametric model, but are often inferior to the nonparametric method when the parametric model is not appropriate. It is convenient in those cases to "transform" the data to ranks, and to use the parametric method on the ranks instead of the data. These are called "rank transformation methods."

Example

In some cases the rank transformation method results in a nonparametric method. An early example involves Spearman's rho, published in 1904, which is simply the Pearson product-moment correlation coefficient r calculated on the ranks of the data rather than the data itself. Thus one can test the hypothesis of independence of two variables paired as in (X, Y), without any assumptions regarding the nature of the bivariate distribution from which they came, while the parametric model assumes a bivariate normal distribution. The observations on X are replaced by their ranks from 1 to n, the observations on Y are replaced by their ranks from 1 to n, and the ranks are placed in the original n pairs where the original data were. The usual correlation coefficient r is calculated on the ranks instead of the data, and the usual hypothesis test is conducted. In the case of independence of X and Y the distribution of Spearman's rho is asymptotically (for large n) the same as the distribution of Pearson's r. The exact distribution of Spearman's rho can be found, and is given in tables (see Conover 1999, for example), which is useful when n is small.

RT-1

There are several classifications of the transformation to ranks, as outlined by Conover and Iman (1981). The first type of rank transformation involves ranking all of the data together as one group, from smallest to largest, and then replacing the data in each of the original groups with their ranks. For example, in the case of two independent samples the observations in each sample are replaced with their ranks in the combined sample. Then for a test of equal means the two-sample t-test is computed on the ranks instead of the original data, and the test statistic is compared with the t-distribution in the usual way as an approximate test. With small sample sizes exact distributions of the test statistic can be obtained. This is equivalent to the *Mann-Whitney Test*, also known as the *two-sample Wilcoxon Test* (see ▶Wilcoxon–Mann–Whitney Test). An extension to the case of several independent samples is obvious, with the one-way ▶analysis of variance being computed on the ranks instead of the original data, and the F-tables being consulted for significance. This is equivalent to the *Kruskal-Wallis Test*. Details of these tests may be found in Conover (1999).

RT-2

A second type of rank transformation involves subsets of the data being ranked separately from other subsets, as in the correlation case mentioned earlier where the observations on X were ranked among themselves, and the observations on Y were ranked among themselves. The original data are replaced by their resulting ranks, and the statistic computed on the ranks. If independence is of interest, r is calculated, resulting in Spearman's rho, as mentioned earlier.

Another example of this second type of rank transformation is in the two-way layout, where the observations in each row are ranked among themselves only, and a two-way analysis of variance is computed on these ranks to see if there is a significant difference in the column means.

Thus we obtain a form of the *Friedman Test*. In the case of only two columns we obtain a form of the ►*Sign Test*.

RT-3

This brings us to a third type of rank transformation, where the ranks are determined after an appropriate re-expression of the data. Again consider pairs of data, n observations on a bivariate (X, Y) random variable. If the null hypothesis is equal means rather than independence, as was the case in the previous paragraph, the differences $X - Y$ are first computed, and then these differences are ranked on the basis of their absolute values $|X - Y|$ with the smallest absolute difference getting rank 1, and so on. Then the signs of the difference are applied to the ranks, and the one-sample t-test is computed on these signed ranks.

RT-4

The fourth type of rank transformation is an extension of the second type and third type combined. That is, subgroups of data are re-expressed, such as by subtracting a covariate or dividing by the consumer price index. Then each re-expressed subgroup is ranked by itself, and the standard parametric test is applied to the ranks. This could lead to an ►analysis of covariance by testing equality of means on the ranks of the re-expressed groups.

Another example of this fourth type of rank transformation is a nonparametric test for equal slopes presented by Hogg and Randles (1975). Several groups of paired data (X, Y) are first combined to find the least squares regression estimate $y = a+bx$. Then the residuals $(Y-y)$ from this model are ranked overall, and compared with the ranks of the $X's$ as described in their paper in a rank version of the parametric test for the same hypothesis.

Discussion

The rank transformation may result in a nonparametric test as indicated in the examples above, or the result may be a robust test such as when the first type of rank transform is applied to a two-way layout, or it may result in a test that is not even always robust such as applying the first type of rank transformation to a two-way layout with several observations per cell and trying to test for interaction.

About the Author

Dr. William Jay Conover received his Bachelor of Science in Mathematics from Iowa State University and his Master of Arts and Ph.D. in Mathematical Statistics from Catholic University of America. He is Paul Whitfield Horn Professor of Statistics, area of Information Systems and Quantitative Sciences, College of Business Administration, Texas Tech University. He was Elected Fellow of the American Statistical Association "for significant contributions to nonparametric statistics, for wide ranging and effective statistical consulting, and for excellence as a teacher and administrator" (1979). Among many his awards, Professor Conover was awarded the 1986 Don Owen Award and 1999 Wilks Medal. He has (co-)authored about 40 refereed papers and several books, including highly-regarded text *Practical Nonparametric Statistics* (3rd edition, John Wiley & Sons, 1999). His publications have been cited approximately 400 times each year for the last two decades, as reported by the Science Citation Index and the Social Sciences Citation Index. He is listed in in Who's Who in America (since 1987), and in Who's Who in the World, (since 1990–1991).

Ranked Set Sampling

Douglas A. Wolfe
Professor and Chair
The Ohio State University, Columbus, OH, USA

Introduction

In experimental settings where data are collected with the goal of making inferences about some aspects of an underlying population it is always important to design the study in such a way as to obtain as much useful information as possible while minimizing the overall cost of the experiment. This is particularly true when the initial step in collecting these data is to select the particular units from the finite or infinite population on which measurements

are to be taken. In this context, the goal of minimizing experimental cost is most often equivalent to minimizing the sample size while still achieving the desired accuracy of the inferences that follow.

The most commonly used approach for collecting data from a population is that of a simple random sample (SRS). If the population is infinite, the observations in a SRS are independent and identically distributed random variables. Even if the population is finite and sampling is done without replacement so that the sample observations are no longer independent, there is still a probabilistic guarantee that each measurement in the SRS can be considered as representative of the population. Despite this assurance, there is a distinct possibility that a specific SRS might not provide a truly representative picture of the complete population and larger sample sizes might be required to guard against such atypical samples.

Statisticians have, of course, developed a number of ways to guard against such unrepresentative samples without resorting to unduly large sample sizes. Sampling designs such as stratified sampling, probability sampling, and ►cluster sampling all provide additional structure on the sampling process that improves the likelihood that a collected sample provides a good representation of the population while trying to control the sampling costs involved in both the selection of the units to include in the sample and the cost of making the actual measurements on the selected units.

A novel sampling approach with this goal in mind was introduced by McIntyre (1952, reprinted in 2005) for situations where taking the actual measurements for sample units is difficult (e.g., costly, destructive, time-consuming, etc.), but there are inexpensive mechanisms readily available for either informally or formally ranking a set of sample units. Sample data collected via such a preliminary ranking scheme are known in the literature as ranked set sample (RSS) data.

Balanced Ranked Set Samples

To obtain a RSS of k observations from a population, we first select a SRS of k^2 units from the population and randomly divide them into k subsets of k units each. Within each of these subsets, the k units are rank ordered (least to greatest) by some informative mechanism (such as visual comparisons, expert opinion, or through the use of auxiliary variables) that does not involve actual measurements on the attribute of interest for the sample units. The unit that is judged to be the smallest in the first of these rank ordered subsets is then included in the RSS and the attribute of interest is formally measured for this unit. This measurement is denoted by $X_{[1]}$, where [1] is used instead of the usual round bracket (1) for the smallest order statistic because $X_{[1]}$ is only judgment ranked to be the smallest among the k units in the first subset; it may or may not actually have the smallest measurement among the k units.

The same ranking process is used to judgment rank the second subset of k units and the item ranked as the second smallest of the k units is selected and its attribute measurement, $X_{[2]}$, is obtained and added to the RSS. From the third subset of size k we select the unit judgment ranked to be the third smallest and add its attribute measurement, $X_{[3]}$, to the RSS. This process continues until we add the attribute measurement for the unit ranked to the largest of the k units in the final subset of size k, denoted by $X_{[k]}$, to the RSS.

The resulting collection of k measurements $X_{[1]}, \ldots, X_{[k]}$ is called a *balanced ranked set sample of size k*, where the term balanced refers to the fact that we have collected one judgment order statistics for each of the ranks $1, 2, \ldots, k$. This entire process is called a *cycle* and k is the *set size*. To obtain a balanced RSS with a desired total number of measured observations (i.e., total sample size) $n = kq$, we repeat the entire process for q independent cycles, yielding the balanced RSS of size n : $X_{[i]j}$, $i = 1, \ldots, k$; $j = 1, \ldots, q$.

To illustrate the advantages of RSS over SRS, we consider the problem of estimation of a population mean. Let $X_1, \ldots, X_n$ be a SRS of size n from a distribution with mean μ and finite variance σ^2. Let $X_{[1]}, \ldots, X_{[n]}$ be the judgment order statistics for a balanced RSS from this distribution based on a single cycle with set size n. Let

$$\overline{X} = \frac{1}{n}\sum_{i=1}^{n} X_i \qquad \text{and} \qquad \overline{X}^* = \frac{1}{n}\sum_{j=1}^{n} X_{[j]}$$

be the corresponding SRS and RSS sample means, respectively. It is well known that the SRS mean $\overline{X}$ is unbiased for μ and that $Var(\overline{X}) = \frac{\sigma^2}{n}$. Dell and Clutter (1972) and Takahasi and Wakimoto (1968) showed that the RSS sample mean $\overline{X}^*$ is also an unbiased estimator of μ, and this is true even when there are errors in the ranking mechanism used to obtain the RSS data. Moreover, they provided an explicit formula for the variance of $\overline{X}^*$, namely,

$$\begin{aligned} Var(\overline{X}^*) &= \frac{\sigma^2}{n} - \frac{1}{n^2}\sum_{j=1}^{n}\left(\mu^*_{[j]} - \mu\right)^2 \\ &= Var(\overline{X}) - \frac{1}{n^2}\sum_{j=1}^{n}\left(\mu^*_{[j]} - \mu\right)^2, \end{aligned} \tag{1}$$

where $\mu^*_{[j]} = E(X_{[j]})$, for $j = 1, \ldots, n$.

Since $\sum_{j=1}^{n}\left(\mu^*_{[j]} - \mu\right)^2 \geq 0$, it follows from Eq. (1) that the variance of the SRS mean $\overline{X}$ is always at least as large as the

variance of the RSS mean $\overline{X}^*$, regardless of the accuracy of the ranking process. Thus the RSS mean $\overline{X}^*$ is a more precise estimator of the population mean μ than the SRS mean $\overline{X}$ based on the same number of measured observations. The gain in precision is a monotonically increasing function of the quantity $\sum_{j=1}^{n}\left(\mu^*_{[j]}-\mu\right)^2$, which is itself an increasing function of the accuracy of the judgment rankings. The more reliable the judgment ranking process, the more separated will be the judgment order statistic expectations, $\mu^*_{[r]}, r = 1,\ldots,n$, and the more improvement we can expect from using RSS instead of SRS. The worst-case scenario where there is no gain from using RSS occurs when $\mu^*_{[1]} = \mu^*_{[2]} = \cdots = \mu^*_{[n]} = \mu$, which corresponds to no information in our ranking process and thus completely random rankings.

Unbalanced Ranked Set Samples

For most settings, balanced RSS is the natural and preferred approach. There are, however, settings where measuring different numbers of the various judgment order statistics (unbalanced RSS) can lead to improved RSS procedures. This is the case, for example, when we are estimating the location parameter θ for a unimodal, symmetric distribution. In that setting when the ranking process is reasonably accurate, the optimal RSS would be to measure the sample median from each of the k sets, resulting in an extremely unbalanced RSS, and then estimate θ by the average of these k set sample medians. Stokes (1995), Bhoj (1997), and Kaur et al. (1997) were the first to point out the optimality of unbalanced RSS under appropriate conditions.

Other Factors Affecting RSS

Properties of procedures based on RSS data are affected by a number of factors that are unique to this sampling approach. First, and probably foremost, is the accuracy of the ranking process. While the balanced RSS sample mean is always as efficient as the SRS sample mean based on the same number of measured observations, this gain in efficiency can be minimal if the ranking process is not reasonably accurate. Moreover, the SRS sample mean can even be more efficient than estimators based on unbalanced RSS data when the ranking process is not reliable. There have been a number of approaches in the literature to modeling this degree of imperfection in the rankings. Frey (2007) provides a general discussion of these approaches and presents a broad class of imperfect ranking models that can be used to assess the effect of imperfect ranking on RSS procedures. A second factor that affects the properties of RSS procedures is the set size. Generally speaking, the effectiveness of RSS procedures improves with increasing set size but this is counterbalanced by the fact that the ranking accuracy generally decreases with increased set size. Finally, the relative costs of sampling, ranking, and measuring units can be an important factor to consider in evaluating RSS versus SRS competitors.

Resources

The original paper by McIntyre (1952, 2005) is a good place to start with understanding the motivation behind the RSS sampling approach. Kaur et al. (1995) and Patil (1995) provide general reviews of the research and applications involving RSS data and Wolfe (2004) gives a general introduction to RSS methodology with a special emphasis on nonparametric procedures. Cheng et al. (2004) have the only monograph/textbook on the subject.

Ranking and Selection Procedures and Related Inference Problems

S. Panchapakesan
Professor Emeritus
Southern Illinois University, Carbondale, IL, USA

Introduction

A statistical ranking or selection procedure is typically called for when the experimenter (the decision-maker) is faced with the problem of comparing a certain number k of populations in order to make a decision about preferences among them.

Consider k populations, each characterized by the value of a parameter θ. In an agricultural experiment, for example, the different populations may represent different varieties of wheat and the parameter θ may be the average yield of a variety. The classical approach in this situation is to test the so-called homogeneity hypothesis H_0 that $\theta_1 = \cdots = \theta_k$, where the θ_i are the unknown values of the parameter for the k populations. In the case of the familiar one-way classification model, the populations are assumed to be normal with unknown means $\theta_1, \ldots, \theta_k$, and a common unknown variance σ^2. The homogeneity hypothesis H_0 is tested using Fisher's ▶analysis of variance (ANOVA) technique. However, this usually does not solve the real problem of the experimenter, which is not simply to accept or reject the homogeneity hypothesis. The real goal is often to choose the best population (the variety with the largest average yield). The inadequacy of the ANOVA is not in the design aspects of the procedure; it rather lies in the types of decisions that are made on the basis of the data. The attempts to formulate the decision problem in order to achieve this realistic goal of selecting the best treatment mark the beginnings of ranking and selection theory.

The formulation of a k-sample problem as a multiple decision problem enables one to answer the natural questions regarding the best populations. The formulation of multiple decision procedures in the framework of what has now come to be known as ranking and selection procedures began with the now-classic paper by Bechhofer (1954).

Basic Formulations of the Ranking and Selection Problem

We have k populations, $\Pi_1, \ldots, \Pi_k$, each indexed by a parameter θ, where the cumulative distribution function (cdf) of Π_i is $F(x;\theta_i)$ for $i = 1, 2, \ldots, k$. We assume that the family $\{F(x;\theta)\}$ is stochastically increasing in θ, i.e., $F(x;\theta_1) \geq F(x;\theta_2)$ for $\theta_1 \leq \theta_2$ for all x, and that the parameters can be ordered from the smallest to the largest. Denote the true ordered θ-values by $\theta_{[1]} \leq \theta_{[2]} \leq \ldots \leq \theta_{[k]}$. To fix ideas, we assume that larger the value of θ, more preferable is the population. Hence, the population associated with $\theta_{[k]}$ is called the *best* population. We assume that there is no prior information as to the correspondence between the ordered and the unordered θ_i. Ranking and selection problems have generally been formulated adopting one of two main approaches known as the *indifference-zone formulation* and the *subset selection formulation.*

In the indifference-zone formulation due to Bechhofer (1954), the goal is to select a fixed number of populations. Consider the basic goal of selecting the one best population. Based on samples of size n taken from each population, we seek a procedure to select one of the populations as the best. The natural procedure would be to compute estimates $\hat{\theta}_1, \hat{\theta}_2, \ldots, \hat{\theta}_k$ from each sample and claim that the population that yielded the largest $\hat{\theta}_i$ is the best population. Here, a correct selection occurs when the selected population is the best. We require a guaranteed minimum probability of a correct selection (PCS), denoted by P^*, whenever $\theta_{[k]}$ is sufficiently larger than $\theta_{[k-1]}$. Let $\delta = \delta(\theta_{[k]}, \theta_{[k-1]})$ denote a suitably defined measure of the separation between the populations associated with $\theta_{[k]}$ and $\theta_{[k-1]}$. Let $\Omega = \{\vec{\theta} = (\theta_1, \theta_2, \ldots, \theta_k)\}$. Define $\Omega(\delta^*) = \{\vec{\theta} \,|\delta(\theta_{[k]}, \theta_{[k-1]}) \geq \delta^* > 0\}$. For specified δ^* and $P^*(1/k < P^* < 1)$, it is required that

$$PCS \geq P^* \text{ whenever } \vec{\theta} \in \Omega(\delta^*). \tag{1}$$

To be meaningful, we choose $P^* > 1/k$; otherwise, the requirement (1) can be met by randomly choosing one of the populations as the best. The region $\Omega(\delta^*)$ of the parameter space Ω is called the *preference-zone* (PZ) as this is where we have strong preference for a correct selection.

The complement of the PZ is known as the *indifference-zone* (IZ), a region where we do not require a guaranteed PCS. The PCS in the PZ depends, in general, on the configuration of $\vec{\theta}$. In many cases, there is a *least favorable configuration* (LFC) of $\vec{\theta}$ for which the PCS attains a minimum over the PZ for any sample size. If we can make the PCS at the LFC equal to P^*, then the probability requirement (1) will be satisfied. The usual choices for $\delta = \delta(\theta_{[k]}, \theta_{[k-1]})$ are $\delta = \theta_{[k]} - \theta_{[k-1]}$ in the case of a location parameter and $\delta = \theta_{[k]}/\theta_{[k-1]}$ in the case of a scale parameter. In the case of nonnegative θ which is not a scale parameter, one may choose either of these two special forms depending on other aspects of the problem.

Bechhofer (1954) introduced the IZ formulation by considering k normal populations with means $\theta_1, \ldots, \theta_k$, and a common known variance σ^2. Here, $\delta = \theta_{[k]} - \theta_{[k-1]}$. Based on samples of size n from these normal populations, he proposed the natural selection procedure, say R_1, which selects the population that yielded the largest sample mean. The LFC for R_1 is $\theta_{[1]} = \cdots = \theta_{[k-1]} = \theta_{[k]} - \delta^*$. For a specified (δ^*, P^*), the minimum sample size needed to meet the probability requirement (1) is given by

$$n = \left\langle 2\left(\sigma H/\delta^*\right)^2 \right\rangle, \tag{2}$$

where $\langle b \rangle$ stands for the smallest integer greater than or equal to b, H satisfies

$$\Pr\{Z_1 \le H, \ldots, Z_{k-1} \le H\} = P^*, \tag{3}$$

and the Z_i are standard normal variables with equal correlation $\rho = 0.5$.

Some generalized goals that have been considered are: (I) Selecting the t best populations for $t \ge 2$, (a) in an ordered manner or (b) in an unordered manner, and (II) Selecting a fixed subset of size m that will contain at least s of the t best populations.

The first of these itself is a special case of the general ranking goal of Bechhofer (1954), which is to partition the set of k populations into s nonempty subsets $I_1, I_2, \ldots, I_s$ consisting of $k_1, k_2, \ldots, k_s$ $(k_1 + k_2 + \cdots + k_s = k)$ populations, respectively, such that for $\Pi_i \in I_\alpha$, $\Pi_j \in I_\beta$, $1 \le \alpha < \beta \le s$, we have $\theta_i < \theta_j$.

In the above general ranking problem, Fabian (1962) introduced the idea of Δ–correct ranking. Roughly speaking, a ranking decision is Δ–correct if wrongly classified populations are not too much apart. The special case of $s = 2$ and $k_1 = k - 1$ for a location parameter family is of interest. In this case, a Δ-correct ranking is equivalent to selecting one population Π_i for which $\theta_i > \theta_{[k]} - \Delta$, $\Delta > 0$; such a population is called a *good* population. The goal of selecting a good population has been considered by several subsequent authors.

In the normal means selection problem of Bechhofer (1954) mentioned previously, if the common variance σ^2 is unknown, a single-sample procedure does not exist. It can be seen from (2) that the minimum sample size n needed in order to satisfy the probability requirement (1) cannot be determined without the knowledge of the variance. In this case, a two-stage selection procedure is necessary to control the PCS. The first two-stage procedure for this problem was studied by Bechhofer et al. (1954). This procedure uses the first stage samples to obtain an estimate of σ^2.

In the subset selection formulation for selecting the best (i.e., the population associated with $\theta_{[k]}$), we seek a rule which will select a nonempty subset of random size that includes the best population. Here no assertion is made about which population in the selected subset is the best. The size S of the selected subset is determined by the sample data. In contrast with the IZ formulation, there is no specification of a PZ (or an IZ). The experimenter specifies P^*, the minimum PCS to be guaranteed no matter what the unknown values of the θ_i are. The selection rule is based on the estimates $\hat{\theta}_1, \hat{\theta}_2, \ldots, \hat{\theta}_k$. The expected size of the selected subset is a performance characteristic of a procedure.

In the case of normal means problem, assuming a common known variance σ^2, Gupta (1954, 1965) proposed a procedure based on a sample of size n from each population. This rule, say R_2, selects population Π_i if the sample mean $\overline{X}_i$ from it satisfies:

$$\overline{X}_i \ge \overline{X}_{[k]} - d\sigma/\sqrt{n}, \tag{4}$$

where d is a positive constant to be chosen so that the minimum PCS is guaranteed. The LFC in this case is given by $\theta_1 = \theta_2 = \cdots = \theta_k$. By equating the PCS at the LFC to P^*, we get $d = \sqrt{2H}$, where H is given by (3).

When σ^2 is unknown, Gupta (1954) proposed the rule R_3 which is R_2 with σ^2 replaced by the pooled sample variance s^2 based on $\nu = k(n-1)$ degrees of freedom and a different constant d', which turns out to be the one-sided upper $(1 - P^*)$ equicoordinate point of the equicorrelated $(k-1)$–variate central t distribution with equal correlation $\rho = 0.5$ and the associated degrees of freedom ν.

Seal (1955) proposed a class of procedures that included Gupta's maximum-type procedure and an alternative (average-type) procedure that Seal advocated using. The superiority of Gupta's procedure under certain slippage configurations and with regard to certain optimality properties and its comparative ease in handling theoretical details accelerated the growth of the subset selection literature.

Subset selection can be thought of as a screening procedure towards selecting one population as the best. The IZ approach has no requirements regarding correct selection when the true parametric configuration lies in the IZ, whereas the (random size) subset selection formulation does not control the size of the selected subset. A modified formulation, called the *restricted subset selection*, puts an upper bound for the (random) size of the selected subset (see Santner 1975). Using the restricted subset selection formulation for the goal of selecting a subset of the k populations whose size does not exceed $m(1 \le m \le k)$ so that the selected subset includes at least one of the $t(1 \le t \le k-1)$ best with a guaranteed probability, Panchapakesan (2005) has provided a fresh look at the salient features of the IZ and subset selection approaches.

Over the last almost six decades, several aspects of selection and ranking have been investigated. Substantial accomplishments have been made concerning procedures for specific univariate and multivariate parametric families, conditional procedures, nonparametric procedures, sequential and multistage procedures, procedures for restricted families such as the IFR (increasing failure rate) and IFRA (increasing failure rate on the average) distributions, decision-theoretic developments, and Bayes and empirical Bayes procedures. For detailed accounts of these, see Gupta and Panchapakesan (1979, 1985, 1996), Panchapakesan (2006) and the references contained therein.

Inference Problems Associated with Ranking and Selection

One related inference problem is the point and interval estimation of the ordered parameters, $\theta_{[1]}, \ldots, \theta_{[k]}$. Some attempts have been made to combine selecting the population associated with $\theta_{[k]}$ and estimating $\theta_{[k]}$ with simultaneous probability control; see, for example, Rizvi and Lal Saxena (1974). Another related inference problem is the estimation of the PCS for a selection procedure; see, for example, Gupta et al. (1990). Another interesting problem is known as *estimation after selection* in which the interest is to estimate the parameter of the selected population in the case of a procedure for selecting one population, or to estimate a known function such as the average of the parameters of the selected populations in the case of subset selection. Here the object of inference depends on the sample data that are to be used in the procedure. Such a statistical procedure has been called a *selective inference procedure*. This is different from a nonselective inference procedure in which the identity of the object of inference is fixed and is determined before the data were obtained. For references to several papers dealing with this, see Gupta and Panchapakesan (1996) and Panchapakesan (2006).

In a given situation, we may use a natural rule to select the best population and may want to simultaneously test if the selected population is uniquely the best. Such a problem was first considered by Gutmann and Maymin (1987). Recently, a few papers have appeared dealing with location and scale parameter cases and selecting the best multinomial cell using inverse sampling. For a discussion of these, see Cheng and Panchapakesan (2009) and the references given therein.

Concluding Remarks

Our aim here is to give a brief introduction to ranking and selection procedures. As such, we have given only a few important references. Gupta and Panchapakesan (1979) provide a comprehensive survey of the literature up to the date with a bibliography of some 600 main references. For references to later developments and other books on the subject see Gupta and Panchapakesan (1985, 1996) and Panchapakesan (2006).

About the Author

Subrahmanian Panchapakesan is Professor Emeritus of Mathematics at the Southern Illinois University at Carbondale. He has published close to 90 journal articles, book chapters and reports, mostly on ranking and selection. He is a member of the ASA, IMS, and the International Statistical Institute (elected). Professor Panchapakesan is a co-author (with Shanti S. Gupta) of the well known text *Multiple Decision Procedures: Theory and Methodology of Selecting and Ranking Populations* (John Wiley and Sons, 1979) and a co-editor (with N. Balakrishnan) of *Advances in Statistical Decision Theory and Applications* (Boston: Birkhäuser, 1997). He received the 2003 Thomas L. Saaty Prize for Applied Advances in the Mathematical and Management Sciences (awarded by the *American Journal of Mathematical and Management Sciences*). He is currently Associate Editor of *Communications in Statistics: Theory and Methods* and *Communications in Statistics: Simulation and Computation* (2002–), and an Editorial Board Member of *American Journal of Mathematical and Management Sciences* (1993–).

Ranks

Elisabeth Svensson
Professor Emerita
Swedish Business School at Örebro University, Örebro, Sweden

Uni-variate Ranking

A common approach in nonparametric statistical method is to transform data to ranks. A ranking of n ordered observations $\{x_1 < x_2 <, \ldots, < x_n\}$ will be a set of n ranks $\{r_1 <, \ldots, < r_n\}$ where x_i is represented by the rank r_i in calculations. The rank sum is $\frac{1}{2}n(n+1)$, and $\sum r^2 = \frac{n^3 - n}{12}$. Hence the mean rank is $\frac{1}{2}(n+1)$ and the variance $\frac{1}{12}(n^2-1)$ assuming uniform distribution of all possible rankings. For untied observations the rank r_i equals the number of observations less than x_{i+1}, $i = 1, \ldots, n$.

Assessments on scales with a limited number of categories will produce groups of observations that are tied to the same category, which means that these observations will share the same rank value. The midrank of an observation in the i^{th} category, $i = 1, \ldots, m$, is then

$$\bar{r}_i = \sum_{v=1}^{i-1} x_v + \tfrac{1}{2}(x_i + 1),$$

where x_v denotes the vth category frequency, $v = 1, \ldots, m$. Then $\sum r^2 < \frac{1}{12}(n^3 - n)$ and the variance is decreased, the correction term being

$$t^{(X)} = \sum_{v=1}^{m} \left(x_v^3 - x_v\right).$$

The mid-ranks of the marginal distribution X of the Fig. 1 are (2, 9, 23, 41).

The calculations of the Wilcoxon–Mann–Whitney test statistics (see ►Wilcoxon–Mann–Whitney Test) of difference between two independent groups of data and of the Spearman rank-order correlation coefficient are based on this type of rank transformations.

Augmented Ranking

In the evaluation of paired assessments made on rating scales regarding reliability of inter- or intra-rater agreement but also regarding change in outcome, the pairs of data can be transformed to ranks taking account of the information given by the pairs of data. In this *augmented ranking approach*, (aug-rank), by Svensson, the ranks are tied to the pairs of data (X, Y), i.e., to the observations in the cells of a square contingency table alternatively to

X / Y	C_1	C_2	C_3	C_4	Total
C_4			1 (31; 49)	1 (50; 50)	2
C_3		2 (13.5; 31.5)	2 (29.5; 33.5)	14 (42.5; 41.5)	18
C_2	1 (3; 15)	1 (12; 16)	11 (23; 22)	3 (34; 29)	16
C_1	2 (1.5; 1.5)	8 (7.5; 6.5)	3 (16; 12)	1 (32; 14)	14
Total	3	11	17	19	50

Ranks. Fig. 1 Example of a frequency distribution of paired assessments of a four-point rating scale, and the pairs of augmented ranks $\left(\bar{R}_{ij}^{(X)}; \bar{R}_{ij}^{(Y)}\right)$

X / Y	C_1	C_2	C_3	C_4	Total
C_4				2	2
C_3			1	17	18
C_2			16		16
C_1	3	11			14
Total	3	11	17	19	50

Ranks. Fig. 2 The rank-transformable pattern of agreement, RTPA, uniquely defined by the two sets of marginal distributions

the points of a scatter plot of data from visual analogue scale assessments. This means that the augmented rank of the assessments X depends on the pairing with Y.

The mean augmented rank according to the assessments X is

$$\overline{R}_{ij}^{(X)} = \sum_{k=1}^{i-1}\sum_{l=1}^{m} x_{kl} + \sum_{l=1}^{j-1} x_{il} + \frac{1}{2}(1 + x_{ij})$$

for $1 \le i,j \le m$, where x_{ij} is the *ijth* cell frequency, i and $j = 1,\ldots,m$ and m is the number of categories. The augmented mean rank of the observations in the *ijth* cell according to assessments Y, $\overline{R}_{ij}^{(Y)}$, is defined correspondingly, see Fig. 1. This aug-rank approach makes it possible to identify and separately analyse a possible systematic component of observed disagreement from the occasional, noise, variability, (see ►Measures of Agreement). A complete agreement in all pairs of aug-ranks, $\overline{R}_{ij}^{(X)} = \overline{R}_{ij}^{(Y)}$, for all i and $j = 1,\ldots,m$ defines *the rank-transformable pattern of agreement* (RTPA), which is uniquely related to the two marginal distributions, see Fig. 2.

Rao–Blackwell Theorem

Arthur Cohen
Professor
Rutgers University, Piscataway, NJ, USA

The Rao–Blackwell Theorem (RB Theorem) attributed to C.R. Rao and David Blackwell links the notions of sufficient statistics and unbiased estimation. Let $\mathbf{X}$, a random vector represent the data. Assume the distribution of $\mathbf{X}$ depends on a parameter $\boldsymbol{\theta}$. A statistic $S(\mathbf{X})$ is said to be sufficient if the conditional distribution of $\mathbf{X}$ given S does not depend on $\boldsymbol{\theta}$. A statistic $T(\mathbf{X})$ is said to be an unbiased estimator of $g(\boldsymbol{\theta})$, a function of $\boldsymbol{\theta}$, if $E_{\boldsymbol{\theta}}T(\mathbf{X}) = g(\boldsymbol{\theta})$ where E stands for expected value. The RB Theorem, which is constructive says the following:

Let $U(\mathbf{X})$ be any unbiased estimator of $g(\boldsymbol{\theta})$ and let σ_U^2 be the variance of U. Let

$$W(\mathbf{X}) = E[U(\mathbf{X})|S(\mathbf{X})].$$

That is, $W(\mathbf{X})$ is the conditional expected value of $U(\mathbf{X})$ given $S(\mathbf{X})$. Then $W(\mathbf{X})$ is unbiased and $\sigma_U^2 \ge \sigma_W^2$, where σ_W^2 is the variance of W.

Evaluating unbiased estimators by their variance clearly corresponds to evaluating estimators using a squared error loss function. A well known extension of the RB Theorem is achieved by replacing a squared error loss function with any convex loss function.

The utility of the theorem is highlighted in situations where it is easy to find a simple unbiased estimator of $g(\boldsymbol{\theta})$. Sometimes this can be done using only a subset of the data and then the construction typically yields an excellent unbiased estimator. We proceed with some applications and an extension of the theorem.

One issue in quality control is to estimate the proportion of items produced whose measurements do not

meet specifications i.e. fall outside a given interval (L, U). Assuming measurements are normal with mean μ and variance σ^2 the quantity to estimate is

$$p = 1 - \int_L^U \varphi(z; \mu, \sigma^2) dz,$$

where $\varphi(z; \mu, \sigma^2)$ is the normal density. Based on a sample of size n, labeled $x_1, \ldots, x_n$ sufficient statistics are $\bar{x} = \sum x_i/n$, $s^2 = \sum(x - \bar{x})^2/(n-1)$. A simple unbiased estimator of p is

$$\begin{aligned} \hat{p} &= 0 \quad \text{if } L \le x_1 \le U. \\ &= 1 \quad \text{otherwise} \end{aligned}$$

Lieberman and Resnikoff (1955) Rao–Blackwellize $\hat{p}$ by deriving $E(\hat{p}|\bar{x}, s^2)$ resulting in what turns out to be the minimum variance unbiased estimator of p.

Cohen and Sackrowitz (1974) consider a common mean model. That is, consider two independent random samples, $x_1, \ldots, x_m$ from $N(\mu, \sigma_x^2)$ and $y_1, \ldots, y_n$ from $N(\mu, \sigma_y^2)$. In the course of estimating the common mean μ it was desired to seek an unbiased estimator of $\gamma = \sigma_x^2/(\sigma_x^2 + \sigma_y^2)$. For both m and n greater than or equal to 5, the sample could be split up in such a way to quickly find an unbiased estimator of γ. Then the simple estimator could be Rao–Blackwellized. This type of application is also suitable to find a good unbiased estimator of a correlation coefficient or intraclass correlation coefficient as was done in Olkin and Pratt (1958).

Cohen et al. (1985) consider the problem of estimating a quantile of a symmetric distribution. The cases of known and unknown centers of symmetry are studied. Convex combinations of a pair of ►order statistics from the sample are intuitive simple estimators of a quantile that exceeds 0.5. That is, suppose $X_{(1)} \le \ldots \le X_{(n)}$ are the order statistics from a population whose center of symmetry is known to be θ_0. Then the ordered values of $Y_j = |X_j - \theta_0|$ are sufficient statistics. The Rao–Blackwellized version of the convex combination then is a superior estimator of the quantile in terms of mean squared error.

Given two independent samples from populations with distributions characterized by parameters θ_1 and θ_2 respectively, suppose population i, $i = 1$ *or* 2 is selected if $\bar{X}_i$ is the larger sample mean. Suppose we wish to estimate the mean of the selected population. Note such a mean is a random variable. An estimator of a selected mean is said to be unbiased if its expected value equals the expected value of the selected mean. By taking an additional single observation from the selected population, and Rao–Blackwellizing it, using all the data Cohen and Sackrowitz (1989) display an estimator of the selected mean that is minimum variance conditionally unbiased under some assumptions regarding the underlying distributions.

An extension of the RB Theorem and the construction aspect of it appears in Brown et al. (1976). The extension gives a construction based on a conditional expectation of a decision procedure given the sufficient statistic that leads to a better procedure for all bowl shaped loss functions simultaneously even those that are not convex. Furthermore the construction preserves the property of median unbiasedness of any estimator.

Rating Scales

Elisabeth Svensson
Professor Emerita
Swedish Business School at Örebro University, Örebro, Sweden

Rating scales have been used in psychology and psychophysics for over 100 years, and the use of rating scales and other kinds of ordered classifications is nowadays inter-disciplinary and unlimited. As there are no standardised rules for the operational definitions of qualitative variables, a considerable variety in types of rating scales for the same variable, in different applications, is common. A *rating scale* consists of a number of ordered categorical recordings of an item.

The verbal descriptive scale (VDS), also called the verbal rating scale, consists of a discrete number of verbally described ordered response categories, or description of criteria, grading the level of responses. The set of categories can also refer to a time scaling, also called a frequency-of-use scale, like "often, seldom, never," Fig. 1.

A *Likert scale* is a type of VDS, the descriptive categories being agreement levels to statements. Figure 2 shows two different operational definitions of perceived health, a VDS-5 scale and a Likert scale from the same ▶questionnaire, The Short-Form 36 (SF-36). The categories of the VDS represent five levels of perceived health, from excellent to poor. The Likert scale has one level of the variable, in this case "excellent health," and five levels of agreement with the statement of excellent health. The response categories except for a complete agreement with the statement (definitely true) contain no information about other levels of health. Hence the Likert scale assessments are just comparable with the binary responses: yes my health is excellent, no my health is not excellent.

A numerical rating scale (NRS) consists of a range of numerals indicating the ordered response levels without any description of the categories, except from the end points. Figure 3 shows a seven-point NRS of pain.

A visual analog scale (VAS) consists of a straight line anchored by the extremes of the variable being measured. The variable can be measured by a bipolar construct of the VAS, the anchors being opposing adjectives, or by a mono-polar scale, the anchors being "no sign at all" to "the most extreme alternative." A rating method that combines the verbal descriptor scale and the VAS, called the *graphic rating scale (GRS)* consists of a line with no breaks or divisions. There should be three to five discrete categories beneath the horizontal line, and the extreme categories should not be worded such that they are never employed, see Fig. 4.

A *pictogram* is a visual scale, the categories being faces or other pictures with different expressions illustrating the variable of interest.

VDS-6 intensity scale	VDS-4 grading of symptom	VDS-5 time scale
How much. . . ?	[ ] no evidence	**How often. . . ?**
[ ] Extremely high	[ ] slight signs	[ ] None of the time
[ ] Very high	[ ] moderate signs	[ ] A little of the time
[ ] Moderate	[ ] considerable signs	[ ] Some of the time
[ ] Slight		[ ] Most of the time
[ ] Very low		[ ] All of the time
[ ] non-existing		

Rating Scales. Fig. 1 Examples of verbal descriptive scale categories

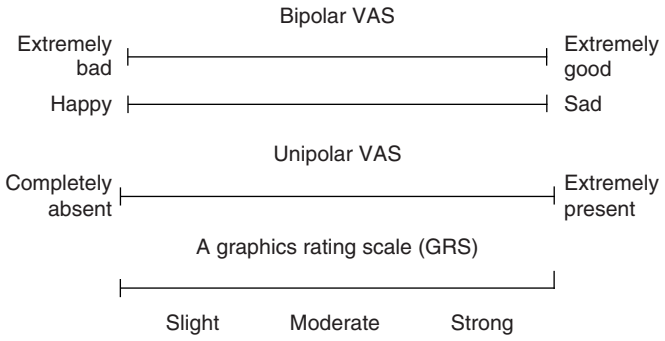
VDS-5 scale of health	Likert scale of excellent health
In general, would you say your health is	My health is excellent
[ ] Excellent	[ ] Definitely true
[ ] Very good	[ ] Mostly true
[ ] Good	[ ] Don't know
[ ] Fair	[ ] Mostly false
[ ] Poor	[ ] Definitely false

Rating Scales. Fig. 2 Examples of two different types of scales for assessment of health from the Short-Form-36 (SF-36), item 1 and item 11d, respectively

"How is your pain now?"

0	1	2	3	4	5	6
no pain at all						unbearable pain

Rating Scales. Fig. 3 Example of a numeric rating scale (NRS-7) of pain



Rating Scales. Fig. 4 Examples of Visual analogue scales (VAS) and a Graphic rating scale (GRS)

A *transitional scale*, the categories being *completely disappeared*, *much better*, *somewhat better, unchanged, somewhat worse, much worse* is useful when patient's perceived change after treatment is evaluated.

Assessments on rating scales, of any kind, produce ordinal data, the responses indicating only an ordering, although the use of numerical labelling could give a false impression of mathematical values. These so-called rank-invariant properties of ordinal data are well recognized, and several authors have stressed the fact that arithmetic operations are not appropriate for such data, therefore rank based statistical methods are recommended for analysis of data from rating scales.

Record Statistics

Mohammad Ahsanullah[1], Valery B. Nevzorov[2]
[1]Professor
Rider University, Lawrenceville, NJ, USA
[2]Professor
St. Petersburg State University, St. Petersburg, Russia

In 1952, Chandler defined the so-called record times and record values and gave groundwork for a mathematical theory of records. For six decades beginning his pioneering work, about 500 papers and some monographs devoted to different aspects of the theory of records appeared. This theory relies largely on the theory of ►order statistics and is especially closely connected to extreme order statistics. Records are very popular because they arise naturally in many fields of studies such as climatology, sports, medicine, traffic, industry and so on. Such records are memorials of their time. The annals of records reflect the progress in science and technology and enable us to study the evaluation of mankind on the basic of record achievements in various areas of its activity. A large number of record data saved for a long time inspirited the appearance of different mathematical models reflecting the corresponding record processes and forecasting the future record results.

Definitions of Records

Let $X_1, X_2, \ldots$ be a sequence of random variables and $X_{1,n} \le X_{2,n} \le \ldots \le X_{n,n}$, $n = 1, 2, \ldots$, be the corresponding

order statistics. For any $n = 1, 2, \ldots$ denote also $M(n) = X_{n,n} = \max\{X_1, X_2, \ldots, X_n\}$ and $m(n) = X_{1,n} = \min\{X_1, X_2, \ldots, X_n\}$. Now one can define the classical upper record times $L(n)$ and upper record values $X(n)$ as follows:

$$L(1) = 1,\ X(1) = X_1 \text{ and then}$$

$$L(n+1) = \min\{j : X_j > X(n)\}, \quad X(n+1) = X_{L(n+1)},$$

$$n = 1, 2, \ldots \tag{1}$$

One can use the following alternative definitions:

$$L(1) = 1, \quad L(n+1) = \min\{j : X_j > M(L(n))\}, \ldots$$
$$n = 1, 2, \ldots, \tag{2}$$

and

$$X(n) = M(L(n)), \quad n = 1, 2, \ldots$$

If we replace the sign $>$ and $M(L(n))$ in (2) by $<$ and $m(L(n))$, respectively, we obtain the definitions of the lower record times and the lower record values. Indeed, the theories of upper and lower records coincide practically in all their details, since the lower records for the sequence $X_1, X_2, \ldots$ correspond to the upper records for the sequence $-X_1, -X_2, \ldots$ Using the sign $\geq$ in (1) instead of $>$ we introduce the so-called weak upper records, when any repetition of the previous record value is also considered as a new record. Analogically, the sign $\leq$ in (1) gives the opportunity to define the weak lower record times and the weak lower record values. Note that the theory of weak records has practical meaning only for sequences of the initial X's, which have discrete distributions.

The so-called kth records are a natural extension of records. The kth record times $L(n,k)$ and the kth record values $X(n,k)$ for any $k = 1, 2, \ldots$ are defined as follows:

$$L(1,k) = k, \quad L(n+1,k) = \min\{j > L(n,k) : X_j$$
$$> X_{j-k,j-1}\},\ n = 1, 2, \ldots, \tag{3}$$

and

$$X(n,k) = X_{L(n,k)-k+1,L(n,k)}, \quad n = 1, 2, \ldots \tag{4}$$

To be precise, (3) and (4) define the kth upper record times and the kth upper record values respectively. One can also introduce the kth lower record times and the kth lower record values changing the event $X_j > X_{j-k,j-1}$ in (3) by $X_j < X_{k,j-1}$ and replacing $X_{L(n,k)-k+1,L(n,k)}$ in (4) by $X_{k,L(n)}$. If $k = 1$ then definitions of kth record values $X(n,k)$ and kth record times $L(n,k)$ coincide with the definitions of $X(n)$ and $L(n)$ given in (1).

We will use $N(n)$ to denote the number of records among random variables $X_1, X_2, \ldots, X_n$, $n = 1, 2, \ldots$, and $N(n,k)$ will denote the number of kth records in a sequence $X_1, X_2, \ldots, X_n$ respectively.

Sequential Ranks and Record Indicators

The essential role in the theory of records play the sequential ranks $R(n)$, the record indicators ξ_j, $j = 1, 2, \ldots$, and the indicators of the *kth* records $\xi_j(k)$, $j = 1, 2, \ldots$, $k = 1, 2, \ldots$. The sequential rank $R(n)$ denotes the rank of X_n among $X_1, X_2, \ldots, X_n$, i.e.,

$$X_n = X_{R(n),n},\ n = 1, 2, \ldots$$

The record indicator ξ_j is defined as follows: $\xi_j = 1$ if X_j is a record value and $\xi_j = 0$ otherwise. Analogically, the indicator $\xi_j(k)$ can be defined for any $k = 1, 2, \ldots$ and $j \geq k$:

$\xi_j(k) = 1$, if X_j is the kth record value and $\xi_j(k) = 0$ otherwise. There are some useful relations between record indicators and sequential ranks. We will formulate some simple equalities for indicators of the upper records. Indeed, analogical results are also valid for the lower records. Note, that

$$\{\xi_j = 1\} = \{R(j) = j\} = \{X_j = M(j)\} = \{X_j = X_{j,j}\}$$
$$= \{X_j \text{ is a record value}\}$$

and for any $k = 1, 2, \ldots$ and $j \geq k$

$$\{\xi_j(k) = 1\} = \{R(j) \geq j - k + 1\} = \{X_{j-k+1,j} \geq X_{j-k,j-1}\}$$
$$= \{X_j > X_{j-k,j-1}\} = \{X_j \text{ is a } kth \text{ record}\}.$$

The record indicators allow us to give convenient relations for the numbers of records $N(n)$ and $N(n,k)$:

$$\{N(n) = m\} = \{\xi_1 + \ldots + \xi_n = m\},$$
$$n = 1, 2, \ldots,\ m = 1, 2, \ldots, n; \tag{5}$$
$$\{N(n,k) = m\} = \{\xi_k(k) + \ldots + \xi_n(k) = m\},$$
$$n = k, k+1, \ldots,\ m = 1, 2, \ldots, n-k+1. \tag{6}$$

The classical theory of records is connected with the situation when the initial sequence of random variables $X_1, X_2, \ldots$ is a sequence of independent random variables with a common continuous distribution function. In this case, sequential ranks and record indicators have a number of useful and rather convenient properties.

Theorem 1 For independent identically distributed random variables $X_1, X_2, \ldots$ with a continuous distribution function F the sequential ranks $R(1), R(2), \ldots$ are independent and $P\{R(n) = m\} = 1/n$, $m = 1, 2, \ldots, n$, $n = 1, 2, \ldots$

Theorem 2 Under conditions of Theorem 1, for any fixed $k = 1, 2, \ldots$, indicators $\xi_k(k), \xi_{k+1}(k), \ldots$ are independent and $P\{\xi_j(k) = 1\} = k/j$, $j = k, k+1, \ldots$

As a partial case of Theorem 2 it follows that under conditions of Theorem 1 record indicators $\xi_1, \xi_2, \ldots$ are independent and $P\{\xi_j = 1\} = 1 - P\{\xi_j = 0\} = 1/j$, $j = 1, 2, \ldots$

These results together with equalities (5) and (6) allow us to find that the distributions of $N(n)$ and $N(n,k)$ are expressed as distributions of sums of independent random variables. One can also see that under conditions of Theorem 1, there are some convenient relations for the *kth* record times $L(n,k)$ and, in particular, for the record times $L(n)$:

$$P\{L(n,k) > m\} = P\{N(m,k) < n\} = P\{\xi_k(k) + \xi_{k+1}(k) + \ldots + \xi_m(k) < n\} \quad (7)$$

and

$$P\{L(n) > m\} = P\{N(m) < n\} = P\{\xi_1 + \xi_2 + \ldots + \xi_m < n\}. \quad (8)$$

It follows from relations (7) and (8) that if $X_1, X_2, \ldots$ is a sequence of independent identically distributed random variables with any continuous distribution function F, then distributions of record times and numbers of records do not depend on F.

One more important situation in the classical record theory is connected with sequences of independent identically distributed random variables having a discrete distribution. Without loss of generality, we can suppose that X's take nonnegative integer values. For discrete distributions we introduce another type of record indicators. Let $\eta_n = 1$ if n is a record value in the sequence $X_1, X_2, \ldots$, that is there exists such $m = 1, 2, \ldots$ that $X(m) = n$, and $\eta_n = 0$ otherwise (compare with indicators ξ_n!). Analogously, for any $k = 1, 2, \ldots$ we can introduce indicators $\eta_n(k)$ for kth record values : $\eta_n(k) = 1$, if n is a kth record value in the sequence $X_1, X_2, \ldots$, and $\eta_n(k) = 0$ otherwise. The following results are valid for such type of indicators.

Theorem 3 Let $X, X_1, X_2, \ldots$ be a sequence of independent identically distributed random variables taking values $0, 1, 2, \ldots$ with probabilities $p_n = P\{X = n\} > 0$, $n = 0, 1, 2, \ldots$ Then for any fixed $k = 1, 2, \ldots$ indicators $\eta_n(k)$, $n = 0, 1, 2, \ldots$, are independent and

$$P\{\eta_n(k) = 1\} = 1 - P\{\eta_n(k) = 0\} = (p_n / P\{X \geq n\})^k, \quad n = 0, 1, 2, \ldots$$

Indeed, under $k = 1$, as a partial case of this theorem, one gets that record indicators $\eta_0, \eta_1, \eta_2, \ldots$ are independent and $P\{\eta_n = 1\} = 1 - P\{\eta_n = 0\} = p_n / P\{X \geq n\}$, $n = 0, 1, 2, \ldots$

It is easy to see that under conditions of Theorem 3, we can express distributions of *kth* record values for discrete random variables via distributions of sums of independent indicators:

$$P\{X(n,k) > m\} = P\{\eta_0(k) + \ldots + \eta_m(k) < n\}, \quad m = 0, 1, 2, \ldots, \ n = 1, 2, \ldots, \quad (9)$$

and, in particular, under $k = 1$ one has equality

$$P\{X(n) > m\} = P\{\eta_0 + \ldots + \eta_m < n\}, \ m = 0, 1, 2, \ldots, \ n = 1, 2, \ldots \quad (10)$$

As an example, we can consider the case, when X's have the geometric distribution with some parameter $0 < p < 1$, that is $P\{X_j = n\} = (1-p)p^n$, $n = 0, 1, 2, \ldots$, for $j = 1, 2, \ldots$. In this situation, $P\{\eta_n(k) = 1\} = (1-p)^k$ and $P\{\eta_n(k) = 0\} = 1 - (1-p)^k$, for any $n = 0, 1, 2, \ldots$. It means that the sum $\eta_0(k) + \ldots + \eta_m(k)$ has the binomial $B(m+1, q)$ distribution with a parameter $q = (1-p)^k$. Hence,

$$P\{X(n,k) > m\} = \sum_{j=0}^{n-1} ((m+1)!/j! \ (m+1-j)!) q^j (1-q)^{m+1-j}, \quad \text{if } 1 \leq n \leq m+1,$$

and

$$P\{X(n,k) > m\} = 1, \text{ if } n > m+1.$$

It was mentioned above that for discrete distributions it is useful to introduce weak records together with classical (strong) record values. Weak records may arise, for example, in some sports competitions where any athlete who repeats the record achievement is also declared as a record-holder. If we consider X's having a common discrete distribution, it is useful to introduce one more type of record statistics. Let conditions of Theorem 3 be valid. We define random variables $\mu_0, \mu_1, \mu_2, \ldots$, where μ_n denotes the number of those weak records in the sequence $X_1, X_2, \ldots$ that are equal to n. The following result is valid.

Theorem 4 Let $X, X_1, X_2, \ldots$ be a sequence of independent identically distributed random variables taking values $0, 1, 2, \ldots$ with probabilities $p_n = P\{X = n\} > 0$, $n = 0, 1, 2, \ldots$ Then for any fixed $k = 1, 2, \ldots$, random variables $\mu_0, \mu_1, \mu_2, \ldots$ are independent and

$$P\{\mu_n = m\} = (1 - r(n))(r(n))^m, \ n = 0, 1, 2, \ldots; \ m = 0, 1, 2, \ldots,$$

where

$$r(n) = p_n / P\{X \geq n\}.$$

Let $X_\omega(1), X_\omega(2), \ldots$ denote the weak (upper) record values in the sequence $X_1, X_2, \ldots$ Then for any $n = 1, 2, \ldots$

and $m = 0, 1, 2, \ldots$ the following relation is valid:

$$P\{X_\omega(n) > m\} = P\{\mu_0 + \mu_1 + \ldots + \mu_m < n\}. \quad (11)$$

Thus, we see that there are some convenient representations of record values, record times, numbers of records ((5–11) among them), which allow us to impress these record statistics in terms of sums of independent random variables.

Distributions of Record Times

Let us consider the classical case, when $X_1, X_2, \ldots$ are independent and have a continuous distribution function F. Using the independence of the corresponding record indicators $\xi_1, \xi_2, \ldots$ one gets for any $n = 1, 2, \ldots$ and $1 < j(1) < j(2) < \ldots < j(n)$ that

$$\begin{aligned} &P\{L(1) = 1, L(2) = j(2), \ldots, L(n) = j(n)\} = \\ &\quad P\{\xi_1 = 1, \xi_2 = 0, \ldots, \xi_{j(2)-1} = 0, \xi_{j(2)} = 1, \\ &\quad \xi_{j(2)+1} = 0, \ldots, \xi_{j(3)-1} = 0, \\ &\xi_{j(3)} = 1, \ldots, \xi_{j(n)-1} = 0, \xi_{j(n)} = 1\} = \\ &\quad P\{\xi_1 = 1\}P\{\xi_2 = 0\} \ldots P\{\xi_{j(2)-1} = 0\} \\ &\quad P\{\xi_{j(2)} = 1\}P\{\xi_{j(2)+1} = 0\} \ldots \\ &\quad P\{\xi_{j(3)-1} = 0\}P\{\xi_{j(3)} = 1\} \ldots \\ &\quad P\{\xi_{j(n)-1} = 0\}P\{\xi_{j(n)} = 1\} = \\ &\quad 1/(j(2) - 1)(j(3) - 1) \ldots (j(n) - 1)j(n). \end{aligned} \quad (12)$$

Note that here the joint distribution of record times does not depend on F. Now one can see from (12) that

$$\begin{aligned} P\{L(n) = m\} = \sum 1/(j(2) - 1)(j(3) - 1) \\ \ldots (j(n-1) - 1)(m - 1)m, \end{aligned}$$

where the sum is taken over all $j(2), j(3), \ldots, j(n-1)$, such that $1 < j(2) < j(3) < \ldots < j(n-1) < m$.

It follows from (12) also that

$$\begin{aligned} P\{L(n) = j(n)|L(n-1) = j(n-1), L(n-2) \\ = j(n-2), \ldots, L(2) = j(2), L(1) = 1\} \\ = j(n-1)/j(n)(j(n) - 1) \end{aligned}$$

and

$$P\{L(n) = j|L(n-1) = i\} = i/j(j-1), \quad n = 2, 3, \ldots, j > i.$$

Hence, we see that the sequence of record times $L(1), L(2), \ldots$ in the announced situation forms a Markov chain (see ▶Markov Chains).

It was mentioned above that record times are closely related to the random variables $N(n)$, since for any $n = 1, 2, \ldots$ and $m = 1, 2, \ldots$ the following equalities are valid:

$$P\{L(n) > m\} = P\{N(m) < n\}$$

and

$$P\{L(n) = m\} = P(N(m-1) = n-1,\ N(m) = n\}. \quad (13)$$

Equalities (5) and (13) allow us to express the distributions of $L(n)$ in terms of independent record indicators:

$$\begin{aligned} P\{L(n) = m\} &= P\{N(m-1) = n-1, \xi_m = 1\} \\ &= P\{N(m-1) = n-1\}/m \\ &= P\{\xi_1 + \xi_2 + \ldots \xi_m - 1 \\ &= n-1\}/m. \end{aligned} \quad (14)$$

Representations (5) and (14) of $N(m)$ and $L(n)$ give a possibility to find the distributions of these record statistics via the Stirling numbers of the first kind $S_n(k)$, which are defined by equalities

$$x(x-1)\ldots(x-n+1) = \sum_{k\geq 0} S_n(k)x^k.$$

It appears that

$$P\{N(m) = k\} = (-1)^k S_m(k)/m! = |S_m(k)|/m!,$$

$$k = 1, 2, \ldots, m,$$

and

$$P\{L(n) = m\} = |S_{m-1}(n-1)|/m!,\ m = n,\ n+1, \ldots$$

Representations (5) and (14) give the following formulas for the corresponding generating functions:

$$P_m(s) = Es^{N(m)} = s(1+s)(2+s)\ldots(m-1+s)/m!$$

and

$$\begin{aligned} Q_n(s) = Es^{L(n)} &= 1 - (1-s)\sum_{k=0}^{n-1}(-\log(1-s))^k/k! \\ &= \int_0^{-\log(1-s)} v^{n-1}\exp(-v)dv/(n-1)! \end{aligned} \quad (15)$$

Distributions of Record Values

Let us again consider the case when $X_1, X_2, \ldots$ are independent and have a continuous distribution function F. The record value $X(n)$ can be presented as $X_{L(n)}$, where $L(n)$ is

the corresponding record time with a generating function (15). One can see that then

$$P\{X(n) < x\} = P\{X_{L(n)} < x\} = P\{M(L(n)) < x\}, \quad (16)$$

where $M(n) = \max\{X_1, X_2, \ldots, X_n\}$ and $P\{M(n) < x\} = F^n(x)$. It follows from (15) and (16) that

$$\begin{aligned} P\{X(n) < x\} &= P\{M(L(n)) < x\} \\ &= \sum_{m \geq 0} P\{M(m) < x\} P\{L(n) = m\} \\ &= \sum_{m \geq 0} F^m(x) P\{L(n) = m\} = Q_n(F(x)) \\ &= \int_0^{-\log(1-F(x))} v^{n-1} \exp(-v) dv/(n-1)! \end{aligned}$$

The following result is valid for distributions of record values.

Theorem 5 Let $X(1) < X(2) < \ldots$ be the record values in a sequence of independent random variables having a common continuous distribution function F, and let $U(1) < U(2) < \ldots$ be the record values related to the uniform distribution on the interval $[0,1]$. Then for any $n = 1, 2, \ldots$ the random vector $(F(X(1)), \ldots, F(X(n)))$ has the same distribution as $(U(1), \ldots, U(n))$.

Corollary 1 Let $X(1) < X(2) < \ldots$ and $Y(1) < Y(2) < \ldots$ be, respectively, the record values in a sequence of independent random variables $X_1, X_2, \ldots$ having a common continuous distribution function F_1 and in a sequence of independent identically distributed random variables $Y_1, Y_2, \ldots$ with a continuous distribution function F_2. Then for any $n = 1, 2, \ldots$ the vector $(Y(1), Y(2), \ldots, Y(n))$ has the same distribution as the vector $(H_2(X(1)), H_2(X(2)), \ldots, H_2(X(n)))$, where $H_2(x) = G_2(F_1(x))$ and G_2 is the inverse function to F_2. Analogously, the vectors $(X(1), X(2), \ldots, X(n))$ and $(H_1(Y(1)), H_1(Y(2)), \ldots, H_1(Y(n)))$, where $H_1(x) = G_1(F_2(x))$ and G_1 is the inverse function to F_1, are identically distributed.

Let us consider the partial case of record values $Z(1) < Z(2) < \ldots$ related to the standard exponential $E(1)$ distribution (the case, when $F(x) = 1 - \exp(-x)$, $x > 0$). We get

$$P\{Z(n) < x\} = \int_0^x v^{n-1} \exp(-v) dv/(n-1)!,$$

that is, in this situation $Z(n)$ has the gamma-distribution with parameter n. It means that $Z(n)$ has the same distribution as the sum $v_1 + v_2 + \ldots + v_n$ of independent $E(1)$-distributed random variables $v_1, v_2, \ldots$ Moreover, for any $n = 1, 2, \ldots$ the vector $(Z(1), Z(2), \ldots, Z(n))$ has the same distribution as the vector $(v_1, v_1 + v_2, \ldots, v_1 + v_2 + \ldots + v_n)$. It means that the vector $(Z(1), Z(2) - Z(1), \ldots, Z(n) - Z(n-1))$ consists of independent elements and each of these elements has the standard exponential $E(1)$ distribution.

Combining the previous results, we can get the following representation for record values $X(1) < X(2) < \ldots$ related to any continuous distribution function F. Let G below denote the inverse function to F.

Representation 1 For any $n = 1, 2, \ldots$

$$(X(1), X(2), \ldots, X(n)) \stackrel{d}{=} (H(v_1), H(v_1 + v_2), \ldots, H(v_1 + v_2 + \ldots + v_n)),$$

where $v_1, v_2, \ldots$ are independent random variables having the exponential $E(1)$ distribution and $H(x) = G(1 - \exp(-x))$.

Taking into account the property of the exponential records it is not difficult to obtain the joint density function $f_n(x_1, x_2, \ldots, x_n)$ of the record values $Z(1), Z(2), \ldots, Z(n)$. It appears that

$$f_n(x_1, x_2, \ldots, x_n) = \exp(-x_n), \quad \text{if } 0 < x_1 < x_2 < \ldots < x_n, \text{ and } f_n(x_1, x_2, \ldots, x_n) = 0, \quad \textit{otherwise}.$$

In the general case, when $X_1, X_2, \ldots$ have a distribution function F and a density function f, the joint density function of the record values $X(1), X(2), \ldots, X(n)$ is given by the formula

$$f_n(x_1, x_2, \ldots, x_n) = r(x_1) r(x_2) \ldots r(x_n) (1 - F(x_n)), \quad x_1 < x_2 < \ldots < x_n,$$

where $r(x) = f(x)/(1 - F(x))$.

Now we consider the conditional distributions

$$\varphi(x | x_1, x_2, \ldots, x_n) = P\{X(n+1) > x | X(1) = x_1, X(2) = x_2, \ldots, X(n) = x_n\}, \; x_1 < x_2 < \ldots < x_n < x,$$

for record values $X(1) < X(2) < \ldots < X(n) < X(n+1)$. It appears that

$$\begin{aligned} \varphi(x | x_1, x_2, \ldots, x_n) &= P\{X(n+1) > x | X(n) = x_n\} \\ &= (1 - F(x))/(1 - F(x_n)), x > x_n. \end{aligned} \quad (17)$$

It is interesting that equality (17) does not need the continuity of the distribution function F. It follows from (17) that record values $X(1), X(2), \ldots$ form a Markov chain.

If we now consider discrete X's taking values $0, 1, 2, \ldots$ then (17) can be rewritten in the form

$$P\{X(n+1) > j | X(n) = m\} = P\{X > j\}/P\{X \geq m+1\}, \quad j > m \geq n-1.$$

It follows from the latter equality that in this case

$$P\{X(1) = j_1, X(2) = j_2, \ldots, X(n) = j_n\} = P\{X = j_n\}\omega(j_1)\omega(j_2)\ldots\omega(j_{n-1}), \quad 0 \le j_1 < j_2 < \ldots < j_{n-1} < j_n,$$

where $\omega(j) = P\{X = j\}/P\{X > j\}$.

The simplest discrete case is presented by the geometric distribution. The following result is valid.

Theorem 6 Let $X, X_1, X_2, \ldots$ be independent identically distributed random variables such that

$$P\{X = j\} = (1-p)p^{j-1},\ j = 1, 2, \ldots;\ 0 < p < 1,$$

and $X(1) < X(2) < \ldots$ be the record values in a sequence $X_1, X_2, \ldots$ Then the interrecord values $X(1), X(2) - X(1), X(3) - X(2), \ldots$ are independent and have the same geometric distribution as X.

Distributions of *k*th Record Values

The kth record values $X(n,k)$ are a natural extension of records $X(n)$. It is interesting that distributions of the *kth* records can be expressed via distributions of the classical record values. Really, together with a sequence of independent random variables $X_1, X_2, \ldots$ having a common distribution function F, let us consider one more sequence

$$Y_1 = \min\{X_1, X_2, \ldots, X_k\},$$
$$Y_2 = \min\{X_{k+1}, X_{k+2}, \ldots, X_{2k}\}, \ldots$$

Now let $X(n,k)$ be the kth record value based on X's and $Y(n)$ be the classical records based on the sequence $Y_1, Y_2, \ldots$ It appears that for any fixed $k = 2, 3, \ldots$ and any $n = 1, 2, \ldots$ the vector $(X(1,k), X(2,k), \ldots, X(n,k))$ has the same distribution as the vector $(Y(1), Y(2), \ldots, Y(n))$.

Note that this result is valid for discrete X's as well. One can immediately obtain some important results for the *kth* records taking into account the analogous results for the classical record values. For example, if $Z(n,k)$, $n = 1, 2, \ldots$, denote the *kth* records for the standard exponential distribution, then the vector $(Z(1,k), Z(2,k), \ldots, Z(n,k))$ has the same distribution as the vector $(v_1/k, (v_1 + v_2)/k, \ldots, (v_1 + v_2 + \ldots + v_n)/k)$, where $v_1, v_2, \ldots$ are the independent exponentially $E(1)$ distributed random variables. Hence, the following relation is valid for kth records related to a sequence of $X_1, X_2, \ldots$ with a continuous distribution function F.

Representation 2 For any $n = 1, 2, \ldots$

$$(X(1,k), X(2,k), \ldots, X(n,k)) \stackrel{d}{=} (H(v_1/k), H((v_1 + v_2)/k), \ldots, H((v_1 + v_2 + \ldots + v_n)/k),$$

where $v_1, v_2, \ldots$ are independent random variables having the exponential $E(1)$ distribution, $H(x) = G(1 - \exp(-x))$ and G is the inverse function to F.

Some useful results for the kth records follow immediately from representation 2 and analogous results for the classical records. Say, one gets that

$$P\{X(n,k) < x\} = \int_0^{-k\log(1-F(x))} v^{n-1}\exp(-v)dv/(n-1)!$$

and this equality is valid for any $k = 1, 2, \ldots$ and any continuous distribution function F.

Theorem 7 For any $k = 1, 2, \ldots$ the sequence $X(1,k)$, $X(2,k), \ldots$ forms a Markov chain and

$$P\{X(n+1,k) > x | X(n,k) = u\} = ((1 - F(x))/(1 - F(u)))^k, x > u.$$

More complete theory of records is given in monographs (Ahsanullah 1988, 1995, 2004; Ahsanullah and Nevzorov 2001; Arnold et al. 1998; Nevzorov 2000). Different results for record values can be found in references (Adke 1993; Ahsanullah 1978, 1979, 1981, 1987, 1988, 1995, 2004; Ahsanullah and Nevzorov 2001, 2004, 2005; Akhundov and Nevzorov 2008; Akhundov et al. 2007; Andel 1990; Arnold et al. 1998; Bairamov 2000; Balakrishnan and Nevzorov 2006; Ballerini and Resnick 1985, 1987; Berred et al. 2005; Biondini and Siddiqui 1975; Chandler 1952; Deheuvels 1984; Deheuvels and Nevzorov 1994; Dziubdziela and Kopocinsky 1976; Foster and Stuart 1954; Gulati and Padgett 2003; Gupta 1984; Haiman 1987; Houchens 1984; Nagaraja 1978, 1982; Nevzorov 1984, 1987, 1990, 1992, 1995, 2000; Nevzorov and Balakrishnan 1998; Nevzorov et al. 2003; Nevzorova et al. 1997; Pfeifer 1982, 1984, 1991; Renyi A 1962; Resnick 1973; Shorrock 1972a, b; Siddiqui and Biondini 1975; Smith 1988; Smith and Miller 1986; Stepanov 1992; Tata 1969; Vervaat 1973; Williams 1973; Yang 1975).

Recursive Partitioning

Hugh A. Chipman
Canada Research Chair in Mathematical Modelling, Professor
Acadia University, Wolfville, NS, Canada

Introduction

Recursive partition (RP) models are a flexible method for specifying the conditional distribution of a variable y, given a vector of predictor values x. Such models use a tree structure to recursively partition the predictor space into subsets where the distribution of y is successively more homogeneous. The terminal nodes of the tree correspond to the distinct regions of the partition, and the partition is determined by splitting rules associated with each of the internal nodes. By moving from the root node through to the terminal node of the tree, each observation is then assigned to a unique terminal node where the conditional distribution of y is determined. The two most common response types are continuous and categorical, with corresponding tasks often known as regression and classification.

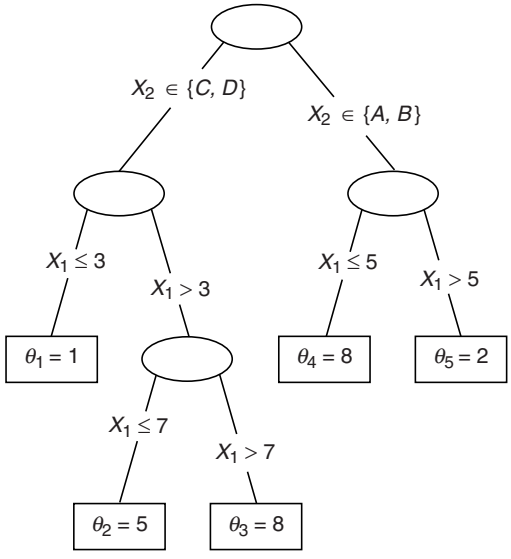
Given a data set, a common strategy for finding a good tree is to use a greedy algorithm to grow a tree and then to prune it back to avoid overfitting. Such greedy algorithms typically grow a tree by sequentially choosing splitting rules for nodes on the basis of maximizing some fitting criterion. This generates a sequence of trees each of which is an extension of the previous tree. A single tree is then selected by pruning the largest tree according to a model choice criterion such as cost-complexity pruning, cross-validation, or hypothesis tests of whether two adjoining nodes should be collapsed into a single node.

Early work in RP models includes Morgan and Sonquist (1963), who developed a recursive partitioning strategy (AID – Automatic Interaction Detection) for a continuous response. There were many offshoots of this work, including Kass (1980) and Hawkins and Kass (1982). Recursive partitioning models were popularized in the statistical community by the book "Classification and Regression Trees" by Breiman et al. (1984). RP models have also been developed in the machine learning community, with work by Quinlan on the ID3 (1986 and references therein) and C4.5 (1993) algorithms being among the most widely recognized.

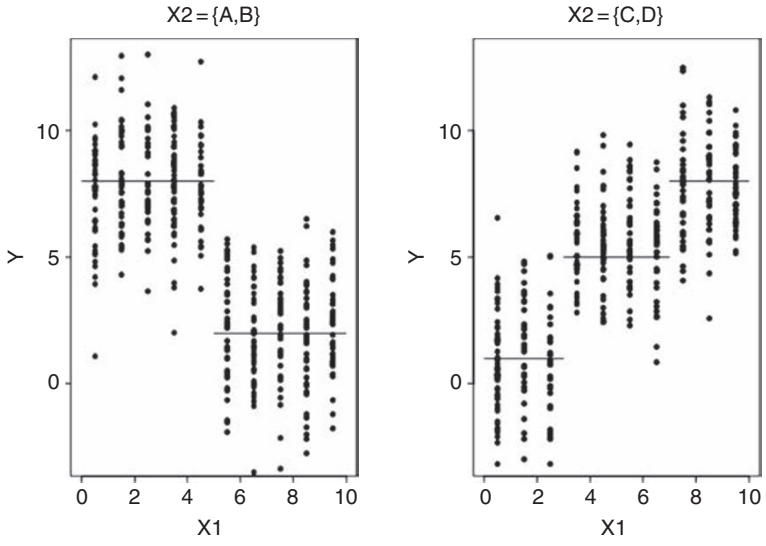
Structure of a RP model

A RP model describes the conditional distribution of y given a vector of predictors $x = (x_1, x_2, \ldots, x_p)$. This model has two main components: a tree T with b terminal nodes, and a parameter $\Theta = (\theta_1, \theta_2, \ldots, \theta_b)$ which associates the (possibly vector-valued) parameter θ_j with the jth terminal node. If x lies in the region corresponding to the jth terminal node then $y|x$ has distribution $f(y|\theta_j)$, where we use f to represent a parametric family indexed by θ_j. The model is called a regression tree or a classification tree according to whether the response y is quantitative or qualitative, respectively. An example of a RP model with binary splits is displayed in Fig. 1, and data sampled from its induced partition is displayed in Fig. 2.

Before describing the example tree, we discuss the general structure of a RP model for the case of a binary tree. A binary tree T subdivides the predictor space as follows: Each internal node has an associated splitting rule which uses a predictor to assign observations to either its left or



Recursive Partitioning. Fig. 1 A regression tree where $y \sim N(\theta, 2^2)$ and $x = (x_1, x_2)$



Recursive Partitioning. Fig. 2 A realization of 800 observations sampled from the tree model depicted in Fig. 1

right child node. The terminal nodes thus identify a partition of the predictor space according to the subdivision defined by the splitting rules. For quantitative predictors, the splitting rule is based on a split value s, and assigns observations for which $\{x_i \leq s\}$ or $\{x_i > s\}$ to the left or right child node respectively. For qualitative predictors, the splitting rule is based on a category subset C, and assigns observations for which $\{x_i \in C\}$ or $\{x_i \notin C\}$ to the left or right child node respectively.

Several assumptions have been made to simplify exposition. First, splitting rules are assumed to subdivide a region into two sub-regions, giving a binary tree. Second, only one predictor variable is assumed to be used for each splitting rule. Both these restrictions can be relaxed.

For illustration, Fig. 1 depicts a regression tree model where $y \sim N(\theta, 2^2)$ and $x = (x_1, x_2)$. x_1 is a quantitative predictor taking values in [0,10], and x_2 is a qualitative predictor with categories (A, B, C, D). The binary tree has nine nodes of which $b = 5$ are terminal nodes. The terminal nodes subdivide the x space into five nonoverlapping regions. The splitting variable and rule are displayed at each internal node. For example, the leftmost terminal node corresponds to $x_1 \leq 3.0$ and $x_2 \in \{C, D\}$. The θ_i value which identifies the mean of y given x is displayed at each terminal node. Note that θ_i decreases in x_1 when $x_2 \in \{A, B\}$, but increases in x_1 when $x_2 \in \{C, D\}$. A realization of 800 observations sampled from this model is displayed in Fig. 2.

If y were a qualitative variable, a classification tree model would be obtained by using an appropriate categorical distribution at each terminal node. For example, if y was binary with categories C_1 or C_2, one might consider the Bernoulli model $P(y \in C_1) = \theta = 1 - P(y \in C_2)$ with a possibly different value of θ at each terminal node. A standard classification rule for this model would then classify y into the category yielding the smallest expected misclassification cost. When all misclassification costs are equal, this would be the category with largest probability.

Learning the RP Model

To learn or estimate a RP model, we assume that a training sample consisting of tuples $(x_i, y_i), i = 1, \ldots, n$ is available. Both the tree T and the terminal node parameters Θ must be estimated using the training data.

For a fixed T, a common assumption is that the response values are i.i.d. within each terminal node. The data in each terminal node can be considered a separate sample, and conventional estimation techniques (e.g., maximum likelihood) yield familiar node parameter estimates $\hat{\theta}_j$ such as the sample mean for a continuous normal response and sample proportions for a categorical multinomial response.

Armed with a recipe for estimating Θ given T, we can now consider estimation of T. First, an objective function must be specified, providing a mechanism to assess the quality of a particular tree T. The log-likelihood of the training data is one such criterion. For a normal response model, the corresponding criterion would be the minimization of a residual sum of squares. For a multinomial response, the multinomial log-likelihood would be used. Ciampi (1991) was one of the first to develop a likelihood-based approach to RP models. Other criteria have been

proposed for specific response classes, such as the Gini index (Breiman et al. 1984) for a categorical response.

With an objective function quantifying the quality of a tree, the estimation problem becomes a search over all possible trees to optimize the objective. Although splitting rules for continuous x are real-valued, the objective function will only change when training points are moved among terminal nodes of the tree. Thus it is common to consider only splitting rules defined at data points, and require that each terminal node contain at least one training point. The search over the set of trees is thus a combinatorial search over a finite but very large discrete space.

The most common search algorithm is a greedy forward search, in which all training observations are initially grouped into a single node. The algorithm considers splitting into two child nodes, examining all possible splits on all possible variables. The splitting rule yielding the best value of the objective function (e.g., the smallest residual sum of squares when summed over the two child nodes) is selected. The procedure is repeated in each child node recursively until a large tree is grown.

Several strategies can be employed to decide how large a tree to grow. In the CHAID algorithm of Kass (1980), hypothesis tests were used to decide when to stop subdividing, yielding a final tree. Breiman et al. (1984) suggest growing a maximal tree, and then pruning away sibling nodes that do not significantly improve the objective function over the value assigned to their parent node. Their reasoning was that the forward greedy search might sometimes stop early, missing significant effects. For example, in the tree displayed earlier, no initial split leads to a large reduction in residual sum of squares because of the interaction pattern. Their backward pruning was facilitated by the idea of cost-complexity pruning, in which a modified objective function was minimized:

$$\text{Loss}(T;\alpha) = \text{RSS}(T) + \alpha|T|, \tag{1}$$

where $|T|$ represents the number of terminal nodes of the tree. Penalty parameter $\alpha \geq 0$ controls the trade-off between tree size and accuracy. Breiman et al. showed that (1) can be minimized as α increases from 0 to ∞ by considering a nested sequence of pruned trees, starting with the largest tree identified. The optimal α and a corresponding tree are selected so as to minimize a cross-validated estimate of the objective function.

While other methods for identifying the best tree have been proposed, the greedy forward search is quick and can be quite effective.

Strengths and Weaknesses of RP Models

The structure of RP models enables them to identify *interactions*. For instance, in Figs. 1 and 2, we see an interaction effect between X_1 and X_2: If $X_2 = \{A, B\}$ then response y decreases with increasing X_1. If $X_2 = \{C, D\}$ then response y increases with increasing X_1. This is perhaps the greatest strength of RP models, and one of the reasons they are used for exploratory data analysis.

This strength is also a weakness. If the relation between predictors and response is *additive*, very large trees will be needed to capture this relationship. For instance, if

$$y = x_1 + x_2 + x_3 + x_4 + x_5 + \text{error},$$

then a tree with 32 terminal nodes will be required to even approximate this function with a single step along each of the five predictor axes.

Trees are popular among practitioners because of their *interpretability*. It is natural to interpret the sequence of conditions leading to a terminal node of a tree. Care must be taken with such interpretations, especially if dependencies exist among predictors. In such cases, multiple trees with different splits on different variables may fit the data equally well.

In addition to dealing with mixed predictor types, RP models can handle missing values of predictors via several strategies. For missing predictor values in the training data, one could (i) treat "missing" as a new category for a categorical predictor, or (ii) identify surrogate splitting variables that produce splits similar to a missing predictor. If predictor values are missing when making predictions for new observations, either of these strategies may be employed, or one may terminate the branching process when a missing value is needed in a branch, and base predictions on the interior node.

The most common form of RP models utilize a single variable for each splitting rule. This *axis alignment* aids in interpretability, but can be a weakness if variation in the response occurs along a linear combination of predictors, rather than along the axes. The additive function of five variables mentioned above is an example of this.

By virtue of subdividing the data into smaller subgroups, an RP model can suffer from *sparsity*, especially if more complex statistical models are utilized in the terminal nodes. For instance, a significant challenge in modifying RP models for survival data with censoring (LeBlanc and Crowley 1993) is the pooled nature of Kaplan–Meier estimates (see ►Kaplan-Meier Estimator) of the survival curve. This data sparsity is one of the primary reasons for the use of simple models in terminal nodes.

A weakness of RP models is *sensitivity* of results to small data perturbations. Breiman (1996) demonstrated that when RP models were fit to bootstrap samples of the data, there could be substantial variation in tree structure. While this would seem to be a weakness, Breiman leveraged this idea to produce Ensemble methods discussed below in section ►"Ensembles of Trees".

Because of the greedy nature of the search over the space of trees, inference for the resultant model is difficult. Although confidence intervals and hypothesis tests can easily be constructed conditional on a specific tree T, the adaptive nature of the learning algorithm means that the statistical properties of estimators, intervals and tests will be seriously undermined. Methods that take account of the search include adjustments for multiple testing (Hawkins and Kass 1982) and Bayesian approaches (Chipman et al. 1998; Denison Mallick and Smith 1998).

Extensions

The popularity of RP models has lead to a number of extensions and the development of related methods.

A variety of search strategies have been proposed as alternatives to the greedy forward stepwise approach. These include the use of stochastic search optimizers such as genetic algorithms (Fan and Gray 2005) and simulated annealing (Sutton 1991; Lutsko and Kuijpers 1994) and MCMC (Chipman et al. 1998; Denison et al. 1998). Tibshirani and Knight (1999) used the bootstrap to perturb data before executing a greedy search.

Variations on the tree structure have also been considered, including splitting rules based on linear combinations of real-valued predictors (Loh and Vanichsetakul 1988). Some RP algorithms (e.g., AID) allow nodes to have more than two child nodes, complicating the search but sometimes making interpretation clearer. Quinlan's C4.5 splits categorical predictors by generating a different child node for each categorical level of the corresponding predictor.

The statistical model in terminal nodes has also been extended to richer models, such as linear regression (Alexander and Grimshaw 1996; Chipman et al. 2002), ►generalized linear models (Chipman et al. 2003), and Gaussian process models (Gramacy and Lee 2008).

Ensembles of Trees

RP models have been used as a "base learner" in a number of algorithms that seek to achieve greater predictive accuracy by combining together multiple instances of a model.

In noticing the sensitivity of trees to small perturbations, Breiman (1996) developed a strategy known as bootstrap aggregation or "Bagging" for generating multiple trees and combining them to achieve greater prediction accuracy. For instance, with a continuous response, each bootstrap tree would be used to generate predictions at a particular test point, and these predictions would be averaged to form an ensemble prediction.

A further enhancement led to Random Forests (Breiman 2001). Additional variation in the search algorithm was introduced by randomizing the choice of predictor in splitting rules. This led to a richer set of trees, and could further improve predictive accuracy.

Another form of ensemble model using RP models is boosting (Freund and Schapire 1997). In this algorithm, a sequence of RP models are learned, each depending on those already identified via data weights that depend on predictive accuracy of earlier RP models. These weights encourage the next RP model to better fit those observations that have been incorrectly classified. At the end of the boosting sequence, an ensemble prediction is generated by a weighted combination of predictions from each learner in the ensemble.

Although neither boosting or random forests require that the base learner be a RP model, these have yielded the most popular and successful form of ensemble model.

Related Work

A model closely related to RP models is the hierarchical mixture of experts model (Jordan and Jacobs 1994). In this model, a different logistic function of the predictors is used in each interior node to probabilistically assign data points to the left and right children. In doing so, the hard boundaries associated with splitting rules are replaced with soft decisions indexed by continuous parameters. In terminal nodes, predictions are given by ►logistic regression. Tree size and topology is typically fixed in advance, and the tree learning algorithm becomes a continuous optimization problem.

Regression Diagnostics

Shuangzhe Liu[1], Alan H. Welsh[2]
[1]Associate Professor, Faculty of Information Sciences and Engineering

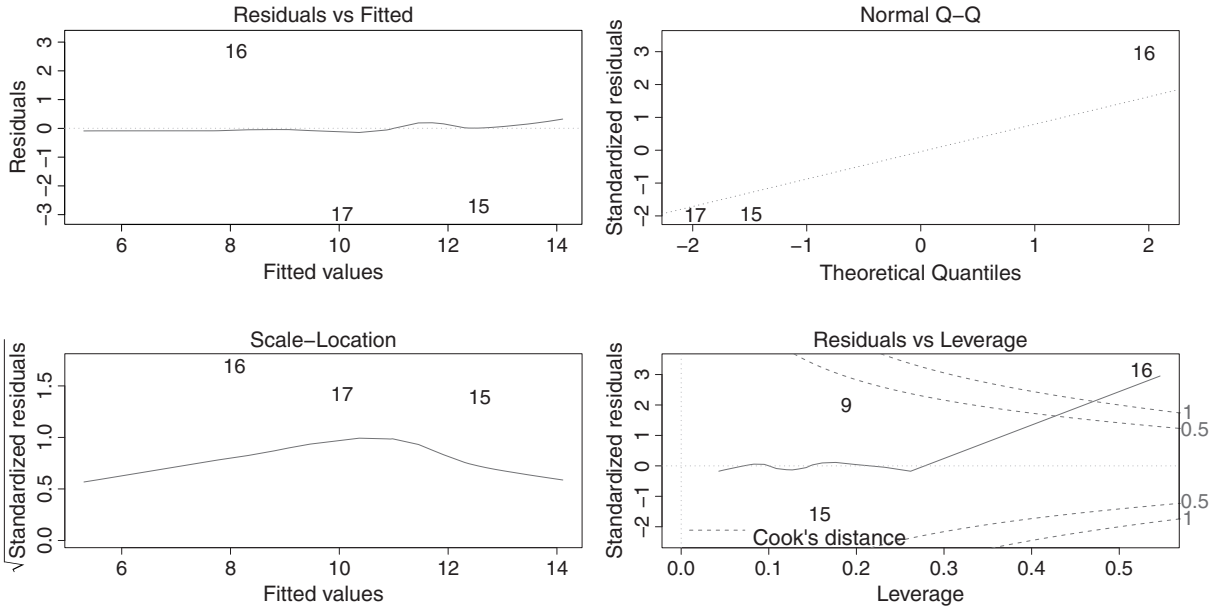
Regression diagnostics are a set of mostly graphical methods which are used to check empirically the reasonableness of the basic assumptions made in the model. These informal methods are an important part of regression modelling: many formal conclusions and inferences (including confidence intervals, statistical tests, prediction etc.) derived from a fitted model only make sense if the assumptions of the model hold. If the regression assumptions are violated, any application of results obtained from the model can be very misleading.

For a data set of n observations of a response variable y and k explanatory variables x_j $(j = 1, \ldots, k)$, the standard linear regression model (see ►Linear Regression Models) for the relationship between the response and the explanatory variables can be written in matrix notation as

$$y = X\beta + \epsilon, \tag{1}$$

where $y = (y_i)$ is an n-vector of observations, $X = (x_{ij})$ is an $n \times k$ matrix of independent variables, $\beta = (\beta_j)$ is a k-vector of unknown parameters and $\epsilon = (\epsilon_i)$ is an n-vector of unobserved random variables, often called errors. The basic assumptions of the model are that the relationship between y and X is linear, the ϵ_i are independent, have constant variance and are normally distributed.

The basic quantities on which diagnostics are based are the residuals and fitted values. For any estimator $\hat{\beta}$ of β, the fitted values are $\hat{y} = X\hat{\beta}$ and the residuals are $\hat{\epsilon} = y - \hat{y} = y - X\hat{\beta}$. The residuals provide information about the errors in the model so are fundamental in diagnostics. Various forms of standardized residuals can also be calculated. If X is of full column rank so $\hat{\beta} = (X'X)^{-1}X'y$ is the least squares estimator of β, the fitted values can be written as $\hat{y} = Hy$, where $H = X(X'X)^{-1}X' = (h_{ij})$ is the hat matrix and the ith diagonal element h_{ii} is called the leverage of the ith observation. The residuals can be standardized as $\hat{\epsilon}_i/s$, where $s^2 = (n-k)^{-1}\sum_{i=1}^{n}\hat{\epsilon}_i^2$, as $\hat{\epsilon}_i/s(1-h_{ii})^{1/2}$ (internally Studentized) or as $\hat{\epsilon}_i/s_{(i)}(1-h_{ii})^{1/2}$ (externally Studentized), where $s^2_{(i)} =$



Regression Diagnostics. Fig. 1 Diagnostic plots based on the least squares fit of a linear regression model to the salinity data of Ruppert and Carroll (1980)

$(n - k - 1)^{-1} \sum_{j \neq i}^{n} \hat{\epsilon}_{(j)}^2$ and $\hat{\epsilon}_{(j)}$ is the residual for the jth observation calculated from the $n - 1$ observations after excluding the jth observation. Other useful quantities include ▶Cook's Distance which is a measure of influence involving the square of the Studentized residual and the potential function $h_{ii}/(1 - h_{ii})$.

The most widely used diagnostic plots are residual plots which plot the residuals against the fitted values (checking for linearity, constant variance and ▶outliers), spread plots which plot the square root of the Studentized residuals against the fitted values (checking for constant variance, outliers), QQ-plots which plot the ordered residuals against their expected values under normality (normality, outliers), and leverage plots which plot Studentized residuals against the leverage (checking for ▶influential observations). These four plots are illustrated in Fig. 1 for the salinity data (Ruppert and Carroll 1980) which have 28 observations and 3 explanatory variables. The plots are supplemented by lines and curves which aid in their interpretation. The most interesting features are the departure from normality in the upper tail (observation 16) shown in the QQ-plot and the confirmation that this observation is influential in the leverage plot. In general, outliers may be difficult to find without the use of robust method: using robust methods, Ruppert and Carroll also identified observations 15 and 17 as outliers in these data. Other useful plots include added-variable plots (examining the relationship between y and x_j after adjusting for the other explanatory variables) and partial-residual plots (checking for linearity). In addition, there are a number of specialized plots which can be used to check for dependence: these include various time series and spatial plots, correlograms (ACF, PACF), variograms and spectrum plots. These methods are extensively documented in the statistical literature.

See for example the list of references at the end of this entry.

Graphical methods are preferred in diagnostics because they are more informative than numerical ones and often suggest ways in which deficiencies in a model can be rectified. A good illustration is Anscombe's (1973) set of 4 different datasets with the same summary statistics but four distinct regression relationships between the response and explanatory variables.

Diagnostic methods are important in all statistical modelling including generalised linear models (de Jong and Heller 2008), time series analysis (Li 2003) etc.

Regression Models with Increasing Numbers of Unknown Parameters

Asaf Hajiyev
Professor, Chair
Baku State University, Baku, Azerbaijan

Introduction

Consider the regression model

$$y_i = f(x_i, \theta) + \varepsilon_i, \quad i = 1, 2, \ldots, N \tag{1}$$

where x_i is the point of observation, y_i an observable value, ε_i a random error at the point x_i, and $\theta = (\theta_1, \theta_2, \ldots, \theta_m)^T$ is the vector of unknown parameters. Let us suppose that the number of unknown parameters m depends on the number of observations N and m may increase, when N becomes larger. Such regressions are called models with increasing number of unknown parameters. The variances of observation error are unknown and may be different. At each point x_i there is only one observable value, y_i, that does not allow estimation of the variance.

Regression models with an increasing number of unknown parameters and with unknown and different variances of observation error are of interest in important applications. This is because, with an increased number of unknown parameters, the unknown function can be approximated more accurately in experiments. Moreover, in some applications, repeated tests at a single point are costly (financially and technically), which hampers the estimation of the unknown error variance, which is different at different observation points.

Regression models have been widely addressed in numerous publications (Demidenko 1989; Huet et al. 1996; Sen and Srivastava 1997), but models with an increasing number of unknown parameters have received little attention, which motivates our interest in this subject. The main aims of our investigations are

- Direct estimation (without estimation of a variance) of the elements of the covariance matrix of the vector $\sqrt{N}(\theta^* - \theta)$, where θ^* is the least square estimator (l.s.e.).
- Construction of a confidence band for the unknown function $f(x, \theta)$.

Linear Regression Models

Let us assume that

$$f(x, \theta) = \theta_1 \phi_1(x) + \theta_2 \phi_2(x) + \ldots + \theta_{m(N)} \phi_{m(N)}(x), \tag{2}$$

where $\phi_1(x), \phi_2(x), \ldots, \phi_{m(N)}(x)$ is a system of linearly independent and bounded functions. Expression (1) can be rewritten in a vector form as

$$Y = X\theta + \varepsilon, \tag{3}$$

where Y is the vector of observable values, X the design matrix, defined as $X = //x \quad ij//, x_{ij} = \phi_i(x_j)$, $i = 1, 2, \ldots, m$; $j = 1, 2, \ldots, n$; with $\theta = (\theta_1, \theta_2, \ldots, \theta_{m(N)})^T$ being the vector of unknown parameters and $\varepsilon = (\varepsilon_1, \varepsilon_2, \ldots, \varepsilon_N)^T$ denoting the error-vector. The number of unknown parameters depends on the number of observations and moreover

$$m(N)/N \to 0, \; as \; n \to \infty. \tag{4}$$

The sequence $\varepsilon_1, \varepsilon_2, \ldots, \varepsilon_N$ is assumed to have uniformly bounded and independent random variables with $E\varepsilon_i = 0, E\varepsilon_i^2 = {\sigma_i}^2$ being unknown, different, and

$$0 < (\sigma_*)^2 \le {\sigma_i}^2 \le (\sigma^*)^2 < \infty.$$

Let $\theta^* = (X^TX)^{-1}X^TY^Y$ be the l.s.e and $trA = \sum_{i=1}^{n} a_{ii}$ be the trace of the matrix A with elements a_{ij}.

Definition 1 The vector $\theta = (\theta_1, \theta_2, \ldots, \theta_{m(N)})^T$ with random elements and increasing dimension converges to zero in probability $\theta \xrightarrow{P} 0$, if $\sum_{i=1}^{m(N)} \theta_i^2 \xrightarrow{P} 0$ as $N \to \infty$.

Let $0 < \lambda_1(N) \le \lambda_2(N) \le \ldots \le \lambda_m(N)$ be eigenvalues of the matrix $(X^TX)/N$.

Theorem 1 Let the conditions (2)–(4) be true. Then $(\theta^* - \theta) \xrightarrow{P} 0$, if and only if $(1/N)tr(X^TX/N) \xrightarrow{P} 0$ as $N \to \infty$.

Definition 2 The vector $\theta^P = ({\theta_1}^P, {\theta_2}^P, \ldots, {\theta_{m(N)}}^P, 0, \ldots, 0)^T$ is called m-finite and p-consistent estimator of the vector $\theta = (\theta_1, \theta_2, \ldots, \theta_N)^T$, if

$$\forall \delta > 0 \; P\left\{\sum_{i=1}^{m(N)} \left({\theta_i}^P - \theta_i\right)^2 < \delta\right\} \ge p \text{ holds true, as } N \to \infty.$$

Example 1 Consider $f(x, \theta) = \sum_{i=1}^{\infty} \theta_i \phi_i < \infty, |\phi_i(x)| \le 1$, $\sum_{i=1}^{\infty} \theta_i^2 < \infty$. The problem is to find such $m(p, N, \delta)$ ($\forall \delta > 0$ and given $0 < p < 1, \quad N > 0$), for which $P\left\{\sum_{i=1}^{m(N)} \left(\theta_i^* - \theta_i\right)^2 < \delta\right\} \ge p$ holds true, where θ_i^* is the l.s.e. on N observations. For simplicity, we assume $E\varepsilon_i = 0, E\varepsilon_i^2 \le 1$.

Consider $y_i = \sum_{i=1}^{m(N)} \theta_i \phi_i(x) + \delta_i$, where

$$\delta_i = \sum_{j=m(N)+1}^{\infty} \theta_i \phi_i(x) + \varepsilon_i, \; \delta_i$$
$$= \sum_{j=m(N)+1}^{\infty} \theta_i \phi_i(x) \to 0 \text{ as } N \to \infty.$$

Assuming that for large values of $N \; P\left\{\sum_{i=1}^{\infty} \left({\theta_i}^* - \theta_i\right)^2 < \delta\right\} \approx P\left\{\sum_{i=1}^{m(N)} \left({\theta_i}^* - \theta_i\right)^2 < \delta\right\}$. If the conditions of the Theorem 1 hold true, then we obtain

$$P\left\{\sum_{i=1}^{m(N)} \left({\theta_i}^* - \theta_i\right)^2 < \delta\right\} \ge 1 - (m+1)/(N\lambda_1(N)\delta)$$

from Chebyshev inequality. Taking $p = 1 - (m+1)/(N\lambda_1(N)\delta)$, we get $m = (1-p)(N\lambda_1(N)\delta) - 1$. Now in the capacity of a consistent estimator of the vector $\theta = (\theta_1, \theta_2, \ldots, \theta_N)^T$, we can take the vector $\theta^P = ({\theta_1}^P, {\theta_2}^P, \ldots, {\theta_{m(N)}}^P, 0, \ldots, 0)^T$, where m was found, above. According to the Theorem 1 the vector θ^* is a consistent estimator of θ.

Estimation of Covariance Matrix

Denote

$$D_N = E(\theta^* - \theta)(\theta^* - \theta)^T$$
$$= (1/N)(X^TX/N)^{-1}[X^T(E\varepsilon\varepsilon^T)X/N](X^TX/N)^{-1}$$
$$= (1/N)(X^TX/N)^{-1}[X^TI(\sigma^2)X/N](X^TX/N)$$

where $I(\sigma^2) = //z_{ij}//$ is an unknown matrix, $//z_{ij}// = \sigma_i\sigma_j\delta_{ij}$, $\delta_{ij}(i, j = 1, 2, \ldots, N)$ is Kroneker symbol

$$C_N = X^TI(\sigma^2)X/N, \; C_N = //c_{kl}//, \; k, l = 1, 2, \ldots, m;$$
$$y^* = X\theta^*,$$

$$I_{kl}(x) = //{a_{ij}}^{kl}//, \; i, j = 1, 2, \ldots, m;$$

$$//{a_{ij}}^{kl}// = \phi_k(x_j)\phi_l(x_j)\delta_{ij}, \; {c_{kl}}^*$$
$$= (1/N)(y^* - y)I_{kl}(x)(y^* - y),$$
$$C_N{}^* = //{c_{kl}}^*//, \; k/l = 1, 2, ..., m.$$

Theorem 2 Let $E{\varepsilon_i}^4 < \infty$ and $\left(m\sqrt{m}\right)/(N\lambda_1(N)) \to 0$, as $N \to \infty$, then

$$\left({c_{ij}}^* - c_{ij}\right) \xrightarrow{P} 0, \quad E\left({c_{ij}}^* - c_{ij}\right) \to 0 \; as \; N \to \infty.$$

Remark 1 In Theorem 2 we do not need the existence of the limit c_{kl}^* and c_{kl}. This is because the difference between them converges to zero, in probability.

Theorem 3 If $\left(m\sqrt{m}\right)/(N\lambda_1(N))$ will be bounded, then $\sqrt{N}(\theta^* - \theta) \Rightarrow N(0, D_N)$ as $N \to \infty$, where $\Rightarrow N(0, D_N)$ means a convergence in probability to the normal distribution with the covariance matrix D_N.

Different approaches for estimating the elements of covariance matrix were suggested in Belyaev and Hajiyev (1979), Hajiyev (2004), and Wu (1986).

Nonlinear Regression Models

Let us assume that $f(x_i, \theta)$ in (1) is a nonlinear function and

$$f(x_i, \theta),\ \partial f(x, \theta)/\partial\theta,\ \partial^2 f(x, \theta)/\partial\theta_i\partial\theta_j, (i, j = 1, 2, \ldots, m)$$

are bounded and continuous functions of (x, θ), $\theta \in \Theta$ is a compact set. Denote

$$f_{ij}(\theta) = \partial f(x_j, \theta)/\partial\theta_i;$$

$F_N(\theta)$ is the matrix with elements $f_{ij}(\theta)$, $0 < \mu_1{}^N(\theta) \le \ldots \le \mu_m{}^N(\theta)$ eigenvalues of the matrix $\left[F_N{}^T(\theta)F_N(\theta)/N\right]$ and $B(r)$ be the sphere of the radius $r > 0$ centered at the point θ^*. A least squares estimator of θ is constructed by the iterative process

$$\theta_N(s+1) = \theta_N(s) + \left[F_N{}^T(\theta_N(s))F_N(\theta_N(s))\right]^{-1} F_N{}^T(\theta_N(s))(y - f(x, \theta_N(s))). \quad (5)$$

The question arises as to whether the iterative process (5) converges or not. Relation (5) can be represented as

$$\theta_N(s+1) = u(\theta_N(s)) = \theta_N(s) + A_N(\theta_N(s))\delta_N(\theta_N(s)),$$

where

$$A_N(\theta_N(s)) = \left[F_N{}^T(\theta_N(s))F_N(\theta_N(s))/N\right]^{-1} F_N{}^T(\theta_N(s))$$

$$\delta_N(\theta_N(s)) = y - f(x, \theta_N(s)),\ \delta_N{}^*(\theta_N(s)) = y - f(x, \theta^*).$$

Define

$$\zeta_{N,r}{}^p(\theta) = m(\partial A_N(\theta)/\partial\theta_p)\varepsilon, p = 1, 2, .., m; \theta \in B(r),$$
$$L_p = \partial u_N(\theta)/\partial\theta_p,$$
$$\tau_N(r) = \max_{p=1,2,\ldots,m}\sup_{\theta\in\Theta}//L_p//.$$

Below, the convergence of random variables is understood as convergence in probability.

Theorem 4 If there exists such N that $m(N)^5/\left[N\left(\lambda_1{}^N(\theta)\right)^4\right] \to 0, r \to 0$, then

$$m(N)\tau_N(r) \to 0 \text{ and for any } p,\ \zeta_{N,r}{}^p(\theta) \to 0, r \to 0.$$

Introduce $\rho_N(\theta) = u_N(\theta) - \theta, \rho^* = \rho(\theta^*)$.

Theorem 5 Let $\theta(0) \in B(r)$ and $\tau_N(r) + (//\rho^*//)/r < 1$. Then under the conditions of Theorem 4, there exists a random variable θ_N such that

$$\sqrt{N}(\theta_N - \theta^*) \Rightarrow N[0, \sum(\theta^*)] \text{ as } N \to \infty,$$

where

$$\sum(\theta^*) = \left[F_N{}^T(\theta^*)F_N(\theta^*)/N\right]^{-1} \left[F_N{}^T(\theta^*)I(\sigma^2)F_N(\theta^*)/N\right]\left[F_N{}^T(\theta^*)F_N(\theta^*)/N\right]^{-1},$$

that is, θ_N is a $\sqrt{N}$ consistent estimator and θ_N can be used as l.s.e. on N observations. Using the approach suggested in Hajiyev and Hajiyev (2009), (similarly as for linear models) the elements of a covariance matrix can be estimated.

The Construction of Asymptotic Confidence Bands

Consider the quadratic form

$$(\theta^* - \theta)^T(D_N)^{-1}(\theta^* - \theta) \le \chi_\gamma{}^2(m)/N. \quad (6)$$

According to Theorem 5, the left side of (6) has asymptotically chi-square distribution random with degrees of freedom m. In (6) instead of D_N^{-1} (according to the Theorem 2) can be used estimates (Hajiyev and Hajiyev 2009) the matrix D_N^{-1} elements. For the construction of a confidence band for $f(x, \theta)$, it is necessary to find $\inf f(x, \theta)$ and $\sup f(x, \theta)$, $\theta \in \varepsilon_\gamma(\theta)$, which are lower and upper boundaries of a confidence band and

$$\varepsilon_\gamma(\theta) = \left[\theta : (\theta^* - \theta)^T\left(D_N{}^{-1}\right)(\theta^* - \theta) \le \chi_\gamma^2(m)/N\right]$$

is the confidence ellipsoid, $\chi_\gamma{}^2(m)$ is the $\gamma > 0$ level quantile of the ▸chi-square distribution with m degrees of freedom.

About the Author

Dr. Asaf Hajiyev is a Professor and Chair, Department of Queuing Systems, Institute of Cybernetics, the Azerbaijan National Academy of Sciences (ANAS) and Head, Department of Probability and Mathematical Statistics, Baku State University. In 1980, he was awarded the Azerbaijan Lenin Komsomol Prize in Science and Technology. He is a Member of Bernoulli Society for Mathematical Statistics and Probability (1986), Elected member of the International Statistical Institute (2000), Elected correspondent-member Azerbaian National Academy of Science (2001), Elected member of the Third World Academy of Sciences (TWAS), Italy (2004). In 2008, he was elected a Member of the Mongolian National Academy of Sciences. Professor Hajiyev is Head of the Coordinating Council of the Azerbaian National Academy of Science in Mathematics. He

was a Member of the Azerbaijan Parliament: first (1995–2000), second (2000–2005), and third (2005–2010) convocations. During 2004–2006, he was elected Vice President of the Parliamentary Assembly of the Black Sea Economy Cooperation. He has authored more than 100 scientific papers and two books, including *Encyclopedia in Theory of Probability and Mathematical Statistics*.

Regression Models with Symmetrical Errors

Francisco José A. Cysneiros
Associate Professor
CCEN-UFPE - Cidade Universitária - Recife, Recife, Brazil

The normality assumption is a very attractive option for the errors of regression models with continuous response variables. However, when it is not satisfied, some transformation can be adopted for the response variable to obtain, at least, the symmetry property. It is known that the estimates of the coefficients in normal regression models are sensitive to extreme observations. Alternatives to the assumption of normal errors have been proposed in the literature. One of those alternatives is to consider that the errors have distributions with heavier tails than the normal distribution, in order to reduce the influence of outlier observations. In this context, Lange et al. (1989) proposed the Student t model with unknown ν degrees of freedom. In the last decade, several results appeared as alternatives to modeling distributions other than the normal errors as, for instance, the symmetrical (or elliptical) distributions. Some of these results can be found in Fang et al. (1990), and Fang and Anderson (1990).

Symmetrical Nonlinear Models

Consider the symmetrical nonlinear model

$$y_i = \mu_i + \epsilon_i, \quad i = 1, \ldots, n \tag{1}$$

where $y_1, \ldots, y_n$ are the observed responses, $\mu_i = \mu_i(\boldsymbol{\beta}; \mathbf{x})$ is an injective and at least twice differentiable function with respect to $\boldsymbol{\beta}$. In addition, we suppose that the derivative matrix $\mathbf{D}_\beta = \partial\boldsymbol{\mu}/\partial\boldsymbol{\beta}$ has rank $p(p < n)$ for all $\boldsymbol{\beta} \in \Omega_\beta \subset I\!R^p$, where Ω_β is a compact set with interior points, $\boldsymbol{\beta} = (\beta_1, \ldots, \beta_p)^T$ is the parameter vector of interest, $\mathbf{x}_i = (x_{i1}, \ldots, x_{ip})^T$ is a vector of explanatory variable values and $\epsilon_1, \ldots, \epsilon_n$ are independent random variables with the symmetrical density function $f_{\epsilon_i}(\epsilon) = g(\epsilon^2/\phi)/\sqrt{\phi}$, $y \in I\!R$, where $g : I\!R \to [0, \infty)$ is such that $\int_0^\infty g(u)du < \infty$. The function $g(\cdot)$ is typically known as the density generator. We will denote $\epsilon_i \sim S(0, \phi, g)$. The symmetrical class includes all symmetrical continuous distributions with heavier and lighter tails than the normal ones. When they exist, $E(Y_i) = \mu_i$ and $Var(Y_i) = \xi\phi$, where $\xi > 0$ is a constant that may be obtained from the expected value of the radial variable or from the derivative of the characteristic function (see, for instance, Fang et al. 1990). The log-likelihood function for $\boldsymbol{\theta} = (\boldsymbol{\beta}^T, \phi)^T$ is given by $L(\boldsymbol{\theta}) = -n/2 \log\phi + \sum_{i=1}^n log\{g(u_i)\}$, where $u_i = \phi^{-1}\{y_i - \mu_i\}^2$. The score functions for $\boldsymbol{\beta}$ and ϕ take, respectively, the forms

$$\mathbf{U}_\beta(\boldsymbol{\theta}) = \frac{1}{\phi}\mathbf{D}_\beta^T\mathbf{V}(\mathbf{y} - \boldsymbol{\mu}) \ \ and$$

$$\mathbf{U}_\phi(\boldsymbol{\theta}) = 2\phi^{-1}\{Q_V(\boldsymbol{\beta}, \phi)/\phi - n\},$$

where $\mathbf{V} = diag\{v_1, \ldots, v_n\}$ with $v_i = -2W_g(u_i)$, $W_g(u) = \frac{g'(u)}{g(u)}$, $g'(u) = \frac{dg(u)}{du}$, $\mathbf{y} = (y_1, \ldots, y_n)^T$, $\boldsymbol{\mu} = (\mu_1, \ldots, \mu_n)^T$, $Q_V(\boldsymbol{\beta}, \phi) = \{(\mathbf{y} - \boldsymbol{\mu})^t\mathbf{V}(\mathbf{y} - \boldsymbol{\mu})\}$. The Fisher information matrix for $\boldsymbol{\theta}$ can be expressed as $\mathbf{K}_{\theta\theta} = diag\{\mathbf{K}_{\beta\beta}, K_{\phi\phi}\}$, where $\mathbf{K}_{\beta\beta} = 4d_g\phi^{-1}\mathbf{D}_\beta^T\mathbf{D}_\beta$ and $K_{\phi\phi} = n(4\phi^2)^{-1}(4f_g - 1)$ with $d_g = E\left\{W_g^2(U^2)U^2\right\}$, $f_g = E\left\{W_g^2(U^2)U^4\right\}$ and $U \sim S(0, 1, g)$. Thus, $\boldsymbol{\beta}$ and ϕ are orthogonal. Due to the similarity between the inference for elliptical and normal models, it is reasonable to expect that for large n and under suitable regularity conditions, the estimators $\hat{\boldsymbol{\beta}}$ and $\hat{\phi}$ are approximately normal of means $\boldsymbol{\beta}$ and ϕ and variance–covariance matrices $\mathbf{K}_{\beta\beta}^{-1}$ and $\mathbf{K}_{\phi\phi}^{-1}$, respectively. General expressions for $W_g(u)$, $W_g'(u)$, d_g, f_g, and ξ may be found, for instance, in Cysneiros and Paula (2005).

Parameter Estimation

Some iterative procedures such as Newton–Raphson, BFGS, and Fisher scoring method can be used. Fisher scoring method can be easily applied to obtain $\hat{\boldsymbol{\theta}}$, where the iterative process can be interpreted as a modified least squares. The iterative process for $\hat{\boldsymbol{\theta}}$ take the form

$$\begin{aligned}\boldsymbol{\beta}^{(m+1)} &= \left\{\mathbf{D}_{\beta}^{T(m)}\mathbf{D}_{\beta}^{(m)}\right\}^{-1}\mathbf{D}_{\beta}^{T(m)}\mathbf{Z}^{(m)},\\ \phi^{(m+1)} &= \frac{1}{n}Q_V(\boldsymbol{\beta}^{(m+1)},\phi^{(m)}), \quad m=0,1,2,\ldots, \quad (2)\end{aligned}$$

where $\mathbf{Z} = \mathbf{D}_{\beta}\boldsymbol{\beta} + \frac{1}{4d_g}\mathbf{V}(\mathbf{y}-\boldsymbol{\mu})$. In linear case, we have $\boldsymbol{\beta}^{(m+1)} = (\mathbf{X}^T\mathbf{V}^{(m)}\mathbf{X})^{-1}\mathbf{X}^T\mathbf{V}^{(m)}\mathbf{y}$. Starting values should be given for $\boldsymbol{\beta}$ and ϕ, for example, least square estimates. As we can see from the iterative process (2), the observations with small value for v_i are down weighted for estimating $\boldsymbol{\beta}$. In particular, for the normal model, we have $v_i = 1$, $\forall i$. For the Student t model with ν degrees of freedom, power exponential with shape parameter k, and logistic type II distributions, the values of v_i are given in the Table 1.

It may be showed for the Student t and logistic type II distributions, v_i is inversely proportional to u_i. This property also follows for the power exponential distribution when $0 < k \leq 1$. Then, robustness aspects of $\hat{\beta}$ against outlying observations appear in these three heavy-tailed error distributions. In general, when the errors of the model have distribution with heavier tails than normal, the values of the weights v_i have small values for u_i large. Thus, models where the distribution of error have heavy tails can reduce the influence of extreme observations, while in the normal nonlinear regression model the weights are equal for all observations. In consequence, estimates in symmetrical regression models are less sensitive to the extreme observations than normal regression models. Extensions in the area of heteroscedastic symmetrical regression models can be found in Cysneiros et al. (2007, 2010) and codes in S-Plus and R to fit symmetrical regression models can be obtained in the Web page www.de.ufpe.br/~cysneiros/elliptical/elliptical.html.

Regression Models with Symmetrical Errors. Table 1
Expression of v_i for some symmetrical distributions

Distribution	v_i
Normal	1
Student-t	$\frac{\nu+1}{(\nu+u_i)}$
Logistic-II	$\frac{2exp(-\sqrt{u_i})-1}{(-2\sqrt{u_i})[1+exp(-\sqrt{u_i})]}$
Power exponential	$\frac{1}{(1+k)u_i^{k/(k+1)}}$

Relationship Between Statistical and Engineering Process Control

Alberto Luceño
Professor
University of Cantabria, Santander, Spain

Introduction

Many industrial processes must be adjusted from time to time to continuously maintain their outputs close to target. The reason for this is that such processes may be affected by disturbances produced, for example, by machines loosing their adjustment, components wearing out, and varying feed stock characteristics. Industrial control is a continual endeavor to keep measures of quality as close as possible to their target values for indefinite periods of time.

This may be attained using process monitoring and process adjustment tools. Monitoring implies continually checking the desired state of the process to detect and eliminate assignable causes of variation that can send the process out of control. Adjustment implies forecasting future deviations and taking corrective actions by feedback and/or feedforward. Process control can potentially benefit by using complementary tools of process monitoring and process adjustment within the same application.

Process Monitoring Techniques

Process monitoring, or process surveillance, is a part of Statistical Process Control (SPC) that is used when the process can be brought to a satisfactory state of statistical control by systematically applying standardization of criteria, materials, methods, practices and processes.

Process monitoring is usually implemented by means of ►control charts, such as the Shewhart charts, the CUmulative SUM (CUSUM) charts, or the Exponentially Weighted Moving Average (EWMA) charts, among others.

The purpose of such methods is to continually check, or supervise, the state of the process in order to detect any conceivable out of control situation as soon as possible while simultaneously minimizing the rate of false alarms (i.e., alarms that eventually turn out to have no special cause).

When an alarm is triggered, a search for the special and potentially assignable cause of variation that presumably produced the alarm should be started. This search should end with the detection of such assignable cause and its permanent removal from the system. If the search fails, so that no special cause is eventually found, the alarm should be counted as a false alarm.

Process Adjustment Techniques

Process adjustment is often considered as a part of Engineering Process Control (EPC) and is used when the process cannot be brought to a satisfactory state of statistical control, even after systematic application of standardization techniques. Much efforts have recently been dedicated, however, to bring some important features of process adjustment to the attention of the statistical community (e.g., see Box and Kramer 1992; Box and Luceño 1997a,b, 2002; Box et al. 2009; Luceño 2003, or Montgomery et al. 1994).

Process adjustment is often implemented by first using forecasting tools to estimate future deviations from target and subsequently modifying, or adjusting, an input compensatory variable so as to make those predicted deviations equal to zero (or to an appropriate small value in asymmetric situations). A process adjustment scheme may use feedback adjustments, feedforward adjustments, or a combination of both. Some types of feedback adjustment schemes are repeated adjustment schemes, constrained adjustment schemes, Proportional Integral Derivative (PID) control schemes, bounded adjustment schemes, among other.

The purpose of these methods is to indicate when and by how much the process has to be sampled and adjusted to keep it close to target. The only actions called for are to sample and to adjust the process when and as indicated by the adjustment scheme. The objective may be to minimize the output variance (or the mean squared error at the output) without any additional constraints, or to minimize the output variance constrained by a bound on the input variance, or by a bound on the frequency of adjustment, or on the frequency of sampling, or on the amount of each adjustment, among other possibilities.

Conclusion

One can tentatively conclude that declarations of alarms and searches for special and potentially assignable causes of variation are not called for in the context of process adjustment techniques, but in the context of process monitoring techniques. By the same token, process adjustments are not called for in the context of process monitoring techniques, but much more appropriately in the context of process adjustment techniques.

Nevertheless, the appropriate combination of process monitoring and process adjustment tools, and their complementary use in SPC, is the subject of controversy within the statistical community. Further information can be found in the bibliography that follows, as well as in many documents produced by the International Organization for Standardization (ISO) and related organizations (e.g., ANSI, DIN, BSI, CEN).

Relationships Among Univariate Statistical Distributions

Lawrence M. Leemis
Professor
The College of William & Mary, Williamsburg, VA, USA

Certain statistical distributions occur so often in applications that they are named. Examples include the binomial, exponential, normal, and uniform distributions. These distributions typically have *parameters* that allow for a certain degree of flexibility for modeling. Two important applications of these common statistical distributions are: (a) to provide a probability model the outcome of a random experiment, and (b) to provide a reasonable approximation to a data set.

Statistical distributions are traditionally introduced in separate sections in introductory probability texts, which obscures the fact that there are relationships between these distributions. The purpose of this section is to overview the various types of relationships between these common univariate distributions.

Common distributions and their relationships are presented in the encyclopedic work of Johnson et al. (1994, 1995) and Johnson et al. (2005). More concise treatments are given in Balakrishnan and Nevzorov (2003), Evans et al. (2000), Patel et al. (1976), Patil et al. (1985a, b), and Shapiro and Gross (1981). Figures that highlight the relationships between distributions are given in Casella and Berger (2002), Leemis and McQueston (2008), Marshall and Olkin (1985), Morris and Lock (2009), Nakagawa and Yoda (1977), Song (2005), and Taha (1982).

Since there are well over 100 named distributions used by probabilists and statisticians, the next three sections simply classify and illustrate some of the relationships.

Special Cases

The first type of relationship between statistical distributions is known as a *special case*, which occurs when one distribution collapses to a second distribution for certain settings of its parameters. Two well-known examples are:

- A ▶gamma distribution collapses to the exponential distribution when its shape parameter equals 1.
- A normal distribution with mean μ and variance σ^2 collapses to a standard normal distribution when $\mu = 0$ and $\sigma = 1$.

There are also certain special cases in which two statistical distributions overlap for a single setting of their parameters. Examples include (a) the exponential distribution with a mean of two and the ▶chi-square distribution with two degrees of freedom, (b) the chi-square distribution with an even number of degrees of freedom and the Erlang distribution with scale parameter two, and (c) the Kolmogorov–Smirnov distribution (all parameters known case) for a sample of size $n = 1$ and the $U(1/2,1)$ distribution, where U denotes the uniform distribution (see ▶Uniform Distribution in Statistics).

Transformations

The second type of relationship between statistical distributions is known as a *transformation*. The term "transformation" is used rather loosely here, to include the distribution of an order statistic, truncating a random variable, or taking a mixture of random variables. Some well-known examples include:

- The random variable $(X - \mu)/\sigma \sim N(0,1)$ when $X \sim N(\mu, \sigma^2)$, where N denotes the normal distribution.
- An Erlang random variable is the sum of mutually independent and identically distributed exponential random variables.
- The natural logarithm of a log normal random variable has the normal distribution.
- A hyperexponential random variable is the mixture of mutually independent exponential random variables.
- An order statistic taken from a sample of mutually independent $U(0,1)$ random variables has the ▶beta distribution.

- A geometric random variable is the floor of an exponential random variable.
- If X has the F distribution with parameters n_1 and n_2, then $\left(1 + (n_1/n_2)X\right)^{-1}$ has the beta distribution.
- If $X \sim U(0,1)$ then the floor of 10^X has the Benford distribution (Benford 1938).

It is also the case that two random variables from different statistical families can be combined via a transformation to form another common distribution, for example,

$$\frac{Z}{\sqrt{Y/n}} \sim t(n)$$

where $t(n)$ is the t distribution with n degrees of freedom, Z is a standard normal random variable, and Y is a chi-square random variable with n degrees of freedom that is independent of Z.

Limiting Relationships

The third type of relationship between statistical distributions is known as a *limiting* or *asymptotic* relationship, which is typically formulated in the limit as one or more parameters approach the boundary of the parameter space. Three well-known examples are:

- A standard normal distribution is the limit of a t distribution as its degrees of freedom parameter approaches infinity.
- If $X_1, X_2, \ldots, X_n$ are mutually independent $U(0,1)$ random variables, then

$$n(1 - \max\{X_1, X_2, \ldots, X_n\})$$

  approaches an exponential random variable in the limit as $n \to \infty$.
- The gamma distribution approaches the normal distribution as its shape parameter approaches infinity.

Bayesian Relationships

The fourth type of relationship between statistical distributions is known as a *Bayesian* or *stochastic parameters* relationship, in which one or more of the parameters of a distribution are considered to be random variables rather than fixed constants. Two well-known examples are:

- If a random variable has a ▶binomial distribution with fixed parameter n and random parameter p which has the beta distribution, then the resulting random variable has the beta–binomial distribution.
- If a random variable has a negative binomial distribution with fixed parameter n and random parameter p which has the beta distribution, then the resulting random variable has the beta-negative binomial distribution.

Internal Properties

The fifth and last type of relationship between statistical distributions is actually a relationship between a statistical distribution and itself. There are occasions when a particular operation on one or more random variables from a certain statistical family result in a new random variable that remains in that family. These are best thought of as properties of a statistical distribution rather than relationships between statistical distributions. Some well-known examples include:

- The *linear combination* property indicates that linear combinations of mutually independent random variables having this particular distribution come from the same distribution family. For example, if $X_i \sim N\left(\mu_i, \sigma_i^2\right)$ for $i = 1, 2, \ldots, n$; $a_1, a_2, \ldots, a_n$ are real constants, and $X_1, X_2, \ldots, X_n$ are mutually independent, then

$$\sum_{i=1}^{n} a_i X_i \sim N\left(\sum_{i=1}^{n} a_i \mu_i, \sum_{i=1}^{n} a_i^2 \sigma_i^2\right).$$

- The *convolution* property indicates that sums of mutually independent random variables having this particular distribution come from the same distribution family. For example, if $X_i \sim \chi^2(n_i)$ for $i = 1, 2, \ldots, n$, and $X_1, X_2, \ldots, X_n$ are mutually independent, then

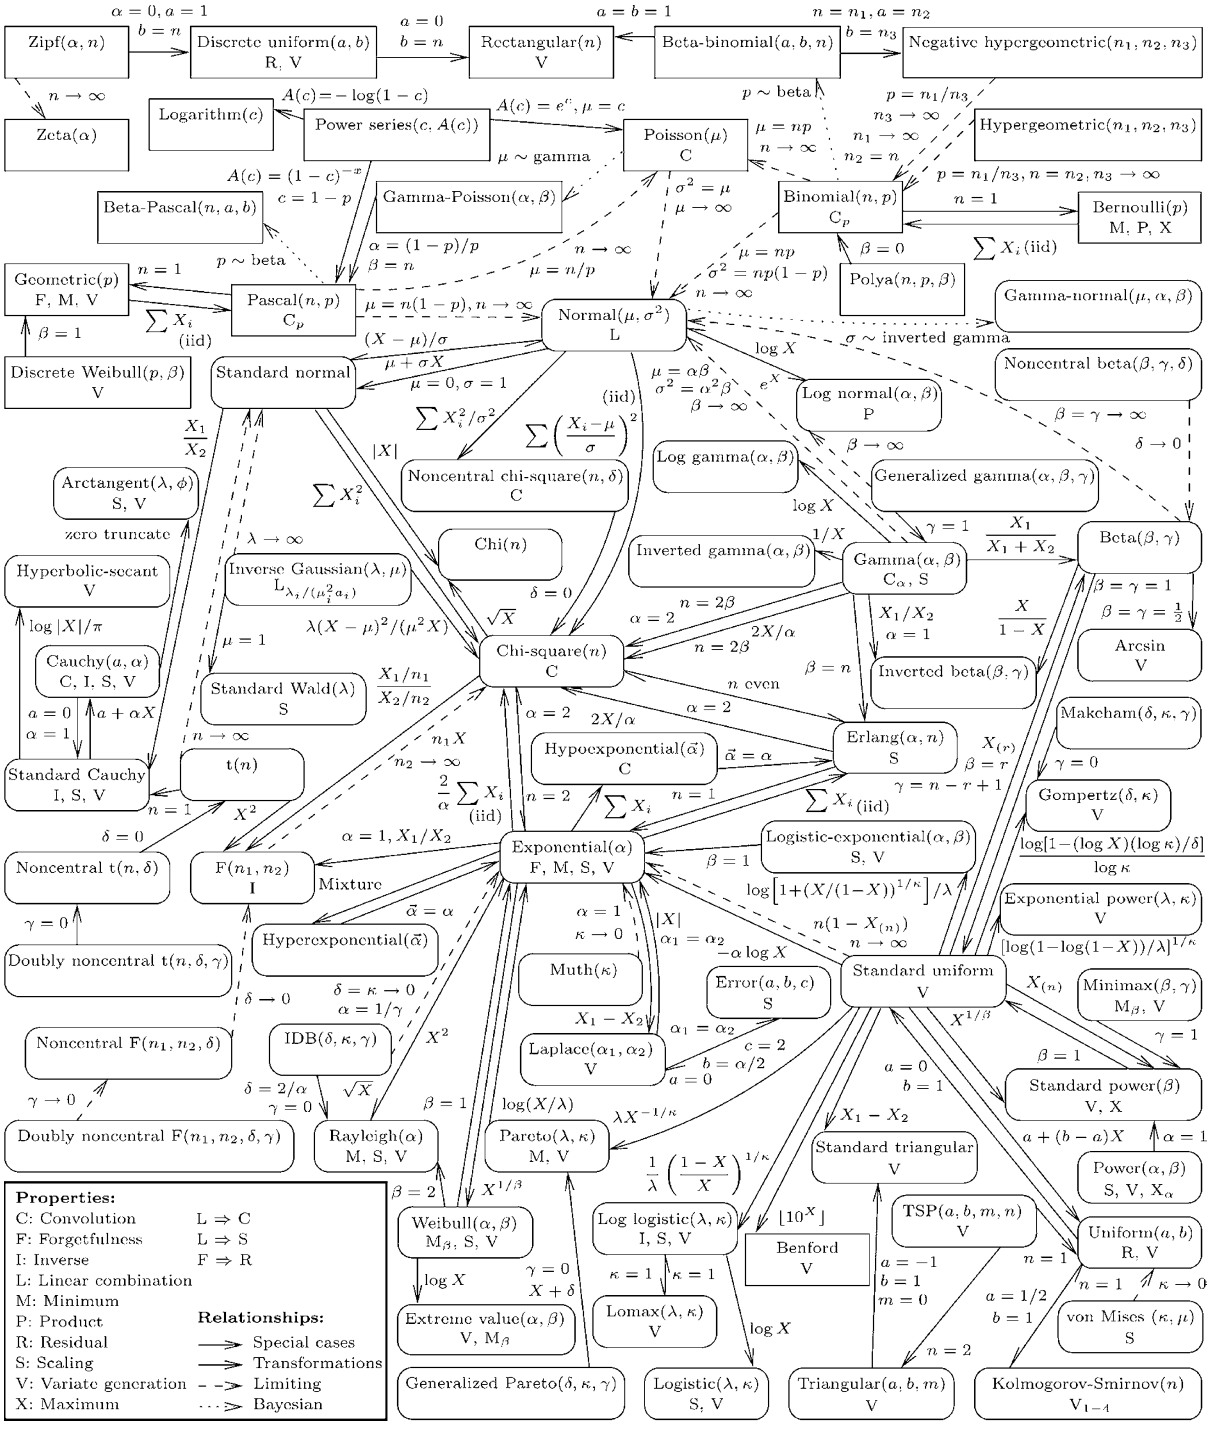
$$\sum_{i=1}^{n} X_i \sim \chi^2\left(\sum_{i=1}^{n} n_i\right),$$

  where χ^2 denotes the chi-square distribution. The convolution property is a special case of the linear combination property.
- The *scaling* property implies that any positive real constant times a random variable having this distribution comes from the same distribution family. For example, if $X \sim Weibull(\alpha, \beta)$ and k is a positive, real constant, then

$$kX \sim Weibull(\alpha k^{\beta}, \beta).$$

- The *product* property indicates that products of mutually independent random variables having this particular distribution come from the same distribution family. For example, if $X_i \sim \log\ normal\left(\mu_i, \sigma_i^2\right)$ for $i = 1, 2, \ldots, n$, and $X_1, X_2, \ldots, X_n$ are mutually independent, then

$$\prod_{i=1}^{n} X_i \sim log\ normal\left(\sum_{i=1}^{n} \mu_i, \sum_{i=1}^{n} \sigma_i^2\right).$$



Relationships Among Univariate Statistical Distributions. Fig. 1 Univariate distribution relationships

- The *inverse* property indicates that the reciprocal of a random variable of this type comes from the same distribution family. For example, if $X \sim F(n_1, n_2)$ then

$$\frac{1}{X} \sim F(n_2, n_1),$$

where F denotes the F distribution.

- The *minimum* property indicates that the smallest of mutually independent and identically distributed random variables from a distribution comes from the same distribution family. For example, if $X_i \sim exponential(\lambda_i)$ for $i = 1, 2, \ldots, n$, and $X_1, X_2, \ldots, X_n$ are mutually independent, then

$$\min\{X_1, X_2, \ldots, X_n\} \sim exponential\left(\sum_{i=1}^{n} \lambda_i\right),$$

  where the exponential parameter is a rate.
- The *residual* property indicates that the conditional distribution of a random variable left-truncated at a value in its support belongs to the same distribution family as the unconditional distribution. For example, if $X \sim U(a, b)$, and k is a real constant satisfying $a < k < b$, then the conditional distribution of X given $X > k$ belongs to the uniform family.

Many of the relationships described here are contained in Fig. 1 from Leemis and McQueston (2008), which is reprinted with permission from *The American Statistician*.

About the Author

Dr. Lawrence Leemis is a Professor and former Department Chair, Department of Mathematics, The College of William & Mary in Virginia, U.S.A. He has authored or co-authored more than 100 articles, book chapters, and reviews. He has published three books: *Reliability: Probabilistic Models and Statistical Methods* (Prentice-Hall, 1995), *Discrete-Event Simulation: A First Course*, with Steve Park, (Prentice-Hall, 2006), and *Computational Probability: Algorithms and Applications in the Mathematical Sciences*, with John Drew, Diane Evans, and Andy Glen (Springer, 2008). He has won more than ten research and teaching awards, including the INFORMS Computing Society Prize in 2006. He is currently an associate editor for *Naval Research Logistics*, and has previously been an associate Editor for *IEEE Transactions on Reliability* and a Book Reviews Editor for the *Journal of Quality Technology*.

Renewal Processes

Kosto V. Mitov[1], Michael A. Zazanis[2]
[1]Professor, Faculty of Aviation

[2]Professor
Athens University of Economics and Business, Athens, Greece

Let $\{X_n; n \in \mathbb{N}\}$ be a sequence of independent, identically distributed random variables with values in $\mathbb{R}^+$ and distribution function F. The process $\{S_n; n \in \mathbb{N}_0\}$ defined

by means of $S_0 := 0$, $S_n := S_{n-1} + X_n$, $n = 1, 2, \ldots$ is called an *ordinary renewal process*. The non-negative random variables X_n are called increments or, in many applications, inter-event times. In connection with the sequence of random points in time, $\{S_n\}$, one can define the *counting process* $N_t = \sum_{n=0}^{\infty} 1(S_n \le t)$, $t \in \mathbb{R}^+$, where $1(A)$ designates the *indicator function* of the event A (which is 1 if A occurs and 0 otherwise). The *renewal function* associated with a renewal process is the increasing, right-continuous function $U(t) := EN_t = \sum_{n=0}^{\infty} F^{*n}(t)$ where $F^{*n}(t)$ denotes the n-fold *convolution* of the distribution function F with itself (hence $F^{*n}(t) = P(S_n \le t)$).

Renewal processes are intimately related to the theory of the so-called *renewal equation* which is a linear integral equation of the form

$$Z(x) = z(x) + \int_0^x Z(x-y)F(dy) \tag{1}$$

where $z : \mathbb{R}^+ \to \mathbb{R}$ is a Borel function, bounded on finite intervals, and F a probability distribution on $\mathbb{R}^+$. F and z are assumed to be given and the object is to determine the (unique) solution Z which is bounded on finite intervals, and study its asymptotic behavior as $x \to \infty$. Its solution is given, in terms of the renewal function by the convolution $Z(x) = \int_0^x z(x-y)U(dy)$.

Renewal processes are important as special cases of random ▶point processes. In this respect the Poisson process (see ▶Poisson Processes) on the real line is the simplest and most important renewal process. They occur naturally in the theory of replacement of industrial equipment, the theory of queues, in branching processes, and in many other applications. In the framework of perpetual replacement of a single item, X_n is the life of the nth such item which, as soon as it fails, is replaced by a new one with independent duration distributed according to F. Then N_t is the number of items used in the time interval $[0, t]$ and S_{N_t} is the time of the last replacement before t. We define three additional processes $\{A_t; t \ge 0\}$, $\{B_t; t \ge 0\}$, and $\{C_t; t \ge 0\}$ as follows: $A_t := t - S_{N_t - 1}$ is the *age*, $B_t := S_{N_t} - t$ is the *remaining life*, and $C_t := A_t + B_t = X_{N_t}$ is the total life duration of the item currently in use. (The age and remaining life are also known as the backward and forward recurrence times.) The statistics of these processes can be described by means of appropriate renewal equations. For instance, if $W_x(t) := P(A_t \le x)$ then conditioning on S_1 (using the so-called "renewal argument") we obtain

$$W_x(t) = (1 - F(t))1(t \le x) + \int_0^t W_x(t-s)dF(s). \tag{2}$$

If we allow the first increment to have a different distribution from all the others, i.e. if we set $S_0 = X_0$ and $S_n = S_{n-1} + X_n$, $n = 1, 2, \ldots$ where X_0 is independent of the $\{X_n\}$ and, unlike them, has distribution F_0, different from F, we obtain a *delayed renewal process*. This type of process is important because it provides additional flexibility in accommodating different initial conditions. Of course, its limiting properties are not affected by this modification. Of particular importance, assuming the mean m to be finite, is the choice $F_0 = F_I$, given by

$$F_I(x) := \frac{1}{m} \int_0^x (1 - F(y))dy. \tag{3}$$

With this choice, $\{S_n\}$ becomes a *stationary point process*. F_I is called the *integrated tail distribution* associated with the distribution F.

Of fundamental importance are the limit theorems related to renewal processes. If $m := \int_0^{\infty} xdF(x)$ denotes the mean of the increments, then the *Elementary Renewal Theorem* states that $\lim_{t\to\infty} t^{-1}U(t) = m^{-1}$. (The result holds also in the case $m = \infty$ provided that we interpret m^{-1} as 0.) A refinement is possible if the increments have finite second moment, in which case $\lim_{t\to\infty} (U(t) - t/m) = EX_1^2/(2m^2)$. An analogous bound, due to Lorden (1970), also holds for all $t \ge 0$: $U(t) \le t/m + EX_1^2/m^2$. When the second moment exists we also have a Central Limit Theorem for the number of events up to time t: As $t \to \infty$, $\frac{N_t - t/m}{\sigma\sqrt{t/m^3}} \xrightarrow{d} Z$ where Z is a standard Normal random variable and $\sigma^2 = Var(X_1)$.

Much deeper is *Blackwell's Theorem* which states that, if F in non-lattice and the mean m is finite then

$$\lim_{t\to\infty} (U(t+h) - U(t)) = h/m \qquad \text{for all } h > 0. \tag{4}$$

(A distribution F on $\mathbb{R}^+$ is *lattice* with lattice size δ if there exists $\delta > 0$ such that the support of F is a subset of $\{n\delta; n = 0, 1, 2, \ldots\}$ and δ is the largest such number.) If F is lattice (δ) then (4) still holds, provided that h is an integer multiple of δ. Also, if $m = \infty$ the theorem still holds with $m^{-1} = 0$. Blackwell's original proof (1948) of (4) depended on harmonic analysis techniques. In the 1970s with the widespread use of coupling techniques simpler probabilistic proofs of the renewal theorem became available. (See Lindvall [1992] for a complete account.) An integral version of Blackwell's theorem, the *Key Renewal Theorem*, states that, if z is directly Riemann integrable then the limit $\lim_{x\to\infty} \int_0^x z(x-y)dU(y)$ exists and equals $m^{-1} \int_0^{\infty} z(x)dx$. This then gives the limiting behavior of any function which satisfies a renewal equation (1). (Direct Riemann integrability is a direct extension of the Riemann

integral from bounded intervals to unbounded ones: Fix $h > 0$ and let $\overline{\gamma}_n(h) = \sup_{nh \le x < (n+1)h} z(x)$, $\underline{\gamma}_n(h) = \inf_{nh \le x < (n+1)h} z(x)$. Set $\overline{I}(h) := \sum_{n=0}^{\infty} h\overline{\gamma}_n(h)$ and $\underline{I}(h) := \sum_{n=0}^{\infty} h\underline{\gamma}_n(h)$. Clearly, if $h_1 > h_2 > 0$ then $\underline{I}(h_1) \le \underline{I}(h_2) \le \overline{I}(h_2) \le \overline{I}(h_1)$, though these quantities may not necessarily be finite. If $\lim_{h\to 0} \underline{I}(h)$ and $\lim_{h\to 0} \overline{I}(h)$ exist and are equal then z is directly Riemann integrable. It should be noted that the direct Riemann integral is more restrictive than either the improper Riemann integral or the Lebesgue integral.)

The discrete version of the renewal theorem is simpler but not elementary. Suppose we are given a probability distribution $\{f_n; n = 1, 2, \ldots\}$ which is *non–arithmetic*, i.e. g.c.d.$\{n : f_n > 0\} = 1$ and has mean $m = \sum_{n=1}^{\infty} nf_n$, and define the renewal sequence $\{u_n; n = 0, 1, 2, \ldots\}$ via $u_0 = 1$, $u_n = f_n + f_{n-1}u_1 + \cdots + f_1 u_{n-1}$. Then $\lim_{n\to\infty} u_n = m^{-1}$ (interpreted as 0 when $m = \infty$). This is the celebrated Erdös–Feller–Pollard (1948) renewal theorem (see Feller [1968, 1971, Vol. 1, Chap. 13]) which marks the beginning of modern renewal theory and played a central rôle in the treatment of ▶Markov chains with countable state space. Interesting behavior arises if the non-arithmetic distribution function $\{f_n\}$ has infinite mean: Suppose that $\sum_{k=n+1}^{\infty} f_k = L(n)n^{-\alpha}$ where $0 < \alpha < 1$ and $L(n)$ is a *slowly varying* function. (A real function L is said to be slowly varying if it is positive, measurable, and for every $\lambda > 0$, $L(\lambda x)/L(x) \to 1$ as $x \to \infty$.) Then (Garsia and Lamperti 1962) $\lim_{n\to\infty} n^{1-\alpha} L(n)u_n = \pi^{-1} \sin \pi\alpha$. If $1/2 < \alpha < 1$, this can be sharpened to $\lim_{n\to\infty} n^{1-\alpha} L(n)u_n = \pi^{-1} \sin \pi\alpha$. Analogous results in continuous time are also proved. Suppose that $F(.)$ is continuous, $F(0+) = 0$, $F(\infty) = 1$, $m = \infty$, and

$$1 - F(t) \sim \frac{t^{-\alpha} L(t)}{\Gamma(1-\alpha)} \Leftrightarrow m(t) := \int_0^t (1 - F(u))du \sim \frac{t^{1-\alpha} L(t)}{\Gamma(2-\alpha)}, \; t \to \infty, \qquad (5)$$

where $\alpha \in [0, 1)$ and $L(\cdot)$ is a slowly varying function at infinity. Under these conditions the growth rate of $U(t)$ is given by (see e.g. Bingham et al. [1987, Chap. 8]),

$$U(t) \sim C_\alpha t/m(t), \text{ as } t \to \infty, \text{ where } C_\alpha = [\Gamma(\alpha+1)\Gamma(2-\alpha)]^{-1}.$$

Erickson (1970) proved a version of Blackwell's theorem in the infinite mean cycle case. It states that if in (5), $\alpha \in \left(\frac{1}{2}, 1\right]$, then for any fixed $h > 0$

$$\lim_{t\to\infty} m(t)[U(t) - U(t-h)] = C_\alpha h.$$

If $\alpha \in \left(0, \frac{1}{2}\right]$, then lim has to be replaced by lim. Several versions of the Key Renewal Theorem in the infinite mean cycle case are also proved in Teugels (1968), Erickson (1970), and Anderson and Athreya (1987).

Using the Key Renewal Theorem one can obtain the asymptotic behavior of the age and the current and residual life. If Y is a random variable with distribution $P(Y \le y) = \frac{1}{m}\int_0^y x dF(x)$ and V is uniform in $[0, 1]$ and independent of Y, then

$$(A_t, B_t, C_t) \xrightarrow{d} (VY, (1-V)Y, Y) \text{ as } t \to \infty.$$

In particular the limiting marginal distribution of the age (which is the same as that of the residual life) is

$$\lim_{t\to\infty} P(A_t \le x) = F_I(x),$$

the integrated tail distribution given in (3). The limiting behavior of these processes gives rise to the so called "renewal paradox." For instance, the limiting distribution of the item currently in use is

$$\lim_{t\to\infty} P(C_t \le x) = \frac{1}{m}\int_0^x y dF(y)$$

with corresponding mean, provided that the second moment of F exists, given by $m + \sigma^2/m$. Hence if we inspect such a process a long time after it has started operating (and is therefore in equilibrium) the part we are going to see will have longer life duration than average. Of course this is simply an instance of *length-biased sampling* and its effects are more pronounced when the variability of the distribution F around its mean is large.

In the infinite mean cycle case the life time processes A_t and B_t have a linear growth to infinity, i.e. the normalized processes A_t/t and B_t/t have non-degenerate limit laws, jointly or separately. This result is usually called the Dynkin–Lamperti theorem (Dynkin 1955; Lamperti 1962). (See also Bingham et al. [1987, Chap. 8]). The theorem states that the condition (5) with $\alpha \in (0, 1)$ is necessary and sufficient for the existence of non-degenerate limit laws for A_t/t, B_t/t,

$$\lim_{t\to\infty} P(A_t/t \le x) = \pi^{-1} \sin \pi\alpha \int_0^x u^{-\alpha}(1-u)^{\alpha-1}, \quad 0 < x < 1,$$

$$\lim_{t\to\infty} P(B_t/t \le x) = \pi^{-1} \sin \pi\alpha \int_0^x u^{-\alpha}(1+u)^{-1} du, \quad x > 0.$$

An important and immediate generalization of the renewal equation (1) is to allow F to be a general positive finite measure on $\mathbb{R}^+$. Setting $\|F\| := F(\mathbb{R}^+)$ one distinguishes the *excessive* case where $\|F\| > 1$, the *defective* case where $\|F\| < 1$, and the *proper* case we have already discussed, where $\|F\| = 1$. In the excessive case one can always find

a (unique) $\beta > 0$ such that $\int_0^\infty e^{-\beta x} dF(x) = 1$. One can define then a probability distribution function $F^\#$ via the relationship $dF^\#(x) = e^{-\beta x} dF(x)$, $x \geq 0$. Multiplying both sides of (1) by $e^{-\beta x}$ and setting $z^\#(x) = e^{-\beta x} z(x)$, $Z^\#(x) = e^{-\beta x} Z(x)$, the proper renewal equation $Z^\#(x) = z^\#(x) + \int_0^x z^\#(x-y) dF^\#(y)$ is obtained. The Key Renewal Theorem then yields

$$\lim_{x\to\infty} e^{-\beta x} Z(x) = \frac{1}{m^\#} \int_0^\infty z^\#(y) dy,$$

which establishes that, asymptotically, Z grows exponentially with rate β. We should point out that the defective case is not entirely similar. While formally one again tries to identify $\beta > 0$ so that $\int_0^\infty e^{\beta x} dF(x) = 1$, this may or may not be possible according to whether the distribution function $\frac{1}{\|F\|} F(x)$ is *light-tailed* or *heavy-tailed*. In the former case one proceeds just as in the excessive case. (For more details see Feller [1968, 1971, Vol. 2, Chap. 11]). This type of analysis is characteristic of the applications of renewal theory to areas such as population dynamics, the theory of collective insurance risk, and to the economic theory or replacement and depreciation (Jorgenson 1974; Feldstein and Rothchild 1974).

Alternating renewal processes arise in a natural way in many situations, like queueing systems and reliability of industrial equipment, where working(busy) periods (X) interchange with idle periods (T). Consider a sequence of random vectors with non-negative coordinates (T_i, X_i), $i = 1, 2, \ldots$. It defines an *alternating renewal sequence* (S_n, S'_{n+1}) as follows $S_0 = 0$, $S'_n = S_{n-1} + T_n$, $S_n = S'_n + X_n = S_{n-1} + (T_n + X_n)$, $n = 1, 2, \ldots$. An interpretation in terms of the reliability theory is the following. There are two types of renewal events: S_n is the moment when the installation of a new element begins (The installation takes time T_n); S'_{n+1} is the moment when the installation ends and the new element starts working. (The working period has length X_n). The renewal process $N(t) = \sup\{n : S_n \leq t\}$ counts the pairs of renewal events in the interval $[0, t]$. The processes $\sigma_t = \max\{0, t - S'_{N(t)+1}\}$ – *spent working time* and $\tau_t = \min\{S_{N(t)+1} - t, X_{N(t)+1}\}$ – *residual working time* generalize the lifetime processes A_t and B_t. Their properties are derived in Mitov and Yanev (2001) in the infinite mean cycle case.

The central place that renewal theory holds in the analysis of stochastic systems is due to the concept of *regeneration*. Let $\{X_t; t \in \mathbb{R}^+\}$ be a process with values in $\mathcal{S}$ (e.g. a Euclidean space $\mathbb{R}^d$) and sample paths that are càdlàg (right-continuous with left-hand limits) a.s.. Such a process is called *regenerative* with respect to a (possibly delayed) renewal process $\{S_n\}$, defined on the same probability space, if, for each $n \in \mathbb{N}$ the *post* S_n *process* $(\{X_{S_n+t}\}_{t\geq 0}, \{S_{n+k} - S_n\}_{k\in\mathbb{N}})$ is independent of $\{S_0, S_1, \ldots, S_n\}$ and its distribution does not depend on n, i.e. $(\{X_{S_n+t}\}_{t\geq 0}, \{S_{n+k} - S_n\}_{k\in\mathbb{N}}) \stackrel{d}{=} (\{X_{S_0+t}\}_{t\geq 0}, \{S_k - S_0\}_{k\in\mathbb{N}})$ for all n. The existence of an embedded, non-lattice renewal process with respect to which the process $\{X_t\}$ is regenerative, together with the finiteness of the mean $m := E[S_1 - S_0]$ is enough to guarantee the existence of a "stationary version," say $\{\tilde{X}_t\}$, to which $\{X_t\}$ converges as t goes to infinity. The statistics of $\{\tilde{X}_t\}$ can be determined by analyzing the behavior of $\{X_t\}$ over any *regenerative cycle*, i.e. a random time interval of the form $[S_n, S_{n+1})$. If $k \in \mathbb{N}$, $t_i \in \mathbb{R}^+$, $i = 1, 2, \ldots, k$, and $f : \mathcal{S}^k \to \mathbb{R}$ is any bounded, continuous function then

$$Ef(\tilde{X}_{t_1}, \ldots, \tilde{X}_{t_k}) = \frac{1}{m} E \int_{S_0}^{S_1} f(X_{t_1+t}, \ldots, X_{t_k+t}) dt.$$

Nowadays, our view of whole areas of probability, including parts of the theory of ▶Markov processes is influenced by renewal theoretic tools and related concepts of regeneration. The analysis of many stochastic models is greatly facilitated if one identifies certain embedded points in time that occur according to a renewal process and with respect to which the process is regenerative. The fact that these regeneration cycles are independent, identically distributed, also facilitates the statistical analysis of the simulation output of regenerative systems.

A detailed representation of the renewal theory and its applications could be found, for instance, in the following books Asmussen (2003), Bingham et al. (1987), Feller (1968, 1971), and Resnick (1992).

Repeated Measures

Geert Molenberghs
Professor
Universiteit Hasselt & Katholieke Universiteit Leuven, Leuven, Belgium

Repeated measures are obtained whenever a specific response is measured repeatedly in a set of units. Examples are hearing thresholds measured on both ears of a set of subjects, birth weights of all litter members in a toxicological animal experiment, or weekly blood pressure measurements in a group of treated patients. The last example is different from the first two examples in the sense that the time dimension puts a strict ordering on the obtained measurements within subjects. The resulting data are therefore often called longitudinal data. Obviously, a correct statistical analysis of repeated measures or longitudinal data can only be based on models which explicitly take into account the clustered nature of the data. More specifically, valid models should account for the fact that repeated measures within subjects are allowed to be correlated. For this reason, classical (generalized) linear regression models are not applicable in this context. An additional complication arises from the highly unbalanced structure of many data sets encountered in practice. Indeed, the number of available measurements per unit is often very different between units, and, in the case of longitudinal data, measurements may have been taken at arbitrary time points, or subjects may have left the study prematurely, for a number of reasons (sometimes known but mostly unknown). A large number of models have been proposed in the statistical literature, during the last few decades. Overviews are given in Verbeke and Molenberghs (2000) and Molenberghs and Verbeke (2005).

According to Lavrakas (2008), a representative sample is one that ensures external validity in relationship to the population of interest the sample is meant to represent. In addition, it should be said that a representative sample is a probability sample, so, *sampling errors* for estimates can be calculated and the *estimates* from the sample survey can be generalized with confidence to the sampling population.

Random selection, i.e., being objective and unbiased, is an essential element of *survey sampling*. There are many factors that affect the representativeness of a sample, though traditionally attention has mostly been paid to sample design and coverage. More recently, the focus has extended to the nonresponse issues.

Zarkovic (1956), Kruskal and Mosteller (1980), Bellhouse (1988), Kish (2002), and Rao (2005) wrote histories of random sampling methods as representative methods. The statistical literature gives examples of all the meanings for "representative sampling," such as: general acceptance for data; absence of selective forces; miniature of the population; typical or ideal cases; and proper coverage of the population. Kruskal and Mosteller (1979) added the following new meanings: representative sampling as a specific sampling method; representative sampling as permitting unbiased estimation; and representative sampling as sufficient to serve a particular purpose. Occasionally, it is also determined as a vague term.

The development of modern *sampling theory* started in around 1895 when the Norwegian statistician A.N. Kiaer, the first director of Statistics Norway, published his *Representative Method* and was the first to promote "the representative method" over the ►*census* as a complete enumeration. Kiaer stated that if a sample was representative with respect to variables for which the population distribution was known, it would also be representative with respect to other survey variables. For Kiaer, a representative sample is a "miniature" of the actual population, though the selection of units is based on *purposive selection*, according to a rational scheme based on general results of previous investigations. He presented his thoughts at a meeting of the International Statistical Institute in Bern in 1895. Many famous statisticians did not agree on Kiaer's new approach, as no measure of the accuracy of the estimates could be obtained. A basic problem was that the representative method lacked a formal theory of inference.

It was Sir A.L. Bowley, an English statistician, who pioneered the use of *simple random sampling*, for which the accuracy measures of estimates could be computed. He introduced *stratified random sampling* with *proportional allocation*, leading to a representative sample with equal *inclusion probabilities*. By the 1920s, the representative method was widely used. In 1924, the International Statistical Institute played a prominent role with its formation of a committee to report on the representative method. In 1935, Polish scientist J. Neyman published his now famous paper (Neyman 1934). He developed a new theory and laid the theoretical foundations for design-based sampling or the probability sampling approach to inference from survey samples. He showed that stratified random sampling is preferable to ►balanced sampling and introduced the *optimal allocation* of units based on efficiency in his theory of stratified random sampling without replacement, by relaxing the condition of equal inclusion probabilities for sampling units. In 1943, M.H. Hansen and W.N. Hurwitz published their theory of *multistage cluster samples*. In 1944, W.G. Madow and L.H. Madow conducted the first theoretical study of the precision of *systematic sampling*. The classical theory of survey sampling was more or less completed in 1952. Horvitz and Thompson (1952) completed the classical theory, and the *random sampling* approach was almost unanimously accepted. Most of the classical books on *sampling* were also published by then: W.G. Cochran in 1953 (see the last edition: Cochran 1977), Deming (1950), Hansen et al. (1953a, b), and Yates (1949). Later, a great contribution to probability sampling was given by Kish (1965).

The representative method is applied in *survey research*, *both social and business*, in *official statistics*, for *public opinion polling*, in *market research*, etc. It is also applied for *audit sampling* and *statistical quality control*.

The sampling technique used by G. Gallup was *quota sampling* for opinion polling. Gallup's approach was in great contrast with that of *Literary Digest* magazine, the

leading polling organization at that time. This magazine conducted regular "America Speaks" polls with a *convenient sample* of the sample size near to two million people. The presidential election of 1936 turned out to be decisive for both approaches (Rao 2005). Gallup correctly predicted using a sample size of 3,000 that the candidate Alf Landon would beat Franklin Roosevelt. It seemed to be strange how could a prediction based on such a large sample be wrong? The explanation was the fatal flaw in the *Literary Digest*'s sampling mechanism. The automobile registration lists and telephone directories applied were not representative samples. In the 1930s, cars and telephones were typically owned by the middle and upper classes. More well-to-do Americans tended to vote Republican and the less well-to-do were inclined to vote Democrat. Therefore, Republicans were over represented in the *Literary Digest* sample. As a result of this famous historical error, opinion researchers learned that the *manner of selection* of a sample is more important than the *sample size*. Also, among nonprobability sample designs, a *quota sample*, if well designed, would be the most similar to a probability sample as a representative one.

In a sample survey, researchers must judge whether the sample is actually representative of the target population. The best way of ensuring a representative sample is to have a complete sampling frame (i.e., directory, list or map) covering all the elements in the population, and to know that each and every element (e.g., person, household, enterprise, etc.) on the list has a nonzero probability (equal or unequal) of being included in the sample. Furthermore, it is necessary to use random selection to draw elements from the sampling frame into the sample based either on a random number generator or on systematic selection procedure. Also, it is essential to collect complete data from every single sampled element.

Completely up-to-dated sampling frames of the populations of interest are very rare. If there are elements in the target population with a zero probability of selection, sample estimates cannot be generalized to these elements. For example, if unemployed persons belong to the population of interest, but were not registered as unemployed, then they would have a zero probability of inclusion in the sample. Further, very modern Internet surveys, Tele-Voting and Push Polling samples are not based on solid sampling frames and instead use non-representative sample designs. As such, the results in such surveys cannot be generalized to the overall population and users should be aware that these are nothing more than amusement techniques.

First, to judge the representativeness of a sample, the use of some prior knowledge about the population main variables structures is recommended, for comparison with the sample structures. Occasionally, an extra random sample is helpful. Further, to correct for biases, survey researchers apply post-stratification. Post-stratification is the process of weighting some of the respondents in the responding sample relative to others, so that the characteristics of the responding sample are essentially equal to those of the target population for those characteristics that can be controlled to complete coverage data (e.g., age, gender, educational level, geography, etc.). Applying post-stratification adjustments reduces the bias due to *noncoverage and nonresponse*. And finally, it is necessary to limit the conclusions to those elements in the sampling frame to only those with a nonzero probability of inclusion. In other words, to avoid biases, researchers need to estimate coverage, and both unit and item-nonresponse.

About the Author

Dr. Ksenija Dumicic is Professor, and, since 2006 Head of Department of Statistics, Faculty of Economics and Business, University of Zagreb, Croatia. She is founder of the postgraduate studies, Statistical Methods for Economic Analysis and Forecasting. She has been a member of Editorial Boards for several journals in Croatia, Serbia and Bosnia and Herzegovina. She has authored and coauthored more than 80 papers and two books in statistical research methodology. She specializes in statistical sample survey methods and has supervised over 10 postgraduate students.

Research Designs

Roxana Toma, G. David Garson
North Carolina State University, Raleigh, NC, USA

Introduction

Research design is a term broadly referring to any plan for gathering data systematically in such a way as to be able to arrive at conclusions. On the subject selection dimension, designs may be experimental, quasi-experimental, or non-experimental. On the measurement dimension, designs may be between-subjects or within-subjects.

Experimental studies are characterized by ►randomization of subjects into treatment and control groups. Control groups may receive no treatment or some standard treatment, where "treatment" is exposure to some stimulus. Randomization serves to control for variables which are not included explicitly in the study. In quasi-experimental designs, treatment and comparison groups are not composed of randomized subjects, even if data are gathered through random sampling. In the absence of randomization, control for confounding variables must be accomplished explicitly through statistical techniques. Finally, a design is non-experimental if there is systematic collection of data with respect to topics of interest but there is no randomization of subjects as in experimental studies nor statistical controls as in quasi-experimental designs. Most case study designs exemplify this category.

By type of measurement, between-subjects designs are the most common. The researcher is comparing between subjects who experience different treatments. There are different subjects for each level of the independent variable(s). Any given subject is exposed to only one level and comparisons are made between subjects' reactions or effects. In contrast, in within-subjects designs the same subjects are measured for each level of the independent variable, as in before-after studies or panel studies. Similar subjects, as in matched pair's designs, are of the same type. When subjects are measured more than once, within-subjects designs are also called repeated measures designs. Since the subjects are the same for all levels of the independent variable(s), they are their own controls (i.e., subject variables are controlled). However, there is greater danger to validity in the form of carryover effects due to exposure to earlier levels in the treatment sequence (e.g., practice, fatigue, attention) and there is danger of attrition in the sample. Counterbalancing is a common but not foolproof strategy to address carryover effects: e.g., half the subjects get treatment *A* first, then *B*, while the other half get B first, then *A*.

Factorial and Block Designs

Factorial designs use categorical independent variables to establish groups. For instance, in a two factor design, the independent variables might be information type (fiction, non-fiction) and media type (television, print, Internet), generating two times three = six categories. A factorial design is "fully crossed" if there is a group for every possible combination of factors (independent variables). An "incomplete" factorial design, leaving out some of the groups, may be preferred if some combinations of values of factors are nonsensical or of no theoretical interest. In experimental designs, an equal number of subjects are assigned randomly to each of the six possible groups (e.g., to the fiction-television group). The researcher might then measure subjects on information retention. A null outcome would be indicated by the average retention score being the same for all six groups of the factorial design. Unequal mean retention scores would indicate a main effect of information type or media type, and/or an interaction effect of both. Quasi-experimental designs may also be factorial, but groups are established by stratified random sampling, not randomization of subjects, entailing the need for more complex and explicit statistical controls and possibly less conclusive results.

Balanced designs are simply factorial designs where there are equal numbers of cases in each subgroup (cell) of the design, assuring that the factors are independent of one another (but not necessarily the covariates). Unbalanced designs have unequal n's in the cells formed by the intersection of the factors.

Randomized block designs stratify the subjects and for each strata, a factorial design is run. This is typically done when the researcher is aware of nuisance factors that

need to be controlled (e.g., there might be an air conditioned room stratum and a no air conditioning stratum) or if there were other mitigating structural factors known in advance (e.g., strata might be different cities). That is, the blocking variables which stratify the sample are factors which are considered to be control variables, not independent variables as they would be in a simple factorial design. Randomized block designs seek to control for the effects of main factors and their interactions, controlling for the blocking variable(s).

Nested designs have two or more factors, but the levels of one factor are never repeated as levels in the other factor(s). This happens in hierarchical designs, for instance, when a forester samples trees, then samples seedlings of each sampled tree for survival rates. The seedlings are unique to each tree and represent a random factor. Likewise, a researcher could sample drug companies, then could sample drug products for quality within each sampled company. This contrasts with crossed designs of ordinary two-way (or higher) analysis of variance, in which the levels of one factor appear as levels in another factor (e.g., tests may appear as levels across schools). We can get the mean of different tests by averaging across schools, but we cannot get the mean survival rate of different seedlings across trees because each tree has its own unique seedlings. Likewise, we cannot compute the mean quality rating for a drug product across companies because each company has its own unique set of products. Latin square and Graeco-Latin square designs discussed below are nested designs.

Random Versus Fixed Effects Designs

Most designs are fixed effects models, meaning that data are collected on all categories of the independent variables. In random effects models (also called random factors models), in contrast, data are collected only for a sample of categories. There is replaceability, meaning that the levels of the factor are randomly or arbitrarily selected and could be replaced by other, equally acceptable levels. The purpose of random effects modeling is generalizability – the researcher wishes to generalize findings beyond the particular, randomly or arbitrarily selected levels in the study. For instance, a researcher may study the effect of item order in a ►questionnaire. Six items could be ordered 720 ways. However, the researcher may limit him- or herself to the study of a sample of six of these 720 ways. The random effects model in this case would test the null hypothesis that the effects of ordering are zero. Note that "mixed factorial design" is also possible simply by having a random effects model with a fixed factor and a random factor.

Treatment by replication design is a common random effects model. The treatment is a fixed factor, such as exposure to different types of public advertising, while the replication factor is represented by the particular respondents who are treated. Sometimes it is possible and advisable to simplify analysis from a hierarchical design to a simple treatment by replication design by shifting the unit of analysis. An example would be to use class averages rather than student averages in a design in which students represent a random factor nested within teachers as another random factor (the shift drops the student random factor from analysis). Note also that the greater the variance of the random effect variable, the more levels are needed (e.g., more subjects in replication) to test the fixed (treatment) factor at a given alpha level of significance.

Common Experimental Designs

A very large number of research designs have been devised for experimental design. Though not exclusive to experimental design, the most prevalent examples are outlined below.

Completely randomized designs assign an equal number of subjects randomly to each of the cells formed by the factors. In the quasi-experimental mode, where there is no control by randomization, the researcher must measure and employ controls explicitly by using covariates.

Latin square designs extend block designs to control for two categorical variables. This design requires that the researcher assume all interaction effects are zero. Normally, if one had three variables, each of which could assume four values, then one would need $4^3 = 64$ observations just to have one observation for every possible combination. Under Latin square design, however, the number of necessary observations is reduced to $4^2 = 16$ because the third variable is nested. For instance, suppose there are 4 teachers, 4 classes, and 4 textbooks. The 16 groups in the design would be the 16 different class-textbook pairs. Each teacher would teach in each of the four classes, using a different text each time. Each class would be taught by each of the four different teachers, using a different text each time. However, only 16 of the 64 possible teacher-class-textbook combinations would be represented in the design because textbooks represent a nested factor, with each class and each teacher being exposed to a given textbook only once. Eliminating all but 16 cells from the complete (crossed) design requires the researcher to assume that there are no significant teacher-textbook or class-textbook interaction effects, only the main effects for teacher, class, and textbook.

Graeco-Latin square designs extend Latin square block designs to control for three categorical variables.

Split-plot designs. Like randomized complete block designs, in split plot designs there is still a blocking factor but each block is split into two segments and segments are assigned to the blocks in random order. Within any segment, treatments are assigned in random order. For instance, in a study of health improvement effects, the blocking factor might be in the form of three age groups, treatment in the form of three levels of dosage of medicine, with the segmentation variable being two brands of medicine. Splitting the three age blocks yields six segments, with each age group having a Brand A and Brand B segment. Each of the six segments is homogenous by brand. Split-plot designs are used when homogeneity rather than randomization within blocks is required (in agriculture, for instance, equipment considerations could dictate that any given plot segment only receive one brand of fertilizer).

Split-plot repeated measures designs can be used when the same subjects are measured more than once. In a typical split-plot repeated measures design, subjects are measured on some variable over a number of trials. Subjects are also split by some grouping variable. In this design, the between-subjects factor is the group (treatment or control) and the repeated measure is, for example, the test scores for two trials. The resulting statistical output will include a main treatment effect (reflecting being in the control or treatment group) and a group-by-trials interaction effect (reflecting treatment effect on posttest scores, taking pretest scores into account).

Common Quasi-Experimental Designs

As with experimental designs, numerous types of quasi-experimental designs exist, many enumerated in the classic work of Cook and Campbell (1979).

One-group posttest-only design. This design lacks a pretest baseline or a comparison group, making it impossible to come to reliable conclusions about a treatment effect.

Posttest-only design with nonequivalent comparison groups. In this common social science design, it is also impossible to come to reliable conclusions about treatment effect based solely on posttest information on two nonequivalent groups since effects may be due to treatment or to nonequivalencies between the groups.

Posttest-only design with predicted higher-order interactions. The presence of an interaction effect creates two or more expectations compared to the one-expectation one-group posttest-only design. Because there are more expectations, there is greater verification of the treatment effect but the explanation accounting for the interaction is more complex and therefore may be less reliable.

One-group pretest-posttest design. This is a common but flawed design subject to such threats to validity as history (events intervening between pretest and posttest), maturation (changes in the subjects that would have occurred anyway), regression toward the mean (the tendency of extremes to revert toward averages), testing (the learning effect on the posttest of having taken the pretest), and the like.

Two-group pretest-posttest design using an untreated control group. If a comparison group which does not receive treatment is added to what otherwise would be a one-group pretest-posttest design, threats to validity are greatly reduced. This is the classic experimental design but in quasi-experimental design, since the groups are not equivalent, there is still the possibility of selection bias.

Double pretest design. The researcher can strengthen pretest-posttest designs by having two (or more) pretest measures to establish if there is a trend in the data independent of the treatment effect measured by the posttest.

Regression-discontinuity design. If there is a treatment effect, then the slope of the regression line relating scores before and after treatment would be the same, but there would be a discontinuous jump in the intercept (and possibly also change in slope) following treatment. This design is extended in the simple interrupted time series design in which there are multiple pretests and posttests. The trend found in multiple pretests can be compared to the trend found in multiple posttests to assess whether apparent post-treatment improvement may simply be an extrapolation of a maturation effect which was leading toward improvement anyway.

Regression point displacement design. In this design there is a treatment group (e.g., a county) and a large number of comparison groups (e.g., other counties in the state). For instance, in a study of the effect of an after-school intervention on juvenile crime, the researcher might regress juvenile crime rates on median income in the pretest condition and note the position of the test county in the regression scattergram. In the posttest condition, the regression is re-run and the location of the test county is noted. If displaced on the scattergram, the researcher concludes that the intervention had an effect. This type of design assumes no misspecification of the model and assumes an invariant relation of independents to dependents between pretest and posttest.

Other designs. Cook and Campbell (1979) discussed other research designs for which space does not permit discussion here. These include nonequivalent dependent variables pretest-posttest designs, removed-treatment pretest-posttest designs, repeated-treatment designs, switching replications designs, reversed-treatment pretest-posttest nonequivalent comparison groups designs,

cohort designs with cyclical turnover, four-group designs with pretest-posttest and posttest-only groups, interrupted time series designs with a nonequivalent no-treatment comparison group, interrupted time series designs with nonequivalent dependent variables, interrupted time series designs with removed treatment, interrupted time series designs with multiple replications, and interrupted time series designs with switching replications.

Residuals

Samprit Chatterjee
Professor Emeritus of Statistics
Graduate School of Business Administration
Professor
New York University, New York, NY, USA

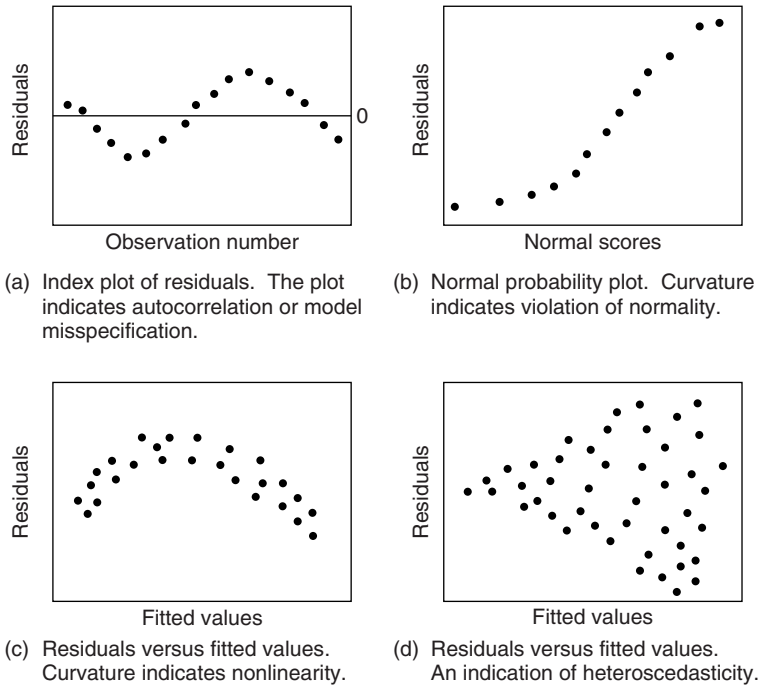
Residual is an important concept in statistical model building. Residual is defined as the difference between an observed value (Y) and the value fitted by a statistical model $\hat{Y}$

$$\text{Residual}_i = Y_i - \hat{Y}_i$$

A large value of the residual (positive or negative) shows the model does not fit the particular data point. The pattern of the residuals will often reveal the inadequacy of the fitted model. A plot of the residuals, often called the residual plot, is an important tool in regression model building. In this article we will concentrate on the role of residuals in regression analysis.

With n observations in a regression data set there will be n residuals. The sum of the n residuals from a least squares fit will be zero. Instead of working with the residuals as defined above we usually work with the standardized residuals. The residuals are scaled so they have unit standard deviation. We will call the standardized residuals for brevity residual. We will be talking about residuals obtained from least squares fit in our discussion.

The magnitude and the pattern of the distribution of residuals will reveal a great deal about the adequacy of the model describing the data. For moderate sized data the residuals can be thought of as normal deviates (mean 0, and Standard deviation 1). Large residuals, with values greater than 2 or 2.5, are called ►outliers. The data points



(a) Index plot of residuals. The plot indicates autocorrelation or model misspecification.

(b) Normal probability plot. Curvature indicates violation of normality.

(c) Residuals versus fitted values. Curvature indicates nonlinearity.

(d) Residuals versus fitted values. An indication of heteroscedasticity.

Residuals. Fig. 1 Several configurations illustrating possible violations of model assumptions

corresponding to the outliers are not well fitted by the model. These points should be examined carefully, as they often represent transcription errors or contamination of the data. By contamination of data we mean an observation which comes from another population. As an example consider a data set of weekly production of a factory. Most weeks have 5 workdays, but there may be few weeks with only 4 workdays. The weeks with 4 workdays will not be well fitted by the model, and those weeks will be outliers.

The residual plot should show no structure. The distribution should appear random. Instead of trying to describe random structure (an impossible task!) we provide examples of some commonly observed structures of residual plots, and indicate the model deficiencies they indicate.

The four graphs depicted in Fig. 1 give some of the commonly observed pattern of residual plots which indicate model deficiencies. Plot (c) indicates the data has a nonlinear component which is not included in the specified mode. Inclusion of a squared term in the model will remove the structure from the residuals.

The graph (a) indicates that the successive values are correlated, a common feature of time series data. This pattern may also arise if the model is misspecified. Methods for removing auto regression have to be adopted. Working with successive differences is a good first step.

The graph (d) indicates that the error variance is not constant and increases with size. The data is often classified as heteroscedastic. This is often referred to as the size effect. To account for the size effect, sometimes we work with logarithms of the data, use weighted least squares, or introduce a variable which reflects size.

The graph (b) is the normal plot of the residuals and is used to assess the normality of the residuals. This plot is not very effective for small sample sizes.

The residual plots are one of the most effective diagnostic plots for model fitting. No regression analysis is complete without a residual plot analysis.

Response Surface Methodology

André I. Khuri
Professor Emeritus
University of Florida, Gainesville, FL, USA

Response surface methodology (RSM) is an area of statistics that incorporates the use of design and analysis of experiments along with model fitting of a response of interest denoted by y. One of the main objectives of RSM is the determination of operating conditions on a group of control (or input) variables that yield optimal response values over a certain region of interest denoted by $\mathcal{R}$.

In a typical response surface (RS) investigation, several factors are first identified by the experimenter as having possible effects on the response y. In some experiments, the number of such factors may be large. In this case, factor screening is carried out in order to eliminate factors deemed to be unimportant. This represents the first stage in the RS investigation. The execution of this stage requires the use of an initial design which consists of a number of specified settings of the control variables. Each set of such settings is used to produce a value on the response y. A low-degree polynomial model, usually chosen to be of the first degree, is then fitted to the resulting data set. Following factor screening, additional experiments are carried out which lead to a new region of experimentation where the actual exploration of the response will take place. By this we mean fitting a suitable polynomial model of degree higher than the one used in the initial screening stage. Such a model can be expressed as

$$y = \boldsymbol{f}'(\boldsymbol{x})\boldsymbol{\beta} + \epsilon, \tag{1}$$

where $\boldsymbol{x} = (x_1, x_2, \ldots, x_k)'$ is a vector of k of control variables representing the levels of the factors that were retained after the initial screening, $\boldsymbol{f}(\boldsymbol{x})$ is a vector function of $\boldsymbol{x}$ whose elements consist of powers and cross products of powers of $x_1, x_2, \ldots, x_k$ up to a certain degree denoted by d. Typically, $d = 2$ or higher depending on the adequacy of model (1). Furthermore, $\boldsymbol{\beta}$ is a vector of p unknown parameters and ϵ is a random experimental error term assumed to have a zero mean. A commonly used form of model (1) is the second-degree model,

$$y = \beta_0 + \sum_{i=1}^{k} \beta_i x_i + \sum \sum_{i<j} \beta_{ij} x_i x_j + \sum_{i=1}^{k} \beta_{ii} x_i^2 + \epsilon. \tag{2}$$

In this case, the elements of $\boldsymbol{\beta}$ consist of β_0, the β_i's, β_{ij}'s, and β_{ii}'s $(i, j = 1, 2, \ldots, k,\ i < j)$. The quantity $\boldsymbol{f}'(\boldsymbol{x})\boldsymbol{\beta}$ in model (1) is called the mean response at $\boldsymbol{x}$ and is denoted by $\eta(\boldsymbol{x})$. Thus,

$$\eta(\boldsymbol{x}) = \boldsymbol{f}'(\boldsymbol{x})\boldsymbol{\beta}. \tag{3}$$

In order to estimate the parameter vector $\boldsymbol{\beta}$, a series of n experiments is carried out in each of which the response y is measured at specified settings of $x_1, x_2, \ldots, x_k$. Let $\boldsymbol{x}_u = (x_{u1}, x_{u2}, \ldots, x_{uk})'$, where x_{ui} is the setting of x_i at the uth experimental run, and let y_u denote the corresponding response value $(i = 1, 2, \ldots, k,\ u = 1, 2, \ldots, n)$. From model (1) we then have

$$y_u = \boldsymbol{f}'(\boldsymbol{x}_u)\boldsymbol{\beta} + \epsilon_u,\ \ u = 1, 2, \ldots, n. \tag{4}$$

Model (4) can be expressed in matrix form as

$$\boldsymbol{y} = \boldsymbol{X}\boldsymbol{\beta} + \boldsymbol{\epsilon}, \tag{5}$$

where $\boldsymbol{y} = (y_1, y_2, \ldots, y_n)'$, $\boldsymbol{X}$ is a matrix of order $n \times p$ whose uth row is $\boldsymbol{f}'(\boldsymbol{x}_u)$, and $\boldsymbol{\epsilon} = (\epsilon_1, \epsilon_2, \ldots, \epsilon_n)'$. The first

column of $\boldsymbol{X}$ is $\mathbf{1}_n$, the column of n ones. The $n \times k$ matrix,

$$\boldsymbol{D} = \begin{bmatrix} x_{11} & x_{12} & \dots & x_{1k} \\ x_{21} & x_{22} & \dots & x_{2k} \\ . & . & \dots & . \\ . & . & \dots & . \\ . & . & \dots & . \\ x_{n1} & x_{n2} & \dots & x_{nk} \end{bmatrix}, \tag{6}$$

whose rows consist of the settings of $x_1, x_2, \dots, x_k$ used at the n experimental runs is called the *design matrix*. If $\boldsymbol{\epsilon}$ is assumed to have a zero mean and a variance–covariance matrix $\sigma^2 \boldsymbol{I}_n$, where σ^2 is an unknown variance component and $\boldsymbol{I}_n$ is the matrix of ones of order $n \times n$, then $\boldsymbol{\beta}$ is estimated by the ordinary least-squares estimator,

$$\hat{\boldsymbol{\beta}} = (\boldsymbol{X}'\boldsymbol{X})^{-1}\boldsymbol{X}'\boldsymbol{y}. \tag{7}$$

The variance–covariance matrix of $\hat{\boldsymbol{\beta}}$ is

$$\mathrm{Var}(\hat{\boldsymbol{\beta}}) = (\boldsymbol{X}'\boldsymbol{X})^{-1}\sigma^2. \tag{8}$$

Using formula (3), an estimate of the mean response, $\eta(\boldsymbol{x})$, at a point $\boldsymbol{x}$ in the region of interest, $\mathcal{R}$, is given by

$$\hat{\eta}(\boldsymbol{x}) = \boldsymbol{f}'(\boldsymbol{x})\hat{\boldsymbol{\beta}},$$

which is also known as the *predicted response* at $\boldsymbol{x}$ and is denoted by $\hat{y}(\boldsymbol{x})$. Thus,

$$\hat{y}(\boldsymbol{x}) = \boldsymbol{f}'(\boldsymbol{x})\hat{\boldsymbol{\beta}}. \tag{9}$$

The variance of $\hat{y}(\boldsymbol{x})$ is then of the form

$$\mathrm{Var}[\,\hat{y}(\boldsymbol{x})] = \sigma^2 \boldsymbol{f}'(\boldsymbol{x})(\boldsymbol{X}'\boldsymbol{X})^{-1}\boldsymbol{f}(\boldsymbol{x}). \tag{10}$$

This is called the *prediction variance*. The process of selecting the design matrix $\boldsymbol{D}$ and the subsequent fitting of model (1) represents the second stage of the RS investigation.

The third stage involves the determination of optimum operating conditions on the control variables, $x_1, x_2, \dots, x_k$, that yield either maximum or minimum values of $\hat{y}(\boldsymbol{x})$ over the region $\mathcal{R}$. This is a very important stage since it amounts to determining the settings of the control variables that should be used in order to obtain "best" values for the response. For example, if y represents the yield of some chemical product, and if the corresponding control variables consist of x_1 = reaction temperature and x_2 = length of time of the reaction, then it would be of interest to determine the settings of x_1 and x_2 that result in a maximum yield.

The proper choice of the design matrix $\boldsymbol{D}$ given in formula (6) is very important. This is true because $\boldsymbol{D}$ is used to predict the response and determine its prediction variance (see formula (10)). The size of the latter quantity has to be small in order to get good quality predictions. This is particularly true since the optimization of $\hat{y}(\boldsymbol{x})$ in formula (9) leads to the determination of optimum operating conditions on $x_1, x_2, \dots, x_k$ in the third stage of a RS investigation.

Several criteria are available for the choice of the design $\boldsymbol{D}$. Some of these criteria pertain to the prediction variance, such as *D-optimality* and *G-optimality*. A review of such criteria can be found in several textbooks such as Khuri and Cornell (1996, Chap. 12), Atkinson and Donev (1992, Chap. 10) and Myers and Montgomery (1995, Sect. 8.2.1), among others. Other design criteria deal with the minimization of the bias caused by fitting the wrong model as explained in Box and Draper (1959, 1963).

If model (1) is of the first degree, that is,

$$y = \beta_0 + \sum_{i=1}^{k} \beta_i x_i + \epsilon, \tag{11}$$

then common designs for fitting the model are 2^k factorial, Plackett-Burman, and simplex designs. These are referred to as *first-order designs*. A coverage of such designs can be found in, for example, Khuri and Cornell (1996, Chap. 3) and Myers and Montgomery (1995, Chaps. 3, 4, and 7). On the other hand, if model (1) is of the second degree, as shown in formula (2), then common second-order designs include 3^k factorial, the central composite design, and the Box-Behnken design. A coverage of these designs can be found in, for example, Khuri and Cornell (1996, Chap. 4), which also includes reference to other lesser-known second-order designs (see also Myers and Montgomery 1995, Sect. 7.4).

Methods for the determination of optimum conditions on the control variables depend on the nature of the fitted model in (1). If it is of the second degree, as in model (2), then the method of ridge analysis can be used to optimize $\hat{y}(\boldsymbol{x})$ in (9). This method was introduced by Hoerl (1959) and later formalized by Draper (1963) (see also Khuri and Cornell 1996, Chap. 5). A more recent modification of this method that takes into account the size of the prediction variance was given by Khuri and Myers (1979).

Historically, the development of RSM was initiated by the work of Box and Wilson (1951) which introduced the sequential approach in a RS investigation. The article by Box and Hunter (1957) is considered to be a key paper, which along with the one by Box and Wilson (1951), provided an outline of the basic principles of RSM. Several review articles were also written about RSM. These include those by Mead and Pike (1975), Myers

et al. (1989, 2004), and Myers (1999). In addition, a comprehensive coverage of RSM can be found in the books by Khuri and Cornell (1996), Myers and Montgomery (1995), and Box and Draper (2007).

New developments and modeling trends were introduced into the RSM literature in the late 1970s. They provided further extensions of the classical techniques used in RSM. Some of these developments include the *analysis of multiresponse experiments*, which deals with several response variables that are measured for each setting of a group of control variables (see Khuri 1996a), the *response surface approach to robust parameter design* (see, for example, Myers et al. 1992), *response surface models with random effects* (see Khuri 1996b, 2006). Furthermore, in the design area, several graphical techniques were introduced for comparing response surface designs. These include the use of *variance dispersion graphs*, as in Giovannitti-Jensen and Myers (1989), the *quantile plots* of the prediction variance, as in Khuri et al. (1996), and the *fraction of design space plots* by Zahran et al. (2003). The main advantage of the graphical approach is its ability to explore the prediction capability of a response surface design throughout the region of interest, $\mathcal{R}$. By contrast, standard design optimality criteria, such as *D*- or *G-optimality*, use single-valued criteria functions to evaluate a given design. This does not give adequate information about the design's performance at various locations inside the region $\mathcal{R}$.

About the Author

Dr. André I. Khuri is Professor Emeritus, Department of Statistics, University of Florida, Gainesville, Florida, USA. He is a Fellow of the American Statistical Association (since 1992) and an Elected Member of the International Statistical Institute (since 1989). He holds two PhDs, one in mathematics (University of Florida, 1969) and one in statistics (Virginia Tech, 1976). He has published more than 100 papers in statistics journals, in addition to 5 books, including *Response Surfaces* (1987, Dekker; 2nd edition, 1996) with John Cornell, *Statistical Tests for Mixed Linear Models* (1998, Wiley) with Thomas Mathew and Bimal Sinha, *Advanced Calculus with Applications in Statistics* (1993, Wiley; 2nd edition, 2003), *Response Surface Methodology and Related Topics* (2006, an edited book, World Scientific), and *Linear Model Methodology* (2009, Chapman & Hall/CRC). Professor Khuri was Associate Editor of *Technometrics* (1983–1992) and *Journal of Statistical Planning and Inference* (1995–2003). Currently, he is Editorial Advisor for *Journal of Probability and Statistical Science* (since 2003).

Ridge and Surrogate Ridge Regressions

Ali S. Hadi
Professor and Vice Provost
The American University in Cairo, Cairo, Egypt
Emeritus Professor
Cornell University, Ithaca, NY, USA

Ridge regression is a method for the estimation of the parameters of a linear regression model (see ▶Linear Regression Models) which is useful when the predictor variables are highly *collinear*, that is, when there is a strong linear relationship among the predictor variables. Hoerl (1959) named the method *ridge regression* because of its similarity to ridge analysis used in his earlier work to study second-order response surfaces in many variables. Some standard references for ridge regression are Hoerl and Kennard (1970, 1976), Belsley et al. (1980), and Chatterjee and Hadi (2006).

The standard linear regression model can be written as

$$\mathbf{Y} = \mathbf{X}\boldsymbol{\beta} + \boldsymbol{\varepsilon}, \tag{1}$$

where $\mathbf{Y}$ is an $n \times 1$ vector of observations on the response variable, $\mathbf{X} = (\mathbf{X}_1, \ldots, \mathbf{X}_p)$ is an $n \times p$ matrix of n observations on p predictor variables, $\boldsymbol{\beta}$ is a $p \times 1$ vector of regression coefficients, and $\boldsymbol{\varepsilon}$ is an $n \times 1$ vector of random errors. It is usual to assume that $E(\boldsymbol{\varepsilon}) = \mathbf{0}$, $E(\boldsymbol{\varepsilon}\boldsymbol{\varepsilon}^T) = \sigma^2\mathbf{I}_n$, where σ^2 is unknown constant and $\mathbf{I}_n$ is the identity matrix of order n.

Without loss of generality, we also assume that $\mathbf{Y}$ and the columns of $\mathbf{X}$ are centered and scaled to have unit length so that $\mathbf{X}^T\mathbf{X}$ and $\mathbf{X}^T\mathbf{Y}$ are matrices of correlation coefficients. If a variable $\mathbf{V}$ is not centered or scaled, it's i-th element, v_i, can be replaced by $(v_i - \bar{v})/\sqrt{\sum_{i=1}^n (v_i - \bar{v})^2}$.

An estimate for $\boldsymbol{\beta}$ is obtained by minimizing

$$\|\mathbf{Y} - \mathbf{X}\boldsymbol{\beta}\|^2, \tag{2}$$

where $\|\cdot\|$ denotes the Euclidean (or L_2) norm. The minimization of this ordinary least squares (OLS) problem leads to the so-called system of normal equations,

$$\mathbf{X}^T\mathbf{X}\boldsymbol{\beta} = \mathbf{X}^T\mathbf{Y}. \tag{3}$$

Provided that $\left(\mathbf{X}^T\mathbf{X}\right)^{-1}$ exists, the solution of this system of linear equations is given by

$$\hat{\boldsymbol{\beta}} = \left(\mathbf{X}^T\mathbf{X}\right)^{-1}\mathbf{X}^T\mathbf{Y}, \tag{4}$$

with $E(\hat{\boldsymbol{\beta}}) = \boldsymbol{\beta}$ and $\mathrm{Var}(\hat{\boldsymbol{\beta}}) = \sigma^2(\mathbf{X}^T\mathbf{X})^{-1}$.

If collinearity is present, the linear system in (3) is said to be *ill-conditioned* and $\hat{\boldsymbol{\beta}}$ in (4) can be unstable, that is, a slight change in the data can result in a substantial change in the values of the estimated regression coefficients. Furthermore, collinearity usually inflates the variance of $\hat{\boldsymbol{\beta}}$ and this in turn deflates the t-statistics for testing the significance of the regression coefficients, which can lead to the wrong conclusion that the coefficients of some important predictors are statistically insignificant.

A measure for assessing the condition of the linear system in (3) is the condition number of $\mathbf{X}$, which is defined as $\kappa = \sqrt{\lambda_1/\lambda_p}$, where λ_1 and λ_p are the largest and smallest eigenvalues of $\mathbf{X}^T\mathbf{X}$, respectively. Large values of the condition number indicate ill-conditioned system. A measure for assessing the effect of collinearity on variance inflation is the *variance inflation factor* (VIF). For the j-th predictor variable X_j, the VIF is the j-th diagonal element of $(\mathbf{X}^T\mathbf{X})^{-1}$. It can be shown that $\mathrm{VIF}_j = 1/\left(1 - R_j^2\right)$, where R_j^2 is the multiple correlation coefficient when X_j is regressed on all other predictor variables. When X_j has a strong linear relationship with all other predictors, R_j^2 would be very large (close to 1), causing VIF_j to be very large. As a rule of thumb, values of variance inflation factors greater than 10 are indicative of the presence of collinearity.

To obtain a stable (*regularized*) solution, we replace the problem in (2) by minimizing

$$\|\mathbf{Y} - \mathbf{X}\boldsymbol{\beta}\|^2 + k\|\boldsymbol{\beta}\|^2, \tag{5}$$

for some value of $k > 0$, suitably chosen by the user. The explicit solution of the problem in (5) is

$$\hat{\boldsymbol{\beta}}(k) = (\mathbf{X}^T\mathbf{X} + k\mathbf{I}_p)^{-1}\mathbf{X}^T\mathbf{Y} = (\mathbf{X}^T\mathbf{X} + k\mathbf{I}_p)^{-1}\mathbf{X}^T\mathbf{X}\hat{\boldsymbol{\beta}}, \tag{6}$$

where $\mathbf{I}_p$ is the identity matrix of order p. The expected value and variance of $\hat{\boldsymbol{\beta}}(k)$ are

$$E(\hat{\boldsymbol{\beta}}(k)) = (\mathbf{X}^T\mathbf{X} + k\mathbf{I}_p)^{-1}\mathbf{X}^T\mathbf{X}\boldsymbol{\beta} \tag{7}$$

and

$$\mathrm{Var}(\hat{\boldsymbol{\beta}}) = \sigma^2(\mathbf{X}^T\mathbf{X} + k\mathbf{I}_p)^{-1}\mathbf{X}^T\mathbf{X}(\mathbf{X}^T\mathbf{X} + k\,\mathbf{I}_p)^{-1}. \tag{8}$$

In statistics, the solution $\hat{\boldsymbol{\beta}}(k)$ is known as *ridge regression* (see Hoerl 1962) and the ridge parameter k is a penalizing factor. But more generally, it is known as the Tikhonov regularization (TR) method (Tikhonov 1943) and the factor k is known as the Tikhonov factor.

By comparing (4) and (6), one can see that the ridge estimator is obtained by adding a small positive quantity k to each of the diagonal elements of the matrix $\mathbf{X}^T\mathbf{X}$. Clearly, when $k = 0$, the ridge estimator in (6) becomes the OLS estimator in (4). It is clear from (7) that for $k > 0$, ridge estimators are biased for $\boldsymbol{\beta}$.

The variance inflation factors as a function of k are the diagonal elements of the matrix $(\mathbf{X}^T\mathbf{X} + k\mathbf{I}_p)^{-1}\mathbf{X}^T\mathbf{X}(\mathbf{X}^T\mathbf{X} + k\mathbf{I}_p)^{-1}$. Hoerl and Kennard (1970) show that there exists a value of $k > 0$ such that

$$E[(\hat{\boldsymbol{\beta}}(k) - \boldsymbol{\beta})^T(\hat{\boldsymbol{\beta}}(k) - \boldsymbol{\beta})] < E[(\hat{\boldsymbol{\beta}} - \boldsymbol{\beta})^T(\hat{\boldsymbol{\beta}} - \boldsymbol{\beta})], \quad (9)$$

which means that the total mean square error of the ridge estimators are less than that of the OLS.

The choice of the ridge parameter k is therefore important. The optimal value of k is difficult to find, but there exists several alternative methods for estimating k. First, an appropriate value of k can be found graphically by examining the *ridge trace*, which is a simultaneous plot of the elements of $\hat{\boldsymbol{\beta}}(k)$ versus k (usually between 0 and 1). The smallest value of k, for which (a) the estimated vector of regression coefficients, $\hat{\boldsymbol{\beta}}(k)$, is stable, (b) the variance inflation factors are less than 10 (close to 1), and (c) the residual sum of squares is close to its minimum value, is chosen and used in (6) to obtain the ridge estimators.

Second, numerical methods for estimating k have been proposed. For example, Hoerl et al. (1975) suggest estimating k by $\hat{k} = p\hat{\sigma}^2/(\hat{\boldsymbol{\beta}}^T\hat{\boldsymbol{\beta}})$, where $\hat{\sigma}^2 = SSE/(n-p)$ and SSE is the OLS residual sum of squares. Other numerical methods have also been suggested; see, for example, Lawless and Wang (1976), Wahba et al. (1979), Hoerl and Kennard (1981), Masuo (1988), Khalaf and Shukur (2005), and Dorugade and Kashid (2010).

Forms of ridge regression other than (6) are possible. For example the ridge parameter k (which is a scalar) can be replaced by a diagonal matrix with possibly different diagonal elements, or even with a full $p \times p$ matrix, but these alternatives are less common in practice.

More recently, Jensen and Ramirez (2008) cast some doubt about the ability of ridge estimators to actually improve the condition of an ill-conditioned linear system and provide stable estimated regression coefficients and smaller variance inflation factors. Note that the ridge estimator in (6) is the solution of the linear system

$$(\mathbf{X}^T\mathbf{X} + k\mathbf{I}_p)\boldsymbol{\beta} = \mathbf{X}^T\mathbf{Y}, \quad (10)$$

which replaces the system of normal equations in (3). The condition number of the matrix $(\mathbf{X}^T\mathbf{X} + k\mathbf{I}_p)$ on the left-hand side of (10) is $\sqrt{(\lambda_1 + k)/(\lambda_p + k)}$, which is smaller than the condition number of $(\mathbf{X}^T\mathbf{X})$, which is $\sqrt{\lambda_1/\lambda_p}$. Thus adding k to each of the diagonal elements of $\mathbf{X}^T\mathbf{X}$ improves its condition. But the matrix $\mathbf{X}$ on the right-hand side of (10) remains ill-conditioned. To also improve the condition of the right-hand side of (10), Jensen and Ramirez (2008) propose replacing the ill-conditioned regression model in (1) by the *surrogate* but less ill-conditioned model

$$\mathbf{Y} = \mathbf{X}_k\boldsymbol{\beta} + \boldsymbol{\varepsilon}, \quad (11)$$

where $\mathbf{X}_k = \mathbf{U}(\boldsymbol{\Lambda} + k\mathbf{I}_p)^{1/2}\mathbf{V}^T$, the matrices $\mathbf{U}$ and $\mathbf{V}$ are obtained from the *singular-value decomposition* of $\mathbf{X} = \mathbf{UDV}^T$ (see, e.g., Golub and van Loan 1989) with $\mathbf{U}^T\mathbf{U} = \mathbf{V}^T\mathbf{V} = \mathbf{I}_p$, and $\mathbf{D}$ is a diagonal matrix containing the corresponding ordered singular values of $\mathbf{X}$. Note that the square of the singular values of $\mathbf{X}$ are the eigenvalues of $\mathbf{X}^T\mathbf{X}$, that is, $\mathbf{D}^2 = \boldsymbol{\Lambda}$. Because $\mathbf{X}_k^T\mathbf{X}_k = \mathbf{X}^T\mathbf{X} + k\mathbf{I}_p$, the least squares estimator of the regression coefficients in (11) is the solution of the linear system

$$(\mathbf{X}^T\mathbf{X} + k\mathbf{I}_p)\boldsymbol{\beta} = \mathbf{X}_k^T\mathbf{Y}, \quad (12)$$

which is given by

$$\hat{\boldsymbol{\beta}}_s(k) = (\mathbf{X}^T\mathbf{X} + k\mathbf{I}_p)^{-1}\mathbf{X}_k^T\mathbf{Y}. \quad (13)$$

Jensen and Ramirez (2008) study the properties of the surrogate ridge regression estimator, $\hat{\boldsymbol{\beta}}_s(k)$, in (13), and using a case study they demonstrate that the surrogate estimator is more conditioned than the classical ridge estimator, $\hat{\boldsymbol{\beta}}(k)$, in (6). For example, they observe that (a) the condition of the variance of $||\hat{\boldsymbol{\beta}}_s(k)||$ is monotonically increasing in k and (b) the maximum variance inflation factor is monotonically decreasing in k. These properties do not hold for the classical ridge estimator, $\hat{\boldsymbol{\beta}}(k)$.

Rise of Statistics in the Twenty First Century

Jon R. Kettenring
Drew University, Madison, NJ, USA

Introduction

As the end of the first decade of the twenty first century approaches, it is fair to say that statistics as a profession is on the rebound in ways that matter. In recent years there have been recurring laments about missed opportunities and lack of respect for statistics and statisticians. Yet, statisticians are on the move, identifying and embracing new opportunities, and being increasingly expansive in defining the scope of their field and its relationship to the world at large.

A sign of progress is the growing recognition by outsiders of the importance of the statistics discipline. For example, a recent editorial in *Science* magazine (Long and Alpern 2009), based on a new report, "Scientific Foundations for Future Physicians," argues that "students should arrive at medical school prepared in the sciences, including some areas not currently required, such as statistics and biochemistry."

Even more recently, this dramatic headline appeared on the front page of *The New York Times*: "For today's graduate, just one word: statistics." The accompanying article (Lohr 2009) talked about "the rising stature of statisticians," "the new breed of statisticians" who analyze "vast troves of data," and how the "data explosion" is "open[ing] up new frontiers" for statistics.

The goal in this essay is to discuss a few disparate factors that are relevant to my thesis about the current rise of and strong future for statistics and statisticians.

Renewal

One of the great qualities of the statistics profession, and an important reason for optimism about the future, is its tradition of introspection, self-assessment, and adjustment, leading to renewal of how we view our field, how we teach our subject, and how we interact with others. In part, this reflects the healthy questioning that statisticians engage in whenever confronted with a new problem. We want to know the whole story. We are politely but usefully skeptical of everything we are told. We examine all assumptions. We strive for quality data and supportable conclusions drawn from sound analyses. We know how to unlock underlying truths from complex and noisy circumstances. We recognize our limitations but also are able to develop new methods as needed.

Education

►Statistics education has received considerable attention and improvement during the last 50 years. It is even an accepted area for research – and we've learned a lot about how to teach students more effectively. Statistics courses are now frequently found in high schools in the U.S. Over 100,000 high school students take the Advanced Placement Examination in Statistics annually. Introductory courses for college students are often taught by specialists who have devoted careers to perfecting ways of breaking novices gently and carefully into the wonders of statistical thinking. The wide availability of statistical software has allowed students to experience first hand what it is like to analyze real data.

Consulting courses have been a popular way to expose graduate students to current data analysis and modeling

problems. Going a step further, there are now success stories that involve the orchestrated merging of statistics education, consulting, and research. A well-developed example of this synergistic approach, from the University of California at Riverside, is described by Jeske et al. (2007). As a result of such efforts, students are entering the workforce with wider experiences and broader skill sets.

Another plus has been the evolution of postdoctoral programs in statistics. Once rarities, they are increasingly common in academia, government, industry and research institutes such as the National Institute of Statistical Sciences (NISS) in the U.S.A. In the past 18 years, NISS has engaged more than 60 postdoctoral students in cross-disciplinary research projects.

Still, the potential for *substantial* improvements remains, and a few specific ones are spelled out in Lindsay et al. (2004). The recent eye-catching proposal by Brown and Kass (2009), based on their experience working together in neuroscience, calls for strong reforms based on "deepening cross-disciplinary involvement" and "a broad vision of the discipline of statistics." The aggressive changes that they propose amount to a culture change (comment by Gibbs and Reid in the discussion) and won't come easily (comment by Johnstone) but are necessary to keep up with "big science" (comment by Nolan and Temple Lang).

Cross-Disciplinary Research

Statistics has always been driven in part by applications. It is only in the last few decades that full-blown cross-disciplinary research involving statistics has become widely accepted within the profession. Now it is not only part of the culture but it is also spurring growth as statisticians respond to new data problems such as those posed by neuroscience. Other fruitful fields are easy to tick off as well, e.g., ▶bioinformatics, healthcare, life sciences, climate change, the environment, manufacturing, business strategy, privacy and confidentiality, bioterrorism, and national defense. Increasingly, the associated problems involve the analysis of massive datasets, i.e., ones of extraordinary size and complexity. When confronted with such challenges, teamwork is perhaps the most effective strategy and is very likely to trump purely statistical ones (Kettenring 2009).

A variety of other examples of cross-disciplinary work are listed in Lindsay et al. (2004), under the heading of statistics in science and industry, to illustrate the now common "interplay between statistics and other scientific disciplines." It is also worth noting that funding opportunities for such crossover activities have been on the rise.

Credentials

Within the American Statistical Association (ASA) there have been strong debates for at least 15 years about the need for credentialing (as in accreditation based on experience or certification based on testing) of professional statisticians. In a perfect world there would be no need for more than a suitable academic degree, but ours is not so neat and tidy. Practitioners with no degrees in statistics but excellent records of accomplishment often have difficulty achieving the stature that they deserve or require for success in their careers. Similar problems are encountered by those who work in fringe areas or for small employers where the professionalism of statisticians is misunderstood or underappreciated. We also face the unfortunate companion situation of practitioners who claim competency in statistics but lack it. This can result in damaging malpractice.

Similar concerns were no doubt behind earlier movements by the Royal Statistical Society, the Statistical Society of Canada, and the Statistical Society of Australia Inc. to provide accreditation programs that help to differentiate practitioners who are good at statistics from those who only claim to be. Motivated in part by the apparent success of these ventures, the ASA has taken several steps along the same path, culminating in approval in August 2009 of a plan (Bock et al. 2009) to launch its own *voluntary* accreditation program for professional statisticians.

In a randomized survey of ASA members, 41% reported that they would apply to such a program were it offered because it would provide evidence of competency and a credential useful for employment, among other factors. This change in thinking from "why do we need such a thing" to "maybe the time is right" illustrates that the field is evolving not only in theoretical and philosophical ways but also in very pragmatic ones aimed at meeting the needs of practitioners operating in very competitive environments.

Time will tell, but if these credentialing programs fulfill their potential, they will have served a very useful purpose by helping to legitimize and support a broad class of professionals who are highly qualified to practice statistics.

Journals

Journals are an essential component of the statistics infrastructure. They serve as a collective record of historical and current developments in the field. JSTOR, e.g., provides a very important centralized archive and point of access for more than 40 of the leading ones in statistics and probability. It includes journals such as *Biometrika*, the *Journal of the American Statistical Association (JASA)*, the *Journals of the Royal Statistical Society (JRSS)*, and *Technometrics*. Yet there are many more. The Current Index

to Statistics lists over 160 "core" journals on its website, www.statindex.org/CIS/news/CIS_core_journals.pdf. As of April 2009 the website, http://w4.stern.nyu.edu/ioms/research.cfm?doc_id=3532, hosted by the Stern School at New York University, included over 200 names under the heading of statistics and probability. Its breadth reflects the soft boundary view of statistics. Examples include *Analytical Chemistry, Econometrica*, the *Journal of Machine Learning Research*, and *Water Resources Research*.

Comparing journals across fields is dicey business, but it is tempting to see where one stands. In Lindsay et al. (2004) it was observed that *JASA* was "far and away the most cited mathematical science journal" for the period 1991–2001. I've also taken note of more recent data on the website www.eigenfactor.org, where 68 journals in probability and statistics are ranked based on cross-journal citation patterns, along with nearly 8,000 others. Citations of a journal to itself are not counted. The journals are quantified by their "Eigenfactor Score," which measures "the journal's total importance to the scientific community", and the "Article influence Score," which measures "the average influence, per article, of the papers in a journal" (Bergstrom et al. 2008). For the most recent year available, 2007, based on citations to the previous five years, the top four in the probability and statistics category are *JASA*, *Statistics in Medicine*, the *Annals of Statistics*, and *JRSS Series B* by the first measure, and *JRSS Series B*, *JASA*, the *Annals of Statistics*, and *Biostatistics* by the second. (The last title is a convenient reminder of the enormous success story of ►biostatistics as a subfield that has led the way in growth and career opportunities.)

The median Article Influence Score is 0.45 across all journals and 0.70 for those in the probability and statistics category. In comparison, the medians are 0.72 for neuroscience, 0.62 for mathematics, 0.60 for psychology, 0.58 for economics, and 0.59 for physics. The point is that statistics journals are publishing articles of relatively broad interest and high influence, at least by this measure. The vitality of our better journals provides a strong backbone for the future of statistics research, practice, and education.

Holistic Statistics

In Kettenring (1997), under the heading of "holistic statistics," I asked whether statistics in the twenty first century should be equated so strongly to the more traditional core topics of statistics as it had been in the past and followed with these points:

- There is a natural tension between narrowly focused pursuits of science vs. broader ones that favor synthesis and interdisciplinarity.
- The core of statistics should be nourished by surrounding itself with vigorous areas of application.
- Broad-minded statisticians are needed to work across boundaries and operate in fast-paced environments.
- A more inclusive definition of statistics would better reflect its strong interdisciplinary character.
- Such an inclusive interpretation of statistics is where the future lies.

In similar spirit, Hand (2009) talks about the importance of "greater statistics" (Chambers 1993) as an overarching discipline that deals with (quoting Chambers) "everything related to learning from data." It is this expansive view of statistics that I intended in the title of this essay and what Hand has in mind when he talks about the "magic" of modern statistics.

Wrap Up

Taking a bit of license with a popular adage, we can safely say that the future of statistics isn't what it used to be. These are meant to be encouraging words for students looking for a field of study that is full of life and much needed in a modern information age that is swamped with data and in need of help on what to do about it. Or, as the distinguished economist Hal Varian put it in Lohr (2009), "I keep saying that the sexy job in the next 10 years will be statisticians. And I'm not kidding."

Acknowledgments

The author was President of the American Statistical Association in 1997. He thanks Daniel Jeske, Alan Karr, and David Morganstein for their suggestions.

About the Author

Dr. Jon R. Kettenring is Past President of the American Statistical Association (1997). He has been Director of RISE since 2008. Previously, he was Executive Director of the Mathematical Sciences Research Center at Telcordia Technologies. Throughout his career, he has maintained a strong interest in statistics research and its application to solve real problems in the telecommunications industry. He is a Fellow of ASA and AAAS and an Elected Member of the International Statistical Institute. The National Institute of Statistical Sciences sponsored The Future of Data Analysis Conference in his honor at Avaya Labs Research, Basking Ridge, NJ (September 30, 2005).

Risk Analysis

Michael R. Greenberg
Professor
Rutgers University, New Brunswick, NJ, USA

Introduction

Risk analysis originated in safety and systems engineering and following the events at the Three Mile Island nuclear facilities in the United States developed into an interdisciplinary approach to better understand and manage hazards. It has been applied to many human and ecological health issues, such as air borne spread of biological agents, destruction of the United States chemical weapons stockpile, cyber attacks, facility safety, food contamination, hazardous waste management, medical decision-making, nuclear power and waste management, and natural hazards such as earthquakes, floods, and tornadoes. Several of the ideas and models can be extended to economic, social, and even political risk.

Risk analysis is divided into risk assessment and risk management, although feedback loops exist among the stages. To provide continuity to this entry, the author uses the example of a terrorist planning to kill bus riders.

Risk Assessment

Risk assessors try to answer three questions.

1. What can go wrong?
2. What are the chances that something with serious consequences will go wrong?
3. What are the consequences if something does go wrong?

This so-called "triplet" of questions (Kaplan and Garrick 1981; Garrick 1984) can be written as follows:

$$R = (S, P, C)$$

where R is the risk; S is a hypothesized risk scenario event of what can go wrong; P is the probability of that scenario occurring; and C are the consequences.

Scenarios

Analysts create risk scenarios. For example, the terrorist could board a bus and detonate a bomb or leave a bomb near a stop and detonate it remotely. When there are thousands of potential triggering scenarios, analysts identify the worst consequences and then they work backward to scenarios that could produce them.

Analysts use fault trees or event trees to build out risk assessment scenarios. Event trees start with an event and follow it through branches. Some of the branches lead to insignificant consequences, while others end in serious outcomes. Fault tree analyses begin with the end state and work backwards to identify the event or sequence of events that will trigger it. They also are used together.

Likelihood

Quantification of the ►likelihood of events was the major improvement introduced by risk assessment to safety analysis. Analysts develop a probability distribution of the likelihood of events, and then apply them to the trees. This step, the author believes, is the most difficult challenge faced by risk assessors (Hora 2007; Aven and Renn 2009; Committee on Methodological Improvements to the Department of Homeland Securities Biological Agent Risk Analysis, National Research Council 2007; Cox 2009; Dillon et al. 2009).

When there is no deliberate intent driving an event, for instance, a bus has a flat tire and crashes, then estimating probabilities from historical records and experiences make sense. The problem is how to estimate the likelihood

of a deliberate attack. Do we assume that the terrorists are intent as well as capable and will adjust to countermeasures? If a terrorist is assumed to achieve optimal or near optimal success, then we need to game theoretic or more generally agent-based modeling to support these estimates.

Eliciting likelihood estimates from experts is part science and part art. Expert opinion can be obtained through surveys. The results may not translate directly into an absolute measurement of likelihood, but perhaps an ordinal scale that can be used to set priorities. The key is training the experts to participate in the survey (Hora 2007; Aven and Renn 2009; Committee on Methodological Improvements to the Department of Homeland Securities Biological Agent Risk Analysis, National Research Council 2007).

Consequences

Estimating consequences is part three of the risk assessment process. In the case of the bus passengers, the worst outcomes would be death of all the riders and for a transit system it would also be public fear of using the bus. When all the branches are followed, the results include estimates of the number of deaths, injuries, physical damage to assets, environmental effects, and local/regional economic impacts. These consequences are ranked with regard to severity.

Summarizing, risk assessments produce a list of risks. What to do about them is the responsibility of risk managers.

Risk Management

The author offers the following three questions for risk managers:

1. How can consequences be prevented or reduced?
2. How can recovery be enhanced, if the scenario occurs?
3. How can key local officials, expert staff, and the public be informed to reduce concern and increase trust and confidence?

Prevention

Risk managers try to contain risk within an acceptable (typically regulatory-based) level by implementing mitigation measures. These options are engineered and behavioral, and collectively they can be seen as the essence of a multi-criteria decision-making model (MCDM) (Chankong and Haimes 2008), where prevention options $O_i(i = 1, 2, \ldots, m)$ are defined and the decision-maker(s) evaluate them based on selected criteria $C_j(j = 1, 2, \ldots, n)$. In the case of our at risk bus passengers, the company can monitor the bus stops, and train the drivers can look for suspicious behavior (they are already trained to deal with rowdy and intoxicated riders).

Prevention is partly based on engineering options, life cycle cost, union contracts, ethical and other considerations, and requires blending of quantitative and qualitative data into a multi-criteria decision making framework. The audience for this volume recognizes the problems of scarcity of data, lack of knowledge, and subjectivity. Various mathematical and statistical techniques are available in the literature to deal with decision-making with uncertainties (Chankong and Haimes 2008; Heinz Center 2000; Skidmore and Toya 2002; Greenberg et al. 2007; Bedford and Cooke 2001; Edwards et al. 2007).

Two difficult challenges for risk managers are the time and space dimensions. In fact, we do not know a great deal about the geographical and temporal impacts of risk-related events (Zinn 2009). The direct consequences of a bus explosion event include impacts on the passengers and the driver. But indirect effects could include fear of using the bus, leading to a loss of revenue for the system and for businesses that depend on it, and to induced income effects caused by job losses. That is, when people lose their jobs, they begin to reduce their purchases.

The local impact is the area directly impacted by the event. Regional impacts occur in surrounding areas that are affected by direct losses. State, national and international impacts are felt as economic consequence ripples across the landscape. Some of these impacts are felt immediately or within a month or two of the event. Others are intermediate in length and measured in months and even a year or two out from the events. If the event is large enough there will also be long-term impacts that can be measured for many years. For example, the author has studied the impact of large scale loss of energy supply, leading to loss of confidence in the region and relocation out of the area. Yet we also have learned that a devastated region will receive funds from insurance companies, not-for-profits, and government agencies (Singpurwalla 2006), so negative consequences may be less than had been anticipated.

Economic impact tools allow us to estimate some of the consequences of such risk management decisions, albeit each of these has important data requirements, limitations, and capabilities (Modarres et al. 2010). The key to successfully using the economic models is the willingness of analysts to probe deeply into the events and through the stages that follow. Using sophisticated models without first understanding the event is a waste of time and money.

Recovery

Even the best efforts to prevent risk events sometimes fail. Every risk manager needs a plan to respond to events. Like

the risk mitigation response, these options are both human and engineered. The response options $R_i(i = 1, 2, \ldots, m)$ are defined and the decision-maker(s) evaluate them based on selected criteria $C_j(j = 1, 2, \ldots, n)$. In the case of our bus passengers, for example, police would cordon off the area, ambulances would arrive, and the injured would be moved to a nearest health care facility that is able to treat those that are alive.

Communications

At some major risk-related events, there are misunderstandings about who is in charge, who should perform what function, and sometimes the results are tragic. Firemen and police should be fully equipped and trained to deal with hazards. Transit workers and upper-level managers should know how to cope with passengers who show signs of suspicious behavior, and how to prevent panic rather than contribute to it. A good deal of research is focusing on crisis communications specifically and risk communications more generally, and principles have been articulated about how to manage risk events. However, it will take a systematic and ongoing effort to diffuse these suggestions to managers and to front-line employees.

Summary

Risk analysis is a multidisciplinary field that includes researchers trained in physics, chemistry, biology, engineering, mathematics, economics, psychology, geography, sociology, communications, political science and others. This essay touches on the six key questions that risk analysts try to answer. Some good books are available (Bedford and Cooke 2001; Edwards et al. 2007; Zinn 2009; Singpurwalla 2006; Modarres et al. 2010). However, in a rapidly moving field like this, most books are out of date quickly. The author recommends consulting two journals: *Risk Analysis: an International Journal* and the *Journal of Risk Research*.

Acknowledgments

I would like to thank colleagues of many years for helping me learn about risk analysis, especially Vicky Bier, Tony Cox, John Garrick, Bernard Goldstein, Ortwin Renn, Paul Slovic, and Yacov Haimes.

About the Author

Dr. Michael R. Greenberg is Professor and Associate Dean of the Faculty of the Edward J. Bloustein School of Planning and Public Policy of Rutgers University. He is Director, National Center for Neighborhood and Brownfields, and Director, Rutgers National Transportation Security Center of Excellence. He has been a member of National Research Council Committees that focus on waste management, such as the destruction of the U.S. chemical weapons stockpile and nuclear weapons. Professor Greenberg has contributed more than 500 publications to scientific journals like *Cancer Research*, *American Journal of Epidemiology*, *Risk Analysis*, *American Journal of Public Health*, and public interest ones like *Urban Affairs Review*, *Housing Policy Debate*, *Society*, *the Sciences*, and *Public Interest*. He has received awards for research from the United States Environmental Protection Agency, the Society for Professional Journalists, the Public Health Association, the Association of American Geographers, and Society for Risk Analysis. In 2003, he received the Distinguished Career Achievement Award, International Society for Risk Analysis. He has supervised about 70 PhD students. Currently, Professor Greenberg is the Editor-in-Chief, *Risk Analysis: An International Journal*.

Robust Inference

Elvezio Ronchetti
Professor
University of Geneva, Geneva, Switzerland

►Robust statistics deals with deviations from ideal parametric models and their dangers for the statistical procedures derived under the assumed model. Its primary goal is the development of procedures which are still reliable and reasonably efficient under small deviations from the model, i.e., when the underlying distribution lies in a neighborhood of the assumed model. Robust statistics is then an extension of parametric statistics, taking into account that parametric models are at best only approximations to reality. The field is now some 50 years old. Indeed one can consider Tukey (1960), Huber (1964), and Hampel (1968) the fundamental papers which laid the foundations of modern robust statistics. Book-length expositions can be found in Huber (1981, 2nd edition by Huber and Ronchetti 2009), Hampel et al. (1986), Maronna et al. (2006).

More specifically, in robust testing one would like the level of a test to be stable under small, arbitrary departures from the distribution at the null hypothesis (*robustness of validity*). Moreover, the test should still have good power under small arbitrary departures from specified alternatives (*robustness of efficiency*). For confidence intervals, these criteria correspond to stable coverage probability and length of the confidence interval.

Many classical tests do not satisfy these criteria. An extreme case of nonrobustness is the F-test for comparing two variances. Box (1953) showed that the level of this test becomes large in the presence of tiny deviations from the normality assumption (see Hampel et al. 1986; 188–189). Well known classical tests exhibit robustness problems too. The classical t-test and F-test for linear models are relatively robust with respect to the level, but they lack robustness of efficiency with respect to small departures from the normality assumption on the errors (cf. Hampel 1973; Schrader and Hettmansperger 1980; Ronchetti 1982; Heritier et al. 2009: 35). Nonparametric tests are attractive since they have an exact level under symmetric distributions and good robustness of efficiency. However, the distribution free property of their level is affected by asymmetric contamination (cf. Hampel et al. 1986: 201). Even ►randomization tests which keep an exact level, are not robust with respect to the power if they are based on a non-robust test statistic like the mean.

The first approach to formalize the robustness problem was Huber's (1964, 1981) minimax theory, where the statistical problem is viewed as a game between the Nature (which chooses a distribution in the neighborhood of the model) and the statistician (who chooses a statistical procedure in a given class). The statistician achieves robustness by constructing a minimax procedure which minimizes a loss criterion at the worst possible distribution in the neighborhood. More specifically, in the problem of testing a simple hypothesis against a simple alternative, Huber (1965, 1981) found the test which maximizes the minimum power over a neighborhood of the alternative, under the side condition that the maximum level over a neighborhood of the hypothesis is bounded. The solution to this problem which is an extension of ►Neyman-Pearson Lemma, is the censored likelihood ratio test. It can be interpreted in the framework of capacities (Huber and Strassen 1973) and it leads to exact finite sample minimax confidence intervals for a location parameter (Huber 1968). While Huber's minimax theory is one of the key ideas in robust statistics and leads to elegant and exact finite sample results, it seems difficult to extend it to general parametric models, when no invariance structure is available.

The infinitesimal approach introduced in Hampel (1968) in the framework of estimation, offers an alternative for more complex models. The idea is to view the quantities of interest (for instance the bias or the variance of an estimator) as functionals of the underlying distribution and to use their linear approximations to study their behavior in a neighborhood of the ideal model. A key tool is a derivative of such a functional, the influence function (Hampel 1974) which describes the local stability of the functional.

To illustrate the idea in the framework of testing, consider a parametric model $\{F_\theta\}$, where θ is a real parameter and a test statistic T_n which can be written (at least asymptotically) as a functional $T(F_n)$ of the empirical distribution function F_n. Let $H_0 : \theta = \theta_0$ be the null hypothesis and $\theta_n = \theta_0 + \Delta/\sqrt{n}$ a sequence of alternatives. We consider a neighborhood of distributions $F_{\epsilon,\theta,n} = (1-\epsilon/\sqrt{n})F_\theta + (\epsilon/\sqrt{n})G$, where G is an arbitrary distribution and we can view the asymptotic level α of the test as a functional of a distribution in the neighborhood. Then by a von Mises expansion of α around F_{θ_0}, where $\alpha(F_{\theta_0}) = \alpha_0$, the nominal level of the test, the asymptotic level and (similarly) the asymptotic power under contamination can be expressed as

$$\lim_{n\to\infty} \alpha(F_{\epsilon,\theta_0,n}) = \alpha_0 + \epsilon \int IF(x;\alpha,F_{\theta_0})dG(x) + o(\epsilon), \tag{1}$$

$$\lim_{n\to\infty} \beta(F_{\epsilon,\theta_n,n}) = \beta_0 + \epsilon \int IF(x;\beta,F_{\theta_0})dG(x) + o(\epsilon), \tag{2}$$

where

$$IF(x;\alpha,F_{\theta_0}) = \phi(\Phi^{-1}(1-\alpha_0))IF(x;T,F_{\theta_0}) \Big/ [V(F_{\theta_0},T)]^{1/2},$$

$$IF(x;\beta,F_{\theta_0}) = \phi(\Phi^{-1}(1-\alpha_0) - \Delta\sqrt{E})IF(x;T,F_{\theta_0}) \Big/ [V(F_{\theta_0},T)]^{1/2},$$

$\alpha_0 = \alpha(F_{\theta_0})$ is the nominal asymptotic level, $\beta_0 = 1 - \Phi(\Phi^{-1}(1-\alpha_0) - \Delta\sqrt{E})$ is the nominal asymptotic power, $E = [\xi'(\theta_0)]^2 \Big/ V(F_{\theta_0},T)$ is Pitman's efficacy of the test, $\xi(\theta) = T(F_\theta)$, $V(F_{\theta_0},T) = \int IF(x;T,F_{\theta_0})^2 dF_{\theta_0}(x)$ is the asymptotic variance of T, and $\Phi^{-1}(1-\alpha_0)$ is the $1-\alpha_0$ quantile of the standard normal distribution Φ and ϕ is its density (see Ronchetti 1979; Rousseeuw and Ronchetti 1979). More details can be found in Markatou and Ronchetti (1997) and Huber and Ronchetti (2009, Chap. 13).

Therefore, bounding the influence function of the the test statistic T from *above* will ensure *robustness of validity* and bounding it from *below* will ensure *robustness of efficiency*. This is in agreement with the exact finite sample result about the structure of the censored likelihood ratio test obtained using the minimax approach.

In the multivariate case and for general parametric models, the classical theory provides three asymptotically equivalent tests, Wald, score, and likelihood ratio test, which are asymptotically uniformly most powerful with respect to a sequence of contiguous alternatives. If the parameter of the model is estimated by a robust estimator such as an M-estimator T_n defined by the estimating equation $\sum_{i=1}^n \psi(x_i;T_n) = 0$, natural extensions of the three classical tests can be constructed by replacing the score function of the model by the function ψ. This leads to formulas similar to (1) and (2) and to optimal bounded influence tests (see Heritier and Ronchetti 1994).

About the Author

Professor Elvezio Ronchetti is Past Vice-President of the Swiss Statistical Association (1988–1991). He was Chair, Department of Econometrics, University of Geneva (2001–2007). He is an Elected Fellow of the American Statistical Association (2001) and of the International Statistical Institute (2008). Currently he is an Associate Editor, *Journal of the American Statistical Association* (2005–present) and Director of the Master of Science and PhD Program in Statistics, University of Geneva (2009–present). He is the co-author (with F.R. Hampel, P.J. Rousseeuw, and W.A. Stahel) of the well known text *Robust Statistics : The Approach Based on Influence Functions* (Wiley, New York, 1986, translated also into Russian), and of the 2nd edition of Huber's classic *Robust Statistics* (with P. J. Huber, Wiley 2009.)

Robust Regression Estimation in Generalized Linear Models

Nor Aishah Hamzah[1], Mohammed Nasser[2]
[1]Professor

The idea of ▶generalized linear models (GLM) generated by Nelder and Wedderburn (1972) seeks to extend the domain of applicability of the linear model by relaxing the normality assumption. In particular, GLM can be used to model the relationship between the explanatory variable, X, and a function of the mean, μ_i, of a continuous or discrete responses. More precisely, GLM assumes that $g(\mu_i) = \eta_i = \sum_{j=1}^{p} x_{ij}\beta_j$, where $\beta = (\beta_1, \beta_2, \ldots, \beta_p)^T$ is the p-vector of unknown parameters and $g(\cdot)$ is the link function that determines the scale on which linearity is assumed. Models of this type include logistic and probit regression, Poisson regression, linear regression with known variance, and certain models for lifetime data.

Specifically, let $Y_1, Y_2, \ldots, Y_n$, be n independent random variables drawn from the exponential family with density (or probability function)

$$f(y_i; \theta_i, \phi) = \exp\left\{\frac{y_i\theta_i - b(\theta_i)}{a(\phi)} + c(y_i, \phi)\right\} \qquad (1)$$

for some specific functions $a(\cdot)$, $b(\cdot)$, and $c(\cdot, \cdot)$. Here, $E(Y_i) = \mu_i = b'(\theta_i)$ and $\mathrm{var}(Y_i) = b''(\theta_i)a(\phi)$ with usual notation of derivative.

The most common method of estimating the unknown parameter, β, is that of maximum likelihood estimation (MLE) or quasi-likelihood methods (QMLE), which are equivalent if $g(\cdot)$ is the canonical link such as the logit function for the ▶logistic regression, the log function for ▶Poisson regression, or the identity function for the Normal regression. That is, when $g(\mu_i) = \theta_i$, the MLE and QMLE estimator of β are the solutions of the p-system of equations:

$$\sum_{i=1}^{n}(y_i - \mu_i)x_{ij} = 0, \quad j = 1, \ldots, p. \qquad (2)$$

The estimator defined by (2) can be viewed as an M-estimator with score function

$$\psi(y_i; \beta) = (y_i - \mu_i)x_i \qquad (3)$$

where $x_i = (x_{i1}, x_{i2}, \ldots, x_{ip})^T$.

Since the score function defined by (3) is proportional to x and y, the maximum possible influence in both the x and y spaces are unbounded. When y is categorical, the problem of unbounded influence in x remains and in addition, the breakdown possibility by inliers arises (Albert and Anderson 1984). As such, the corresponding estimator of β based on (2) is therefore non-robust. Any attempt to improve the estimation of such β should limit such influences. Two basic approaches are usually employed in order to address the problems stated above, that is: (a) diagnostics and (b) robust estimation.

Diagnostic Measures

In most diagnostics approaches, the MLE is first employed and subsequently diagnostics tools are used to identify potential influential observations. For details on diagnostic measures, readers are referred to the published works of Pregibon (1981, 1982), McCullagh and Nelder (1989), Johnson (1985), Williams (1987), Pierce and Schafer (1986), Thomas and Cook (1990), and Adimari and Ventura (2001).

While these techniques have been quite successful in identifying individual influential points, its generalization to jointly influential points cannot guarantee success. The development of a robust method in the early 1980s provides an option that offers automatic protection against anomalous data. A recent trend in diagnostic research is (a) to detect wild observations by using the classical diagnostic method after initially deploying the robust method (Imon and Hadi 2008) or (b) to use robust method in any case (Cantoni and Ronchetti 2001; Serigne and Ronchetti 2009).

Robust Estimation

Since the score function in (3) is subject to influence of outlying observation, both in the X and y, appropriate robust estimations are those of the GM-estimates. These include the Mallows-type (Pregibon 1979) and Schweppe-type (Stefanski et al. 1986; Künsch et al. 1989). The proposed methods are discussed here. Let

$$\ell(\theta_i, y_i) = \log f(y_i; \theta_i, \phi) = \frac{y_i\theta_i - b(\theta_i)}{a(\phi)} + c(y_i, \phi) \quad (4)$$

and define the i-th deviance as $d_i = d_i(\theta_i) = 2\{\ell(\tilde{\theta}_i, y_i) - \ell(\theta_i, y_i)$, where $\tilde{\theta}_i$ is the MLE based on observation y_i alone, that is, $\tilde{\theta}_i = (b')^{-1}(y_i)$. The deviance d_i can be interpreted as a measure of disagreement of the i-th observation and the fitted model. Thus, MLE that aims at maximizing the likelihood function also aims at minimizing the deviances, specifically minimizing $M(\beta) = \sum_{i=1}^{n} d_i(\theta)$.

In an attempt to robustify the MLE, the first modification of the MLE introduced by Pregibon (1979) is to replace the minimization criterion with $M(\beta) = \sum_{i=1}^{n} \rho(d_i)$.

The function $\rho(\cdot)$ acts as a filter that limits the contribution of extreme observations in determining the fits to the data. Minimizing the criterion above can be obtained by finding the root solutions to the following score function

$$\sum_{i=1}^{n} \psi(d_i) = \sum_{i=1}^{n} w_i s_i x_{ij} = 0, \quad j = 1, \ldots, p, \quad (5)$$

with $s_i = \partial\ell(\theta_i, y_i)/\partial\eta_i$, and $w_i (0 \le w_i \le 1)$ given by $w(d_i) = \partial\rho(d_i)/\partial d_i$. Note that this is simply the weighted version of the maximum likelihood score equations with data-dependent weights.

Mallows-Type GM Estimate

Based on Huber's loss function, the corresponding weight function $w_i = \min\{1, (H/d_i)^{1/2}\}$ with adjustable tuning constant H, which aims at achieving some specified efficiency, can be used (Pregibon 1982). By solving (5), one can obtain a class of Mallows M-estimates. This type of estimation is resistant to poorly fitted data, but not to extreme observations in the covariate space that may exert undue influence on the fit.

Schweppe-Type GM Estimate

Extending the results obtained by Krasker and Welsch (1982) and Stefanski et al. (1986), Künsch et al. (1989) proposed bounded influence estimators that are also conditionally Fisher-consistent. Subject to a bound b on the measure of sensitivity $\gamma_\psi (\gamma_\psi \le b < \infty)$, the following modification to the score function was proposed:

$$\psi_{BI} = \left\{ y - \mu - c\left(x^T\beta, \frac{b}{(x^T B^{-1} x)^{1/2}} \right) \right\} w_b(|r(y, x, \beta, B)|(x^T B^{-1} x)^{1/2}) x^T$$

where $c(\cdot, \cdot)$ and B are the respective bias-correction term and dispersion matrix chosen so that the estimates are conditionally Fisher-consistent with bounded influence, with weight function of the form $w_b(a) = \min\{1, b/a\}$ based on Huber's loss function. As in Schweppe-type GM estimates, $w_b(\cdot)$ downweight observations with a high product of corrected residuals and leverage. Details on the terms used here can be found elsewhere (see, e.g., Huber (1981) on infinitesimal sensitivity).

Besides the general approach in robust estimation in GLM several researchers put forward various other estimators for specific case of GLM. For example, when y follows a Gamma distribution with log link function, Bianco et al. (2005) considered redescending M-estimators and showed that the estimators are Fisher-consistent without any correction term. In the logistic model, Carrol and Pederson (1993) proposed weighted MLE to robustify estimators, Bianco and Yohai (1996) extended the work of Morgenthaler (1992) and Pregibon (1982) on M-estimators while Croux and Haesbroeck (2003) developed a fast algorithm to execute Bianco–Yohai estimators. Gervini (2005) presented robust adaptive estimators and recently Hobza et al. (2008) opened a new line proposing robust median estimators in ▶logistic regression (see also Hamzah 1995). The robust Poisson regression model (RPR) (see ▶Poisson Regression) was proposed by Tsou (2006) for the inference about regression parameters for more general count data; here one need not worry about the correctness of the Poisson assumption.

Outliers

The following Table (Hand et al. 1994: 278) contains 20 measurements of the speed of light in suitable units (km/s minus 299000) from the classical experiments performed by Michelson and Morley in 1887.

880	880	880	860	720
720	620	860	970	950
880	910	850	870	840
840	850	840	840	840

We may represent our data as

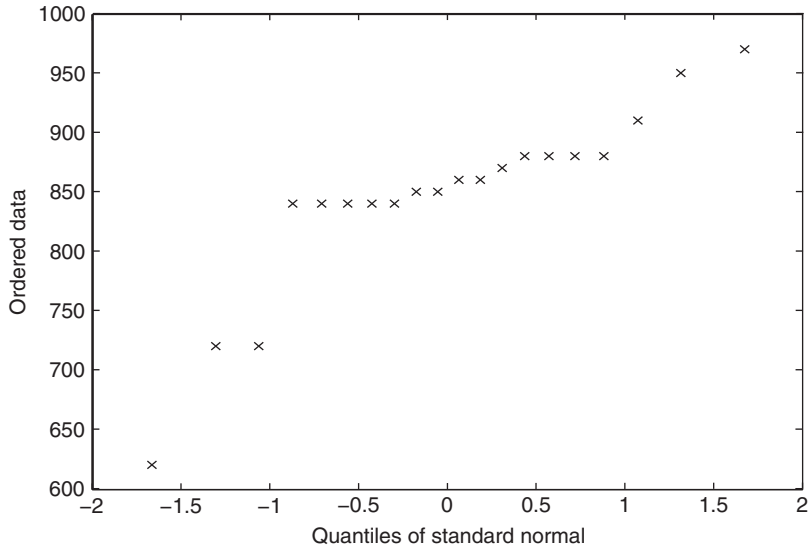
$$x_i = \mu + u_i,\ i = 1, \ldots, n \qquad (1)$$

where $n = 20$, μ is the true (unknown) speed value and u_i are random observation errors. We want a point estimate $\widehat{\mu}$ and a ►confidence interval for μ.

Figure 1 is the normal QQ-plot of the data. The three smallest observations clearly stand out from the rest. The central part of the plot is approximately linear, and therefore we may say that the data are "approximately normal."

The left-hand half of the following Table shows the sample mean and standard deviation (SD) of the complete data and also of the data without the three smallest observations (the right-hand half will be described below).

	Mean	SD	Median	MADN
Complete data	845.0	79.1	855.0	29.6
3 obs. omitted	872.9	38.5	860.0	29.6



Robust Statistical Methods. Fig. 1 Speed of light: normal QQ-plot of data

We see that these three observations inflate the SD and diminish the mean.

The confidence intervals with level 0.95 for the mean with the complete data and with the three outliers removed are respectively [807.94, 882.06] and [853.14 892.74].

We see that even data from a carefully controlled experiment may contain atypical observations ("outliers") which may overly influence the conclusions from the experiment. Although the proportion of outliers is low (3/20=15%) they have a serious influence.

The oldest approach to deal with this problem is to employ some diagnostic tool to detect ▶outliers, delete them, and then recompute the statistics of interest. Barnett and Lewis (1998) is a useful source of methods for outlier detection.

Using a good outlier diagnostic is clearly better than doing nothing, but has its drawbacks:

- Deletion requires a subjective decision. When is an observation "outlying enough" to be deleted?
- The user or the author of the data may feel uneasy about deleting observations
- There is a risk of deleting "good" observations, which results in underestimating data variability
- Since the results depend on the user's subjective decisions, it is difficult to determine the statistical behavior of the complete procedure.
