Let $N_{n,k}$ denote the number of non-overlapping success runs of length k in n (≥ 1) independent trials with success probability p $(0 < p < 1)$. The ▶asymptotic normality of a normalized version of $N_{n,k}$ was established by von Mises (see Feller 1968:324), where a simpler proof is presented). Its exact pmf was obtained by Hirano (1986) and Philippou and Makri (1986), who named the distribution *binomial distribution of order k with parameter vector* (n, p). They

found that, for $x = 0, 1, \ldots, [n/k]$,

$$P(N_{n,k} = x) = \sum_{i=0}^{k-1} \sum \binom{x_1 + x_2 + \cdots + x_k + x}{x_1, x_2, \ldots, x_k, x} p^n \times \left(\frac{q}{p}\right)^{x_1 + x_2 + \cdots + x_k}, \quad (12)$$

where $[u]$ denotes the greatest integer in u and the inner summation is taken over all non-negative integers $x_1, x_2, \ldots, x_k$ satisfying the condition $x_1 + 2x_2 + \cdots + kx_k + i = n - kx$. The following exact formula for the mth descending factorial moment μ'_m of $N_{n,k}$ was established by Antzoulakos and Chadjiconstantinidis (2001),

$$\mu'_m = m! p^{km} \sum_{j=0}^{\min(n-km,m)} (-1)^j \binom{m}{j} p^j \times \sum_{i=0}^{[\frac{n-km-j}{k}]} \binom{m+i-1}{i} \binom{m+n-k(m+i)}{m} p^{ki}. \quad (13)$$

The above results for the pmf's of T_k and $N_{n,k}$ give exact formulas for the reliability of a *consecutive-k-out-of-n:F system*, which is very important in Engineering. For more on distributions of order k and their applications, we refer to Balakrishnan and Koutras (2002).

About the Authors

Professor Andreas Philippou is a member of the Greek Statistical Authority and he has been teaching statistics and probability at the University of Patras since 1980. He has also taught earlier at the University of Texas at El Paso and the American University of Beirut. He wrote 75 papers, mainly in statistics and probability, and edited 7 books on Fibonacci numbers and their applications. He served as Vice-President of Hellenic Aerospace Industry (1981–1982), Vice-Rector of the University of Patras (1983–1986), and Minister of Education (1988–1990), Member of the House of Representatives (1991–2001) and Member of the Tax Tribunal (2004–2007) of the Republic of Cyprus. Professor Philippou is Grande Ufficiale of Italy and Honorary President of the Mathematical Association of Cyprus. He is a reviewer of more than 400 papers and books (including papers written by Paul Erdős, Peter Hall, C. R. Rao, and N. Balakrishnan).

Dr. Demetrios Antzoulakos is Associate Professor at the University of Piraeus where he has been teaching since 1997. He has also taught earlier at the University of Crete. He wrote 30 research papers mainly on the topics of statistical process control and distribution theory of runs and patterns.

Diversity

Tarald O. Kvålseth
Professor Emeritus
University of Minnesota, Minneapolis, MN, USA

Introduction

Diversity is a concept that appears in various fields of study. In the most general situation involving a set of s exhaustive and mutually exclusive events with probabilities (or proportions) p_i $(i = 1, \ldots, s)$, diversity is an attribute that depends on s and all the individual p_i's. In particular, diversity is typically considered to increase with increasing s and with increasing evenness (uniformity) among the p_i's.

For any given s, diversity is considered to be minimum for the degenerate distribution P_s^0 and maximum for the completely even (uniform) distribution P_s^1 defined by

$$P_s^0 = (0,\ldots,0,1,0,\ldots,0),\ P_s^1 = (1/s,\ldots,1/s). \quad (1)$$

As a clarification of these concepts and their measurement, consider a generic measure of diversity D that takes on the value $D(P_s)$ for the probability distribution $P_s = (p_1,\ldots,p_s)$ with

$$D\left(P_s^0\right) \le D\left(P_s\right) \le D\left(P_s^1\right) \quad (2)$$

for the P_s^0 and P_s^1 in (1). Furthermore, define the normed form of $D(P_s)$ as

$$D^*(P_s) = \frac{D(P_s) - D\left(P_s^0\right)}{D\left(P_s^1\right) - D\left(P_s^0\right)} \in [0,1] \quad (3)$$

which effectively controls for s. From (3),

$$D(P_s) = D\left(P_s^0\right) + D^*(P_s)\left[D\left(P_s^1\right) - D\left(P_s^0\right)\right] \quad (4)$$

showing that $D(P_s)$ is an increasing function of both the evenness (uniformity) $D^*(P_s)$ and of $D(1/s,\ldots,1/s)$, which, for an appropriate measure D, is strictly increasing in s.

Numerous measures of diversity D and evenness D^* have been proposed. This is especially the case in biology (and ecology) where such measures are frequently used. In such applications, the concern is with a sample or a population of s different species, with p_i being the probability of the event that a randomly selected specimen belongs to the ith species for $i = 1,\ldots,s$. The $P_s = (p_1,\ldots,p_s)$ is then usually referred to as the *species abundance distribution* and s is often called the *species richness.*

Commonly Used Measures

The most widely used diversity measures appear to be the following:

$$D_1(P_s) = s, \quad (5)$$

$$D_2(P_s) = 1 - \sum_{i=1}^{s} p_i^2, \quad (6)$$

$$D_3(P_s) = -\sum_{i=1}^{s} p_i \log p_i. \quad (7)$$

where both base −2 and base −e (natural) logarithms are being used. The D_2 is most often referred to as the *Simpson index*, after Simpson (1949), although it is sometimes called the *Gini index* (e.g., Upton and Cook 2002). However, in some historical comments about D_2 and $1 - D_2$, Good (1982) suggested that "it is unjust to associate ρ with any one person" (where $\rho = 1 - D_2$). The measure of D_3 is the Shannon's entropy (Shannon 1948).

While D_1 has very limited information content, both D_2 and D_3 can be seen to have a number of desirable properties. In particular, for both $i = 2$ and $i = 3$, D_i is (a) zero-indifferent (expansible), i.e., $D_i(p_1,\ldots,p_s,0) = D_i(p_i,\ldots,p_s)$, (b) permutation symmetric in the p_i's, (c) continuous in the p_i's and (d) strictly Schur-concave in P_s (Marshall and Olkin 1979, ch. 3) and also strictly concave (in the usual sense). Also, with $D_i\left(P_s^0\right) = 0$ for both $i = 2$ and $i = 3$ in (2)–(4),

$$D_i(P_s) = D_i^*(P_s) D_i\left(P_s^1\right),\ i = 2,3 \quad (8)$$

with the evenness measure $D_i^*(P_s)$ for $i = 2,3$ (Magurran 2004, ch. 4) and showing that $D_i(P_s)$ increases with both evenness and s since $D_2\left(P_s^1\right) = 1 - 1/s$ and $D_3\left(P_s^1\right) = \log s$.

The D_2 in (6) has the advantage of having a reasonable probabilistic meaning, which helps with interpretation of its numerical values. In terms of a statistical experiment with s possible events whose probability distribution is $P_s = (p_1,\ldots,p_s)$, $D_2(P_s)$ is simply the probability that two independent repetitions of the experiment result in two different events occurring. In the case of a biological sample or population, $D_2(P_s)$ is the probability that two specimen, selected at random with replacement, belong to different species. By contrast, the D_3 in (7) has no such convenient probability interpretation. As a measure of diversity, this ▶entropy has no real or important, theoretical or practical, advantage over D_2. Nevertheless, and for no good reason, the D_3, often referred to as the Shannon index, remains a most popular diversity measure, causing some to lament that "Simpson's index remains inexplicably less popular than the Shannon index" (Magurran 2004: 115).

Cardinal Measures

Various other diversity measures and their corresponding evenness measures have been suggested (e.g., Magurran 2004). Some of these are cardinal measures or so-called *numbers equivalent* measures. Such a measure ranges in value from 1 for the distribution P_s^0 to s for the distribution P_s^1 in (1). For some diversity measure D, the numbers equivalent D_e is defined as being the number of elements in an equiprobable (completely even or uniform) distribution for which the value of D equals $D(P_s)$ for any given $P_s = (p_1,\ldots,p_s)$, i.e.,

$$D\left(1/D_e(P_s),\ldots,1/D_e(P_s)\right) = D(P_s) \quad (9)$$

where $D_e(P_s)$ is not necessarily an integer number, although this expression can only be strictly true in the integer case.

From (6), (7), and (9), the numbers equivalent of D_2 and D_3 (with base −e logarithms) are readily seen to be

$$D_4(P_s) = D_{2e}(P_s) = \frac{1}{1 - D_2(P_s)} = \frac{1}{\sum_{i=1}^{s} p_i^2},$$

$$D_5(P_s) = D_{3e}(P_s) = e^{D_3(P_s)}. \tag{10}$$

It is clear from (10) that, for the distributions in (1), $D_4\left(P_s^0\right) = D_5\left(P_s^0\right) = 1$ and $D_4\left(P_s^1\right) = D_5\left(P_s^1\right) = s$. Also, by subtracting 1 from $D_4(P_s)$, one gets the following measure (Kvålseth 1991):

$$D_6(P_s) = \frac{1}{\sum_{i=1}^{s} p_i^2} - 1 \tag{11}$$

which has a statistical odds interpretation equivalent to the probability interpretation of $D_2(P_s)$: it is the odds that different events will occur during two independent repetitions of a statistical experiment. Or, in the case when two specimen are randomly selected with replacement from a biological community (sample or population), $D_6(P_s)$ is the odds that the specimen will be of different species.

An interesting and rather intuitive diversity measure can be formulated by simply adjusting s for the absolute differences between the p_i's as follows:

$$D_7(P_s) = s - \sum_{1 \le i < j \le s} \sum |p_i - p_j| \tag{12}$$

where, for the distribution in (1), $D_7\left(P_s^0\right) = 1$ and $D_7\left(P_s^1\right) = s$. Since the summation term in (12) can be shown to be strictly Schur-convex (Marshall and Olkin 1979: 13, 411), $D_7(P_s)$ is strictly Schur-concave in P_s.

If the p_i's are ordered such that $p_{[1]} \ge p_{[2]} \ge \ldots \ge p_{[s]}$ and since

$$\sum_{1 \le i < j \le s} \sum |p_i - p_j| = \sum_{i=1}^{s-1} \sum_{j=i+1}^{s} (p_{[i]} - p_{[j]}) = \sum_{i=1}^{s} (s + 1 - 2i) p_{[i]}$$

the $D_7(P_s)$ in (12) can also be expressed as

$$D_7(P_s) = 2 \sum_{i=1}^{s} i p_{[i]} - 1. \tag{13}$$

The D_7 in (12)–(13) has been discovered and re-discovered as a potential diversity measure (Carmargo 1993; Kvålseth 1998; Patil and Taillie 1982). While Carmargo (1993) proposed $D_7(P_s)/s \in [1/s, 1]$ as an evenness index for which the lower bound depends on s, a preferred measure of evenness would seem from (3) to be

$$D_7^*(P_s) = \frac{2 \sum_{i=1}^{s} i p_{[i]}}{s - 1} \in [0, 1]. \tag{14}$$

Families of Measures

Parameterized families of diversity measures have also been proposed and of which some of the above measures are special members. Hill (1973) proposed the following inverse self-weighted arithmetic mean of order β:

$$D_{(\beta)}(P_s) = \left(\sum_{i=1}^{s} p_i^{\beta+1} \right)^{-1/\beta}, \quad -\infty < \beta < \infty \tag{15}$$

($\beta = \alpha - 1$ in Hill's notation). Patil and Taillie (1982) proposed

$$D^{(\beta)}(P_s) = \left(1 - \sum_{i=1}^{s} p_i^{\beta+1} \right) \Big/ \beta, \; -1 \le \beta < \infty. \tag{16}$$

From (5) to (7) and (16), it is seen that $D_1 = D^{(-1)} + 1$, $D_2 = D^{(1)}$, and $D_3 = D^{(0)}$ (in the limiting sense of $\beta \to 0$ and with natural logarithm in (7)). Also from (10) and (15), $D_4 = D_{(1)}$ and $D_5 = D_{(0)}$ (in the limit as $\beta \to 0$). It can also be seen from (9), (15) and (16) that $D_{(\beta)}$ is simply the numbers equivalent of $D^{(\beta)}$.

Statistical Inferences

Consider now that the p_i's are multinomial sample estimates (and estimators) $p_i = n_i/N$ for $i = 1, \ldots, s$ and with sample size $N = \sum_{i=1}^{s} n_i$. One may then be interested in making statistical inferences about the population value $D(\Pi_s)$ of some diversity measure D for the corresponding population distribution $\Pi_s = (\pi_1, \ldots, \pi_s)$. In particular, besides the estimate $D(P_s)$, one may want to construct a confidence interval for $D(\Pi_s)$. When N is reasonably large and $D(\Pi_s)$ is differentiable, it follows from the *delta method* Agresti (2002) that $D(P_s)$ has approximately a normal distribution with mean $D(\Pi_s)$ and estimated variance

$$\hat{\sigma}_D^2 = \frac{1}{N} \left[\sum_{i=1}^{s} p_i \hat{\phi}_{Di}^2 - \left(\sum_{i=1}^{s} p_i \hat{\phi}_{Di} \right)^2 \right] \tag{17}$$

where

$$\hat{\phi}_{Di} = \left. \frac{\partial D(\Pi_s)}{\partial \pi_i} \right|_{\pi_i = p_i}, \; i = 1, \ldots, s \tag{18}$$

i.e., $\hat{\phi}_{Di}$ is the partial derivative of $D(\Pi_s)$ with respect to π_i, which is then replaced with p_i, for $i = 1, \ldots, s$.

From (17)–(18) and for the D_i in (6), (7), (10), (11), and (13), the following estimated variances are obtained:

$$\hat{\sigma}^2_{D2} = \frac{4}{N}\left[\sum_{i=1}^{s} p_i^3 - \left(\sum_{i=1}^{s} p_i^2\right)^2\right], \tag{19}$$

$$\hat{\sigma}^2_{D3} = \frac{1}{N}\left[\sum_{i=1}^{s} p_i(\log p_i)^2 - \left(\sum_{i=1}^{s} p_i \log p_i\right)^2\right], \tag{20}$$

$$\hat{\sigma}^2_{D4} = \frac{4}{N\left(\sum_{i=1}^{s} p_i^2\right)^4}\left[\sum_{i=1}^{s} p_i^3 - \left(\sum_{i=1}^{s} p_i^2\right)^2\right], \tag{21}$$

$$\hat{\sigma}^2_{D5} = \left[D_5(P_s)\right]^2 \hat{\sigma}^2_{D3},\ \hat{\sigma}^2_{D6} = \hat{\sigma}^2_{D4}, \tag{22}$$

$$\hat{\sigma}^2_{D7} = \frac{4}{N}\left[\sum_{i=1}^{s} i^2 p_{[i]} - \left(\sum_{i=1}^{s} i p_{[i]}\right)^2\right] \tag{23}$$

where D_3 in (7) and (10) and hence (20) and D_5 in (22) are assumed to be based on natural logarithms.

For example, consider the multinomial frequencies $n_i = 17, 33, 20, 30$ for which $D_2(P_4) = 0.7322$, and from (19), $\hat{\sigma}^2_{D2} = 0.00017$. Consequently, an approximate 95% confidence interval for $D_2(\Pi_4)$ becomes $0.7322 \pm 1.96\sqrt{0.00017}$, or $(0.71, 0.76)$. Similarly, from (13) and (23), $D_7(P_4) = 3.4200$ and $\hat{\sigma}^2_{D7} = 0.0466$ so that an approximate 95% confidence interval for $D_7(\Pi_4)$ is $3.4200 \pm 1.96\sqrt{0.0466}$ or $(3.00, 3.84)$.

Divisible Statistics

Estate V. Khmaladze
Professor
Victoria University of Wellington, Wellington, New Zealand

Suppose $\nu_{in}, i = 1, \ldots, M$, are frequencies of M disjoint events in a sample of size n. Suppose the probabilities of these events are $p_i, i = 1, \ldots, M$. The statistics of the form

$$\sum_{i=1}^{M} g(\nu_{in}, np_i) \quad \text{or} \quad \sum_{i=1}^{M} h\left(\frac{\nu_{in} - np_i}{\sqrt{np_i}}, np_i\right)$$

are called divisible or additively divisible statistics. The total space was "divided" into disjoint events, then frequencies of these events were treated, so to say, "individually" and only then an aggregated sum was formed – hence the term. It will be more justified when we start speaking about finer and finer divisions of the space.

Examples of divisible statistics are easy to find. To some extent, to attribute to them the name of divisible statistics is similar to the discovery that we speak prose, as statisticians could very well have used and studied them without paying attention or knowing that these were divisible statistics. In the following examples,

$$X^2_{nM} = \sum_{i=1}^{M} \frac{(\nu_{in} - np_i)^2}{np_i}, \quad L_{nM} = \sum_{i=1}^{M} \nu_{in} \ln \frac{\nu_{in}}{np_i},$$

$$\mu_n = \sum_{i=1}^{M} \mathbb{I}\{\nu_{in} > 0\},$$

where $\mathbb{I}\{A\}$ denotes the indicator function of the event A, the reader will easily recognize the classical chi-square goodness of fit statistic, the maximum likelihood statistic for the ►multinomial distribution and what is often called an "empirical vocabulary" – the number of different events

in a sample. Versions of this latter statistic are often used in problems of statistical diversity, cryptology and analysis of texts:

$$\mu_n(0) = \sum_{i=1}^{M} \mathbb{I}\{\nu_{in} = 0\},$$
$$\mu_n(k) = \sum_{i=1}^{M} \mathbb{I}\{\nu_{in} = k\},\ k = 1, 2, \ldots.$$

The classical theory studies the asymptotic behavior of divisible statistics when the sample size $n \to \infty$, but the number of different events M stays fixed.

In many problems, however, a different setting is necessary: not only $n \to \infty$, but also $M \to \infty$ at the same time, so that $p_i, i = 1, \ldots, M$, form a triangular array of an increasing number of diminishing probabilities. Indeed, in statistical analysis of random number generators often no less than $M = 10^7$ different events are identified and samples of $n = 10^7$–10^8 are generated. In analysis of a corpus of a language, the number of different words is often of the order $M = 10^5$–10^6, while the size of texts analyzed is about $n = 10^6$–10^7 word-usages (see, e.g., Baayen 2001; Simpson et al. 2002).

As a rule, however, one cannot access this asymptotic range by using the classical results first and then letting M tend to ∞. For example, although it is true that

$$X^2_{nM} \to_d \chi^2_{M-1},\ n \to \infty, \quad \text{and}$$
$$\frac{\chi^2_{M-1} - (M-1)}{\sqrt{2(M-1)}} \to_d N(0,1),\ M \to \infty,$$

where χ^2_{M-1} is a chi-square random variable with $M-1$ degrees of freedom and $N(0,1)$ is a standard normal random variable, for most cases it is not true that

$$\frac{X^2_{nM} - (M-1)}{\sqrt{2(M-1)}} \to_d N(0,1)$$

if $n, M \to \infty$ simultaneously and $n/M \to const$.

One of the frequently used tools to study the asymptotic behavior of divisible statistics is the so-called Poissonization (see, e.g., Ivchenko and Medvedev 1980; Morris 1975): if sample size N is Poisson(n) random variable then frequencies $\nu_{iN}, i = 1, \ldots, M$, become independent Poisson(np_i) random variables and for $B_n \subset \mathbb{R}$

$$P\left\{\sum_{i=1}^{M} g(\nu_{in}, np_i) \in B_n\right\} = \frac{P\left\{\sum_{i=1}^{M} g(\nu_{iN}, np_i) \in B_n, N = n\right\}}{P\{N = n\}}.$$

In the numerator of the right side there is now a sum of independent random variables, which is convenient. Some trouble is, however, that the probability of $N = n$ tends to 0 and some sort of a local limit theorem must be used, while the probability on the left side is obviously of a global nature. In certain problems limit theorems for the process of partial sums

$$Z_n(m) = \sum_{i=1}^{m} g(\nu_{in}, np_i),\ m = 1, 2, \ldots, M,$$

are needed and the use of Poissonization above, again, becomes technically unpleasant.

Alternative approach, demonstrated in Khmaladze (1983), suggests the use of an "additional" object – the filtration $\{\mathcal{H}_{mn}\}_{m=1}^{M}$, where each σ-algebra $\mathcal{H}_{mn}$ is generated by the first m frequencies $\nu_{1n}, \ldots, \nu_{mn}$. The gain here lies in the following: in functional limit theorems for the resulting semi-martingale $\{Z_n(m), \mathcal{H}_{mn}\}_{m=1}^{M}$, conditional distribution of $\nu_{m+1,n}$ given $\mathcal{H}_{mn}$ plays a central role (see, e.g., Liptzer and Shiryaev 1980; Rebolledo 1975); however, this distribution is extremely simple – just binomial distribution $b(\cdot, \tilde{n}_{m+1}, \tilde{p}_{m+1})$ with parameters

$$\tilde{n}_{m+1} = n - \sum_{i=1}^{m} \nu_{in} \quad \text{and} \quad \tilde{p}_{m+1} = p_{m+1} \Big/ \left(1 - \sum_{i=1}^{m} p_i\right).$$

This allows to prove the functional limit theorem, that is, convergence to a Brownian motion (see ▶Brownian Motion and Diffusions), for the martingale part of $\{Z_n(m), \mathcal{H}_{mn}\}_{m=1}^{M}$ in a simple and natural way.

True that if $\max p_i \to 0$, while $n, M \to \infty$, the mutual dependence of multinomial frequencies $\nu_{in}, i = 1, \ldots, M$, decreases, but there is an increasing number of them. Therefore the process $\{Z_n(m), \mathcal{H}_{mn}\}_{m=1}^{M}$ should not be expected to converge to a process with independent increments. Centered and normalized in a usual way and in time $t = m/M$ this process converges to a Gaussian semi-martingale,

$$W(t) + K(t), \quad t \in [0,1],$$

where W is a Brownian motion and the compensator K, which accounts for the above mentioned dependence, is a process with differentiable trajectories.

This result, and its extensions, was established in Khmaladze (1983) under an assumption that all frequencies ν_{in} are asymptotically Poisson random variables. A very interesting case arises when some of the frequencies can be asymptotically Gaussian, that is, some probabilities in our triangular array do not decrease sufficiently quickly. Indeed, in a typical corpus of a contemporary language, with word-count of order 10^6, some words will occur tens of thousands of times, while many others only a few hundred times, while still many more will occur only a few times.

In this mixed case even an asymptotic expression for the expected values

$$E\sum_{i=1}^{M} h\left(\frac{v_{in}-np_i}{\sqrt{np_i}}, np_i\right)$$

becomes an object of research. In particular, asymptotic expressions for $E\mu_n(k)$ may reveal the presence or absence of well known limiting expressions like Zipf's law or Karlin–Rouault law (see, e.g., Baayen 2001; Karlin 1968; Rouault 1978). Also the central limit theorem (see ►Central Limit Theorems) for the mixed case is yet to be established. At the moment of writing this article some work on this was in progress (e.g., Khmaladze 2009; Kvizhinadze and Wu 2010).

Dummy Variables

Nataša Erjavec
Professor, Faculty of Economics
University of Zagreb, Zagreb, Croatia

D

A dummy variable is a binary variable that can take only two values, 0 and 1. It is often used in the regression model to incorporate qualitative (categorical) explanatory variables, such as gender (male or female), marital status (single or married), union membership (yes or no), etc. In the above examples, the dummy variable can be defined to take the value one if the observation relates to a male and zero for a female (or vice versa), one for single and zero if married, one for a union member and zero if a nonmember. The dummy variable can then be used in a standard regression model like any other regressor (Green 2002). As an example, if we are interested whether earnings are subject to gender discrimination, the simple regression model can be defined as

$$Y_i = \alpha + \beta X_i + \gamma D_i + \varepsilon_i \quad (1)$$

in which the regressand (Y) are earnings and the regressor (X) is the working hours of an individual. In the model, one dummy variable is introduced that takes the value one ($D_i = 1$) if the ith individual is male and zero ($D_i = 0$) if the individual is female. The parameter γ in Eq. (1) represents the difference between the expected earnings of men and women who work the same hours.

In general, the qualitative (categorical) variable can have k classifications (categories). The examples are ethnicity (i.e., Hispanic, black, or white), region (north, south, east, and west) in a study of salary levels in a sample of highly educated employees or the effects of company size (small, medium, or large) on wages. In such cases, in the standard regression model $(k-1)$ dummy variables are required, one less than the number of classifications. In this way, the dummy trap (perfect ►multicollinearity when the model cannot be estimated) is avoided. For example, when analyzing the effects of company size on wages in which there are three types of companies (small, medium, and large), $k = 3$, two dummy variables are required in the regression model. Thus, the regression model (1) can be extended to

$$Y_i = \alpha + \beta X_i + \gamma D_{Mi} + \delta D_{Li} + \varepsilon_i \quad (2)$$

where the dummy variable D_{Mi} takes the value of one if the ith individual works in a medium size company and zero otherwise, while D_{Li} takes the value of one if the ith individual works in the large company and zero otherwise. The small company is taken as a reference category to

which Eq. (2) applies. The dummy variable for the reference category is not included. In Eq. (2), the parameter γ now represents the expected extra earnings of an individual who works in medium size company relative to the earnings of an individual in the reference category, i.e., in a small company.

Dummy variables have many applications. For example, with dummy variables one can treat seasonality in the data or capture the effect of ►outliers (e.g., abrupt shifts in data). Furthermore, in the regression model, a dummy variable can be used as a regressor variable for coefficient stability tests, for obtaining predictions or for imposing cross-equation constraints (Maddala 2002). On the other hand, a dummy variable as a regressand variable is used in the linear probability model, logit model, and probit model.

Durbin–Watson Test

Walter Krämer
Professor and Chairman
Technische Universität Dortmund, Dortmund, Germany

The Durbin–Watson test is arguably, next to the method of ►least squares, the most widely applied procedure in all of statistics; it is routinely provided by most software packages and almost automatically applied in the analysis of economic time series when a researcher is fitting a linear regression model (see ►Linear Regression Models)

$$y = X\beta + u, \tag{1}$$

where y $(T \times 1)$ and X $(T \times K$, nonstochastic, rank $K)$ denote the vector of observations of the dependent and the matrix of observations of K independent (regressor-) variables, respectively, β is a $K \times 1$ vector of unknown regression coefficients to be estimated, and u $(T \times 1)$ is an unobservable vector of stochastic errors (disturbances, latent variables) with mean zero and equal variances. In the case of uncorrelated disturbances it is known from the ►Gauss-Markov-Theorem that the ordinary least squares estimator $\hat{\beta}$ for β, where $\hat{\beta} = (X'X)^{-1}X'y$ is best linear unbiased (BLUE) for β. In a time-series context, however, one often suspects that the components u_t of u might be correlated with each other, so it is of much interest to test whether the latter is indeed the case.

Due to the vastness of the alternative, there is no hope that a uniformly most powerful test exists (Anderson 1948) and one has to focus on more restricted alternatives. The one investigated by Durbin and Watson (1950, 1951, 1971) stipulates that the u_t's follow a stationary first order autoregressive process

$$u_t = \rho u_{t-1} + \epsilon_t \quad (|\rho| < 1, \epsilon_i \sim iid), \quad t = 2, \ldots, T \tag{2}$$

so the correlation matrix V of u is given by

$$V = \begin{bmatrix} 1 & \rho & & \rho^{T-1} \\ \rho & 1 & & \rho^{T-2} \\ \vdots & \vdots & \ddots & \vdots \\ \rho^{T-1} & \rho^{t-2} & & 1 \end{bmatrix} \tag{3}$$

and the null hypothesis boils down to $H_0 : \rho = 0$. The DW test statistic is

$$d = \frac{\sum_{t=2}^{T} (\hat{u}_t - \hat{u}_{t-1})^2}{\sum_{t=1}^{T} \hat{u}_t^2} = \frac{\hat{u}' A \hat{u}}{\hat{u}'\hat{u}}, \tag{4}$$

where $\hat{u} = y - X\hat{\beta}$ and

$$A = \begin{bmatrix} 1 & -1 & & & 0 \\ -1 & 2 & \ddots & & \\ & \ddots & \ddots & \ddots & \\ & & \ddots & 2 & -1 \\ 0 & & & -1 & 1 \end{bmatrix}. \tag{5}$$

It is easily checked that $0 \le d \le 4$. With positive serial correlation among the u_t's, neighboring u_t's and thus $\hat{u}_t$'s will tend to be close to each other, i.e., d will tend to be small. On the other hand, when ρ is negative, d will be large. A plausible two-sided test therefore rejects H_0 whenever d moves too far from 2, the mid-point of its range. One-sided tests will reject H_0 whenever d is too small $(H_1 : \rho > 0)$ or too large $(H_1 : \rho < 0)$.

Before the era of modern computers, the usefulness of this rule was compromised by the dependence of the null distribution on the regressor matrix X. Given T and K and selected significance levels, Durbin and Watson provided upper and lower bounds for the critical values; no conclusion was possible for a test statistic in between (the "inconclusive range"). Today, exact prob-values are easily available via some variant of the Imhof-algorithm (1961). Also, there exist competitors like the Breusch (1978)–Godfrey (1978) test which do not require fixed regressors or AR(1)-alternatives.

The theoretical foundation for the DW test dates back to Anderson (1948). He showed that whenever the disturbance vector u has density

$$f(u) = K\, exp\left[-\frac{1}{2\sigma^2}((1+\rho^2)u'u - 2\rho u'\phi u)\right], \qquad (6)$$

where K is some constant and ϕ is a symmetric $T \times T$ matrix, a uniformly most powerful test of $H_0 : \rho = 0$ against $H_1 : \rho > 0$ is given by

$$\frac{\hat{u}'\phi\hat{u}}{\hat{u}'\hat{u}} > k, \qquad (7)$$

provided the columns of X are linear combinations of eigenvectors of ϕ. This result is linked to the DW test as follows: The inverse of $\mathsf{Cov}(u)$ is

$$\frac{1}{\sigma_u^2}V^{-1} = \frac{1}{\sigma_\epsilon^2}\begin{bmatrix} 1 & -\rho & & & 0 \\ -\rho & 1+\rho^2 & \ddots & & \\ & \ddots & \ddots & \ddots & \\ & & \ddots & 1+\rho^2 & -\rho \\ 0 & & & -\rho & 1 \end{bmatrix} \qquad (8)$$

$$= \tfrac{1}{2\sigma_\epsilon^2}[(1+\rho^2)I - 2\rho\phi - \rho(\rho-1)C],$$

where

$$\phi = \frac{1}{2}\begin{bmatrix} 1 & 1 & & & 0 \\ 1 & 0 & \ddots & & \\ & \ddots & \ddots & \ddots & \\ & & \ddots & 0 & 1 \\ 0 & & & 1 & 1 \end{bmatrix}$$

and C= diag(1,0,…,0,1). Thus when we neglect the term $\rho(1-\rho)C$, the density of u is of the form (6), and from Anderson's result, an UMP rejection region against $H_1 : \rho > 0$ is obtained from large values of $\hat{u}'\phi\hat{u}/\hat{u}'\hat{u}$. Since $A = 2I - 2\phi$, this is equivalent to rejecting whenever $d = \frac{\hat{u}'A\hat{u}}{\hat{u}'\hat{u}}$ is too small.

A crucial condition for the approximate optimality of the DW test is that the column space of X be spanned by eigenvectors of ϕ. Much less is known about the power of the DW test when this condition fails. In fact, the power of the DW test can even drop to zero for certain regressors (Krämer 1985). This is so because for regressions without an intercept, d tends to some constant $\bar{d}$ as $\rho \to 1$. If $\bar{d}$ is less than the critical level $d^\star$ corresponding to the given X matrix and significance level, the limiting power of the DW test is 1, otherwise it is zero (neglecting the possibility that $\bar{d} = d^\star$).

Econometrics

Peter Kennedy
Professor Emeritus
Simon Fraser University, Burnaby, B.C., Canada

Several definitions of econometrics exist, a popular example being "Econometrics is the study of the application of statistical methods to the analysis of economic phenomena." The variety of definitions is due to econometricians wearing many different hats. First, and foremost, they are *economists*, capable of utilizing economic theory to improve their empirical analyses of the problems they address. At times they are *mathematicians*, formulating economic theory in ways that make it appropriate for statistical testing. At times they are *accountants*, concerned with the problem of finding and collecting economic data and relating theoretical economic variables to observable ones. At times they are *applied statisticians*, spending hours with the computer trying to estimate economic relationships or predict economic events. And at times they are *theoretical statisticians*, applying their skills to the development of statistical techniques appropriate to the empirical problems characterizing the science of economics. It is to the last of these roles that the term "econometric theory" applies, and it is on this aspect of econometrics that most textbooks on the subject focus.

The workhorse of econometrics is the linear regression model (see ▶Linear Regression Models), extended in a wide variety of nonlinear ways. So, for example, the log of wages might be regressed on explanatory variables such as years of education and a dummy for gender, with interest focusing on the slope of years of education, reflecting the return to investing in education, and the slope of the gender dummy, measuring discrimination in the labor market. Because this kind of empirical analysis is an important element of traditional statistics, one might naturally ask "How does econometrics differ from statistics?" There are two main differences between econometrics and statistics. The first stems from the fact that most economic data come from the real world rather than from controlled experiments, forcing econometricians to develop special techniques to deal with the unique statistical problems that accompany such data. The second difference is that econometricians believe that economic data reflect strategic behavior by the individuals and firms being observed, and so they employ models of human behavior to structure their data analyses. Statisticians are less willing to impose this kind of structure, mainly because doing so usually is not fully consistent with the data. Econometricians ignore such inconsistencies, so long as they are not gross, to enable them to address issues of interest. Some examples can illustrate these differences, the first four below resulting in Nobel prizes for econometricians.

1. Other things equal, females with young children earn higher wages than females without young children. Why? Females with children only appear in the labor market if their wage is large enough to entice them away from being a homemaker; this means that a sample of female wage earners is not a random sample of potential female workers – other things equal, low-wage earners are under-represented. This *self-selection* phenomenon causes bias in estimates of the wage equation, a bias that is of consequence because it narrows the estimated discrimination gap between male and female wages.
2. Economics is all about people making choices in a world of scarcity. People make choices (and thereby produce data for the econometrician) by maximizing an objective function. How do people choose which transportation mode to use to commute to work? Economic theory suggested addressing this question using the *random utility* model in which people choose on the basis of which option provides them with the greatest utility. Viewing the problem this way greatly enhanced the development of *multinomial logit/probit* analyses, resulting in markedly superior predictions of the ridership of the San Francisco bay area rapid transit system, then under construction.
3. For many years, in time series data it was thought that it did not make sense to employ levels and first differenced data in the same specification, and statisticians were careful to avoid doing this. But economic theory suggested that a certain combination of levels

Miodrag Lovric (ed.), *International Encyclopedia of Statistical Science*, DOI 10.1007/978-3-642-04898-2,

data, representing an economic equilibrium position, could be compatible with differenced data. This concept of *cointegration* has changed forever the way in which time series analysis is undertaken.

4. Why would we ever be interested in how volatile some variable will be in the future? When pricing financial instruments such as options such information is crucial. An econometrician developed a way of addressing this problem, creating a major statistical industry, referred to as ARCH, *autoregressive conditional heteroskedasticity*.
5. Supply and demand curves are at the heart of economic analysis. When we regress quantity on price how do we know if the result is an estimated supply curve, an estimated demand curve, or garbage (a linear combination of the two)? To some the solution to this *identification* problem in the late 1940s marked the beginning of econometrics as a separate discipline. (But to others the founding of the Econometric Society and its journal *Econometrica* in the early 1930s marks the beginning of econometrics.)
6. The interaction of supply and demand illustrates another special feature of econometric work. Suppose we are estimating a demand curve and suppose amount demanded changes due to a bump in the error term in the demand equation. This shifts the demand curve, changes the intersection of the supply and demand curves, and so changes price. A regression of quantity on price produces biased estimates because the explanatory variable price is correlated with the error term in the demand equation. This dilemma of *simultaneous equation bias* is widespread, occurring whenever variables feed back to one another. *Instrumental variable* estimation, developed by econometricians, is a way of avoiding bias in this context.
7. When a sporting event is sold out, we don't know the actual demand for tickets; all we know is that the demand was at least as big as the venue's seating capacity. When estimating the determinants of demand what should we do with the observations on sold-out games? Estimation in the context of such *limited dependent variables* is another example of special estimation procedures developed by econometricians.

For a much more detailed overview of econometrics, including discussion of its historical development, see Geweke et al. (2008). For both students and practitioners, Kennedy (2008) is a very popular source of information on econometrics, offering intuition, skepticism, insights, humor, and practical advice. Section 1.1, beginning on p. 6, offers general commentary on "What is Econometrics?" and provides further references.

About the Author

Peter Kennedy received his BA from Queen's in 1965 and Ph.D. from Wisconsin in 1968. He is Professor Emeritus, Simon Fraser University. He held visiting positions at Cornell, Wisconsin, the London School of Economics, Singapore, Deakin, Cape Town, Canterbury, Curtin, Adelaide, Otago, and EERC (Ukraine). Peter Kennedy is best known as the author of *A Guide to Econometrics* (sixth edition, 2008, Wiley-Blackwell). He is the recipient of four awards for excellence in teaching, and one award for excellence in research. Upon retiring from Simon Fraser University in 2008, he stepped down as an associate editor of the *International Journal of Forecasting* and of *Economics Bulletin*, but continues to edit the research section of the *Journal of Economic Education*.

"Kennedy's Guide is a handbook of important concepts, techniques, and mathematical results that are developed at length in the standard textbooks but for which insights, interpretations, and intuition are missing. The popularity of his earlier three editions and their presence on students' shelves around the world documents the usefulness of Kennedy's ability to communicate the essence of econometrics without losing the reader in technical details" (Becker W. E., *The Journal of Economic Education*, 30, 1999, p. 89.).

Econometrics: A Failed Science?

Jan Kmenta
Professor Emeritus
University of Michigan, Ann Arbor, MI, USA
Center for Economic Research and Graduate Education, Prague, Czech Republic

The official beginning of ►econometrics can be traced to the first issue of *Econometrica* (1933), the journal

dedicated to the "advancement of economic theory in its relation to statistics and mathematics." This makes it clear that the development of economic theory as a discursive process is to be supplemented by quantitative analysis and that econometrics is a part of economics. The earliest major attempts at specifying and estimating economic relationships include the famous – and to this day used – Cobb-Douglas production function (1928), the first macro-econometric models of Jan Tinbergen (1936 and 1939), and various unsuccessful attempts at estimating supply and demand functions in the 1930s.

The first systematic development of the mathematical formulation of economic theory, without which rigorous research in econometrics could not exist, is due to Paul Samuelson's *Foundations of Economic Analysis* (1947). The next step was the development of econometric methods largely due to the work of the researchers at the Cowles Commission at the University of Chicago (1939–1955). The resulting series of monographs included a solution to the identification problem that allowed separate estimations of supply and demand functions. An irony of fate is that the solution of the identification problem was provided already by Tinbergen in an overlooked article written in German and published in Vienna in 1930. The Cowles Commission monographs laid foundation to the formulation and estimation of simultaneous equation models that swamped the econometric literature in the 1960s and 1970s. All of this led W.C. Mitchell, one of the founders of the National Bureau for Economic Research (NBER), to declare in 1950 that "we must expect a recasting of old problems into new forms amenable to statistical attack."

The monographs of Cowles Commission would not have made an impact on the profession of economics and would not have led to the ensuing "scientific revolution" in economics – had they not given rise to a number of early popularizers who translated the sophisticated and technical language of the monographs into a language understandable to economists. Prominent among these were Gerhard Tintner, Henri Theil, Lawrence Klein, and Denis Sargan who carried the torch of econometric enlightenment in the 1950s and 1960s.

The subsequent two decades were marked by the introduction of the computer technology that enabled implementation of Monte Carlo experiments, formulation and estimation of large macro-econometric models, handling of large micro-data sets, and ►numerical integration of Bayesian inference. Indeed, at a conference in Princeton in 1972 computers were reported to have been of only moderate influence in various disciplines except economics. Of course, the use of computers required an accessory development of software. In this context a breakthrough was made by Harry Eisenpress who in 1962 compiled a program for computing maximum likelihood estimates of the coefficients of simultaneous equation models.

The introduction of computer technology really helped econometrics to take off. The macro-econometric modeling efforts were crowned by the Nobel Prize awarded to Lawrence Klein in 1980, the upsurge of micro-econometrics culminated with the award of the Nobel Prize to James Heckman and Daniel McFadden in 2000, and the modern "time series revolution" was blessed by the award of the Nobel Prize to Robert Engle and Clive Granger in 2003.

However, the golden years of econometrics were not without criticism. Articles and books with ominous sounding titles made an appearance that did not go unnoticed in the profession. Following are some of the titles appearing in the literature:

"Econometrics: Alchemy or Science?" (Hendry 1980)
"Lets Take the 'Con' out of Econometrics" (Leamer 1983)
"Data Mining" (Lovell 1983)
"What Will Take the Con out of Econometrics" (McAleer et al. 1985)
"The Foundations of Econometrics: Are There Any?" (Swamy et al. 1985)
Economics in Disarray (wiles and Routh 1985)
The Death of Economics (Ormerod 1994)

There were several bases for these criticisms, one of which was the poor specification and forecasting performance of econometric models. The sharpest criticism came from Sims (1980) who declared that "among academic macro-economists the conventional methods (of macro-econometric modeling), have not just been attacked, they have been discredited." Sims' response to the challenge was the introduction of the vector-autoregressive (VAR) model formulation (see ►Vector Autoregressive Models).

Another line of criticism, coming from David Hendry, was about estimation being the focus of econometric practice. According to Hendry (1980), "what should have been a relatively minor aspect of the subject, namely estimation, has been accorded the centre of the stage…the three golden rules of econometrics are test, test, test !" The common practice of "data mining," (see ►Data Mining) namely trying different model formulations until the estimated parameters conform to the pre-judgment of the investigator, also did not escape criticism. A sarcastic but fitting description of this practice is due to Leamer (1983) who noted that "if you torture data long enough, Nature will confess."

Hendry (1980) provided further elaboration of this point by a cute example, "Econometricians have found their Philosopher's stone. It is called regression analysis and it is used for transforming data into 'significant results'.

Deception is easily practiced." As an example, Hendry came up with his own 'theory of inflation' in which the price level is a function of a variable $C(t)$ and an auto regressive disturbance, where $C(t)$ is cumulative rainfall in the UK. The fit was spectacular, even better than if $C(t)$ was replaced by the quantity of money.

Perhaps the most serious criticism was leveled against the alleged meager contribution of econometrics to economic knowledge. The earliest criticism on this count came from Leontief (1971) who in his presidential address declared that, "in no other field of empirical inquiry has so massive and sophisticated statistical machinery been used with such indifferent results." Blaug (1980) elaborated on this theme by stating that, "empirical work that fails utterly to discriminate between competing explanations quickly degenerates into a sort of mindless instrumentalism and it is not too much to say that the bulk of empirical work in modern economics is guilty on that score."

The "time series revolution" in econometric practice, initiated by Engle and Granger in the 1970s, does not help in the direction of expanding economic knowledge either. On the contrary the mechanistic modeling of time series analysis pushes econometrics away from economics. This "revolution" is based on the contention – not rejected by statistical tests – that many economic variables have infinite variances, that is, that they grow without limit in time, and thus observed relationships maybe purely fictitious. The consoling fact is that while the variables themselves have infinite variances, typically the linear combinations of their first differences may well have variances that are finite. However, there are some serious problems with the way time series analysis is presented in the text books and applied in research. With respect to the former, the standard approach of teaching time series analysis ignores completely the classical econometrics, whose basic foundation is the regression model. A logical way would be to explain which of the assumptions of the classical regression model are likely to be violated when dealing with economic time series data. This would then be followed by discussion of the undesirable consequences of this on the properties of the least squares estimators and what to do about it. As it is, there is a complete disassociation between classical econometrics and time series econometrics. A lack of connection between time series analysis and economics as such is even more remarkable. The standard explanation of the long-run path of any economic variables as being purely determined by the passage of time plus a stochastic disturbance, with no reference to economic factors, is "primitive beyond words" (Kocenda and Cerny 2007). As for the so-called "co-integration analysis," uncovering that certain economic variables move together in stable relationships and looking for their economic interpretation is in contrast to the traditional deductive approach in which theory comes first and is followed by testing.

A final bone of contention regarding econometrics are the common results of empirical research that conflict with each other. This was pointedly illustrated by Leamer (1985) in his comments on the study of the deterrent of capital punishment …"there was a great outpouring of papers that showed that the results depend on (i) which variables are included; (ii) which observations are included; (iii) how simultaneity is treated, etc."

The source of failure of econometrics to satisfy its critics is undoubtedly due to, "a huge credibility gap between economic theory, empirical evidence and policy prescriptions" (Phillips 1988). The fault is on both sides; on the side of economic theorists as well as on the side of applied econometricians. Most economic theorists do not allow for the stochastic nature of the world, and most applied researchers tend to be very casual about the stochastic specifications of their models. Most of the work of economic theorists deals with deterministic models, while most of the applied workers treat the stochastic disturbance in their models as an afterthought barely worth mentioning. There are exceptions, of course, and they should be appreciated. In the field of micro-economics, the shining example of stochastic consciousness are the labor economists, while in the field of macro-economics the orchid goes to the dynamic stochastic general equilibrium models (DSGE), the modern successors of the simultaneous equation models of yesterday. On the whole, though, the gap between economic theory and empirical research is daunting. To rescue the reputation of econometrics and to "advance economic theory in relation to statistics and mathematics" it is, in my opinion, absolutely necessary for economic theory and econometrics to merge. There should be no separation between economic theory and econometrics as it by and large exists today.

About the Author

Jan Kmenta received his B.Ec with First Class Honors from the University of Sydney, Australia in 1955 and graduated from Stanford University with a Ph.D. in Economics with a minor in Statistics in 1964. He is a Fellow of the American Statistical Association since 1970 and a Fellow of the Econometric Society since 1980. Professor Kmenta has received the Alexander von Humboldt Foundation Award

for Senior U.S. Scientists (1979–1980). He was awarded an Honorary Doctorate from the University of Saarland, Germany (1989), and in 1998 he was the first recipient of the Karel Engliš Medal from the Academy of Sciences of the Czech Republic. In 2007 he received an annual award from the Czech Society of Economic for long-term contribution to the development of teaching of economics in the Czech Republic. Professor Kmenta has published a number of articles in prominent economic and statistical journals. He was ranked as 40th among all economists ranked by the total number of citations (1971–1985). Professor Kmenta is well known as the author of the internationally respected text *The Elements of Econometrics* (University of Michigan Press, 2nd edition, 1997), that was translated into several foreign languages.

Economic Growth and Well-Being: Statistical Perspective

Zarylbek I. Kudabaev
Chairman of the Statistical Society of Kyrgyz Republic, Professor, Head of Economic Department
American University of Central Asia, Bishkek, Kyrgyz Republic

► There is a clear case for complementing GDP with statistics covering the other economic, social and environmental issues, on which people's well-being critically depends.
European Commission (2009)

Access to well-developed, cross-cutting, high-quality shared information is a basic need of an effective democracy. The more information people have about economic and social conditions and trends in their countries, the better able they are to demand from politicians policies that improve economic growth and development. Another issue is the public's trust in its government. If people don't believe the figures that their official statistical bodies produce, they are likely to lose trust in government as a whole, which can have a negative impact on the democratic process.

So, the challenge is avoiding a gap between the official statistics on economic performance and the public's perception of their own living conditions. Such a gap has been evident over a long period in many countries around the world, but it is especially the case for the developing countries. Possible reasons for the gap between the official statistics and people's perceptions are misuse of certain statistics or the poor quality of official statistics.

Misuse of Certain Statistics

Statistical data produced for one purpose may not be appropriate for other purposes. A good example is gross domestic product (GDP), which tells us a nation's total income and the total expenditure on its output of goods and services and mainly is a measure of market production. GDP is not well suited as a metric of well-being, but it has been increasingly used for this purpose. GDP fails to capture such factors as unpaid work of households, distribution of income among the population groups, and depletion of resources, which creates a problem in using GDP (or GDP per capita) as an indicator of well-being. For example, if inequality in income distribution among population groups increases enough relative to the increase in average GDP per capita, then most people will be worse off even though average income is increasing. Or, if the number of cars drastically increases, then GDP goes up, but it

also leads to traffic jams and an increase in air pollution. In these examples, from the public's perspective, an increase in GDP does not improve their quality of life at all. For these reasons the original architects of the United Nations System of National Accounts (SNA) knew that well-being could not be measured by national income alone.

Low Quality of Official Statistics

Developing countries are more likely to produce official statistics of lower quality. Due to economic difficulties, developing countries struggle with making significant investments to develop statistical systems that are able to produce, using internationally recognized methodologies, a whole set of necessary indicators of economic and social progress.

The quality of official statistics might also be low because existing methodologies are imperfect. For example, consider how well statisticians can measure a non-observed, or shadow, economy. The economy of any country consist of two parts, observed and non-observed. The share of non-observed (shadow) economy in the GDP can be significant, especially in developing countries (up to 50% and higher). Also, it is well known that, in developing countries, many city-dwellers and internal migrants from rural areas are able to survive only because of their employment in the non-observed economy. Therefore, it is not possible to ignore a measure of non-observed economy in terms of both economic growth and development (well-being). It has to be separately estimated (measured) and then included in the country's GDP. There are several methodologies, based on different approaches, for measurement of the non-observed economy: conducting surveys of households on production of goods and services in the non-observed economy, labor force surveys, analysis of cash operations, analysis of electricity supply, and so on. But the problem is that all of the existing methodologies for measurement of the non-observed economy are not as good as those for the observed economy, and they should be improved significantly. The same criticism can applied to the statistical data on services, which should be improved as well.

What Should Be Done?

Statistical indicators for economic performance, although they are well developed, need to be improved in order to provide accurate monitoring of the evolution of modern economies (Stiglitz et al. 2009). Evolution toward a more complex economy means the growth of the share of services and production of a more complex quality of goods.

The "Going beyond GDP" strategy is very promising as a better measure of societal well-being, quality of life, and progress. "Going beyond GDP" does not mean dismissing GDP and production measures. It means complementing GDP with statistics on which people's well-being critically depends.

Well-being is multidimensional and includes not just economic but also social, environmental, and governance, and, as mentioned in (Stiglitz et al. 2009), the following dimensions should be considered simultaneously:

1. Material living standards (income, consumption, and wealth)
2. Health
3. Education
4. Personal activities including work
5. Political voice and governance
6. Social connections and relationships
7. Environment (present and future conditions)
8. Insecurity, of an economic as well as a physical nature

Real implementation of the "Going beyond GDP" strategy is a huge challenge for statisticians, and it likely requires a shift in emphasis from measuring economic production to measuring people's well-being.

Ideally, national accounts of well-being should be developed for the successful monitoring of social progress, as is already done for monitoring of economic progress (Michaelson et al. 2009). Forty-eight indicators of the Millennium Development Goals (MDG), in combination with the indicators of SNA, could be a good basis for construction of the national accounts of well-being.

How can developing countries improve their statistical products? International organizations and well-developed countries could play a key role. Strengthening the statistical capacities should become an important part of their programs of support for developing countries.

Economic Statistics

Yasuto Yoshizoe
Professor, President of the Japan Statistical Society
Aoyama Gakuin University, Tokyo, Japan

Introduction

In this article, we regard economic statistics as a branch of applied statistics which deals with the following topics: (1) collection of statistics on socioeconomic conditions, (2) compilation of surveys and registered records to produce various economic indicators, such as consumer price index or GDP, (3) evaluation of economic indicators from the viewpoint of reliability.

Economic statistics is closely related to official statistics, since most of the statistics of the society and economy are provided by official organizations like national statistical offices or intergovernmental organizations such as United Nations, OECD, and World Bank. On the other hand, economic statistics is different from econometrics in a narrow sense. Typically, objective of econometrics lies in developing the theory and its applications to various economic data. In contrast, economic statistics places more emphasis on quality of data before applying sophisticated methods to analyze them. In other words, we are more interested in appropriate interpretation of the data paying attention to their detailed characteristics.

Here, we describe some typical issues from economic statistics: censuses, sample surveys, index numbers, system of national accounts, followed by an illustrative example.

Censuses – Complete Enumeration

Consumers and producers consist of two major components in economics. Correspondingly, two fundamental information of economic statistics are (1) population and households, and (2) firms and establishments. U.S. Census Bureau, http://www.census.gov/econ/, provides definitions of firms and establishments among other related concepts.

To construct reliable statistics on these subjects, the complete enumeration is required. A ►*census* is the procedure of collecting information about all members of a population. In many countries, population censuses are carried out periodically. In contrast, information of firms and establishments are obtained either by statistical surveys (so-called economic censuses) or by registered information collected through some legal requirement.

The complete enumeration is necessary to provide accurate information for small areas. In planning the location of elementary schools, hospitals or care agencies for elderly people, local governments need information for small areas. If the censuses or registration records provide accurate information, local governments can depend on them in making important policies.

Another role of the census is that it provides a list of households or firms/establishments. Such a list is used as the *sampling frame*, and it plays an essential role in many sampling surveys described in the next section. In this sense, inaccurate censuses, or administrative records that are out of date, reduces the reliability of sample surveys, and eventually increase social costs.

For household surveys, efficient sampling designs, such as stratified sampling, become difficult if accurate sampling frame is not available. The inaccurate sampling frame can sometimes cause extremely biased estimates for business surveys due to frequent entry/exit behavior of firms/establishments. An example is given later.

Sample Surveys

Since economic conditions vary dynamically, we need monthly or quarterly indicators, such as consumer price index or industrial production index. These statistics have to be compiled from sample surveys on households and/or establishments. Therefore, the accuracy of sampling survey is crucial in maintaining reliability of economic indicators. Major factors that affect performance of the estimators are: sampling design (e.g., simple random sampling, stratified sampling, cluster sampling, etc.) and estimation methods (e.g., linear estimator, ratio estimator, regression estimator, etc.). See Cochran (1977), Groves et al. (2004), Lesser and Kalsbeek (1992), and Särndal et al. (1992) for detail.

The auxiliary information available from censuses are used to set up appropriate strata, or to apply a ratio estimation, resulting in more efficient and inexpensive surveys. An example of ratio estimator is to use the size of population who are older than 15 years (Y) to estimate the number of employees (X). Let the sample means are $\bar{x}$ and $\bar{y}$ in a sample of size n from a population of size N. In case of simple random sampling, the linear estimator is $\hat{X} = N\bar{x}$. On the other hand, if population Y is obtained from a census and additional registration records, then the ratio estimator defined by $\hat{X}_r = Y(\bar{x}/\bar{y})$ can be applied. Since X and Y are correlated, $\hat{X}_r$ has a smaller variance than $\hat{X}$.

More important and difficult task is that we need to evaluate the *non-sampling errors*, such as nonresponse caused by many reasons, possible bias from a deteriorated sampling frame, etc. In the example above, the ratio estimator may become worse if Y is incorrectly measured.

As for business surveys, about 5% of establishments start business and another 5% shut down annually in case of Japan. It is clear that maintaining accurate list of establishments is vital for high quality of economic statistics.

Index Numbers

►Index numbers are widely used to compare levels and evaluate changes of economic variables over time or among regions (see Schultze and Mackie 2002; ILO 2004). Typically, the base value equals 100, but it can be other values. For example, the real GDP can be regarded as a quantity index, if we choose its base value as the nominal GDP of the base year. Most often, index numbers are used to compare economic variables, such as unemployment or prices, over time. In some cases, however, index numbers may compare geographic areas at a specific time. Such an example is the *purchasing power parity*, which is an international comparison of prices among countries.

As for price index and quantity index, the most well-known formulas are Laspeyres, Paasche, and Fisher. If we deal with $i = 1, \ldots, n$ commodities (goods or services), we need to collect data of prices p_{it} and quantities q_{it} at time t. Then the three price indexes (base period is $t = 0$) are defined as Laspeyres: $P_L = \sum p_{it}q_{i0}/\sum p_{i0}q_{i0}$, Paasche: $P_P = \sum p_{it}q_{it}/\sum p_{i0}q_{it}$, and Fisher: $P_F = \sqrt{P_L P_P}$. Similarly, quantity indexes are defined by interchanging p and q in the definitions.

These formulas are, however, too superficial for practical purposes. In calculating consumer price index (CPI), national statistical offices of developed countries adopt much more complicated methods using vast amount of related data. The price of a specific merchandize (a pack of milk, for example) varies among stores and areas. Moreover, there are several kinds of milk that consumers purchase in a given period. The observed prices are averaged by some method before the price is used as p_{it} in an index formula like Laspeyres. Hence, we should review and evaluate the appropriateness of the specific method employed. The judgment also depends on the data collection procedure of prices and weights, which varies among national statistical offices.

Since CPI has a rigorous background in economic theory, there is a good amount of reference, including the definition of the *true index number*. Helped by the theory, some statistical offices provide, although approximately, the *superlative price index*, which has enhanced the reliability of CPI.

In other applications of index numbers, however, the interpretation cannot be so exact, and the quality of an index is judged by coverage of commodities and reliability of data sources used in calculating the index. For example, the Bank of Japan publishes a monthly price index called Corporate Goods Price Index (CGPI). It is a Laspeyres price index, but the prices are mixtures of producers prices and wholesale prices. Thus, despite the title, experienced economists do not regard summary CGPI (for all commodities) as a price index but an indicator of business activities. On the other hand, since the data collection process guarantees high reliability of CGPI data, collected prices are quite important for many official statisticians to calculate other statistics involving prices.

System of National Accounts

The purpose of the United Nations System of National Accounts (SNA) is to provide an integrated accounts of significant economic activities to make international or temporal comparisons possible (Lequiller and Blades 2006). The most important implication of SNA to economic statistics is that the system provides the conceptual and actual basis to judge and achieve coherence among all statistical sources available in a country. In this sense, national accounts are the core of modern economic statistics.

Since the data from national accounts are so rich and full, it is not easy for economists to understand the whole system. To make things more complicated, some important changes have been made in the new version called SNA 2003 followed by a revision (SNA 2008). The difference from the earlier version becomes quite important for drawing meaningful analytical conclusions when we are interested in making inflation forecasts or in assessing economic growth capabilities.

Rigorously speaking, the national accounts system adopted by national statistical offices differ in some extent from country to country. Therefore, we need to make sure whether the differential in economic growth observed in the 1990s between the United States and the European Union is real or not. The answer is that it just reflected the different treatment of prices of the products for information and communication technology (ICT), where rapid technical changes have been taking place.

The quality of national accounts depends heavily on the statistical system of the country. To be more specific, GDP and other national accounts are not the result of a single survey, but the result of combining a mixture of various data from many sources. Since it is practically impossible for national accounts to cover all units in a country, a significant number of adjustments has to be made. In the process of adjusting those data to achieve coherence with SNA, quite often, some obscure methods are applied. Hence, it is quite difficult to obtain a formal assessment on the accuracy of the GDP, and an attempt to construct an interval estimation is almost meaningless. National accounts should be regarded at best as approximations.

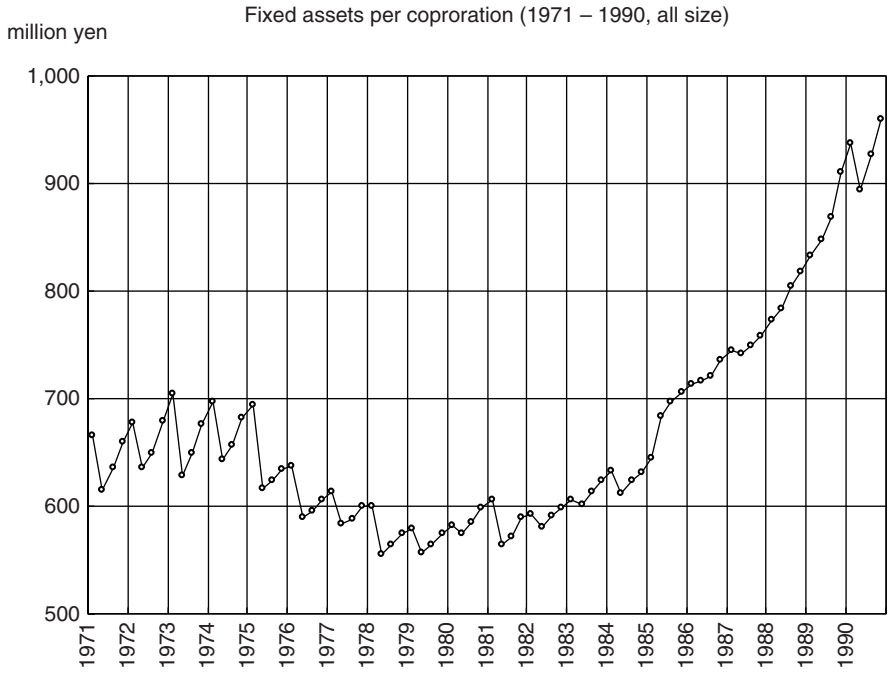
Another current issue is increasing publication of quarterly accounts in many countries. One of the essential objectives of economic statistics is to provide appropriate information to policy-makers at the right moment. In particular, it is requested to provide the newest information regarding the business cycle. In this context, traditional annual national accounts are not useful, and the demand for quarterly accounts has been increasing. The availability and the reliability of the statistics or administrative records is the key to reliable quarterly GDP, but in some countries, even monthly GDP are compiled by national statistical offices or by private research institutions.

Today, it is well-known that GDP is not a single measure of well-being, and it has many drawbacks. Yet, GDP remains to be the most important economic statistics as it defines a standard. To conclude, we should be aware of the usefulness and limitations of GDP and other economic statistics.

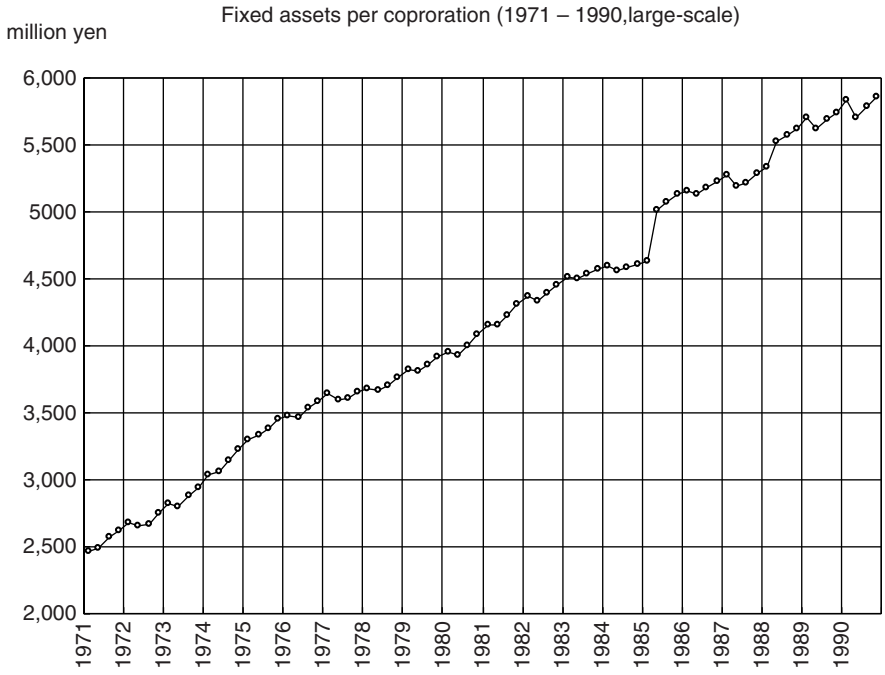
An Example

In this section, we describe some issues in the statistics of corporation. Refer to Yoshizoe et al. (2007) for a more detailed description.

The Japanese Ministry of Finance publishes *Financial Statement Statistics of Corporations by Industry* consisting of *Annual Survey* and *Quarterly Survey*, whose accuracy is vital for the government to judge the current economic situation. The large-scale corporations are quite few in number (the population ratio is 0.5%), but their influence is predominant (37.5% in sales, 56.9% in profit, and 52.0%



Economic Statistics. Fig. 1 All corporations



Economic Statistics. Fig. 2 Large-scale corporations

in fixed assets, in 2005). Nevertheless, trends of small-scale corporations are also important, especially in economic forecasts.

One of the problems is that some statistics related to small-scale corporations occasionally show unnatural patterns. Figures 1 and 2 show "fixed assets per corporation" of all corporations and those of large-scale corporations, respectively. Figure 1 indicates considerable drops each year from January–March period to April–June period. On the other hand, Fig. 2 for large-scale corporations (enumerated completely) does not show noticeable drops. We found out that the gaps in Fig. 1 was caused by the sampling design.

Since the response burden is rather heavy for small corporations, sample corporations are replaced after a year. Thus, newly sampled corporations start to respond to the questionnaires in April–June period. During the survey period (one year), some corporations go out of business and drop out of the survey. On the other hand, newly established corporations which start operating in that year cannot be included in the survey until the new list of corporations becomes available. The fact that these new entrants are usually smaller in size means that in *Quarterly Survey*, the corporations that survive and respond throughout the survey period tend to have better business performance than average. This in turn implies that, in the sample, indicators such as fixed capital per corporation will gradually have upward bias from April–June to January–March in the next year. When corporations are selected from the new list which becomes available in April, the new sample represent the population more appropriately. Thus, the sampling design explains a major portion of the gaps in the statistics.

We also examined the way corporations provide financial statements as another possible source of the gap. While large-scale corporations prepare quarterly statements, most small-scale corporations only prepare annual statements reflecting the difference of legal requirement. Moreover, it is often said that interim financial results are systematically different from the final financial statement even for large corporations. If we look at Fig. 2 carefully, we can find occasional gaps from January–March to April–June. The difference between provisional settlement of account and the final statement explains the gaps for larger corporations, hence a similar systematic behavior may partially explain the gaps of small-scale corporations. Further analyses and possible solutions for the gap problem can be found in the reference given above.

Edgeworth Expansion

Zhidong Bai
Professor
Northeast Normal University, Changchun, China

Introduction

In many statistical problems, for example, hypothesis testing and confidence region estimation, it is necessary to know the distribution functions of statistics of interest. When they are not exactly known, one might like to have an approximation of the unknown distribution as accurately as possible. One of the possibilities is the normal approximation. However, it is proved that normal approximation has an unimprovable rate of $O(n^{-1/2})$. To obtain a more accurate approximation for the distribution function, F_n, of a random variable X_n, Chebyshev (1890) expanded the function $\psi(t)/\phi(t)$ (definition given below) into a power series of (it) and obtained a formal asymptotic expansion of F_n. Edgeworth (1905, 1907) expanded $\chi(t,u)$ into a power series of u and then, by setting $u = 1$, obtained another formal expansion that is equivalent to a rearrangement of the Chebyshev expansion. Although the two are equivalent in the sense of formal expansion, the Edgeworth expansion (EE) provides an optimal approximation when only a finite number of moments of X_n exist.

Formal Expansion

Suppose that all moments of X_n exist and additionally all *cumulants* (also called *semi-invariants*) ν_{nk} of X_n exist. In this case, the characteristic function of X_n can be written as

$$\psi_n(t) = \exp\left(\sum_{r=1}^{\infty} \frac{\nu_{nr}(it)^r}{r!}\right) = \phi(t)\exp\left(\sum_{r=3}^{\infty} \frac{\nu_{nr}(it)^r}{r!}\right),$$

where $\phi(t) = \exp\left(-i\mu t - \frac{t^2\sigma^2}{2}\right)$, $\mu = \nu_{n1}$ and $\sigma^2 = \nu_{n2}$. In applications, the parameters μ and σ^2 are independent of n and $\nu_{nr}, r \geq 3$, has the order of $n^{-(r-2)/2}$.

Expand $\exp\left(\sum_{r=3}^{\infty} \frac{\nu_{nr}(it)^r u^{r-2}}{r!}\right)$ into a power series in u:

$$\chi(t,u) = \exp\left(\sum_{r=3}^{\infty} \frac{\nu_{nr}(it)^r u^{r-2}}{r!}\right) = 1 + \sum_{j=1}^{\infty} p_{nj}(it)u^j, \quad (1)$$

where $p_{nj}(x)$ is a polynomial with powers of x ranging between $j+2$ and $3j$ and coefficients depending on the cumulants ν_{nr}, $r = 3, 4, \ldots, j+2$. Some examples:

$$p_{n1}(it) = \frac{(it)^3\nu_{n3}}{6},\ p_{n2}(it) = \frac{(it)^4\nu_{n4}}{24} + \frac{(it)^6\nu_{n3}^2}{72},\ p_{n3}(it) = \frac{(it)^5\nu_{n5}}{120} + \frac{(it)^7\nu_{n3}\nu_{n4}}{144}.$$

Differentiating r times with respect to x both sides of the formula $\frac{1}{2\pi}\int e^{-itx}e^{-t^2/2}dt = \frac{1}{\sqrt{2\pi}}e^{-x^2/2} \equiv \varphi(x)$, the density of the standard normal variable, we have

$$\frac{1}{2\pi}\int (it)^r e^{-itx-t^2/2}dt = (-1)^r\frac{d^r}{dx^r}\varphi(x) = H_r(x)\varphi(x),$$

where H_r is the r-th Chebyshev–Hermitian polynomial. From this, one can easily derive that the inverse Fourier transform of $(it)^r\exp(it\mu - t^2\sigma^2/2)$ is $\sigma^{-r}H_r\left((x-\mu)/\sigma\right)\varphi\left((x-\mu)/\sigma\right)$.

Write $p_{nj}(it) = \sum_{r=j+2}^{3j} b_{nr}(it)^r$. By noting that

$$\psi_n(t) = \phi(t)\left(1 + \sum_{j=1}^{\infty} p_{nj}(it)\right),$$

the distribution function of X_n can be written as

$$F_n(x) = \Phi\left(\frac{x-\mu}{\sigma}\right) - \sum_{j=1}^{\infty} Q_{nj}\left(\frac{x-\mu}{\sigma}\right)\varphi\left(\frac{x-\mu}{\sigma}\right),$$

where $Q_{nj}(x) = \sum_{r=j+2}^{3j} b_{nr}\sigma^{-r}H_{r-1}(x)$. This is called the *formal Edgeworth expansion* (FEE) of $F_n(x)$. The first success of rigorous theory was done by Cramér (1928).

Validity of Edgeworth Expansion

The FEE may not be valid in three senses: (1) in real applications, not all orders of moments exist and thus the FEE is not well-defined; (2) even if all terms of FEE are well-defined, the series may not converge; and (3) the equality may not be true even if the series converges. To this end, one needs to establish a valid approximation when only the first k ($k \geq 3$) moments are finite. In this case, all terms Q_j, $j \leq k-2$ in the FEE are well-defined and thus, our task reduces to establishing error bounds for

$$R_n(x) = F_n(x) - \left[\Phi\left(\frac{x-\mu}{\sigma}\right) - \sum_{j=1}^{k-2} Q_j\left(\frac{x-\mu}{\sigma}\right)\varphi\left(\frac{x-\mu}{\sigma}\right)\right]. \tag{2}$$

If the error bound for $R_n(x)$ is given by the form $Kg(n,k)$, the bound is then called a *uniform estimation*; if the bound is of the form $Kg(n,k)(1+|x|)^{-k}$, the bound is then called a *nonuniform estimation*, where K is an absolute constant and $g(n,k) \to 0$ describing the order of the convergence. The quantity in the brackets is called the $(k-2)$-term EE of $F_n(x)$ or X_n.

Sum of Independent Random Variables

Suppose that for each n, $\{X_{nj}, j = 1,2,\ldots,n\}$ is a sequence of random variables with means 0, variances σ_{nj}^2, finite k-th moments and ▶characteristic functions $v_{nj}(t)$ satisfying

$$\limsup_{|t|\to\infty} \sup_n \frac{1}{n}\sum_{j=1}^{n} |v_{nj}(t)| < 1 \tag{3}$$

(called the *Cramér condition*), then for the distribution function $F_n(x)$ of $S_n = B_n^{-1}\sum_{j=1}^n X_{nj}$, we have

$$|R_n(x)| \leq B\left(\frac{\sum_{k=1}^n \mathrm{E}|Z_{njx}|^k}{B_n^k(1+|x|)^k} + \frac{\sum_{j=1}^n \mathrm{E}|W_{njx}|^{k+1}}{B_n^{k+1}(1+|x|)^{k+1}}\right),$$

where $B_n^2 = \sum_{j=1}^n \sigma_{nj}^2$, $Z_{njx} = X_{nj}I(|X_{nj}| > B_n(1+|x|)$ and $W_{njx} = X_{nj}I(|X_{nj}| \leq B_n(1+|x|)$. If the r-cumulants of X_{nj} is denoted by v_{jr}, then the cumulants of S_n is given by $\mu = 0$, $\sigma^2 = 1$ and for $r \geq 3$, $v_{nr} = B_n^{-r}\sum_{j=1}^n v_{jr}$.

When the random variables are independent and identically distributed (IID) with mean 0 and variance σ^2 and r-th cumulant v_r, we have $v_{nr} = n^{-(r-2)/2}v_r/\sigma^r$ and thus $Q_{nj}(x) = n^{-j/2}q_j(x)$ the EE of F_n.

Function of Sample Means

Suppose that $\{\mathbf{Y}_1,\ldots,\mathbf{Y}_n\}$ is a sequence of iid random m-vectors with mean vector $\boldsymbol{\mu}$, covariance matrix Σ and finite k-th moment. Assume the function H defined on R^m is $k-1$ times continuously differentiable in a neighborhood of $\boldsymbol{\mu}$. By the Taylor expansion of $H(\bar{\mathbf{Y}})$, one has

$$\sqrt{n}\left(H(\bar{\mathbf{Y}}) - H(\boldsymbol{\mu})\right) = \sum_{r=1}^{k-1}\frac{\sqrt{n}}{r!}\sum_{i_1+\cdots+i_m=r} l_{i_1,\ldots,i_m} \prod_{j=1}^{m} i_j!(\bar{Y}_{(j)} - \mu_{(j)})^{i_j} + R_k, \tag{4}$$

where $l_{i_1,\ldots,i_m} = \frac{\partial^r H(\boldsymbol{\mu})}{\partial\mu_{(1)}^{i_1}\cdots\partial\mu_{(m)}^{i_m}}$, $\bar{Y}_{(j)}$ and $\mu_{(j)}$ are the j-th components of $\bar{\mathbf{Y}}$ and $\boldsymbol{\mu}$, respectively. If the cumulants are defined by those of the first term on the right-hand side of Eq. (1), then the $(k-2)$-term EE for $\sqrt{n}(H(\bar{\mathbf{Y}}) - H(\boldsymbol{\mu}))$ is valid with a uniform bound $o(n^{-(k-2)/2})$ if $\sigma^2 > 0$ and the Cramélr condition

$$\limsup_{\|\mathbf{t}\|\to\infty} |\mathrm{E}e^{i\mathbf{t}'\mathbf{Y}_1}| < 1, \tag{5}$$

holds, where $\sigma^2 = \boldsymbol{\ell}'\Sigma\boldsymbol{\ell}$ and the j-th component of $\boldsymbol{\ell}$ is $\frac{\partial H(\boldsymbol{\mu})}{\partial\mu_j}$.

Partial Cramér Condition

Condition (3) may not hold when $\mathbf{Y}_1$ contains a discrete component and the moment condition may not be minimal when some component of $\boldsymbol{\ell}$ is 0. To this end, we have the following theorem.

Theorem 1 *The $(k-2)$-term EE of $\sqrt{n}\left(H(\bar{\mathbf{Y}}) - H(\boldsymbol{\mu})\right)$ is valid with a uniform bound $o(n^{-(k-2)/2})$ if the following conditions hold:*

(1) *The following partial Cramér condition holds*

$$\limsup_{|t|\to\infty} \mathrm{E}|\mathrm{E}(e^{itY_{(1)}}|Y_{(2)},\ldots,Y_{(m)})| < 1.$$

(2) *There is an integer $p < m$ such that $\ell_1 \neq 0$ and $l_{0,\ldots,0,i_{p+1},\ldots,i_m} = 0$, provided $i_{p+1}+\cdots+i_m \geq 1$, where ℓ_1 is the first component of $\boldsymbol{\ell}$.*

(3) $\mathrm{E}|Y_{(j)}|^k < \infty$ *for* $j = 1,\ldots,p$ *and* $\mathrm{E}|Y_{(j)}|^{k/2} < \infty$.

Cornish–Fisher EE

For a constant $\alpha \in (0,1)$, denote by $\xi = \xi_{n,\alpha}$ and $z = z_\alpha$ the quantiles of F_n and $\Phi\left(\frac{z-\mu}{\sigma}\right)$, respectively. In view of the EE of F_n, one may expect ξ can be approximated by z of the form

$$\xi = z + \sum_{j=1}^{k-2}\eta_{n,j}n^{-j/2} + o(n^{-(k-2)/2}), \tag{6}$$

which is called the Cornish–Fisher EE of quantiles. Indeed, the coefficients $\eta_{n,j}$ can be determined by submitting (6)

into the valid EE of F_n, that is,

$$F_n(\xi) = \Phi\left(\tfrac{\xi-\mu}{\sigma}\right) - \sum_{j=1}^{k-2} Q_{n,j}\left(\tfrac{\xi-\mu}{\sigma}\right)\varphi\left(\tfrac{\xi-\mu}{\sigma}\right) + R_n.$$

As an example, for the iid case with $\mu = 0$ and $\sigma = 1$, we give expressions of the first three η_j as follows

$$\eta_1 = \frac{1}{6}\nu_3(z^2-1),\ \eta_2 = \frac{\nu_4}{24}(z^3-3z) - \frac{\nu_3^2}{36}(2z^3-5z)$$
$$\eta_3 = \frac{\nu_5}{120}(z^4-6z^2+3) - \frac{\nu_3\nu_4}{24}(4z^5-2z^3+5z) + \frac{\nu_3^3}{324}(12z^4-53z^2+17).$$

About the Author

"Zhidong has a legendary life. He was adopted into a poor peasant family at birth. He spent his childhood during the Chinese resistance war against Japan." (*Advances in statistics: proceedings of the conference in honor of Professor Zhidong Bai on His 65th Birthday*, Eds. Zehua Chen, Jin-ting Zhang, Feifang Hu, World Scientific Publishing Company, 2008, Preface). Zhidong Bai has started his illustrious career as a truck driver's team leader during the Cultural Revolution in China (1968–1978), but he managed to become a Professor of statistics, North East Normal University, China, and Department of Statistics and Applied Probability, National University of Singapore. He is a Fellow of the Institute of Mathematical Statistics (1995), and Fellow of the Third World Academy of Science (1990). Dr. Bai was the Editor of the *Journal of Multivariate Analysis* (1991–2001), and Associate editor of the *Journal of Statistical Planning and Inference* (2001–2003) and *Statistica Sinica* (1991–2000). Currently, he is the Associate editor of the *Journal of Probability and Statistics* and *Sankya*. He has published seven papers related to Edgeworth expansion (he was the first who proposed the concept of Partial Cramér condition, and published a series of papers in *Ann. Statist.*, *JMVA* and *Sankya* to solve a series of problems), and over 120 refereed papers in other areas (including 10 papers with Professor C.R. Rao). He has also (co)authored three books, including *Ranked set sampling. Theory and applications* (with Chen, Z.H. and Sinha, B.K., Springer-Verlag, New York, 2004). In 2008, the Conference in Honor of Professor Zhidong Bai on his 65th Birthday was held at the National University of Singapore.

"Professor Bai represents a special generation who experienced the most difficult period in China but never gave up their quest for science and eventually excelled in the world arena. This special issue is not only to honor Professor Bai for his great achievements but also to inspire the young generation to devote themselves to the promotion of Statistics in China as China enters into a great new era." (Loc. cit.)

Zhidong Bai is a professor of the School of Mathematics and Statistics at Northeast Normal University and Department of Statistics and Applied Probability at National University of Singapore. He is a Fellow of the Third World Academy of Sciences and a Fellow of the Institute of Mathematical Statistics.

Effect Modification and Biological Interaction

Sander Greenland
Professor
University of California-Los Angeles, Los Angeles, CA, USA

The term *effect modification* has been applied to two distinct phenomena. For the first phenomenon, effect modification simply means that some chosen measure of effect

varies across levels of background variables. This phenomenon is thus more precisely termed effect-measure modification, and in the statistics literature is more often termed heterogeneity or "interaction" (Greenland et al. 2008), although "interaction" is more often used as a synonym for a product term in a regression model (*see* **Interaction**). For the second phenomenon, effect modification means that the mechanism of effect differs with background variables, which is known in the biomedical literature as *dependent action* or (again) "interaction." The two phenomena are often confused, as reflected by the use of the same terms ("effect modification" and "interaction") for both. In fact they have only limited points of contact.

Effect-Measure Modification (Heterogeneity of Effect)

To make the concepts and distinctions precise, suppose we are studying the effects that changes in a variable X will have on a subsequent variable Y, in the presence of a background variable Z that precedes X and Y. For example, X might be treatment level such as dose or treatment arm, Y might be a health outcome variable such as life expectancy following treatment, and Z might be sex (1 = female, 0 = male). To measure effects, write Y_x for the outcome one would have if administered treatment level x of X; for example, if $X = 1$ for active treatment, $X = 0$ for placebo, then Y_1 is the outcome a subject will have if $X = 1$ is administered, and Y_0 is the outcome a subject will have if $X = 0$ is administered. The Y_x are often called *potential outcomes* (*see* **Causation and causal inference**).

One measure of the effect of changing X from 0 to 1 on the outcome is the difference $Y_1 - Y_0$; for example, if Y were life expectancy, $Y_1 - Y_0$ would be the change in life expectancy. If this difference varied with sex in a systematic fashion, one could say that the difference was modified by sex, or that there was heterogeneity of the difference across sex. Another common measure of effect is the ratio Y_1/Y_0; if this ratio varied with sex in a systematic fashion, one could say that the ratio was modified by sex.

For purely algebraic reasons, two measures may be modified in very different ways by the same variable. Furthermore, if both X and Z affect Y, absence of modification of the difference implies modification of the ratio, and vice-versa. For example, suppose for the subjects under study $Y_1 = 20$ and $Y_0 = 10$ for all the males, but $Y_1 = 30$ and $Y_0 = 15$ for all the females. Then $Y_1 - Y_0 = 10$ for males but $Y_1 - Y_0 = 15$ for females, so there is 5-year modification of the difference measure by sex. But suppose we measured the effects by expectancy ratios Y_1/Y_0, instead of differences. Then $Y_1/Y_0 = 20/10 = 2$ for males and $Y_1/Y_0 = 30/15 = 2$ for females as well, so there is no modification of the ratio measure by sex.

Consider next an example in which $Y_1 = 20$ and $Y_0 = 10$ for males, and $Y_1 = 30$ and $Y_0 = 20$ for females. Then $Y_1 - Y_0 = 10$ for both males and females, so there is no modification of the difference by sex. But $Y_1/Y_0 = 20/10 = 2$ for males and $Y_1/Y_0 = 30/20 = 1.5$ for females, so there is modification of the ratio by sex.

Finally, suppose $Y_1 = 20$ and $Y_0 = 10$ for males, and $Y_1 = 60$ and $Y_0 = 40$ for females. Then $Y_1 - Y_0 = 10$ for males and $Y_1 - Y_0 = 20$ for females, so the Y-difference is smaller among males than among females. But $Y_1/Y_0 = 20/10 = 2$ for males and $Y_1/Y_0 = 30/20 = 1.5$ for females, so the Y-ratio is larger among males than among females. Thus, modification can be in the opposite direction for different measures of effect.

Biological Interaction

The preceding examples show that one should not in general equate the presence or absence of effect-measure modification to the presence or absence of interactions in the biological (mechanistic) sense, because effect-measure modification depends entirely on what measure one chooses to examine, whereas the mechanism is the same regardless of that choice. Nonetheless, it is possible to formulate mechanisms of action that imply homogeneity (no modification) of a particular measure. For such a mechanism, the observation of heterogeneity in that measure can be taken as evidence against the mechanism (assuming of course that the observations are valid). It would be fallacious however to infer the mechanism is correct if homogeneity was observed, because many other mechanisms (some unimagined) would imply the observation.

A classic example is the simple "independent action" model for the effect of X and Z on Y, in which subjects affected by changes in X are disjoint from subjects affected by changes in Z (Greenland and Poole 1988; Weinberg 1986). This model implies homogeneity (*absence* of modification by Z) of the average X effect on Y when that effect is measured by the difference in the average Y. In particular, suppose Y is a disease indicator (1 if disease occurs, 0 if not). Then the average of Y is the proportion getting disease (the incidence proportion, often called the risk) and the average Y difference is the risk difference. Thus, in this context, the independent action model implies that the risk difference for the effect of X on Y will be constant across levels of Z; in other words, the risk difference will be homogeneous across Z, or unmodified by Z.

If both X and Z have effects, this homogeneity of the difference forces ratio measures of the effect of X on Y

to be heterogeneous across Z. When additional factors are present in the model (such as confounders) homogeneity of the risk differences can also lead to heterogeneity of the excess risk ratios (Greenland 1993a). Thus, under the simple independent action model, the independence of the X and Z effects will cause the measures other than the risk difference to be heterogeneous, or modified, across Z.

Biological models for the mechanism of X and Z interactions can lead to other patterns. For example, certain multistage models in which X and Z act at completely separate stages of a multistage mechanism can lead to homogeneity of ratios rather than differences, as well as particular dose–response patterns. Special caution is needed when interpreting observed patterns, however, because converse relations do not hold: Different plausible biological models may imply identical patterns of the effect measures (Moolgavkar 1986).

Synergism and Antagonism

Taking the simple independent-action model as a baseline, one may offer the following *dependent-action* definitions for an outcome indicator Y as a function of the causal antecedents X and Z. *Synergism* of $X = 1$ and $Z = 1$ in causing $Y = 1$ is defined as necessity and sufficiency of $X = 1$ and $Z = 1$ for causing $Y = 1$, i.e., $Y = 1$ if and only if $X = 1$ and $Z = 1$. We also may say that $Y = 1$ in a given individual would be a synergistic response to $X = 1$ and $Z = 1$ if $Y = 0$ would have occurred instead if either $X = 0$ or $Z = 0$ or both. In potential-outcome notation where Y_{xz} is an individual's outcome when $X = x$ and $Z = z$, this definition says synergistic responders have $Y_{11} = 1$ and $Y_{10} = Y_{01} = Y_{00} = 0$. *Antagonism* of $X = 1$ by $Z = 1$ in causing $Y = 1$ is defined as necessity and sufficiency of $Z = 0$ in order for $X = 1$ to cause $Y = 1$. This definition says antagonistic responders to X or Z have $Y_{10} = 1$ or $Y_{01} = 1$ or both, and $Y_{11} = Y_{00} = 0$.

With these definitions, synergism and antagonism are not logically distinct concepts, but depend on the coding of X and Z. For example, switching the labels of "exposed" and "unexposed" for one factor can change apparent synergy to apparent antagonism, and vice-versa (Greenland et al. 2008; Greenland and Poole 1988). The only label-invariant property is whether the effect of X on a given person is altered by the level of Z, i.e., the action of X is dependent on Z. If so, by definition we have biological interaction.

Absence of any synergistic or antagonistic interaction among levels of X and Z implies homogeneity (*absence* of modification by Z) of the average X effect across levels of Z when the X effect is measured by the differences in Y across levels of X (Greenland and Poole 1988; Greenland 1993b). The converse is false, however: Homogeneity of the difference measures (e.g., lack of modification of the risk difference) does not imply absence of synergy or antagonism, because such homogeneity can arise through other means (e.g., averaging out of the synergistic and antagonistic effects across the population being examined) (Greenland et al. 2008; Greenland and Poole 1988).

A more restrictive set of definitions is based on the sufficient-component cause model of causation (Greenland et al. 2008; Rothman 1976; VanderWeele and Robins 2007). Here, for two binary indicators X and Z, *synergism* of the effects of $X = 1$ and $Z = 1$ is defined as the presence of $X = 1$ and $Z = 1$ in the same sufficient cause of $Y = 1$, i.e., the sufficient cause cannot act without both $X = 1$ and $Z = 1$. Similarly, *antagonism* of the $X = 1$ effect by $Z = 1$ is defined as the presence of $X = 1$ and $Z = 0$ in the same sufficient cause of $Y = 1$. These definitions are also coding dependent.

Extensions to Continuous Outcomes

The use of indicators in the above definitions may appear restrictive but is not. For example, to subsume a continuous outcome T such as death time, we may define Y_t as the indicator for $T \leq t$ and apply the above definitions to each Y_t. Similar devices can be applied to incorporate continuous exposure variables (Greenland 1993b). The resulting set of indicators is of course unwieldy, and in application has to be simplified by modeling constraints (e.g., proportional hazards for T).

Effect Size

Shlomo Sawilowsky[1], Jack Sawilowsky[1], Robert J. Grissom[2]
[1]Wayne State University, Detroit, MI, USA
[2]San Francisco State University, San Francisco, CA, USA

In general, an effect size (ES) measures the extent parameters differ or variables are related. Effect-size methodology is barely out of its infancy and yet the effect size has already been proclaimed as the statistical coin of the realm for the 21st century. It was primarily due to the diligence of Cohen (1962, 1969, 1977, 1988) that the role and importance of the ES has attained great prominence in ▶power analysis, statistical analysis, and product and program evaluation.

The raw score difference may be a naïve ES measure in the context of a two independent samples layout consisting of a treatment and control group when the intervention is modeled as shift in location. It cannot always be prudently used to assess the magnitude of an intervention, or for that matter even a naturally occurring phenomenon, if arbitrary measures of the dependent variable (e.g., *Minnesota Multiphasic Personality Inventory subscale*, *Tennessee Self Concept Scale*) are used as a stand-in for latent variables, as opposed to inherently meaningful dependent variables (e.g., weight in pounds or kilograms, length of hospital stay).

The two primary parametric ES families are (1) d, a standardized difference between group's means, and (2) r^2, a measure of the proportion of variance in a variable that is attributable to the variability of another variable. (The Pearson correlation, r, is an ES measure of bivariate association.) Kirk (1996) listed 40 effect size indices among the d and r families, and the list has grown since then.

Cohen's (1969) d estimator of population d is the difference between two sample means divided by the pooled estimate of the assumed common population standard deviation:

$$d = \frac{\overline{X}_T - \overline{X}_C}{s_{Pooled}}$$

where $\overline{X}_T$ = mean of the treatment group, $\overline{X}_C$ = mean of the control group, and s_{Pooled} is the pooled standard deviation.

In the case of two samples of equal size the point-biserial correlation (r_{PB}) can be approximately obtained from d:

$$r_{PB_{X_1X_2}} = \frac{d}{\sqrt{d^2 + 4}},$$

where X_1 is a truly dichotomous independent variable (e.g., treatment group membership or gender) and X_2 is a continuous dependent variable.

Although his warning to be flexible about such very general designations in various areas of research is widely ignored, Cohen provided rule of thumb descriptors of the magnitude of d: $d \leq 0.2$ = small, $d = 0.5$ = medium, and $d \geq 0.8$ = large. Sawilowsky (1985) defined $d \geq 1.2$ = very large.

Glass' Δ (Glass et al. 1981) and Hedges' g (Hedges and Olkin, 1985) are indices that are related to d. They are obtained by substituting one group's standard deviation for the estimate based on the pooled variance to counter heterogeneity of variance (the ΔES), or substituting each $(n_i - 1)$ for each n_i, in the denominator when pooling variances for a better estimate of the assumed common population variance (the g ES). When sample sizes reach $n_1 = n_2 \approx 20$ these three indices tend to converge at the second decimal. A benefit of standardizing the mean difference via any of these three methods is it permits a ▶meta-analysis of ESs from different studies that used the same two levels of an independent variable, but different measures of the same latent dependent variable.

In terms of association, r^2 is called the sample coefficient of determination. (R^2, preferred by some textbook authors, refers to a hypothetical population parameter; see King 1986.) A related statistic, r^2_{adj}, is used in multiple regression to adjust for the number of variables in the model. Some caution is necessary in its use because squaring r, which can be positive or negative, yields a directionless r^2, and limitations inherent in r apply to r^2 (e.g., no causality is implied). To ensure correct interpretation of r^2, r (with its sign) should also be reported.

An approximate value of r^2 can be obtained from t:

$$r^2 = \frac{t^2}{t^2 + df}, \quad (1)$$

where t = obtained value of the Student t statistic and df = degrees of freedom. In terms of the two variable general linear model,

$$r^2 = \hat{\eta}^2 = \frac{SS_{Between}}{SS_{Total}},$$

where $SS_{Between}$ = sum of squares between groups and SS_{Total} = total sum of squares. ($\hat{\eta}^2$ is a sample estimate of the population η^2, the proportion of explained variance.) The $\hat{\eta}^2$ ES and its bias-adjusted counterpart, ω^2, can be extended to one-way and factorial ANOVA and MANOVA. According to Cohen, a general rule of thumb is $r^2 \leq 0.09$ = small, $0.09 < r^2 \leq 0.25$ = medium, and $r^2 > 0.25$ = large. Alternately, for r^2_{PB} or $\hat{\eta}^2$, 0.01 = small, 0.06 = medium, and 0.14 = large.

Attacks against hypothesis testing in the last quarter of the 20th century were accelerated with the emergence of the ES. For a response, see Sawilowsky (2003a). However, considerable controversy did arise regarding emerging ES reporting requirements in scholarly journals. For example, Thompson (1996:29, 1999:67) recommended the ES "can and should be reported and interpreted in all studies, regardless of whether or not statistical tests are reported" (1996), and "even [for] nonstatistically significant effects" (1999). This advice was initially, albeit lukewarmly, endorsed by the American Psychological Association (Wilkinson and APA 1999; APA 2001).

An invited debate on this topic was published in the *Journal of Modern Applied Statistical Methods* in 2003 (see, e.g., Sawilowsky 2003b, c) where it was argued that the ES should only be reported in the presence of a statistically significant hypothesis test. That is, the evidence against a null hypothesis must first be shown to be statistically significant before it makes sense to quantify the ES. Indeed, the typical null hypothesis implies that an ES = 0.

Subsequently, the APA (2010) recanted its support for publishing effect sizes in the absence of a statistically significant test result by at least removing active language supporting Thompson's recommendation. Thus, the words of Cohen prevailed: "The null hypothesis always means the effect size is zero...[but] when the null hypothesis is false, it is false to some specific degree, i.e., the effect size (ES) is some specific nonzero value in the population" (Cohen 1988:10). (In more current usage "nil hypothesis" would substitute for "null hypothesis".)

Nevertheless, this controversy persists. A primary reason is due to a misunderstanding attributable to r being commonly interpreted via r^2, even though no statistical test has been conducted. For example, suppose $r_{X_1X_2} = 0.2$. Then, $r^2 = 0.04$, indicating 4% of the variability in the X_1 scores are attributable to the X_2 variable. Similarly, if $r_{X_1X_3} = 0.8$, then $r^2 = 0.64$, or 64%. Using r^2 as the ES measure of the sample data, the X_3 variable is shown to be sixteen $\left(\frac{0.64}{0.04} = 16\right)$ times more effective in attributing variance in the X_1 scores than the X_2 variable, even though no statistical test has been conducted.

Rearranging (1), for $r \neq \pm 1$, Student's t is expressed in terms of r as:

$$t = \frac{r_{X_1X_2}}{\sqrt{(1 - r_{X_1X_2})(1 + r_{X_1X_2})/df}}.$$

Student's t can also be expressed in terms of r_{PB} as:

$$t = r_{PB_{X_1X_2}} \sqrt{\frac{N-2}{(1 - r_{PB_{X_1X_2}})(1 + r_{PB_{X_1X_2}})}},$$

where N = number of scores, and $r_{PB_{X_1X_2}} \neq \pm 1$. In either case it is erroneously believed that inherent in calculating a Pearson correlation for descriptive purposes a hypothesis test result, Student's t, has likewise been obtained. This is not correct, because r (or r_{PB}) is only a measure of co-relationship, whereas t determines the statistical significance of that correlation. The explained amount of variance in the dependent variable, r^2, is only a function of the size of r, whereas t is obtained based on the size of r as well as the size of the df. "Although t and r are related, they are measuring different things" (Gravetter and Wailnau 2005:431). Hence, knowing only the magnitude of r is insufficient to inform statistical significance.

The converse is also true. Conducting a Student's t test informs statistical significance, but does not convey the magnitude of an ES. Also, the result of an experiment might be statistically significant, but the ES might be too small to attain practical significance (e.g., no or insufficient clinical benefit).

Additional caution is in order in interpreting the magnitude of an ES. In terms of the explained proportion of variance ES, consider the Abelson (1985) paradox. The r^2 associated with batting average and the outcome of American baseball games was found to be 0.003, not quite $\frac{1}{3}$ of 1%, although it is universally accepted that batting average is the single most important characteristic of a successful baseball player. Therefore, heed Cohen's (1988:535) warning, "The next time you read that 'only X% of the variance is accounted for' remember Abelson's Paradox."

Similarly, in terms of the strength of an effect in an ANOVA layout, consider the Sawilowsky (2003a) paradox. The 1887 Michelson-Morley interferometer experiment was designed to detect the luminiferous ether. An effect of 30 kilometers/second (km/s) was hypothesized, but obtained results were only 5–7.5 km/s, with a paltry ES of $\hat{\eta}^2 = 0.005$. What is commonly referred to as the most famous *null* result in physics was not 0 km/s as might be imagined. Instead, it was actually more than 16,750

miles/h, a speed that exceeds Earth's satellite orbital velocity! The next time you read *Eta* squared was only "$\frac{1}{X}$ of 1%" remember Sawilowsky's Paradox.

Effect sizes developed to accompany parametric hypothesis tests have parametric assumptions (e.g., homoscedasticity, normality), which must not be overlooked. There have been advances in developing nonparametric ESs to accompany nonparametric tests. For example, see Hedges and Olkin (1984, 1985), Kraemer and Andrews (1982), and Newcombe (2006). Emphasizing confidence intervals for ESs, Grissom and Kim (2005) discussed traditional and robust parametric ESs for contingency tables with nominal or ordinal outcome categories (phi, risk difference, relative risk, odds ratio, cumulative odds ratio, and generalized odds ratio), and the nonparametric stochastic superiority ES for continuous or ordinal data: $\Pr(Y_1 > Y_2)$, where Y_1 and Y_2 are randomly sampled scores from two different populations.

About the Authors

Biography of Shlomo Sawilowsky is in ►Frequentist hypothesis testing: A Defence.

Jack Sawilowsky, M. Ed., is a doctoral student in Evaluation and Research at Wayne State University. He is an Editorial Assistant for the *Journal of Modern Applied Statistical Methods*.

Dr. Robert J. Grissom is Professor Emeritus and Adjunct Professor, Department of Psychology, San Francisco State University, San Francisco, California, retiring early from teaching to focus on research and writing on effect sizes. He was a cofounder and Coordinator of the Graduate Program in Psychological Research. He received his doctorate in Experimental Psychology from Princeton University. He has authored and co-authored articles in edited books, Science magazine, and in methodological journals, where he is a regular reviewer on effect sizes. He is the senior author, with Dr. John J. Kim, of *Effect Sizes for Research: A Broad Practical Approach* (2005), published by Erlbaum; second edition scheduled for publication by Routledge in 2012.

Eigenvalue, Eigenvector and Eigenspace

Pui Lam Leung
Associate Professor, Director
The Chinese University of Hong Kong, Hong Kong, China

Let A be a $n \times n$ matrix and λ be a scalar. The *characteristic equation* of A is defined as

$$det(A - \lambda I_n) = 0, \tag{1}$$

where I_n is an identity matrix of order n and *det* denotes the determinant. The values of λ that satisfy Eq. (1) are called the *characteristic roots* or *eigenvalues* of A. In general, there are n eigenvalues of A. If λ_i is an eigenvalue, then the matrix

$(A - \lambda_i I_n)$ is singular and there exist a non-zero vector v_i such that $(A - \lambda_i I_n)v_i = 0$. Equivalently,

$$Av_i = \lambda_i v_i. \tag{2}$$

v_i is called the eigenvector corresponds to the eigenvalue λ_i. Geometrically, A represents a linear transformation in n-dimensional space. v_i is the direction remains unchanged or *invariant* under this transformation. In general, there are exactly n eigenvalues of A. These eigenvalues are not necessarily distinct and may be real or complex. Note that if v_i is the eigenvector corresponds to λ_i, then any scalar multiple of v_i is also an eigenvector of A. There may be more than one eigenvector correspond to the same eigenvalue λ_i, any linear combination of these eigenvectors will also be an eigenvector. The linear subspace spanned by the set of eigenvectors corresponds to the same eigenvalue together with the zero vector is called an *eigenspace*.

In statistics, we often deal with real symmetric matrices. Many test statistics in *Multivariate linear model* are functions of eigenvalues and eigenvectors of certain matrices. Some basic results concerning eigenvalues and eigenvectors are listed as follow:

1. If A is a real symmetric matrix then its eigenvalues are all real.
2. If A is a $n \times n$ matrix, then the eigenvalues of A and its transpose A' are the same.
3. If A and B are $n \times n$ matrices and A is non-singular, then the eigenvalues of AB and BA are equal.
4. If λ is an eigenvalue of A, then λ^k is an eigenvalue of A^k, where k is any positive integer.
5. If λ is an eigenvalue of a non-singular matrix A, then λ^{-1} is an eigenvalue of A^{-1}.
6. If A is an orthogonal matrix, (i.e., $AA' = I$), then all its eigenvalues have absolute value 1.
7. If A is symmetric, then A is idempotent (i.e., $A^2 = A$) if and only if its eigenvalues take values 0s and 1s only.
8. If A is a positive (non-negative) definite matrix, then all its eigenvalues are positive (non-negative).
9. If A is a real symmetric matrix and λ_i and λ_j are two distinct eigenvalues of A, then the two corresponding vectors v_i and v_j are orthogonal.
10. Let A be a $n \times n$ real symmetric matrix and $H = (v_1, \ldots, v_n)$ be a $n \times n$ matrix whose ith column is the eigenvectors v_i of A corresponds to the eigenvalues λ_i, then

$$H'AH = D = diag(\lambda_1, \ldots, \lambda_n), \tag{3}$$

where D is a diagonal matrix whose diagonal elements are λ_i. Furthermore, Eq. (3) can be rewritten as

$$A = HDH' = \lambda_1 v_1 v_1' + \cdots + \lambda_n v_n v_n'. \tag{4}$$

Equation (3) is known as the *diagonalization* of A while Eq. (4) is known as the *spectral decomposition* of A.

Extrema of Quadratic Form

There is an important theorem which is very useful in *Multivariate analysis* concerning the minimum and maximum of quadratic form.

Theorem Let A be a $n \times n$ positive definite matrix has the ordered eigenvalues $\lambda_1 \geq \cdots \geq \lambda_n > 0$ and the corresponding eigenvectors are $v_1, \ldots, v_n$ and c is a $n \times 1$ vector. Then

1. $\max_{c \neq 0} \frac{c'Ac}{c'c} = \lambda_1$ and the maximum is attained at $c = v_1$.
2. $\min_{c \neq 0} \frac{c'Ac}{c'c} = \lambda_n$ and the minimum is attained at $c = v_n$.
3. $\max_{c \perp v_1, \ldots, v_k} \frac{c'Ac}{c'c} = \lambda_{k+1}$ and the maximum is attained at $c = v_{k+1}$ for $k = 1, 2, \ldots, n-1$. ($c \perp v_1, \ldots, v_k$ means c is orthogonal to $v_1, \ldots, v_k$).

This theorem is important since it provides the theory behind ►*principal component analysis* and ►*canonical correlation analysis*. In principal component analysis, we are looking for a linear transformation $Y = \alpha' X$ of the original variables X such that the variance of Y is maximum. In canonical correlation analysis, we are looking for a pair of linear transformation $U = \alpha' X$ and $V = \beta' Y$ of the original variables X and Y such that the correlation between U and V is maximum.

Software

Standard mathematical and statistical packages, such as MATLAB and R, have built-in function to compute eigenvalues and eigenvectors. The eigenvalues are usually output in descending order and the corresponding eigenvectors are normalized to unit length.

Empirical Likelihood Approach to Inference from Sample Survey Data

J. N. K. Rao
Professor Emeritus and Distinguished Research Professor
Carleton University, Ottawa, ON, Canada

Introduction

Traditional sample survey theory largely focused on descriptive parameters, such as finite population means, totals and quantiles, from samples selected according to efficient probability sampling designs (subject to cost constraints). Associated inferences consist of point estimation, standard errors of estimators and large-sample confidence intervals based on normal approximations. Inferences, based on the known probability distribution induced by the sampling design with the population item values held fixed but unknown, are essentially non-parametric. Standard text books on sampling (e.g., Cochran 1977) provide excellent accounts of the traditional design-based approach. Attempts were also made to integrate sampling theory with mainstream statistical inference based on likelihood functions, but retaining the non-parametric set up. Here we provide a brief account of some methods for sample survey data, based on non-parametric likelihoods. In particular, we focus on the "empirical likelihood" approach which was first introduced in the context of survey sampling by Hartley and Rao (1968) under the name "scale-load approach." Twenty years later, Owen (1988) introduced it in the main stream statistical inference, under the name "empirical likelihood." He developed a unified theory for the standard case of a random sample of independent and identically distributed (IID) variables, and demonstrated several advantages of the approach. In particular, the shape and orientation of empirical likelihood (EL) confidence intervals are determined entirely by the data, and the intervals are range preserving and transformation respecting, unlike the intervals based on normal approximations. An extensive account of EL, including various extensions and applications, is given in the excellent book by Owen (2001).

Scale-Load Approach

Suppose that the finite population U consists of N units labeled $i = 1,\ldots,N$ with associated item values y_i. A sample of units, s, is selected from U with specified probability $p(s)$. Godambe (1966) obtained the non-parametric likelihood function based on the full sample data $\{(i,y_i), i \in s\}$ and showed that it is non-informative in the sense that all possible non-observed values $y_i, i \notin s$ lead to the same likelihood. This difficulty arises because of the distinctness of labels i associated with the sample data that makes the sample unique. To get around this difficulty, Hartley and Rao (1968) suggested data reduction by ignoring some aspects of the data to make the sample non-unique and in turn make the associated likelihood informative. The reduction of sample data is not unique and it depends on the situation at hand. A basic feature of the Hartley–Rao (HR) approach is a specific representation of the finite population, assuming that the possible values of the variable y is a finite set of scale points $y_1^*,\ldots,y_T^*$ for some finite T. The associated population frequencies or "scale loads" are denoted by $N_1^*,\ldots,N_T^*$ and the population parameters can be expressed in terms of the scale loads; for example, the population mean $\overline{Y}$ can be expressed as $\bar{Y} = \sum_t p_t^* y_t^*$ where $p_t^* = N_t^*/N$ and $\sum_t p_t^* = 1$. Under simple random sampling without replacement, the sample labels i may be suppressed from the sample data in the absence of information relating the label to the corresponding item value, and the resulting nonparametric likelihood based on the reduced data $\{y_i, i \in s\}$ is given by the multivariate hyper-geometric distribution that depends on the scale loads N_t^* and the associated sample scale loads n_t^*. Thus the likelihood function based on the reduced sample data is informative, unlike the likelihood based on the full sample data. If the sampling fraction n/N is negligible, then the hyper-geometric likelihood may be approximated by the multinomial likelihood with probabilities p_t^* and associated sample frequencies n_t^* so that the log-likelihood function is given by $l(p^*) = \sum n_t^* \log\left(p_t^*\right)$ where the sum is over the observed non-zero sample scale loads. The resulting maximum likelihood estimator (MLE) of the mean $\overline{Y}$ is the sample mean $\bar{y} = \sum \hat{p}_t^* y_t^* = n^{-1}\sum_{i\in s} y_i$, where $\hat{p}_t^* = n_t^*/n$. Hartley and Rao (1968) also considered ML estimation when the population mean $\overline{X}$ of an auxiliary variable x is known and showed that the MLE is asymptotically equal to the customary linear regression estimator of $\overline{Y}$. The Hartley–Rao (HR) approach readily extends to stratified simple random sampling by retaining the strata labels h to reflect known strata differences and then regarding each stratum as a separate population and applying the scale-load approach to each stratum separately. The traditional stratified mean is the MLE under this approach.

Empirical Likelihood: IID Case

In the case of IID observations $y_1,\ldots,y_n$ from some distribution $F(.)$, Owen (1988) obtained a non-parametric

(or empirical) likelihood function which puts masses $p_i = \Pr(y = y_i)$ at the sample points y_i and the log-EL function is given by $l(p) = \sum_i \log(p_i)$ which is equivalent to the HR scale-load log-likelihood function. Maximizing $l(p)$ subject to $p_i > 0$ and $\sum p_i = 1$ gives maximum empirical likelihood (MEL) estimators of p_i and the mean $\mu = E(y)$ as $\hat{p}_i = 1/n$ and $\hat{\mu} = \sum \hat{p}_i y_i$. Chen and Qin (1993) studied EL in the sampling context, assuming simple random sampling, and considered parameters of the form $\theta = N^{-1}\sum_{i\in U} g(y_i)$ for specified functions $g(.)$ and known auxiliary information of the form $N^{-1}\sum_{i\in U} w(x_i) = 0$. In the special case of $g(y) = y$ and $w(x) = x - \overline{X}$, their results are equivalent to those of HR for estimating the mean $\overline{Y}$. By letting $g(y_i)$ be the indicator function $I(y_i \le t)$, the MEL estimator of the population distribution function is obtained as $\hat{F}(t) = \sum_{i\in s} \hat{p}_i I(y_i \le t)$, where $\hat{p}_i$ is the maximum EL estimator of p_i obtained by maximizing the log-EL function subject to the above restrictions on the p_i and the additional restriction $\sum_{i\in s} p_i w(x_i) = 0$. The estimator $\hat{F}(t)$ is non-decreasing and hence can be used to obtain estimators of population quantiles and other functionals, in particular the population median.

The EL approach can provide non-parametric confidence intervals on parameters of interest, similar to the classical parametric likelihood ratio intervals. For example, the EL intervals on the mean μ for the IID case are obtained by first deriving the profile EL ratio function $R(\mu)$ and then treating $r(\mu) = -2\log R(\mu)$ as χ^2_1, a chi-squared variable with one degree of freedom, where $R(\mu)$ is the maximum of $\prod(np_i)$ subject to the previous restrictions on the p_i and the additional constraint $\sum p_i y_i = \mu$. The $(1-\alpha)$-level EL interval is given by $\{\mu | r(\mu) \le \chi^2_1(\alpha)\}$, where $\chi^2_1(\alpha)$ is the upper α-point of the distribution of χ^2_1. This result is based on the fact that $r(\mu)$ is approximately distributed as χ^2_1 in large samples. As noted earlier, the shape and orientation of EL intervals are determined entirely by the data, and the intervals are range preserving and transformation respecting. Moreover, unlike the traditional normal approximation intervals the EL intervals do not require the evaluation of standard errors of estimators in the IID case and are particularly useful if balanced tail error rates are considered desirable. An important application of EL intervals in audit sampling is reported by Chen et al. (2003). Populations containing many zero item values are encountered in audit sampling, where y_i denotes the amount of money owed to a government agency and $\overline{Y}$ is the average amount of excessive claims. In some previous work on audit sampling, parametric likelihood ratio intervals based on parametric mixture distributions for the variable y were used because they performed better than the normal approximation-based intervals in terms of coverage. On the other hand, the EL intervals compared favorably to the parametric intervals when the assumed parametric distribution holds, and performed better than the parametric intervals under deviations from the assumed parametric distribution, by providing non-coverage rate below the lower bound on $\overline{Y}$ closer to the nominal value and also larger lower bound. Typically, government agencies use the lower bound for the collection of excess amounts claimed.

Pseudo-EL: Complex Surveys

The HR scale load approach or the EL approach does not readily extend to general sampling design involving unequal probability sampling. To circumvent this difficulty, a pseudo-EL approach has been proposed (Chen and Sitter 1999) by regarding the finite population as a random sample from an infinite super-population. This in turn leads to the "census" log-EL function $l_N(p) = \sum_{i\in U} \log(p_i)$ which is simply the finite population total of the $\log(p_i)$. From standard sampling theory, an unbiased estimator of the finite population total $l_N(p)$ is given by $\hat{l}(p) = \sum_{i\in s} d_i \log(p_i)$, where $d_i = 1/\pi_i$ is the design weight associated with unit i and π_i is the associated probability of inclusion in the sample. The pseudo empirical log-likelihood function is defined as $\hat{l}(p)$ and then one can proceed as in section "►Scale-Load Approach" to get point estimators of finite population parameters. For example, in the absence of auxiliary information, the pseudo-MEL estimator of the finite population mean $\overline{Y}$ is given by the well-known ratio estimator $\left(\sum_{i\in s} d_i\right)^{-1}\left(\sum_{i\in s} d_i y_i\right)$. Wu (2004) provided algorithms and R codes for computing the pseudo-MEL estimators. Interval estimation, however, runs into difficulties under this approach because the profile pseudo-EL ratio function obtained from the pseudo-EL does not lead to asymptotic χ^2_1 distribution in large samples. To get around this difficulty, Wu and Rao (2006) proposed an alternative pseudo empirical log-likelihood function. It is given by $\hat{l}_{\mathrm{mod}}(p) = n^* \sum_{i\in s} \tilde{d}_i \log(p_i)$, where $\tilde{d}_i = d_i / \sum_{k\in s} d_k$ are the normalized design weights and n^* is the "effective sample size" defined as the ratio of the sample size n and the estimated design effect; the latter is taken as the ratio of the estimated variance of the point estimator under the specified design and under simple random sampling. This design effect depends on the parameter of interest. For simple random sampling with replacement, $\hat{l}_{\mathrm{mod}}(p)$ reduces to the usual empirical log-likelihood function.

The pseudo-MEL estimator under the modified function remains the same as the estimator obtained from the original pseudo-EL function. But the modification leads to a different pseudo-EL ratio function that leads to asymptotic χ^2_1 distribution and hence the resulting intervals can be used. Wu and Rao (2010) proposed a bootstrap calibration method that bypasses the need of effective sample size and the resulting pseudo-EL intervals are asymptotically valid and performed well in simulation studies.

In a recent application, the modified pseudo-EL method, based on the χ^2_1 approximation, was applied to adaptive cluster sampling which is often used to sample populations that are sparse but clustered (Salehi et al. 2010). Simulation results showed that the resulting confidence intervals perform well in terms of coverage whereas the traditional normal approximation-based intervals perform poorly in finite samples because the distribution of the estimator under ►adaptive sampling is highly skewed.

Various extensions of the EL method for survey data have been reported, including multiple frame surveys and imputation for missing data (see ►Imputation). We refer the reader to a recent review paper (Rao and Wu 2009) on empirical likelihood methods for survey data.

About the Author

Dr. J. N. K. Rao is Distinguished Research Professor at Carleton University, Ottawa, Canada and a long term Consultant to Statistics Canada and a Member of Statistics Canada's Advisory Committee on Methodology. "He published his first research work in sampling at the age of twenty, four years before he received his PhD in 1961. Very quickly Jon became one of the leading researchers in survey sampling and has remained one of the field's leaders to this day" (David Bellhouse, *J.N.K. Rao: An Appreciation of his work*, SSC Annual Meeting, June 2001, Proceedings of the Survey Methods Section, p. 3). Professor Rao received the 2004 prestigious Waksberg Award for survey methodology and the 1993 Gold Medal of Statistical Society of Canada in recognition of "fundamental research achievements, especially in the theory and practice of surveys." Professor Rao is a Fellow of the American Statistical Association and the Institute of Mathematical Statistics. He was elected as a Fellow of the Royal Society of Canada for "fundamental contributions to survey sampling, from its foundational principles to complex survey design and analysis. These contributions have influenced the way surveys are conducted and analyzed." His 1981 paper with Alastair Scott, published in the *Journal of American Statistical Association*, was selected as one of 19 landmark papers in the history of survey sampling for the 2001 centenary volume of the International Association of Survey Statisticians. Currently, he is Associate editor, *Survey Methodology* (1985–). He received Honorary Doctor of Mathematics degree in 2008 from the University of Waterloo. Professor Rao is the author of the well known book *Small Area Estimation* (Wiley-Interscience, 2003).

Empirical Processes

Evarist Giné
Professor
University of Connecticut, Storrs, CT, USA

A basic question in Statistics is how well does the frequency of an event approach its probability when the number of repetitions of an experiment with "statistical regularity"

increases indefinitely, or how well does the average of the values of a function at the observed outcomes approach its expected value. "How well" of course may have different meanings. Empirical process theory has its origin on this question. The counterpart in the "probability model" of averaging the values of a function f at the outcomes of n repetitions of an experiment, is just $P_n f = n^{-1}\sum_{i=1}^{n} f(X_i)$, where X_i, the data, are independent, identically distributed random variables with common probability law P. The variables X_i need not be real but may take values in any measurable space $(S, \mathcal{S})$. The random measure $P_n = n^{-1}\sum_{i=1}^{n}\delta_{X_i}$, where δ_x denotes unit mass at x (the Dirac delta) is the "empirical measure," and $P_n f = \int f dP_n$, assigns to each function its average over the values $X_i(\omega)$, and in particular to each set A the frequency of the occurrences $X_i(\omega) \in A$. This random measure is often understood as a stochastic process indexed by $f \in \mathcal{F}$, $\mathcal{F}$ being a collection of measurable functions (which can in particular be indicators). The object of empirical process theory is to study the properties of the approximation of Pf by $P_n f$, uniformly in $\mathcal{F}$, mainly, probabilistic limit theorems for the processes $\{(P_n - P)f : f \in \mathcal{F}\}$ and probability estimates of the random quantity

$$\|P_n - P\|_{\mathcal{F}} := \sup_{f\in\mathcal{F}} |P_n f - Pf|.$$

This program has a long history. It starts with Bernoulli and de Moivre in the early 1700s: they studied the approximation of the probability of an event, PA, by its frequency, $P_n A$, thus obtaining respectively the Bernoulli law of large numbers and the de Moivre(-Laplace) normal approximation of the binomial law.

Next, Glivenko and Cantelli, in the 1920s showed, for X_i real valued, that $F_n(x) = P_n(-\infty, x]$ converges uniformly almost surely to the "true" distribution function $F(x) = P(-\infty, x]$, and this was the first "uniform" law of large numbers for the empirical measure. Kolmogorov in the 1930s gave the limiting distribution of $\sqrt{n}\sup_{x\in\mathbf{R}} |F_n(x) - F(x)|$, and Dvoretzky–Kiefer–Wolfowitz in the 1950s gave an inequality of the right order, that applies for all values of n, for $\Pr\left\{\sup_{x\in\mathbf{R}} |F_n(x) - F(x)| > \varepsilon\right\}$, namely, this is less than or equal to $2e^{-2n\varepsilon^2}$ (where the constant 2 in front of the exponent was determined by Pascal Pascal Massart (1990), cannot be improved, and neither can the exponent).

The theorem of Kolmogorov is a corollary of Donsker's theorem, who viewed the empirical process as a random function and proved for it a central limit theorem (see ►Central Limit Theorems), that is, a limit theorem for its probability law defined on function space (in this case, the space of right continuous functions with left limits, $D(-\infty, \infty)$, with a separable metric on it, the Skorokhod metric, with the law of a Gaussian process (the P-Brownian bridge) as limit). Then, by the "continuous mapping theorem" $H(\sqrt{n}(F_n - F))$ converges in law to $H(G_F)$ for all functionals H continuous on D, and Kolmogorov's theorem follows by taking $H(f) = \sup_{x\in\mathbf{R}} |f(x)|$. [Actually, Donsker's theorem is a result of efforts by at least Kolmogorov, Skorokhod, Doob, Donsker and, in several dimensions, Dudley]. This was mostly done in the mid 1950s.

Another important area on what we may call the classical empirical process theory is that of the "strong approximation" in a suitable probability space of the empirical process for the uniform distribution (see ►Uniform Distribution in Statistics) on $[0, 1]$ by Brownian bridges, in the supremum norm ("Hungarian constructions"), very useful e.g., in the study of limit theorem of complicated functions of the empirical process (Komlos et al. 1975). Other results include laws of the iterated logarithm and large deviation principles (Sanov's theorem). The book to consult on the classical theory of empirical processes is Shorack and Wellner's (1986).

The Glivenko–Cantelli, Donsker, and Dvoretzky–Kiefer–Wolfowitz results for the empirical distribution function became the models for the striking generalizations that constitute modern empirical process theory. The first is the Vapnik–Červonenkis (V–C) (1971) law of large numbers. These authors gave very sharp combinatorial, non-random conditions on classes of sets $\mathcal{C}$ (classes of functions $\mathcal{F}$ in a subsequent article in 1981) for the empirical measure to converge to the probability law of the observations *uniformly* over the sets in $\mathcal{C}$ (or the functions in $\mathcal{F}$) almost surely, and necessary and sufficient random conditions on these classes for uniformity to take place. A little earlier, Blum and DeHardt had given other also very sharp general conditions (bracketing entropy) for the same result to hold over classes of functions in Euclidean space, see DeHardt (1971). Vapnik–Červonenkis also applied their work to pattern recognition (see ►Pattern Recognition, Aspects of and ►Statistical Pattern Recognition Principles).

The theory greatly gained in scope and applicability with the work of Dudley (1978), where Donsker's central limit theorem (also called invariance principle) was greatly generalized in the spirit of Vapnik–Červonenkis and Blum–deHardt by proving central limit theorems for empirical processes that hold uniformly in $f \in \mathcal{F}$ and by giving concrete meaningful examples of such classes, like classes of sets with differentiable boundaries, or positivity parts of finite dimensional sets of functions; measurability problems had to be overcome, and, more importantly, a relationship had to be provided between the V–C combinatorial quantities and metric entropy, which allowed proving asymptotic equicontinuity

conditions (hence, "uniform tightness") for the empirical process over large classes of functions in a way reminiscent of how Dudley proved his famous entropy bound for ►Gaussian processes.

The articles of Vapnik and Červonenkis and Dudley just mentioned originated the field of modern empirical processes. We now review some of its main developments. The most general form of the central limit theorem under bracketing conditions was obtained by Ossiander (1987). The connection between empirical processes and Gaussian and sub-Gaussian processes and empirical processes was made more explicit by means of random sign and Gaussian randomization (Pollard 1981; Koltchinskii 1986 and, more extensively, in Giné and Zinn (1984), where, moreover, the central limit theorem for classes of sets analogue to the V–C law of large numbers is proved; its conditions were proved later, in 1988, to be necessary by M. Talagrand, who continued some aspects of the work of Giné and Zinn and also gave a "structural" necessary and sufficient condition for the central limit theorem). Talagrand (1987) also has the last word on Glivenko–Cantelli type theorems.

The limit theory contains as well laws of the iterated logarithm, theorems on uniform and universal Donsker classes (very convenient for applications since in Statistics one does not know the law of the data; see Dudley 1987; Giné and Zinn 1991; Sheehy and Wellner 1992 and for the uniform in P Glvienko–Cantelli theorem, Dudley et al. 1991) and the bootstrap of empirical processes (Giné and Zinn 1990) among other types of results.

Particular mention should be made of exponential inequalities for empirical processes, which may be seen as Bernstein or Prokhorov exponential inequalities uniform over large collections of sums of independent random variables, indexed by functions. For the special but conspicuous Vapnik–Červonekis classes of functions, Alexander (1984) and Massart (1986) had versions of such inequalities in the mid 1980s, but Talagrand (1996) obtained a striking, completely general such inequality, just in terms of the supremum of $|f(X)|$ over $\mathcal{F}$ and of $E\sup_{f\in\mathcal{F}}\sum_{i=1}^{n} f^2(X_i)$. The constants in his inequality are not specific, but in a series of articles, P. Massart, T. Klein and E. Rio, and O. Bousquet obtained the best constants. This inequality has applications in many areas of Statistics and, in this author's view, is a true landmark.

Both, limit theorems and exponential inequalities have been extended to U-processes, not necessarily in the greatest generality. See Arcones and Giné (1993) and Major (2006).

Modern empirical process theory has already had and is having a deep impact in pattern recognition and learning theory, M-estimation, density estimation, and quite generally, asymptotic and non-parametric statistics. This will not be reviewed in this article.

The books to consult on modern empirical process theory are those of Pollard (1984), van der Vaart and Wellner (1996), Dudley (1999); for U-processes, de la Peña and Giné (1999); and for Talagrand's and other inequalities for empirical processes, Ledoux (2001).

About the Author

Dr. Evarist Giné is a Professor of Mathematics and (by courtesy) of Statistics at the University of Connecticut. He is an Elected member of the International Statistical Institute, a Fellow of the Institute of Mathematical Statistics and a corresponding member of the Institut d'Estudis Catalans. He has authored/coauthored more than 100 articles in Probability and Mathematical Statistics, as well as two books: *The Central Limit Theorem for Real and Banach Valued Random Variables* (with A. Araujo, Wiley, 1980), and *Decoupling, from Dependence to Independence* (with V. de la Peña, Springer, 1999). He has organized several meetings and special sessions in Probability and Mathematical Statistics, in particular he was the Program Chair of the 5th World Congress of the Bernoulli Society/IMS Annual Meeting. He has been Associate editor of *Annals of Probability*, *Stochastic Processes and Applications*, and *Revista Matemática Hispano-Americana*, and is presently Associate editor of *Bernoulli*, *Journal of Theoretical Probability*, *Electronic Journal and Electronic Communications in Probability*, *TEST* and *Publicacions Matemàtiques*.

Entropy

Tarald O. Kvålseth
Professor Emeritus
University of Minnesota, Minneapolis, MN, USA

Introduction and Definition

Consider that $P_n = (p_1, \ldots, p_n)$, or $\{p_i\}$, is a finite discrete probability distribution with $p_i \geq 0$ for $i = 1, \ldots, n$ and $\sum_{i=1}^{n} p_i = 1$. This distribution may be associated with a set of mutually exclusive and exhaustive events $\{E_1, \ldots, E_n\}$ or with a random variable X taking on a set of n discrete values with probabilities $p_i (i = 1, \ldots, n)$. For such a distribution, the classical definition of *entropy* is given by

$$H(P_n) = -\sum_{i=1}^{n} p_i \log p_i \tag{1}$$

and generally referred to as *Shannon's entropy* after Shannon (Shannon 1948). Two different bases are typically used for the logarithm in (1). In the field of information theory, in which the entropy is of fundamental importance, the base -2 logarithm is the traditional choice, with the unit of measurement of entropy then being a *bit*. If the base $-e$ (natural logarithm) is used, which is mathematically more convenient to work with, the unit of measurement is sometimes called a *nat*. Also, $0 \log 0 = 0$ is the usual convention for (1).

Most generally, the entropy in (1) is considered to be a measure of the amount of *randomness* in a system or of a set of events or of a random variable. Alternatively, the entropy is considered to express the amount of *uncertainty, surprise*, or *information content* of a set of events or of a random variable. In information theory, the p_i's in (1) may be those of a set of messages (events) or those of a random variable X taking on the value i for the ith symbol of an alphabet for $i = 1, \ldots, n$. In thermodynamics and statistical mechanics, where entropy plays an important role, the p_i in (1) is the probability of a system being in the ith quantum state with $i = 1, \ldots, n$. Besides such fundamentally important applications, the entropy in (1) has proved to be remarkably versatile as a measure of a variety of attributes in different fields of study, ranging from psychology (e.g., Garner 1962) to ecology (e.g., Magurran 2004). The wide range of applications of the entropy formula is due in part to its desirable properties and extensions and partly perhaps because of the intrigue held by the entropy concept.

Properties of *H*

Some of the most important properties of the entropy function H in (1) for any $P_n = (p_1, \ldots, p_n)$ may be outlined as follows:

(**P1**) H is continuous in all its arguments $p_1, \ldots, p_n$.

(**P2**) H is (permutation) symmetric in the $p_i (i = 1, \ldots, n)$.

(**P3**) H is zero-indifferent (expansible), i.e., $H(p_1, \ldots, p_n, 0) = H(p_1, \ldots, p_n)$.

(**P4**) $H(0, \ldots, 0, 1, 0, \ldots, 0) = 0$ and $H(1/n, \ldots, 1/n)$ is strictly increasing in n.

(**P5**) H is strictly Schur-concave in P_n and also strictly concave (in the usual or Jensen sense).

These properties are all readily apparent from the definition in (1) and would seem to be reasonable for a measure of randomness. The strict Schur-concavity property ensures that $H(P_n)$ increases strictly as the p_i's become increasingly equal (even or uniform). Stated more precisely in terms of *majorization theory* (Marshall and Olkin 1979), if the probability distribution $P_n = (p_1, \ldots, p_n)$ is majorized by the distribution $Q_n = (q_1, \ldots, q_n)$, denoted as $P_n \prec Q_n$, then, because of the strict Schur-concavity of H, $H(P_n) \geq H(Q_n)$ with strict inequality unless P_n is a permutation of Q_n. From the majorization

$$P_n^1 = (1/n, \ldots, 1/n) \prec P_n = (p_1, \ldots, p_n) \prec P_n^0 = (0, \ldots, 0, 1, 0, \ldots, 0) \quad (2)$$

together with the strict Schur-concavity of H, it follows that

$$H\left(P_n^0\right) \leq H(P_n) \leq H\left(P_n^1\right) \quad (3)$$

with equalities if, and only if, $P_n = P_n^0$ or $P_n = P_n^1$ (Marshall and Olkin 1979: 7, 71, 410).

Another property of H is that of *additivity*. Thus, consider the case of two statistical experiments with their respective events, or, consider the pair of random variables (X, Y) with the joint probability distribution $\{p_{ij}\}$ and the marginal distributions $\{p_{i+}\}$ and $\{p_{+j}\}$ for X and Y, respectively, with $p_{i+} = \sum_{j=1}^{J} p_{ij}$ for all i and $p_{+j} = \sum_{i=1}^{I} p_{ij}$ for all j and with $\sum_{i=1}^{I}\sum_{j=1}^{J} p_{ij} = \sum_{i=1}^{I} p_{i+} = \sum_{j=1}^{J} p_{+j} = 1$. Then, the following property follows from (1):

(**P6**) H is additive, i.e.,

$$H(\{p_{ij}\}) = H(\{p_{i+}p_{+j}\}) = H(\{p_{i+}\}) + H(\{p_{+j}\}) \quad (4)$$

under independence i.e., when the two experiments or when X and Y are independent.

For the case when $p_{i+} = 1/I$ and $p_{+j} = 1/J$ for all i and j, (4) reduces to

$$H\left(\left\{\frac{1}{IJ}\right\}\right) = H\left(\left\{\frac{1}{I}\right\}\right) + H\left(\left\{\frac{1}{J}\right\}\right) \quad (5)$$

which is sometimes referred to as the *weak additivity* property.

Two famous inequalities involving the entropy function H in (1) can be expressed as follows:

(**P7**) For any two probability distributions $P_n = (p_1, \ldots, p_n)$ and $Q_n = (q_1, \ldots, q_n)$,

$$-\sum_{i=1}^{n} p_i \log p_i \leq -\sum_{i=1}^{n} p_i \log q_i \quad (6)$$

which is referred to as *Shannon's fundamental inequality* and is sometimes called the *Gibbs' inequality.*

(**P8**) As a consequence of (6),

$$H(\{p_{ij}\}) \leq H(\{p_{i+}\}) + H(\{p_{+j}\}) \quad (7)$$

which is called the *subadditivity* property of H and of which (4) is the only equality case, which occurs under independence when $p_{ij} = p_{i+}p_{+j}$ for all i and j.

The entropy in (1), as well as other entropy measures, may be derived by using some of these properties as axioms or postulates. Such *axiomatic characterization* approach starts off with a set of axioms specifying some properties that a measure should possess and then showing that a particular function satisfies those axioms (e.g., Aczél and Daróczy 1975; Mathai and Rathie 1975).

Cross-Entropy (Divergence)

The inequality in (6) can also be expressed as

$$D(P_n : Q_n) = \sum_{i=1}^{n} p_i \log\left(\frac{p_i}{q_i}\right) \geq 0 \quad (8)$$

where $D(P_n : Q_n)$ is known as the *cross-entropy,* but is more commonly called the *divergence of P_n from Q_n*. Specifically, it is called the ▶Kullback–Leibler divergence or information (Kullback and Leibler 1951). Since $D(P_n : Q_n)$ is not symmetric in P_n and Q_n, the term *directed divergence* is sometimes used. It differs from the *conditional entropy* defined as $\sum_{i=1}^{I} p_{i+}\left[-\sum_{j=1}^{J}(p_{ij}/p_{i+})\log(p_{ij}/p_{i+})\right]$. To avoid mathematical difficulties with (8), the convention $0 \log 0 = 0$ is used together with the assumption that $q_i = 0$ whenever $p_i = 0$. From (8), $D(P_n : Q_n) = 0$ if, and only if, $P_n = Q_n$. It can also easily be seen that $D(P_n : Q_n)$ is strictly convex in P_n for any given Q_n and strictly convex in Q_n for any given P_n.

The $D(P_n : Q_n)$ in (8) and various other measures and generalizations of divergence (or "distance") are important in statistical inferences (see Pardo 2006 for a recent and extensive treatment of this topic). It is recognized from the form of the expression in (8) that it is related to the likelihood-ratio chi-square statistic G^2 for goodness-of-fit tests. In particular, if the p_i's are multinomial sample probabilities (proportions) $p_i = n_i/N$ for $i = 1, \ldots, n$ with sample size $N = \sum_{i=1}^{n} n_i$ and if $\Pi_{0n} = (\pi_{01}, \ldots, \pi_{0n})$ is the corresponding hypothesized distribution, with $m_i = N\pi_{0i}$ for $i = 1, \ldots, n$, then

$$G^2 = 2ND(P_n : \Pi_{0n}) = 2\sum_{i=1}^{n} n_i \log\left(\frac{n_i}{m_i}\right) \quad (9)$$

which has the asymptotic ▶chi-square distribution under the null hypothesis involving the Π_{0n}- distribution and with the proper degrees of freedom ($n-1$ if Π_{0n} involves no unknown parameters and $n-s-1$ if Π_{0n} involves s unknown parameters that are efficiently estimated).

One particular divergence (cross-entropy) is that from the joint distribution $\{p_{ij}\}$ for the random variables X and Y to their independence distribution $\{p_{i+}p_{+j}\}$, which, from (8) is given by

$$D(\{p_{ij}\}:\{p_{i+}p_{+j}\}) = \sum_{i=1}^{I}\sum_{j=1}^{J} p_{ij}\log\left(\frac{p_{ij}}{p_{i+}p_{+j}}\right) \qquad (10)$$

and is known as the *mutual information* between X and Y, but is also called *transinformation*. This measure reflects in a sense the statistical dependence between X and Y, with $D(\{p_{ij}\}:\{p_{i+}p_{+j}\}) = 0$ if, and only if, X and Y are independent. It can also clearly be expressed in terms of individual entropies from (1) as

$$D(\{p_{ij}\}:\{p_{i+}p_{+j}\}) = H(\{p_{i+}\}) + H(\{p_{+j}\}) - H(\{p_{ij}\}) \qquad (11)$$

which can also be seen to be non-negative from Property (P8) as expressed in (7).

In the case when X and Y are continuous random variables with the joint probability density function $h(x,y)$ and the marginal probability density functions $f(x)$ and $g(y)$, the equivalent of (10) becomes

$$\begin{aligned} D(h(x,y):f(x)g(y)) &= \int_{-\infty}^{\infty}\int_{-\infty}^{\infty} h(x,y) \\ &\quad \log\frac{h(x,y)}{f(x)g(y)}dxdy \\ &= -\int_{-\infty}^{\infty} f(x)\log f(x)dx \\ &\quad + \int_{-\infty}^{\infty}\int_{-\infty}^{\infty} h(x,y) \\ &\quad \log\frac{h(x,y)}{g(y)}dxdy \end{aligned} \qquad (12)$$

provided, of course, that the integrals exist. The first right-side term in (12) is the continuous analog of the discrete entropy in (1). However, this continuous entropy may be arbitrarily large, positive or negative.

Parameterized Generalizations

A number of generalizations of the entropy in (1) have been proposed by introducing one or more arbitrary real-valued parameters. The best known such generalization is the *Rényi entropy of order* α (Rényi 1961) defined by

$$H_{R\alpha}(P_n) = \frac{1}{1-\alpha}\log_2\sum_{i=1}^{n} p_i^{\alpha}, \alpha > 0, \alpha \neq 1 \qquad (13)$$

with α being an arbitrary parameter. Rényi (1961) defined $\alpha \in (-\infty, \infty)$, but $\alpha > 0$ is used in (13) to avoid mathematical difficulties when some $p_i = 0$. While he used only the base -2 logarithm, the natural logarithm could obviously also be used in (13). Rényi's entropy has many of the same properties as Shannon's entropy in (1), including the additivity in property (P6). In the limit as $\alpha \to 1$, and using l'Hôpital's rule, (13) reduces to (1) with base -2 logarithm, showing that Shannon's entropy is a special case of Rényi's entropy.

The second early parameterized generalization of Shannon's entropy was that of Havrda and Charvát (1967) and given by

$$H_{HC\alpha}(P_n) = \frac{1}{2^{1-\alpha}-1}\left(\sum_{i=1}^{n} p_i^{\alpha} - 1\right), \alpha > 0, \alpha \neq 1 \qquad (14)$$

of which the entropy in (1) with base -2 logarithm is the limiting case as $\alpha \to 1$. If $1-\alpha$ is used as the denominator in (14), as is often done, then (1) with base $-e$ (natural) logarithm would be the limiting case of (14) as $\alpha \to 1$.

There have been numerous other generalized entropy formulations (e.g., Arndt 2004, Ch. 6; Kapur 1994; Pardo 2006, Ch. 1). In order to include the great majority of those formulations within a single parameterized generalization, one needs a four-parameter generalized entropy as introduced by Kvålseth (Kvålseth 1991, 1994), i.e.,

$$H_{\alpha\beta\delta}^{\lambda}(P_n) = \lambda\left[\left(\frac{\sum_{i=1}^{n} p_i^{\alpha}}{\sum_{i=1}^{n} p_i^{\delta}}\right)^{\beta} - 1\right] \qquad (15a)$$

$$0 < \alpha < 1 \le \delta,\ \beta\lambda > 0;\ \text{or},\ 0 \le \delta \le 1 < \alpha,\ \beta\lambda < 0 \qquad (15b)$$

with the parameter restriction in (15b) necessary for the entropy in (15a) to be non-negative and strictly Schur-concave. In order for the expression in (15a) to be non-negative, it is found to be sufficient that $(\delta-\alpha)\beta\lambda > 0$ for any real-valued α, β, δ, and λ (using the convention $0^c = 0$ for all real c), but (15b) is found to be required for strict Schur-concavity.

For the particular case when, for instance, $\lambda = \lambda_1 = [(1-\alpha)\beta]^{-1}$ and $\delta = 1$, it follows from (15a) that

$$H_{\alpha 01}^{\lambda_1}(P_n) = \lim_{\beta\to 0} H_{\alpha\beta 1}^{\lambda_1}(P_n) = \frac{1}{1-\alpha}\log_e\left(\frac{\sum_{i=1}^{n} p_i^{\alpha}}{\sum_{i=1}^{n} p_i}\right), \alpha > 0 \qquad (16)$$

which is Rényi's entropy of order α for a *possibly incomplete distribution* when $\sum_{i=1}^{n} p_i \le 1$ (Rényi 1961). The equivalent

form of Shannon's entropy becomes

$$H_{001}^{\lambda_1}(P_n) = \lim_{\alpha\to 0} H_{\alpha 01}^{\lambda_1}(P_n) = \frac{-1}{\sum_{i=1}^{n} p_i} \sum_{i=1}^{n} p_i \log_e p_i \qquad (17)$$

for $\sum_{i=1}^{n} p_i \le 1$. L'Hôpital's rule is used for the limits in (16)–(17). If, instead of setting $\lambda = \lambda_1 = [(1-\alpha)\beta]^{-1}$, $\lambda = \lambda_2 = (2^{(1-\alpha)\beta} - 1)^{-1}$ is used in (15a), then the special cases in (16)–(17) would involve base −2 logarithms. Two very simple members of (15) are the *quadratic entropy* $1 - \sum_{i=1}^{n} p_i^2$ and the *cubic entropy* $1 - \sum_{i=1}^{n} p_i^3$ for $\sum_{i=1}^{n} p_i = 1$ (Kapur and Kesavan 1992: 326–340). Note that, because of the term $\sum_{i=1}^{n} p_i^{\delta}$ in (15), this general formulation also includes incomplete distributions $\left(\sum_{i=1}^{n} p_i < 1\right)$ and hence also the entropy of a single event. Thus, since the generalized entropy, or four-parameter family of entropies, in (15) is zero-indifferent (see also Property (P3)), the entropy of a single event of probability p becomes

$$H_{\alpha\beta\delta}^{\lambda}(p, 0, \ldots, 0) = \lambda(p^{(\alpha-\delta)\beta} - 1)$$

subject to the parameter restriction in (15b) and with two simple particular cases being $1 - p$ (e.g., when $\lambda = 1, \alpha = 2, \delta = \beta = 1$) and the corresponding odds $1/p - 1$.

Various parameterized generalizations have also been proposed for additive and non-additive directed divergence measures. Arndt (2004), Kapur (1994), and Pardo (2006) provide overviews of such generalizations.

While such generalized entropy formulations provide interesting mathematical exercises and explorations, the practical utility of such efforts seem to be somewhat limited. Unless the added flexibility of such generalizations prove useful in particular situations, Shannon's entropy in (1) and (17) is the entropy of choice.

About the Author

Dr. Tarald O. Kvålseth (Ph.D. in Industrial Engineering and Operations Research, University of California, Berkely, 1971) is Professor Emeritus in mechanical engineering, industrial engineering, and biomedical engineering at the University of Minnesota, Minneapolis, USA, where he also served as Director of the Industrial Engineering Division. Before joining the University of Minnesota, he was first on the faculty at Georgia Institute of Technology, USA, then at the Norwegian Institute of Technology where he was Head of Industrial Management. He is the author of numerous papers and editor of three books on ergonomics and has been a member of various organizations, including the American Statistical Association, The Mathematical Association of America, the Institute of Ergonomics & Human Factors, and is a Fellow of the American Association for the Advancement of Science. He has served as chair and committee member of several international conferences and been a member of editorial boards and association boards, including Chair of the Nordic Ergonomics Committee and Vice President of the International Ergonomics Association. He is listed in Marquis Who's Who, including Who's Who in in Science and Engineering, Who's Who in America, and Who's Who in the World.

Introduction

Let $\mathcal{P}$ be a convex set of probability distributions defined on a measurable space $(\mathcal{X}, \mathcal{B})$. The classical definition of entropy as a measure of randomness in $p \in \mathcal{P}$ is what is known as Shannon entropy

$$H(p) = -\sum_{i=1}^{n} p_i \log p_i \tag{1}$$

in the case of a ▶multinomial distribution in n classes with class probabilities, $p_1, \ldots, p_n$, and

$$H(p) = -\int p \log p \, dv \tag{2}$$

in the case of a continuous distribution. These measures were used by Boltzman (1872) and Gibbs (1875–1878) in describing some equilibrium states in thermodynamics and Shannon (1948) in information theory.

The function (1) has been adopted by ecologists as a diversity measure in discussing relative abundance of different species of animals or plants in a locality. Some early references are Pielou (1975), Patil and Taillie (1982), and Rao (1982a, b, c).

While $H(p)$ is defined on $\mathcal{P}$, there is another function $C(q|p)$, defined on $\mathcal{P} \times \mathcal{P}$, called cross entropy (CE), not necessarily symmetric in p and q, designed to examine how close a surrogate model q is to a true model p. A well-known CE is Kullback and Leibler (1951) divergence measure

$$C(q|p) = \sum_{i=1}^{n} p_i \log \frac{p_i}{q_i} \tag{3}$$

in the discrete case of n class multinomial distributions, and

$$C(q|p) = \int p \log \frac{p}{q} dv \tag{4}$$

in the case of continuous distributions.

In this paper, a general discussion of entropy and cross entropy measures, their characterizations, and applications to problems in statistics are given.

Entropy Functional

We state some general postulates governing an entropy function H on $\mathcal{P}$, conceived of as a measure of diversity (or randomness or uncertainty in prediction) as discussed in Rao (1982a, 1986).

$$A_1 : H(p) \geq 0 \quad \forall\, p \in \mathcal{P} \text{ and } H(p) = 0 \text{ iff } p \text{ is degenerate} \tag{5}$$

$$A_2 : H(\lambda p + \mu q) - \lambda H(p) - \mu H(q) = J(p, q : \lambda, \mu) \geq 0 \tag{6}$$

$$\forall\, p,\ q \in \mathcal{P},\ \lambda \geq 0,\ \mu \geq 0,\ \lambda + \mu = 1, \text{ and } = 0 \text{ iff } p = q$$

While A_1 requires H to be a non-negative function, A_2 implies that uncertainty increases if we contaminate p with another member q, i.e., $H(p)$ is a strictly concave function on $\mathcal{P}$. In a paper titled *Entropy* in this volume, Kvålseth gives a number of postulates governing H in addition to A_1 and A_2 and discusses the consequences of each postulate. One important difference is the additional postulate requiring symmetry of H in (5) with respect to $p_1, \ldots, p_n$. Some of the consequences of the postulate A_2 as stated in (6) are as follows:

1. In the class of multinomial distributions, $H(p)$ attains the maximum when all class probabilities are equal if H is symmetric in $p_1, \ldots, p_n$.
2. Dalton and Pielou used the following condition in characterizing a diversity measure:

$$H(p_1, \ldots, p_i, \ldots, p_j, \ldots, p_n) \leq H(p_1, \ldots, p_i + \delta, \ldots, p_j - \delta, \ldots, p_n)$$
$$\text{if } p_i < p_i + \delta \leq p_j - \delta < p_j.$$

This is implied by A_2 if H is symmetric in $p_1, \ldots, p_n$.

Some examples of entropy functions in the case of multinomial distributions with $p_1, \ldots, p_n$ as class probabilities are:

1. $-\sum p_i \log p_i$, Shannon entropy
2. $1 - \sum {p_i}^2$, Gini-Simpson entropy
3. $(1-\alpha)^{-1} \log \sum p_i^{\alpha}$, $\alpha > 0$, $\alpha \neq 1$, Rényi entropy
4. $(\alpha - 1)^{-1} \left(1 - \sum p_i^{\alpha}\right)$, Havrda and Charvát entropy
5. $\sum\sum d_{ij} p_i p_j$, Rao's (1984) quadratic entropy where $d_{11} = \ldots = d_{kk}$ and the $(k-1) \times (k-1)$ matrix $(d_{ik} + d_{jk} - d_{ij} - d_{kk})$ is non-negative definite.

Properties of some of these entropy functions are discussed in Kvålseth in this volume. In the continuous case, some of the entropy functions are:

6. $-\int p \log p \, dv$, Shannon entropy, which may be negative for some p. For example, if

$$p = 2 \text{ for all } x \text{ in } (0, 1/2), \quad -\int p \log p \, dv$$
$$= -\int_0^{1/2} 2 \log 2 dv = -\log 2 < 0$$

7. $(1-\alpha)^{-1} \log \int p^{\alpha} dv$, $\alpha > 0$, $\alpha \neq 1$, Rényi entropy
8. $\int k(x,y)p(x)p(y)dv_x dv_y$, Rao's (1984) quadratic entropy where k is a conditionally negative definite kernel, i.e.,

$$\sum_{i=1}^{n} \sum_{j=1}^{n} k(x_i, x_j) a_i a_j < 0$$

for any n and $x_1, \ldots, x_n$ and $a_1, \ldots, a_n$ such that $\sum a_i = 0$.

Rao's quadratic entropy in the case of multinomial distributions is a function of both the class probabilities and possible differences in species in other aspects. It may not be a symmetric function of class probabilities. For a discussion on the use of Rao's quadratic entropy as an appropriate tool in the ecological studies, reference may be made to papers by Pavoine et al. (2005), Ricotta and Szeidl (2006) and Zoltán (2005). It may be noted that Rao's quadratic entropy reduces to the expression for the variance of the distribution p if $k(x,y) = (x-y)^2$.

Maxwell and Boltzmann obtained what is known as Maxwell-Boltzmann distribution of elementary particles (such as molecules) by maximizing Shannon entropy function, as in 6. above, subject to a restriction on p. Rao (1973, pp. 172–175) obtained the corresponding model by maximizing Rényi's entropy, as in 7. above, subject to the same restriction on p. It would be of interest to try other entropy functions and compare different models.

ANODIV

R. A. Fisher introduced the method of Analysis of Variance (ANOVA) for partitioning the variance of a set of measurements into several components such as "between" and "within" populations, "first order and higher order interactions" of factors, etc. Can a similar analysis be done with other measures of variability such as the mean deviation in the case of quantitative variables and a measure of diversity in the case of qualitative measurements? For instance we may have n populations of individuals and each individual in a population is scored for one of k possible skin colors. We may ask what is the average diversity of skin color within populations? What is the difference in skin color between populations as a whole?

The key to this lies in the choice of a suitable measure of diversity whether the measurements involved are qualitative or quantitative satisfying the postulate A_2

$$H(\lambda_1 p_1 + \cdots + \lambda_k p_k) - \sum_{i=1}^{k} \lambda_i H(p_i) = J_1(\{p_i\}, \{\lambda_i\}) \geq 0 \tag{7}$$

where the first term is the diversity of individuals in the mixed population, the second term is average diversity within populations and the difference is attributed to diversity between populations.

The function J in (7) is called Jensen difference of order 1, and H satisfying (7) as a diversity measure of order 1. Using (7) we have one-way ANODIV (Analysis of Diversity) as in Table 1.

where $P_\bullet = \sum \lambda_i p_i$. In practice, we estimate $H(P_\bullet)$ and $H(P_i)$ based on observed data and λ_i as proportional to sample size n_i of observations from the ith population. The ratio $G = B/T$, has been termed as genetic index of diversity in some population studies to interpret differences between populations as in Lewontin (1972), Nei (1973), and Rao (1982b). It may be noted that G depends on the choice of a suitable measure of diversity relevant to problem under consideration. For some applications reference may be made to Rao (1982a, b, 1984b).

Now, we investigate the condition on $H(\mathcal{P})$ for carrying out a two-way ANODIV. Let us consider populations denoted by $P_{ij}, i = 1, \ldots, r$ and $j = 1, \ldots, s$, where the first index i refers to a locality and the second index j to a specific community. Further, let $\lambda_i \mu_j$ be the relative strength of individuals in locality i and community j, where λ_i and μ_j are all non-negative and $\sum \lambda_i = \sum \mu_j = 1$. We may ask: how are the genetic contributions of individuals between localities and between communities as a whole different? Is the magnitude of genetic differences between the communities different in different localities? Such questions concerning the rs populations can be answered by a two-way ANODIV as in Table 2.

Entropy and Cross Entropy as Diversity and Distance Measures. Table 1 One-way ANODIV for k populations

Due to		Diversity
Between populations	(B)	$J_1(\{p_i\}, \{\lambda_i\})$
Within populations	(W)	$\sum \lambda_i H(p_i)$
Total	(T)	$H(P_\bullet)$

Entropy and Cross Entropy as Diversity and Distance Measures. Table 2 Two-way ANODIV

Due to		Diversity
Localities	(L)	$H(P_{\cdot\cdot}) - \sum_{i=1}^{r}\lambda_i H(P_{i\cdot})$
Communities	(C)	$H(P_{\cdot\cdot}) - \sum_{j=1}^{s}\mu_j H(P_{\cdot j})$
Interaction	(LC)	* by subtraction
Between populations	(B)	$H(P_{\cdot\cdot}) - \sum\lambda_i\mu_j H(P_{ij})$
Within populations	(W)	$\sum\sum\lambda_i\mu_j H(P_{ij})$
Total	(T)	$H(P_{\cdot\cdot})$

In Table 2, $P_{\cdot\cdot} = \sum\sum\lambda_i\mu_j P_{ij}, P_{i\cdot} = \sum\mu_j P_{ij}, P_{\cdot j} = \sum\lambda_i P_{ij}$. What are the conditions under which the entries in Table 2 are non-negative? For B, L, and C to be non-negative, the function $H(\cdot)$ defined on $\mathcal{P}$ should be strictly concave. For the interaction LC to be non-negative

$$\begin{aligned}(LC) &= -\left[H(P_{\cdot\cdot}) - \lambda_i H(P_{i\cdot})\right] + \sum\mu_j\left[H(P_{\cdot j}) - \lambda_i H(P_{ij})\right] \\ &= -J_1\left(\{P_{i\cdot}\} : \{\lambda_i\}\right) + \sum\mu_j J_1\left(\{P_{ij}\} : \{\lambda_i\}\right) \\ &= J_2\left(\{P_{ij}\} : \{\lambda_i\mu_j\}\right) \geq 0 \end{aligned} \tag{8}$$

or J_1 as defined in (7) on $\mathcal{P}^r$ is convex. We represent this condition as C_2 on a diversity measure. If C_1 and C_2 hold, we call such a diversity measure as of order 2. Note the (LC) can also be expressed as

$$\begin{aligned}(LC) &= -\left[H(P_{\cdot\cdot}) - \sum\mu_j H(P_{ij})\right] + \sum\lambda_i\Big[H(P_{i\cdot}) \\ &\qquad -\sum\mu_j H(P_{ij})\Big] \\ &= -J_1\left(\{P_{\cdot j}\} : \{\mu_j\}\right) + \sum\lambda_i J_1\left(\{P_{ij}\} : \{\mu_j\}\right) \end{aligned} \tag{9}$$

or J_1 as a function on $\mathcal{P}^s$ is convex.

We can recursively define higher order Jensen differences J_3 from J_2, J_4 from J_3 and so on, and call $H(\cdot)$ for which $J_0, J_1, \ldots, J_{i-1}$ are convex as the i^{th} order diversity measure. With such a measure we can carry out ANODIV for i-way classified data. A diversity measure for which Jensen differences of all orders are convex is called a perfect diversity measure.

Burbea and Rao (1982a, b, c) have shown that Shannon entropy satisfies the conditions C_0, C_1, and C_2, but not $C_3, C_4, \ldots$ The Havrda and Charvát entropy satisfies C_0, C_1, and C_2 for α in the range $(1, 2]$ when $k \geq 3$ and for α in the range $[1, 2] \cup (3, 11/3)$ when $k = 2$ and $C_3, C_4, \ldots$ do not hold except when $\alpha = 2$ in which case it reduces to Gini-Simpson index. Rényi's entropy satisfies C_0, C_1, and C_2 only for α in $(0, 1)$. Most of the well known entropy functions can be used only for two-way ANODIV but not for higher order ANODIV.

In the case of Rao's quadratic entropy, Jensen differences of all orders are convex, so that ANODIV can be carried out for any order classified data. It is shown by Lau (1985) that an entropy with this property is necessarily Rao's Quadratic Entropy.

Asymptotic distribution of ratios of entries in the ANODIV table, which can be used for tests of hypotheses as in ANOVA, can be obtained by bootstrapping as illustrated in Liu and Rao (1995).

Entropy Differential Metric

Using Fisher Information matrix, Rao (1945) introduced a quadratic differential metric, known as Fisher-Rao metric, over the parameter space of a family of probability distributions and proposed the geodesic distance (Rao distance) induced by the metric as a measure of dissimilarity between probability distributions. Burbea and Rao (1982c) introduced ϕ-entropy functional

$$H_\phi(p) = -\int \phi[p(x)]dv \tag{10}$$

and derived the quadratic differential metric as the Hessian of ϕ, assuming a parametric family of probability densities

$$p(x) = p(x, \theta_1, \ldots, \theta_n).$$

This opens up a wide variety of differential metrics. For instance, the choice of Shannon entropy with

$$\phi(p) = p\log p \tag{11}$$

in (10) gives Fisher-Rao metric. The reader is referred to Burbea and Rao (1982b, c) for the details. Maybank (2008) has written a number of papers on the application of Fisher-Rao metric, Rao distance and the associated Rao Measure. The possibility of using Burbea-Rao metric, which offers wider possibilities may be explored.

Cross Entropy

Characterization

There are situations where the true probability distribution p is not known but we us a surrogate distribution q for an analysis of data arising from p, or p is known but it is easy to generate observations from q to estimate some quantities such as the probability of large deviations in p, by a technique known in statistics as importance sampling as explained in section "▶Some Applications of CE". See also Rubinstein and Kroese (2004). In such a case we need to select q from $\mathcal{Q}$, a chosen family of distributions, such that q is close to an optimum distribution, using a suitable measure of closeness. One such measure, called

cross entropy (CE), used in some problems is Kullback-Leibler (1951) measure of divergence

$$C(q|p) = \int p \log \frac{p}{q} dv. \tag{12}$$

We suggest a few postulates for the choice of CE:

$$B_1 : \; C(q|p) \geq 0 \;\; \forall \; p, q \in \mathcal{P} \text{ and } C(q|p) = 0 \text{ only if } p = q. \tag{13}$$

$$B_2 : \; C(q|\lambda p + \mu q) \leq C(q|p), \;\; \lambda \geq 0, \;\; \mu \geq 0, \;\; \lambda + \mu = 1. \tag{14}$$

The postulate B_2 is a natural requirement as the mixture $\lambda p + \mu q$ has some component of q which brings q closer to $\lambda p + \mu q$.

There are several ways of constructing CEs depending on its use in solving a given problem. A loss function approach is as follows: let p be true probability density and we wish to find q such that

$$\int l(p(x), q(x)) p(x) dx \tag{15}$$

is a minimum, where l is a measure of difference between the likelihoods $p(x)$ and $q(x)$. The choice

$$l(p(x), q(x)) = \log \frac{p(x)}{q(x)} \tag{16}$$

leads to ▶Kullback-Leibler divergence measure

$$C(q|p) = \int p \log \frac{p}{q} dv. \tag{17}$$

The choice

$$l(p(x), q(x)) = \frac{[p(x) - q(x)]^2}{p(x) q(x)} \tag{18}$$

introduced by Rao (2010) leads to

$$\int \frac{(p-q)^2}{pq} p dv = \int \frac{p^2}{q} dv - 1, \tag{19}$$

which has some interesting properties.

A general version of CE, known as Csizar generalized measure, is

$$\int l\left(\frac{q}{p}\right) p dv$$

where

$$l \geq 0, \;\; l(1) = 0 \text{ and } l''(0) > 0. \tag{20}$$

Rao and Nayak (1985) gave a general method of deriving a CE from a given entropy function $H(p)$ as

$$C(q|p) = \lim_{\lambda \to 0} \frac{H(q + \lambda(p-q)) - H(q)}{\lambda} + H(q) - H(p). \tag{21}$$

The choice of $H(p)$ as Shannon entropy in (21) leads to (17), the Kullback-Leibler divergence measure.

Some Applications of CE

A comprehensive account of the use of CE in estimating probability of large deviations and a variety of stochastic and non-stochastic optimization problems is given in Rubinstein and Kroese (2004).

An example of how cross entropy is used is as follows. Suppose the problem is that of estimating $\gamma = E_p[\Phi(x)]$, the expectation of a function $\Phi(x)$ with respect to a given probability distribution $p(x)$. For instance, if we want to find the probability of $x \geq a$, as in the problem of large deviations. we can express it as the expectation of the function $I_{x \geq a}$, where I is the indicator function.

A general Monte Carlo technique of estimating γ is to draw a sample $x_1, \ldots, x_n$ from $p(x)$ and estimate γ by

$$\hat{\gamma} = n^{-1} \sum \Phi(x_i). \tag{22}$$

Observing that

$$\int \Phi(x) p(x) \, dx = \int \Phi(x) \frac{p(x)}{q(x)} q(x) \, dx \tag{23}$$

and

$$\gamma = E_q \left[\Phi(x) \frac{p(x)}{q(x)} \right] \tag{24}$$

we may draw a sample $(x_1', \ldots, x_n')$ from q, known as an importance sampling distribution, and estimate γ by

$$\hat{\gamma} = n^{-1} \sum \Phi(x_i') \, p(x_i') / q(x_i'). \tag{25}$$

The best choice of q which reduces the variance of $\hat{\gamma}$ to zero is

$$q^*(x) = \frac{\Phi(x) p(x)}{\gamma}. \tag{26}$$

However, the solution depends on the unknown γ. An alternative is to choose a family of sampling distributions indexed by a number of parameters

$$q(x, \theta), \;\; \theta = (\theta_1, \ldots, \theta_s) \tag{27}$$

and estimate θ by minimizing $C[q(x, \theta)|q^*(x)]$ with respect to θ. If we are using KL divergence measure, the problem reduces to

$$\max_{\theta} \int q^*(x) \log q(x, \theta) dv \tag{28}$$

which can be solved analytically or by maximizing with respect to the stochastic counterpart

$$\sum_{i=1}^{n} \frac{q^*(x_i)}{q(x_i, \overline{\theta})} \log q(x, \theta) \tag{29}$$

with respect to θ, where, $x_1, \ldots, x_n$ are observations drawn from $q(x, \overline{\theta})$, choosing a fixed value $\overline{\theta}$ of θ. Use of (19) as CE reduces the variance of the estimate (25).

The CE method can also be used to find the maximum or minimum of a mathematical function $f(x)$ defined over a region $\mathcal{R}$, subject to some equality and inequality constraints as in the Travelling Salesman, pattern recognition (see ►Pattern Recognition, Aspects of and ►Statistical Pattern Recognition Principles), and clustering problems. The problem is converted to a stochastic problem by choosing a probability distribution $p(x)$ over the given region $\mathcal{R}$ and a constant γ, and applying the algorithm used in the problem of large deviations, Prob $[f(x) > \gamma]$. The probability distribution $p(x)$ and the constant γ are altered step by step till the large deviation probability becomes negligibly small. For details, the reader is referred to Rubinstein and Kroese (2004).

Epilogue

In his paper in this volume on *The Future of Statistics*, Efron mentions that the nature of statistical methods is constantly changing with the availability of large data sets and increase in computing power. Early development of statistical theory and practice during the first half of the last century was based on parametric models for observed small data sets, and a set of prescribed rules for testing given hypotheses and estimating parameters of the chosen model. A critical discussion of these methods is given in the paper, *Has statistics a future*? *If so, in what form*? (*with discussion*), by Rao (2003).

Efron's bootstrap (see ►Bootstrap Methods) and new computer intensive methods such as boosting, bagging, CART, Lasso, Lars, projection pursuit, machine learning methods as in training ►neural networks, and random forests, have put statistical methodology in a different perspective without use of specific models for data. To these may be added the CE approach described in this paper, which provides a comprehensive computational algorithm for solving a variety of statistical problems, such as estimation of large deviations (see ►Large Deviations and Applications), pattern recognition and clustering, DNA sequence alignment and non-stochastic optimization problems such as The Travelling Salesman Problem.

I would like to mention that the aim of statistical analysis is not just to answer specific questions posed by the customer, but to find hidden patterns in given data, described as ►exploratory data analysis emphasized by Tukey, or ►data mining or bottom-up analysis to use modern terminology. Such an analysis will enable us to frame new hypotheses leading to possible expansion of knowledge. Some of these hypotheses could be tested with the existing data and some of them may need further acquisition of data. For further discussion on the need of statistics in solving problems of the real world, development of statistical methodology in view of technological advances in data collection, availability of large data sets, and emergence of new disciplines like ►bioinformatics raising new problems for data analysis, and training of statisticians, reference may be made to Efron's paper in this volume and Rao (2003).

About the Author

Calyampudi Radhakrishna Rao (born on September 10, 1920, in India) is among the most important statisticians in the past 60 years. He was the eighth in a family of 10 children. Following the usual custom, he was named after the God Krishna, who was also the eighth child of his parents. Rao received MA degree in mathematics from Andhra University (1941) and MA degree in statistics from Calcutta University (1943) with a first class, first rank and a gold medal. He started working in the Indian Statistical Institute (ISI), at Calcutta in 1941. In 1944 while giving a course on estimation at the Calcutta University to the senior students of the master's class a student asked him whether a result similar to the Fisher's information inequality for the asymptotic variance of a consistent estimate exists in small samples. During the same night Rao discovered the result that is today widely known as Cramér-Rao inequality. He obtained his Ph.D. in 1948 from the King's College, Cambridge University, UK, with R. A. Fisher as his thesis advisor (Fisher requested that Rao choose a research problem for his Ph.D. thesis himself). On his return to India Rao was appointed at the ISI as Professor at the age of 29. In India he held several important positions, as the Director of the ISI (1972–1976), Jawaharlal Nehru Professor and National Professor. He was the founder of Indian Econometric Society and the Indian Society for Medical Statistics. Rao took mandatory retirement at the age of 60 and moved to USA where he was appointed as a professor at the University of Pittsburgh (1979–1988). In 1988 he moved to the Pennsylvania State University accepting the newly established Chaired Professorship as Eberly Professor of Statistics (1988–2001). Since 2001 he is Eberly Professor Emeritus of Statistics. Professor Rao has been the President of the International Biometric Society (1973–1975), Institute of Mathematical Statistics (1976–1977) and International Statistical Institute (1977–1979). He has (co-)authored about 350 research papers, 14 books, including *Linear Statistical Inference and its Applications* (John Wiley 1965) and *Statistics and Truth: Putting Chance to Work* (World Scientific Publishing, 1989), both translated into six languages. Professor Rao

is the only living statistician whose two single-authored papers (*Information and the accuracy attainable in the estimation of statistical parameters* and *Large Sample Tests of Statistical Hypotheses Concerning Several Parameters with Applications to Problems in Estimation*) which had a high impact on the development of statistical theory were included in the book *Breakthroughs in Statistics* (Eds. S. Kotz and N. L. Johnson, Springer, 1993/1997). His name is associated with many statistical terms like: Cramér-Rao inequality, Rao-Blackwellization, Rao's Score Test, Fisher-Rao and Rao Theorems on second order efficiency of an estimator, Rao's U test, Fisher-Rao metric, and Rao distance. Other technical terms bearing his name appearing in specialized books are Rao's Quadratic Entropy, Cross Entropy, Rao's Paradoxes, Rao-Rubin, Lau-Rao, Lau-Rao-Shanbhag and Kagan-Linnik-Rao theorems on characterization of probability distributions. For his pioneering contributions to statistical theory and applications Professor Rao has won numerous awards and honors. Just to mention a few, he is a Fellow of Royal Society, UK (1967), a member of the Academy of Arts and Science (1975), and National Academy of Science (1995), US, and a member of three National Academies in India. Professor Rao was awarded numerous medals, including: Guy Medal in Silver of the Royal Statistical Society (1965), Jagdish Chandra Bose Gold Medal (1979), Samuel S. Wilks Memorial Medal (1989), Mahalanobis Birth Centenary Gold Medal (1996), Army Wilks Award (2000). On June 12, 2002, he received the National Medal of Science, the highest scientific honor by the United States. Professor Rao has also received other prestigious awards, such as: Padma Vibhushan award (2001), International Mahalanobis Prize (2003), and India Science Award (2010). For his outstanding achievements, C.R. Rao has been honored with the establishment of an institute named after him: C.R. Rao Advanced Institute for Mathematics, Statistics and Computer Science (C.R. Rao AIMSCS), located in the campus of the University of Hyderabad, India (http://aimscs.org). Nine special issues of several leading international journals were published (1991–2002) and six international conferences were organized in honor of Professor Rao (1980–2010). He was the doctoral thesis advisor for over 50 students who in turn produced more than 350 Ph.D.'s. Professor Rao holds 32 honorary doctorates from universities in 18 countries spanning six continents.

"The first half of the century was the golden age of statistical theory, during which our field grew from ad hoc origins, similar to the current state of computer science, into a firmly grounded mathematical science. Men of the intellectual caliber of Fisher, Neyman, Pearson, Hotelling, Wald, Cramér and *Rao* were needed to bring statistical theory to maturity." (Bradley Efron (1995). The Statistical Century, *Royal Statistical Society News*, **22**, 5, 1–2.)

Environmental Monitoring, Statistics Role in

Jennifer Brown
President of the New Zealand Statistics Association, Head
University of Canterbury, Christchurch, New Zealand

Environmental monitoring is conducted to provide information on status, and changes in status, of an environmental system. Often monitoring is associated with an impact, such as a proposed land development activity or rehabilitation of a habitat. At other times, environmental monitoring is conducted to assess the success (or failure) of a new environment management strategy or change in strategy. Monitoring can also be carried out to provide information on the overall status of a land or water area of special interest in fields such as biodiversity, the welfare of an endangered species or the abundance of a pest species.

In all these examples, the common theme is that monitoring is conducted to provide information. This information may be used in reports and articles that are created to bring about change in management. Typically, such information is numerical – a summary statistic, or a set of data – or some type of numerical measure. This is the role of statistics – statistics is the process used to collect and summarize data to provide relevant information for environmental monitoring.

Some underlying principles apply to information collected from environmental monitoring. The first is that in any monitoring design, the aims and objectives need to be clearly stated, both in a temporal and a spatial scale. The most successful monitoring programmes have aims and objectives that can be quantified to guide development of the survey design and data analysis (Gilbert 1987).

The survey design for the monitoring programme should specify how information is to be collected. Various survey designs can be used, and the important criterion is that they should provide a sample that is representative of the population and provide information relevant to the survey objective. The population can be considered to be an area of land or water that has fixed and delineated boundaries. A reserve or national park is an example of such a population. Other populations may be a species of interest, e.g., a bird population. In the example of a bird species, the population may be finite, although of unknown size, but the spatial boundaries may be unknown if the birds are highly mobile. In other applications, defining the population may be very difficult. For example, when monitoring the impact of a new industrial development in a rural area, delineating the area beyond which there is unlikely to be an effect may be very difficult.

Sample designs that use an element of probability (probability sampling) are recommended so that sample survey theory can be used to estimate sample precision (Thompson 2002). Examples of designs are simple random sampling, stratified sampling, grid-based sampling and spatially balanced designs (Stevens and Olsen 2004).

Statistics is used when a modeling approach is needed to describe the environmental system or for measuring the size of an environmental effect. Examples of an environmental effect are the changes (measured in some way) in environmental status of an area over time, or difference in environmental quality among sites receiving different management treatments (Manly 2008).

The very nature of environmental monitoring is that data are collected over time to allow assessment of change. A special type of statistical analysis is used for such data to account for the temporal correlation. Repeated measures analysis and longitudinal analysis are two terms used to describe different analyses for when environmental samples are collected from the same population over time (Manly 2008, Diggle et al. 2002). A consideration in surveys that are repeated over time is whether the same sites should be visited on each survey occasion or whether new sites should be selected and visited at each occasion. Designs that combine aspects of both are often used, where on each survey occasion, a mix of previous and new sites are surveyed (See, for example, Skalski 1990).

A feature of environmental monitoring that is designed to detect any impact resulting from an event is that information on the environment in the absence of the impact needs to be collected. An environmental impact describes events such as a new industrial development or the implementation of a new management strategy to protect an endangered species. The statistical term for these designs is before/after control/impact (BACI) (Underwood 1994).

In a BACI study, information is collected before the impact both at the control sites and at the site(s) of the future impact. Control sites are those that will not be affected by the impact event. Information is then collected from control sites and from the actual impact sites. This design provides information on the environment in the absence of the impact temporally (i.e., before the impact) and spatially (i.e., the control sites). The BACI statistical analysis considers whether the difference between the control and impact sites increases or decreases after the impact event. The analysis provides a way of quantifying this change in differences. Clearly, for some events, the complete BACI design cannot be used, e.g., unplanned impacts such as oil spills.

A growing area of statistics is spatial analysis and the use of geographic information systems (GIS) to map and describe environmental systems. Environmental monitoring can be designed to provide information on geographic changes in spatial patterns and distributions. Often maps and other well-designed graphical displays can be very informative. A final comment must be made about the logistical support for environmental monitoring. Monitoring programmes rely on (and often assume) data being collected accurately in the field. Whether this is true or not depends heavily on whether the field team have appropriate training and support. It is very important to have consistency in data collection protocols to ensure that any observed variation in summary statistics over time is a result of changes in the environmental system and not simply changes in field staff or their ability. Other considerations are that data need to be recorded accurately and stored in an accessible way.

Statistics plays a vital role in environmental monitoring because the essential ingredient to monitoring is data. A well planned, designed and executed monitoring programme can provide a wealth of information to guide future management and help ensure we maintain healthy environments.

About the Author

Professor Brown is President of the New Zealand Statistical Association, a position she has held since 2008. She is the Head of the Department of Mathematics and Statistics at University of Canterbury. Professor Brown is currently an Associate Editor of *Journal of Agricultural, Biological and Environmental Statistics*, of the *Australian and New Zealand Journal of Statistics*, and of the *International Journal of Ecological Economics and Statistics*.

Equivalence Testing

Dieter Hauschke
Professor
University Medical Centre Freiburg, Freiburg, Germany

Many clinical trials have the objective of showing equivalence between two treatments, usually a test treatment

under development and an existing reference treatment. In such studies the aim is no longer to detect a difference, as in the case when comparing a new treatment with placebo, but to demonstrate that the two active treatments are equivalent within a priori stipulated acceptance limits. Let Y_T and Y_R designate the primary clinical outcome of interest for the test and reference treatment, respectively. A two-sample situation is considered where it is assumed that the outcomes are mutually independent and normally distributed with unknown but common variance σ^2,

$$Y_{Tj} \sim N(\mu_T, \sigma^2),\ j = 1, \ldots, n_1, \text{ and } Y_{Rj} \sim N(\mu_R, \sigma^2),\ j = 1, \ldots, n_2.$$

For equivalence testing it is reasonable to assume that the signs of the corresponding population means μ_T and μ_R are the same and, without loss of generality, positive. Let the interval (δ_1, δ_2), $\delta_1 < 0 < \delta_2$, denote the pre-specified equivalence range, so that the corresponding test problem can be formulated as follows:

$$H_0 : \mu_T - \mu_R \le \delta_1 \text{ or } \mu_T - \mu_R \ge \delta_2 \quad \text{vs}$$
$$H_1 : \delta_1 < \mu_T - \mu_R < \delta_2.$$

A split of the above two-sided test problem into two one-sided test problems (Schuirmann 1987) results in

$$H_{01} : \mu_T - \mu_R \le \delta_1 \quad \text{vs} \quad H_{11} : \mu_T - \mu_R > \delta_1$$

and

$$H_{02} : \mu_T - \mu_R \ge \delta_2 \quad \text{vs} \quad H_{12} : \mu_T - \mu_R < \delta_2.$$

According to the intersection–union principle (Berger and Hsu 1996), H_0 is rejected at significance level α in favor of H_1 if both hypotheses H_{01} and H_{02} are rejected at significance level α:

$$T_{\delta_1} = \frac{\overline{Y}_T - \overline{Y}_R - \delta_1}{\hat{\sigma}\sqrt{\frac{1}{n_1} + \frac{1}{n_2}}} > t_{1-\alpha, n_1+n_2-2} \text{ and}$$
$$T_{\delta_2} = \frac{\overline{Y}_T - \overline{Y}_R - \delta_2}{\hat{\sigma}\sqrt{\frac{1}{n_1} + \frac{1}{n_2}}} < -t_{1-\alpha, n_1+n_2-2},$$

where $\overline{Y}_T$ and $\overline{Y}_R$ denote the corresponding sample means, $t_{1-\alpha, n_1+n_2-2}$ is the $(1-\alpha)$ quantile of the central Student's t-distribution with $n_1 + n_2 - 2$ degrees of freedom and

$$\hat{\sigma}^2 = \frac{1}{n_1 + n_2 - 2}\left(\sum_{j=1}^{n_1}(Y_{Tj} - \overline{Y}_T)^2 + \sum_{j=1}^{n_2}(Y_{Rj} - \overline{Y}_R)^2\right)$$

is the pooled estimator of σ^2.

This is equivalent to

$$\overline{Y}_T - \overline{Y}_R - t_{1-\alpha, n_1+n_2-2}\,\hat{\sigma}\sqrt{\frac{1}{n_1} + \frac{1}{n_2}} > \delta_1 \text{ and}$$

$$\overline{Y}_T - \overline{Y}_R + t_{1-\alpha, n_1+n_2-2}\,\hat{\sigma}\sqrt{\frac{1}{n_1} + \frac{1}{n_2}} < \delta_2,$$

and hence to the inclusion of the two-sided $(1-2\alpha)100\%$ confidence interval for $\mu_T - \mu_R$ in the equivalence range

$$\left[\overline{Y}_T - \overline{Y}_R - t_{1-\alpha, n_1+n_2-2}\,\hat{\sigma}\sqrt{\frac{1}{n_1} + \frac{1}{n_2}}, \overline{Y}_T - \overline{Y}_R + t_{1-\alpha, n_1+n_2-2}\,\hat{\sigma}\sqrt{\frac{1}{n_1} + \frac{1}{n_2}}\right] \subset (\delta_1, \delta_2).$$

In clinical practice the equivalence limits δ_1 and δ_2 are often expressed as fractions of the unknown reference mean $\mu_R \neq 0$, i.e., $\delta_1 = f_1\mu_R$ and $\delta_2 = f_2\mu_R$, $-1 < f_1 < 0 < f_2$. For example $f_1 = -f_2 = -0.2$ corresponds to the common ±20% criterion. The test problem for equivalence can then be formulated as:

$$H_0 : \frac{\mu_T}{\mu_R} \le \theta_1 \text{ or } \frac{\mu_T}{\mu_R} \ge \theta_2 \quad \text{vs} \quad H_1 : \theta_1 < \frac{\mu_T}{\mu_R} < \theta_2,$$

where (θ_1, θ_2), $\theta_1 = 1 + f_1$, $\theta_2 = 1 + f_2$, $0 < \theta_1 < 1 < \theta_2$, is the corresponding equivalence range for the ratio of the expected means μ_T and μ_R. The null hypothesis can be rejected in favor of equivalence, if

$$T_{\theta_1} = \frac{\overline{Y}_T - \theta_1\overline{Y}_R}{\hat{\sigma}\sqrt{\frac{1}{n_1} + \frac{\theta_1^2}{n_2}}} > t_{1-\alpha, n_1+n_2-2} \text{ and}$$
$$T_{\theta_2} = \frac{\overline{Y}_T - \theta_2\overline{Y}_R}{\hat{\sigma}\sqrt{\frac{1}{n_1} + \frac{\theta_2^2}{n_2}}} < -t_{1-\alpha, n_1+n_2-2}.$$

Hauschke et al. (1999) have shown that rejection of H_0 by the two tests T_{θ_1} and T_{θ_2} each at level α is equivalent to inclusion of the $(1-2\alpha)100\%$ confidence interval for μ_T/μ_R, given by Fieller (1954), in the equivalence range (θ_1, θ_2), with

$$[\theta_l, \theta_u] \subset (\theta_1, \theta_2) \text{ and } \overline{Y}_R^2 > a_R,$$

where

$$\theta_l = \frac{\overline{Y}_T\overline{Y}_R - \sqrt{a_R\overline{Y}_T^2 + a_T\overline{Y}_R^2 - a_Ta_R}}{\overline{Y}_R^2 - a_R},$$
$$\theta_u = \frac{\overline{Y}_T\overline{Y}_R + \sqrt{a_R\overline{Y}_T^2 + a_T\overline{Y}_R^2 - a_Ta_R}}{\overline{Y}_R^2 - a_R},$$
$$a_T = \frac{\hat{\sigma}^2}{n_1}t_{1-\alpha, n_1+n_2-2}^2, \quad a_R = \frac{\hat{\sigma}^2}{n_2}t_{1-\alpha, n_1+n_2-2}^2.$$

Note that the condition $\overline{Y}_R^2 > a_R$ implies that $\mu_R \neq 0$

$$\overline{Y}_R^2 > \frac{\hat{\sigma}^2}{n_2}t_{1-\alpha, n_1+n_2-2}^2 \Leftrightarrow \frac{|\overline{Y}_R|}{\hat{\sigma}\sqrt{\frac{1}{n_2}}} > t_{1-\alpha, n_1+n_2-2}.$$

It should be noted that in clinical trials, a significance level of $\alpha = 0.025$ is required for equivalence testing and this refers to the calculation of two-sided 95% confidence intervals (CPMP 2000). Hence, equivalence can be concluded at level $\alpha = 0.025$ if the corresponding two one-sided test problems can be rejected each at level $\alpha = 0.025$.

About the Author

Dr. Dieter Hauschke is a Professor in Biometry, Department of Statistics, University of Dortmund, Germany. Currently, he is working as a scientist at the Institute for Medical Biometry and Medical Informatics, University Medical Center Freiburg, Germany. He was a member of the Advisory Council of the International Biometric Society – German Region (2001–2005) and council member of the International Biometric Society (2006–2010). He is incoming Head (2008–2010), Head (2011–2012) of the committee biometry within German Association of Medical Informatics, Biometry and Epidemiology. He is member of the Editorial Board of the International Journal of Clinical Pharmacology and Therapeutics and he was Associate Editor of the *Biometrical Journal* (2006–2010). Since 2009, he is statistical consultant of the Drug Commission of the German Medical Association and of the Treat-NMD Neuromuscular Network. Prof. Hauschke is author or co-author of more than 75 research articles and book-chapters. He is also co-author of the textbook *Bioequivalence in Drug Development: Methods and Applications* (with V. Steinijans and I. Pigeot, Wiley, 2007).

Ergodic Theorem

Steven P. Lalley
Professor
University of Chicago, Chicago, IL, USA

Birkhoff's Ergodic Theorem

Birkhoff's theorem (see Birkhoff 1931) extends the strong law of large numbers to stationary processes. The theorem is most easily formulated in terms of *measure-preserving transformations*: If $(\Omega, \mathcal{F}, P)$ is a probability space then a measurable transformation $T : \Omega \to \Omega$ is *measure-preserving* if $EX = EX \circ T$ for every bounded random variable X defined on Ω. In this case P is said to be *T-invariant*. Let T be a measure-preserving transformation of a probability space $(\Omega, \mathcal{F}, P)$; then a random variable X defined on $(\Omega, \mathcal{F})$ is *T-invariant* if $X = X \circ T$ almost surely, and an event $F \in \mathcal{F}$ is *T-invariant* if its indicator function is. The collection of all T-invariant events $F \in \mathcal{F}$ is a σ-algebra, denoted by $\mathcal{I}$. The measure-preserving transformation T is *ergodic* if the only bounded, T-invariant random variables are almost surely constant. Denote by T^i the ith iterate of T, that is, $T^{i+1} = T \circ T^i$.

Birkhoff's Theorem. Let T be a measure-preserving transformation of a probability space $(\Omega, \mathcal{F}, P)$. Then for every integrable random variable X defined on $(\Omega, \mathcal{F})$,

$$\lim_{n\to\infty} \frac{1}{n} \sum_{i=1}^{n} X \circ T^i = E(X \,|\, \mathcal{I}) \quad \text{almost surely.} \qquad (1)$$

If T is ergodic, then $E(X|\mathcal{I}) = EX$ almost surely, so in this case the sample averages converge almost surely to the expectation EX.

It is not difficult to see that if T is a measure-preserving transformation of a probability space $(\Omega, \mathcal{F}, P)$ then for every random variable X defined on $(\Omega, \mathcal{F})$ the sequence $X_n := X \circ T^n$ is a stationary sequence, that is, the joint distribution of $X_1, X_2, \ldots$ is the same as that of $X_2, X_3, \ldots$. Conversely, if $X_1, X_2, \ldots$ is a stationary sequence of real random variables defined on some probability space and if μ is the joint distribution of $X_1, X_2, \ldots$, viewed as a random element of $\mathbb{R}^\infty$, then the forward shift operator σ is a measure-preserving transformation of the probability space $(\mathbb{R}^\infty, \mathcal{B}^\infty, \mu)$. Birkhoff's theorem implies that if this shift is ergodic – in which case the stationary sequence $X_1, X_2, \ldots$ is said to be ergodic – then the sequence $X_1, X_2, \ldots$ obeys the strong law of large numbers. Kolmogorov's 0 – 1 Law implies that if the sequence $X_1, X_2, \ldots$ consists of i.i.d. random variables then it is ergodic, when viewed as a stationary sequence. Thus, the

usual strong law of large numbers for sample averages of independent, identically distributed random variables is a corollary of Birkhoff's theorem. In fact, Birkhoff's theorem implies much more: If the sequence $X_1, X_2, \ldots$ is stationary and ergodic, then for any Borel measurable function $F : \mathcal{R}^\infty \to \mathbb{R}$ the sequence

$$Y_n := F(X_n, X_{n+1}, \ldots)$$

is stationary and ergodic, and therefore obeys the strong law of large numbers provided the first moment $|EY_1|$ is finite.

Consequences of Birkhoff's Theorem

Ergodic Markov Chains

An immediate consequence of Birkhoff's theorem is a strong law of large numbers for additive functionals of *ergodic Markov chains*. A Markov chain (see ▶Markov Chains) X_n on a finite or denumerable state space $\mathcal{X}$ is said to be *ergodic* if all states communicate and all states are positive recurrent. Each ergodic Markov chain has a unique stationary probability distribution. If the initial state X_0 is distributed according to the stationary distribution then the sequence $X_0, X_1, X_{2,\ldots}$ is stationary and ergodic, and so the law of large numbers for real-valued functionals $F(X_n)$ follows directly. Moreover, even if the Markov chain is started in an initial distribution ν other than the stationary distribution π, the strong law of large numbers must hold, because the probability measure P^ν governing the non-stationary chain is absolutely continuous relative to the probability measure P^π governing the stationary chain. See Revuz (1984) or Meyn and Tweedie (2009) for similar results concerning Markov chains on non-denumerable state spaces.

Birkhoff's Theorem and Dynamical Systems

Birkhoff's theorem has important implications for deterministic dynamical systems, especially those governed by Hamilton's equations where the Hamiltonian has no explicit time dependence (see Arnold and Avez 1967). According to a fundamental theorem of Liouville, if $\{\Phi_t\}_{t\geq 0}$ is the phase flow of a Hamiltonian system on the phase space $\mathbb{R}^{2N}$ then for each $t > 0$ Lebesgue measure on $\mathbb{R}^{2N}$ is Φ_t-invariant. Lebesgue measure cannot be renormalized to be a probability measure; however, if the level surfaces $H = E$ of the Hamiltonian are *compact*, as is often the case, then Lebesgue measure induces on each energy surface a Φ_t-invariant probability measure, called the *Liouville measure*. The *ergodic hypothesis* of Boltzmann asserts that the Liouville measure-preserving transformation Φ_t is ergodic. When true this implies, by Birkhoff's theorem, that "time averages equal space averages." To date the ergodic hypothesis has been established only for some very special Hamiltonian systems.

The Shannon–MacMillan–Breiman Theorem

Let $\{X_n\}_{n\in\mathbb{Z}}$ be a two-sided stationary process valued in a finite alphabet A. For each finite sequence $x_1x_2\cdots x_n$ in A, denote by $p(x_1x_2\cdots x_n)$ the probability that $X_i = x_i$ for each index $i \in [1, n]$. Similarly, denote by $p(x_0|x_{-1}x_{-2}\cdots x_{-n})$ the conditional probability that $X_0 = x_0$ given that $X_i = x_i$ for every $-n \leq i \leq -1$. The martingale convergence theorem implies that for almost every sequence $x_{-1}x_{-2}\cdots$ (relative to the joint distribution of the process $\{X_n\}_{n\in\mathbb{Z}}$) the limit

$$p(x_0|x_{-1}x_{-2}\cdots) := \lim_{n\to\infty} p(x_0|x_{-1}x_{-2}\cdots x_{-n}) \tag{2}$$

exists. The *Kolmogorov–Sinai entropy* of the stationary process $\{X_n\}_{n\in\mathbb{Z}}$ is defined to be

$$h := -E\log p(X_0|X_{-1X_{-2}\cdots}). \tag{3}$$

Shannon-MacMillan-Breiman Theorem. If the stationary process $\{X_n\}_{n\in\mathbb{Z}}$ is ergodic then with probability one,

$$\lim_{n\to\infty} p(X_1X_2\cdots X_n)^{1/n} = e^{-h} \tag{4}$$

This can be deduced from Birkhoff's theorem, which implies directly that with probability one

$$\lim_{n\to\infty} \frac{1}{n}\sum_{k=1}^{n} \log p(X_k|X_{k-1}X_{k-2}\cdots) = -h. \tag{5}$$

The Shannon–MacMillan–Breiman theorem is of fundamental importance in information theory, for it implies that entropy limits the "compressibility" of a "message" generated by a stationary, ergodic source. See Shannon and Weaver (1949) and Cover and Thomas (2006) for further information.

Kingman's Subadditive Ergodic Theorem

In the 80 years since Birkhoff's paper, dozens of extensions, generalizations, and other progeny of Birkhoff's theorem have been discovered. See Krengel (1985) for an excellent review. One of these subsequent extensions has proved to be of singular importance: this is Kingman's *subadditive ergodic theorem* (see Kingman 1973). Let T be an ergodic, measure-preserving transformation of a probability space $(\Omega, \mathcal{F}, P)$. A double array $\{S_{k,m}\}_{0\leq k\leq m}$ of real random variables defined on $(\Omega, \mathcal{F})$ is called a *subadditive process* relative to T if

$$S_{k,m} \circ T = S_{k+1,m+1}, \tag{6}$$

$$S_{k,n} \leq S_{k,m} + S_{m,n}, \quad \text{and} \tag{7}$$

$$\gamma := \inf_{n\geq 1} n^{-1} E S_{0,n} > -\infty. \tag{8}$$

Observe that if $S_{k,m} = \sum_{i=k+1}^{m} X \circ T^i$ where X satisfies the hypotheses of Birkhoff's theorem then $\{S_{k,m}\}$ is a subadditive process.

Kingman's Theorem. If $\{S_{k,m}\}$ is a subadditive process relative to an ergodic, measure-preserving transformation T of a probability space $(\Omega, \mathcal{F}, P)$, then

$$\lim_{n\to\infty} S_{0,n}/n = \gamma \quad \mu - \text{almost surely.} \tag{9}$$

Kingman's theorem has myriad uses in the study of percolation processes and interacting particle systems. See Liggett (1985) for some of the basic applications.

Subadditive processes also arise naturally in connection with random walks (see ►Random Walk) on groups and semigroups. A *right random walk* on a semigroup G started at the identity $X_0 = 1$ is the sequence X_n of partial products of a sequence $\xi_1, \xi_2, \ldots$ of i.i.d. G-valued random variables, with multiplication on the right:

$$X_n = \xi_1 \xi_2 \cdots \xi_n. \tag{10}$$

The special case where G is a matrix group or semigroup is of particular importance. Let d be an invariant metric on G, that is, a metric such that $d(x, y) = d(xz, yz)$ for all $x, y, z \in G$. For instance, if G is a discrete, finitely generated group then one might choose d to be the natural distance in the *Cayley graph*; if G is a matrix group then one might take d to be the distance induced by the Riemannian metric on G. In any case, the process

$$S_{k,m} := d(\xi_{k+1}\xi_{k+2}\cdots\xi_m, 1)$$

is subadditive, and so Kingman's theorem implies that $d(X_n, 1)/n$ converges almost surely to a constant γ (possibly $+\infty$). Similarly, if $G = \mathcal{M}_d$ is the semigroup of all $d \times d$ real matrices and $\|g\|$ denotes the usual matrix norm of a matrix $g \in G$, then

$$S_{k,m} := \log \|\xi_{k+1}\xi_{k+2}\cdots\xi_m\|$$

is subadditive, and so Kingman's theorem implies that if $\log \|\xi_1\|$ has finite first moment then

$$\lim_{n\to\infty} \|X_n\|^{1/n} = e^{\gamma} \tag{11}$$

almost surely. This is the celebrated *Furstenberg–Kesten* theorem (Furstenberg and Kesten 1960) of random matrix theory. See Bougerol and Lacroix (1985) for further development of the theory of random matrix products.

Erlang's Formulas

M. F. Ramalhoto
Professor
Technical University of Lisbon, Lisbon, Portugal

Mathematical calculations on probabilities have been put in writing mainly since the seventeenth century with the work of mathematicians like Fermat (1601–1665), Pascal (1623–1662), Huygens (1629–1695), Bernoulli (1654–1705), Moivre (1667–1754), Laplace (1749–1827), Gauss (1777–1855), Poisson (1781–1840), and Tchébychev (1821–1894). In the twentieth century the work of Markov, Liapounov,

Khintchine, Kolmogorov, Palm, Wiener, Fisher, Doob, Neumann, Cramer, Takács, Itó, and Santaló, among many others, on probability foundations, ▶stochastic processes, and mathematical statistics provided the basis for what it is called here "*Stochastics*."

There are two stochastic processes that are fundamental, and occur over and over again, often in surprising ways. The deepest results in "*Stochastics*" seem to be concerned with their interplay. One, the Wiener process (the Wiener model of Brownian motion, see ▶Brownian Motion and Diffusions), has been the subject of many books. The other, the Poisson process (the simplest renewal process, i.e., exponential inter-renewal times), has been comparatively a bit more neglected. Kingman (1993) redresses the balance and provides an enjoyable and clearly written introduction to the structure and properties of ▶Poisson processes in one and more dimensions (the book simultaneously addresses the beginner and the expert).

When, in 1875 (June 2) in Boston, Alexander Graham Bell accidentally discovered the possibility of telephone communication he could hardly foresee that by this discovery he had also created the inspiration for ▶queueing theory. In fact, the pioneer work on queueing theory is in Erlang (1909). A. K. Erlang was a Danish engineer and mathematician dealing with the problems and worries of the telephone communication system of the time, whose fundamental papers appeared between 1909 and 1920. He was responsible for the concept of statistical equilibrium, for the introduction of the so-called balance-of-state equations, and for the first consideration of the optimization of a queueing system. Rapid progress was made when the use of queueing theory spread out to many other fields in addition to telephone theory, and mathematicians like William Feller and David Kendall, among many others, became interested in the mathematics of queues. It would be difficult to give a brief outline of the development of the subject with a proper assignment of credits. Many of the most meritorious papers responsible for new methods are now rarely mentioned in the literature, in spite of the progress that they initiated; the D. V. Lindley's integral equation of the single-server queueing system, published in (1952), is an example. Queueing theory (including queueing networks and complex particle systems) is one of the most relevant branches of "*Stochastics*." Indeed, some of the today's most significant problems can be reduced to resource allocation and resource sharing. When the customers are human beings, very often patterns of human behavior and responses have to be brought into the mathematical analysis of the corresponding queueing systems. For instance, Little's law, a celebrated queueing property, does not necessarily hold due to the non-linear human's perception of waiting. Particularly in the queueing systems of the service industry, issues linked to quality improvement and innovation are now more than ever very relevant; an introduction to these issues can be founded in Ramalhoto (2000).

The power of the structure and the mathematical properties of the Poisson process (a few key results often produce surprising consequences) have been recognized in the queueing theory since its foundation in Erlang (1909).

First Erlang Formula

In 1917, A.K. Erlang (who also laid the foundations of modern teletraffic theory) from the analysis of the concept of statistical equilibrium obtained his famous formula (one of the most used formulas in practice even today) for the loss probability of the $M/G/r/r$ queueing system (i.e., Poisson arrival process, arbitrary service time distribution, r servers and zero waiting positions) in steady state:

$$B(r,r\rho) = \left[(r\rho)^r/r!\right]\left[\sum_{i=0}^{r}(r\rho)^i/i!\right]^{-1};\ r \in \mathbb{N},\ \rho \in \mathbb{R}^+ \quad (1)$$

where N and R^+ represent the natural numbers and the positive real numbers, respectively. Here, $r\rho = \lambda E[S]$ is the offered load, ρ is the intensity of traffic, and $E[S] = \mu^{-1}$ is the mean service time. The problem considered by Erlang can be phrased as follows. Calls arrive at a link as a Poisson process of rate λ. The link comprises r circuits, and a call is blocked and lost if all r circuits are occupied. Otherwise, the call is accepted and occupies a single circuit for the holding period of the call. Call holding periods are independent of each other and of arrival times, and are identically distributed with unit mean. This formula gives the proportion of calls that are lost in the $M/G/r/r$ queueing system in steady state. It is called the 1st *Erlang formula*, the Erlang's loss formula, or Erlang B formula. In several telecommunication studies the need arose to extend the definition of the 1st *Erlang formula* to non-integral values of r and to evaluate the derivatives of $B(r,r\rho)$ with respect to r and ρ. The most commonly used extension of the 1st *Erlang formula* is the analytic continuation

$$B(r,a)^{-1} = \int_0^{+\infty} e^{-u}(1-u/a)^r du \quad (2)$$

where $a = r\rho$ (offered load). This is known as the "*continued* 1st *Erlang function*." Jagerman (1984) presents improved computations of the 1st *Erlang formula* and its derivatives, with practical computer programs for immediate application.

Second Erlang Formula

The 2nd *Erlang formula* (also called the Erlang's delay formula or Erlang C formula), first published by Erlang in 1917, is defined in the $M/M/r$ queueing system (i.e., Poisson arrivals, exponential service time, r servers and infinite waiting positions) in steady state as follows:

$$C(r,r\rho) = \left[(r\rho)^r/r!(1-\rho)\right]\left[\sum_{i=0}^{r-1}(r\rho)^i/i! + (r\rho)^r/r!(1-\rho)\right]^{-1}; r \in \mathbb{N}, 0 < \rho < 1. \quad (3)$$

It gives the proportion of customers (calls) that are delayed in the $M/M/r$ queueing system in steady state. Unlike the 1st *Erlang formula*, the 2nd *Erlang formula* is not valid for an arbitrary service time distribution. From (1) and (3), it is clear that the 1st and 2nd *Erlang formulas* are related as follows:

$$C(r,r\rho) = \left[\rho + (1-\rho)B^{-1}(r,r\rho)\right]^{-1}; r \in \mathbb{N}, 0 < \rho < 1. \quad (4)$$

Further results and generalizations of the 1st and 2nd *Erlang formulas* may be found, for example, in the proceedings of international telecommunication and teletraffic conferences.

Third Erlang Formula

Let $C_d(r,r\rho)$ mean the probability that an arbitrary customer on its arrival finds r or more customers in the $M/M/r/r+d$ queueing system (i.e., Poisson arrivals, exponential service time distribution, r servers and d waiting positions) in steady state. That is to say, $C_d(r,r\rho)$ is the stationary probability that an arriving customer is blocked (i.e., not immediately served). It gives the proportion of customers that are delayed or lost in the $M/M/r/r+d$ queueing system in steady state. It is easy to show that $C_d(r,r\rho)$ can be written as follows:

$$C_d(r,r\rho) = \left[((r\rho)^r/r!)\sum_{i=0}^{d}\rho^i\right] \times \left[\sum_{i=0}^{r-1}(r\rho)^i/i! + ((r\rho)^r/r!)\sum_{i=0}^{d}\rho^i\right]^{-1}; \quad r \in \mathbb{N}, d \in \mathbb{N}_0, \rho \in \mathbb{R}^+. \quad (5)$$

From (1) and (5) it is clear that when $d = 0, C_d(r,r\rho)$ coincides with $B(r,r\rho)$, the 1st *Erlang formula*. From (3) and (5) it is clear that the limit of $C_d(r,r\rho)$ as d goes to infinity is the 2nd *Erlang formula* (which is defined only for $0 < \rho < 1$). Therefore, it is reasonable to call $C_d(r,r\rho)$ the 3rd *Erlang formula* (or Erlang's loss-delay formula). From (1) and (5) it is clear that the 3rd *Erlang formula* can be rewritten in terms of the 1st *Erlang formula* as follows:

$$C_d(r,r\rho) = \left[B^{-1}(r,r\rho)\left(\sum_{i=0}^{d}\rho^i\right)^{-1} + 1 - \left(\sum_{i=0}^{d}\rho^i\right)^{-1}\right]^{-1}; \quad r \in \mathbb{N}, d \in \mathbb{N}_0, \rho \in \mathbb{R}^+. \quad (6)$$

The relation (6) shows the ability of the 3rd *Erlang formula* to make use of the results available for the 1st *Erlang formula*; namely through the relation (2) it may be extended to non-integral values of r and d (i.e., the "*continued* 3rd *Erlang function*"). Monotonicity and convexity properties of the 3rd *Erlang formula* in terms of its parameters r, d, ρ, and $r\rho$ (offered load) are also easy to obtain. All these properties are useful in the study of the probabilistic behavior of the $M/M/r/r+d$ queueing system (also called Markovian multi-server finite-capacity queue or multi-server Erlang loss-delay queue). Mainly because most of the relevant system's characteristics can be rewritten as very simple functions of the 3rd *Erlang formula*. For instance, it is easy to show that in steady state both the loss probability and the delay probability depend on r only through the 3rd *Erlang formula*.

Exact Decomposition Formulas for the Multi-Server Erlang Loss-Delay Queue

For the $M/M/r/r+d$ queueing system in steady state each random variable (r. v.) $N'_{r,d}$ (the number of customers waiting in the queue), $NS_{r,d}$, (the number of occupied servers), $N_{r,d}$ (the number of customers in the system; waiting or being served), $T'_{r,d}$ (the waiting time in the queue), and $T_{r,d}$ (the total sojourn time in the system; waiting or being served) is distributed as the sum of two r. v.'s. weighted by the 3rd *Erlang formula*, for $r \in \mathbb{N}, d \in \mathbb{N}_0$ (where the symbol $\sim$ means "distributed as").

$$N'_{r,d} \sim (1 - C_d(r,r\rho))O + C_d(r,r\rho)N_{1,d-1}, \quad (7)$$

where $P(0 = o) = 1$ (i.e., a degenerated r. v.) and $N_{1,d-1}$ is the number of customers in the $M/M/1/1+(d-1)$ queueing system in steady state with the same ρ (which has a truncated geometric distribution with parameters d and $1-\rho$, denoted here by the symbol $G(d,1-\rho)$).

$$NS_{r,d} \sim (1 - C_d(r,r\rho))(X|X < r) + C_d(r,r\rho)R, \quad (8)$$

where $P(R = r) = 1$ and X is a Poisson r. v. of parameter $r\rho$.

$$N_{r,d} \sim (1 - C_d(r,r\rho))(X|X < r) + C_d(r,r\rho)(R + N_{1,d-1}), \quad (9)$$

$$T'_{r,d} \sim (1 - C_{d-1}(r,r\rho))O + C_{d-1}(r,r\rho)E_d, \quad (10)$$

where E_d is a "*generalized*" *Erlang* r. v. with parameters $G(d-1,1-\rho)$ and μ, respectively.

$$T_{r,d} \sim (1 - C_{d-1}(r, r\rho))S_r + C_{d-1}(r, r\rho)(E_d + S_r), \quad (11)$$

where S_r is the service time distribution of each server. The proof is essentially based on rewriting the respective distributions (that can be found in Gross and Harris (1985, pp. 93-102) or Gross et al. (2008)) in terms of the 3rd *Erlang formula*. Therefore, in the steady state, the probabilistic behavior of the $M/M/r/r + d$ queueing system can be obtained in terms of the corresponding probabilistic behavior of the $M/M/r/r$ queueing system and of the $M/M/1/1 + (d-1)$ queueing system, respectively; and its closeness to each one of these two queueing systems is measured by the 3rd *Erlang formula*. Taking limits as d goes to infinity in (7) to (11) (for $0 < \rho < 1$) similar results follow for the $M/M/r$ queueing system, in the steady state, in terms of the $M/M/r/r$ queueing system, the $M/M/1$ queueing systems and the 2nd Erlang formula, respectively.

Further Models

Due to their analytical tractability the queueing systems $M/M/\infty, M/M/1$, and $M/M/1/1 + d$ are by far the most extensively studied queueing systems in the steady state as well as in the time-dependent regime. Moreover, the use of the $M/M/\infty$ queueing system to approximate the $M/M/r/r$ queueing system (and their generalized cases for arbitrary service time distributions) has been studied by several authors, see, for instance, Ramalhoto (1999) and the references therein.

An extension of the decomposition formulas for the $M/M/r/r + d$ queueing system with constant retrial rate is provided in Ramalhoto and Gomez-Corral (1998). This type of queueing system (which, in fact, is a queueing network) is characterized by the feature that if on its arrival the customer finds all servers and waiting positions occupied the customer leaves the service area and enters an orbit, i.e., the retrial group. In the case $r + d < 3$, analytical results were obtained exactly in the same way, as before, by rewriting the corresponding distribution function in terms of the *probability of entering the orbit*. It is shown that the distributions of the "number of customers in orbit" (i.e., the orbit size) and the "total number of servers and waiting positions occupied" can be expressed also as mixtures of two r. v.'s weighted by the *probability of entering the orbit* (which in the retrial case corresponds to the 3rd *Erlang formula*). Another relevant property of these novel formulas is that they display the exact influence of the $M/M/r/r$ queue (which is well approximated by the $M/M/\infty$) and the probability of entering the orbit (in the retrial case) which somehow captures the effect of traffic intensity. Because the physics of the decomposition structures presented do not seem to have much to do with the values of r and d themselves empirical decomposition formulas (of similar kind of the $r + d < 3$ case) were proposed and heuristically explored. Based on them, numerical results for the stationary distribution of the orbit size were obtained for the queueing systems $M/M/2/2 + 1, M/M/3/3, M/M/3/3 + 1$, and $M/M/4/4$ with constant retrial, respectively. A similar methodology may be applicable to more complex types of retrials

The idea behind this decomposition concept is intuitive and simple to understand and use. And it seems to be suitable for obtaining bounds and other approximations for time-dependent regime and non-Markovian queueing systems as well as for new simulation strategies in queueing systems.

About the Author

M. F. Ramalhoto (Maria Fernanda Neto Ramalhoto) is Professor of Probability and Statistics, Department of Mathematics, at Instituto Superior Técnico (IST) of the Technical University of Lisbon since 1987. She was Vice-Rector of the Portuguese Open University (1990–1993). She was a Member of the Executive Council of IST (1987–1988) and the ERASMUS Institutional Coordinator at IST (1987–1990). She is a Fellow of the "Société Européenne pour la Formation des Engénieurs", and Associate Editor of the *European Journal for Engineering Education*. She was Visiting Professor in several universities worldwide, including MIT, Berkeley and Princeton, and Programme Committee Member of several international conferences in Europe, Israel and India. She was a Co-Founder and a Vice-President of the European Network for Business and Industrial Statistics (which now has over a thousand members and a successful annual conference). She was Expert/Evaluator for the Fifth and Sixth Frameworks of the European Union. She is Expert for the Seventh Framework. She is author and co-author (with colleagues from the US, UK, Germany, Italy, and Spain) of research papers in stochastic processes, statistics, quality control, and reliability. She has been Associate Editor of the international journal *Quality Technology and Quantitative Management* since its foundation.

Estimation

Nancy Reid
Professor
University of Toronto, Toronto, ON, Canada

Introduction

Statistical models involve unknown quantities, usually called parameters of the model, and inference about these parameters provides, in principle, understanding about plausible data-generating mechanisms. Inference about these parameters is also a first step in assessing the adequacy of the proposed model, in predicting future patterns likely to be observed from this model, and as a basis for making decisions. Estimation is the process of using the data to make conclusions about the values of unknown quantities in a statistical model.

The theory of point estimation is concerned with a narrower problem: given a parametric model $f(y;\theta)$, that is a density on a sample space $\mathcal{Y}$, with unknown parameter θ taking values in a parameter space Θ, and a set of observations from this model, how do we use these observations to provide a good guess for the true value of θ? In ►nonparametric estimation, Θ is an infinite-dimensional space, for example the space of all distribution functions on $\mathbb{R}$; in parametric estimation Θ is usually a subspace of a well-behaved parameter space, such as $\mathbb{R}^p$ for fixed and known dimension p.

A point estimate of a parameter or a function θ is not often very useful without an associated statement about the accuracy of the point estimate, usually provided as an estimated standard error. More formally, the theory of interval estimation aims to estimate a set of plausible values of θ consistent with the data.

In the early development of statistical science, methods for constructing a point estimate were often developed in the context of particular problems, and some statistical properties of the resulting point estimate were then studied. This led to a number of strategies for point estimation, including the method of moments, the method of ►least squares, and, with Fisher (1922), the method of maximum likelihood estimation; see Aldridge (1997). Least squares estimates were used in the early 19th century in problems in astronomy (Stigler, 1981). The method of moments was very popular in the early 20th century, but except in very complex problems has been superseded by maximum likelihood estimation.

A method for estimation is evaluated by assessment of its statistical properties. Historically, there developed a very large literature on deciding which properties of an estimation method were most relevant, and which methods of estimation satisfied those properties. Some properties commonly proposed for "good" estimators are: unbiased, admissible, minimax, minimum variance, minimum mean-squared error, equivariant, consistent, efficient, asymptotically unbiased, asymptotically optimal, and robust. In the 1940s and 1950s statistical theory emphasized optimality of various methods of point estimation according to some criterion to be specified, such as variance, mean squared error, or risk. The conditions for optimal estimation, by any criterion, are rarely satisfied in a wide enough range of models to inform statistical practice, so attention turned to asymptotic optimality. The maximum likelihood estimator was shown to be consistent and asymptotically efficient, and is now generally computable with standard software, so is usually the first choice of estimation method, at least in parametric families of models. In the 1970s a theory of robust point estimation was developed, to formalize the notion that a "good" method of estimation should be stable under perturbations of the assumed model.

Theory and methods for nonparametric estimation of a wide variety of functional, or infinite-dimensional, parameters has developed very intensively over the past twenty years and have a prominent role in theoretical and methodological statistics. In this note however we will concentrate on finite-dimensional parametric estimation. The classic

text on the theory of point estimation is Lehmann (1983), subsequently revised in Lehmann and Casella (2003). Casella and Berger (1990) and Knight (2000) provide excellent treatments at a somewhat less advanced level. The exposition here draws heavily on Chapter 7 of Davison (2003) and Chapter 8 of Cox and Hinkley (1974).

Defining Point Estimators

Most methods of points estimation are based on minimizing some notion of distance between the data and some aspect of the fitted model. For example, least squares estimators are defined to minimize $\sum_{i=1}^{n}\{y_i - \mu_i(\theta)\}^2$, where we assume that $E(y_i) = \mu_i(\theta)$ has a known form, for example $x_i^T\theta$ for a given p-vector x_i^T. Least absolute deviation estimators minimize $\sum_{i=1}^{n}|y_i - \mu_i(\theta)|$. There may be other unknown parameters in the model; for example if y_i is normally distributed with mean $\mu_i(\theta)$ the variance may also be unknown, and a suitable estimator for the variance is usually taken to be the residual mean square $\Sigma\{y_i - \mu_i(\hat{\theta})\}^2/(n-p)$, where $\hat{\theta}$ is the estimate of the parameters in the mean, and θ is assumed to have dimension p. This estimator of σ^2 is unbiased, as defined below, and widely used, but not optimal under conventional distance measures.

Maximum likelihood estimators are defined to maximize the probability of the observed data, or equivalently to minimize $-2\log f(y;\theta)$. They are defined via

$$L(\hat{\theta}_{ML};y) = \sup_{\theta} L(\theta;y),$$

where $L(\theta;y) \propto f(y;\theta)$ is the likelihood function. In models with smooth differentiable likelihoods that have just one maximum,

$$\nabla_\theta \ell(\hat{\theta}_{ML};y) = 0, \tag{1}$$

where $\ell(\theta;y) = \log L(\theta;y)$. The maximum likelihood estimator can also be defined as an estimate of the value that minimizes the ▶Kullback–Leibler divergence between the parametric model and the true density for y:

$$D(f,g) = \int \log\left\{\frac{g(y)}{f(y;\theta)}\right\} g(y)dy,$$

where we temporarily assume that the true density is $g(\cdot)$ but we are fitting the parametric model $f(y;\theta)$. In the case of independent observations $y_1,\ldots,y_n$, the score equation (1) can be expressed as

$$n^{-1}\sum_{i=1}^{n}(\partial/\partial\theta)\log f(y_i;\hat{\theta}_{ML}) = 0,$$

which is an empirical version of the derivative of $D(f,g)$ with respect to θ. In machine learning applications maximum likelihood estimators are often derived from this point of view, and D is referred to as the negative log-entropy loss function.

The method of moments defines point estimators by equating the theoretical moments of the presumed model to the observed sample moments. These estimators have been largely superseded by maximum likelihood estimators, but are often useful starting points, especially in rather complex models defined, for example, for stochastic systems modeled through sets of partial differential equations. The other class of models for which method of moments estimators are sometimes used is in estimating components of variance in normal theory linear models.

Example 1 Suppose the vector of observations y is taken in k groups of size n, and modeled as

$$y_{ij} = \mu + b_i + \epsilon_{ij}, \quad j = 1,\ldots,n; i = i,\ldots,k,$$

where we assume that $b_i \sim N\left(0,\sigma_b^2\right)$, $\epsilon_{ij} \sim N(0,\sigma^2)$, and the b's and ϵ's are mutually independent. The analysis of between and within group sums of squares leads to the following two statistics:

$$SS_{\text{within}} = \sum_{i=1}^{k}\sum_{j=1}^{n}(y_{ij} - \bar{y}_{i.})^2,$$
$$SS_{\text{between}} = \sum_{i=1}^{k}\sum_{j=1}^{n}(\bar{y}_{i.} - \bar{y}_{..})^2,$$

where $\bar{y}$ indicates averaging over the appropriate subscript. It is not difficult to show that

$$E(SS_{\text{within}}) = k(n-1)\sigma^2,$$
$$E(SS_{\text{between}}) = (k-1)\left(\sigma^2 + n\sigma_b^2\right),$$

which leads to simple method of moments estimators of σ^2 and σ_b^2. If there is very little sample variation among groups, then the estimate of σ_b^2 could be negative, as method of moments does not automatically obey constraints in the parameter space. This example can be extended to much more complex structure, with several levels of variation, and possible dependence among some of the random effects.

Point estimators can also be derived from a Bayesian point of view, although in a fully Bayesian context it is not necessary and may not even be wise to summarize the posterior distribution of the parameters by a point estimate. However, it is relatively straightforward to proceed, assuming the availability of a prior density $\pi(\theta)$, to construct the

posterior density

$$\pi(\theta \mid y) = L(\theta; y)\pi(\theta) / \int L(\theta; y)\pi(\theta)\mathrm{d}\theta,$$

and then to compute the posterior mode, $\hat{\theta}_\pi$, which maximizes $\pi(\theta \mid y)$, or the posterior median, or mean, or some other summary statistic. In most practical applications there will be much more information in the data than in the prior, and $\hat{\theta}_\pi$ will not be very different from the maximum likelihood estimator. This can be made more precise by considering asymptotic properties of Bayesian posterior distributions, under the sampling model. Empirical Bayes estimators can be obtained by using the data to estimate the parameters in the prior distribution, as well as the parameters in the model.

A class of estimators often called *shrinkage* estimators can be derived by minimizing a ►loss function, but imposing a penalty on the resulting estimator of some form. The simplest example is the ridge regression estimator (see ►Ridge and Surrogate Ridge Regressions) associated with ►least squares.

Example 2 Suppose y is an $n \times 1$ vector that follows a normal distribution with mean $X\beta$ and covariance matrix $\sigma^2 I$, where X is an $n \times p$ matrix and β is a $p \times 1$ vector of regression coefficients of interest. The least squares estimator of β minimizes $(y - X\beta)^T(y - X\beta)$, with solution, if X is of full column rank,

$$\hat{\beta} = (X^T X)^{-1} X^T y.$$

If the least squares problems is changed to

$$\min_{\beta} (y - X\beta)^T (y - X\beta), \qquad \text{subject to } \beta^T \beta \le t,$$

then the solution, which also minimizes the penalized sum of squares

$$(y - X\beta)^T (y - X\beta) + \lambda \beta^T \beta,$$

is

$$\hat{\beta}_R = (X^T X + \lambda I)^{-1} X^T y;$$

the individual components $\hat{\beta}_j$ are shrunk towards zero. This is sometimes used if number of components of β is quite large relative to n, as in most settings this would suggest that the individual components cannot all be well determined from the data. There are a great many extensions of this idea, especially in the literature on fitting "smooth" functions, rather than well specified parametric functions, to data. For example, we might replace $X\beta$ by $m_1(x_1) + \cdots + m_p(x_p)$, without specifying very much about the form of m_j. One approach to estimating these functions is to model them as piecewise polynomial, with a large number of parameters, and then to shrink the polynomial coefficients. Empirical Bayes estimators are also usually shrinkage estimators; typically shrinking to some central data value, such as the sample mean, rather than a particular point of interest, such as 0, in the parameter space.

Evaluating Point Estimators

It is conventional to refer to a point estimate as the value computed from a given set of data, and the point estimator as the function of the observations that will be used in practice. Many texts distinguish these two ideas by using upper case letters for random variables, and lower case letters for observed values of these random variables.

Example 3 Suppose we assume that we have a sample $y = (y_1, \ldots, y_n)$ of independent observations of a random vector $Y = (Y_1, \ldots, Y_n)$ with joint density

$$f(y; \mu, \sigma^2) = \frac{1}{\sqrt{(2\pi)^n \sigma^n}} \exp\left\{-\frac{1}{2\sigma^2} \sum (y_i - \mu)^2\right\}. \quad (2)$$

The sample mean $\hat{\mu} = (1/n)\Sigma y_i$ is an estimate of μ, and the estimator $\hat{\mu} = (1/n)\Sigma Y_i$ has a distribution determined by (2); for example $E(\hat{\mu}) = \mu$ and $\mathrm{var}(\hat{\mu}) = \sigma^2/n$. Note that the notation for $\hat{\mu}$ does not distinguish between the estimate and the estimator, but this will usually be clear from the context.

Suppose more generally that we have a vector of observations y of a random vector Y from a parametric model with density $f(y; \theta)$ where $y \in \mathbb{R}^n$ and $\theta \in \mathbb{R}^p$.

Definition 1 An estimator $\hat{\theta} = \hat{\theta}(y)$ is *unbiased* for θ if

$$E\{\hat{\theta}(Y)\} = \theta.$$

The estimator is a minimum variance unbiased estimator if, for any other unbiased estimator $\tilde{\theta}$, we have

$$\mathrm{var}(\hat{\theta}) \le \mathrm{var}(\tilde{\theta}).$$

The expectation and variance are calculated under the model $f(y; \theta)$. When θ is a vector, $\mathrm{var}(\theta)$ is a matrix, and the variance condition above is generalized to $a^T \mathrm{var}(\hat{\theta}) a \le a^T \mathrm{var}(\tilde{\theta}) a$ for all real vectors a of length p. Minimum variance unbiased estimators rarely exist; an exception is in regular exponential family models, where the minimal sufficient statistic is a minimum variance unbiased estimator of its expectation.

An estimator $\hat{\theta}$ is (weakly) *consistent* for θ if it converges to θ in probability, under the model $f(y; \theta)$. A consistent estimator $\hat{\theta}$ is *asymptotically efficient* if the

asymptotic variance of its limiting distribution is as small as possible. The ▶Cramér–Rao inequality establishes that maximum likelihood estimators in regular models are asymptotically efficient, and the lower bound on the asymptotic variance for any consistent estimator is $i^{-1}(\theta)$, where $i(\theta)$ is the expected Fisher information in the model, $E\{-\partial^2 \ell(\theta; Y)/\partial\theta^2\}$.

Bayesian treatments of point estimation often emphasize that estimates based on posterior distributions obtained via proper priors are admissible, meaning that no non-Bayesian estimators have smaller Bayes risk. Bayes risk is defined with respect to a loss function, so depends in an intrinsic way on the units of measurement for the parameter. Admissible estimators are sometimes useful in decision theoretic contexts, but not often in scientific work.

In machine learning contexts where there is the possibility to fit rather complex models to large data sets, performance is often measured by mean-squared error, as biased point estimators such as the shrinkage estimator mentioned above are widely used. The phrase "bias-variance tradeoff" refers to the fact that a biased point estimator can have smaller variance than an unbiased estimator, but that bias and variance cannot be simultaneously minimized. Estimates of functional parameters, such as densities or regression functions, are often compared by means of integrated mean-squared error.

Example 4 Suppose Y is a sample of independent, identically distributed observations each from an unknown density $f(\cdot)$, and the goal is to estimate this density. The kernel density estimator of f is defined as

$$\hat{f}(y) = \frac{1}{nh}\sum_{i=1}^{n} K\left(\frac{y - Y_i}{h}\right),$$

where $h > 0$ is a tuning parameter and $K(\cdot)$ is a kernel function, usually a symmetric probability density function, such as the density for a $N(0,1)$ distribution. The tuning parameter h controls the smoothness of the estimated function $\hat{f}(\cdot)$, by controlling the number of sample points that enter the average in estimating $f(y)$. It can be shown that the squared bias of $\hat{f}$ at a single point y is $O(h^4)$, and the variance is $O(nh)^{-1}$, so the optimal bandwidth can be shown to be $h \propto n^{-1/5}$, with the constant of proportionality depending on the point y and the kernel function $K(\cdot)$.

Robust estimators are defined, following Huber (1981), to be stable under perturbations of the postulated model. From a data analytic point of view, robust estimators are not much affected by ▶outliers, or extremely unusual data points. The motivation for this is that such outliers may be coding mistakes, or may be irrelevant for the inference desired. However this varies widely by application area.

The theory of estimating equations considers the primary object of interest as the equation defining the point estimator, rather than the point estimator itself. For an independent, identically distributed sample $y = (y_1, \ldots, y_n)$, from a model with parameter θ, an estimating equation for θ is given by

$$\sum_{i=1}^{n} g(y_i; \theta) = 0,$$

for a function $g(\cdot)$ to be chosen. An estimating function is unbiased if $E\{g(Y; \theta)\} = 0$, and it would be rare to start with a biased estimating function, as the resulting estimator would not be consistent for θ without further modification. The maximum likelihood estimator is, in regular models, defined by the estimating equation with $g(y; \theta) = (\partial/\partial\theta) \log f(y; \theta)$, but more general classes of estimating equations arise naturally in studies of robustness; see Davison (2003, Ch. 7).

Estimation Problems for Random Fields

Mikhail P. Moklyachuk
Professor
Kyiv National Taras Shevchenko University, Kyiv, Ukraine

Estimation problems for random fields $X(t)$, $t \in \mathbb{R}^n$ (estimation of the unknown mathematical expectation, estimation of the correlation function, estimation of regression parameters, extrapolation, interpolation, filtering, etc) are similar to the corresponding problems for ▶stochastic processes (random fields of dimension 1). Complications usually are caused by the form of domain of points $\{t_j\} = D \subset \mathbb{R}^n$, where observations $\{X(t_j)\}$ are given, and by the dimension of the field. The complications can be overcome by considering specific domains of observations and particular classes of random fields.

Say in the domain $D \subset \mathbb{R}^n$ there are given observations of the random field

$$X(t) = \sum_{i=1}^{q} \theta_i g_i(t) + Y(t),$$

where $g_i(t), i = 1, \ldots, q$, are known non-random functions, $\theta_i, i = 1, \ldots, q$, are unknown parameters, and $Y(t)$ is a random field with $EY(t) = 0$. The problem is to estimate the regression parameters $\theta_i, i = 1, \ldots, q$. This problem includes as a particular case ($q = 1, g_1(t) = 1$), the problem of estimation of the unknown mathematical expectation. Linear unbiased least squares estimates of the regression parameters can be found by solving the corresponding linear algebraic equations or linear integral equations determined with the help of the correlation function. For the class of isotropic random fields, formulas for estimates of the regression parameters are proposed by M. I. Yadrenko (Yadrenko 1983). For example, the estimate $\hat{\theta}$ of the unknown mathematical expectation θ of an isotropic random field $X(t) = X(r,u)$ from observations on the sphere $S_n(r) = \{x \in \mathbb{R}^n, \|x\| = r\}$ is of the form

$$\hat{\theta} = \frac{1}{\omega_n} \int_{S_n(r)} X(r,u) m_n(du), n \geq 2,$$

where $m_n(du)$ is the Lebesgue measure on the sphere $S_n(r)$, ω_n is the square of the surface of the sphere, (r,u) are spherical coordinates of the point $t \in \mathbb{R}^n$.

Consider the extrapolation problem.

1. Observations of the mean-square continuous homogeneous and isotropic random field $X(t)$, $t \in \mathbb{R}^n$ are given on the sphere $S_n(r) = \{x \in \mathbb{R}^n, \|x\| = r\}$. The problem is to determine the optimal mean-square linear estimate $\hat{X}(s)$ of the unknown value $X(s)$, $s \notin S_n(r)$, of the random field. It follows from the spectral representation of the field that this estimate is of the form

$$\hat{X}(s) = \sum_{m=0}^{\infty} \sum_{l=1}^{h(m,n)} c_m^l(s) \int_0^{\infty} \frac{J_{m+(n-2)/2}(r\lambda)}{(r\lambda)^{(n-2)/2}} Z_m^l(d\lambda),$$

where coefficients $c_m^l(s)$ are determined by a special algorithm (Yadrenko 1983). For practical purposes it is more convenient to have a formula where observations $X(t)$, $t \in S_n(r)$, are used directly. The composition theorem for spherical harmonics gives us this opportunity. We can write

$$\hat{X}(s) = \int_{S_n(r)} c(s,t) X(t) dm_n(t),$$

where the function $c(s,t)$ is determined by the spectral function $\Phi(\lambda)$ of the field $X(t)$ (Yadrenko 1983).

2. An isotropic random field $X(t)$, $t = (r,u) \in \mathbb{R}^n$ is observed in the sphere $V_R = \{x \in \mathbb{R}^n, \|x\| \leq R\}$. The optimal liner estimate $\hat{X}(s)$ of the unknown value $X(s)$, $s = (\rho, v) \notin V_R$, of the field has the form

$$\hat{X}(s) = \int_{V_R} C(s,t) X(t) dm_n(t),$$

$$C(s,t) = \sum_{m=0}^{\infty} \sum_{l=1}^{h(m,n)} c_m^l(r) S_{in}^l(u),$$

where coefficients $c_m^l(r)$ are determined via special integral equations

$$b_m(\rho,q) S_m^l(v) = \int_0^R b_m(r,q) c_m^l(r) r^{n-1} dr, \qquad m = 0, 1, \ldots;$$
$$l = 1, 2, \ldots, h(m,n), \quad q \in [0, R].$$

If, for example, $X(t)$, $t = (r,u)$, is an isotropic random field where $b_m(r,q) = a^{|m|} \exp\{-\beta|r-q|\}$, then it is easy to see that $\hat{X}(\rho, v) = \exp\{-\beta|\rho - R|\} X(R, v), v \in S_n$.

Estimation: An Overview

Sara van de Geer
Professor
ETH Zürich, Zürich, Switzerland

Introduction

Let P be a probability distribution on some space $\mathcal{X}$. A *random sample* from P is a collection of independent random variables $X_1, \ldots, X_n$, all with the same distribution P. We then also call $X_1, \ldots, X_n$ independent copies of a population random variable X, where X has distribution P. In statistics, the probability measure P is not known, and the aim is to estimate aspects of P using the observed sample $X_1, \ldots, X_n$. Formally, an estimator, say T, is any given known function of the data, i.e., $T = T(X_1, \ldots, X_n)$.

Example 1. *Suppose the observations are real-valued, i.e., the sample space $\mathcal{X}$ is the real line $\mathbb{R}$. An estimator of the population mean $\mu := EX$ is the sample mean $\hat{\mu} := \sum_{i=1}^n X_i/n$.*

A statistical model is a collection of probability measures $\mathcal{P}$. If the true distribution is in the model class $\mathcal{P}$, we call the model *well-specified*.

In many situations, it is useful to parametrize the distributions in $\mathcal{P}$, i.e., to write

$$\mathcal{P} := \{P_\theta : \theta \in \Theta\},$$

where Θ is the *parameter space*. The *parameter of interest* is some function of θ, say

$$\gamma := g(\theta) \in \Gamma.$$

Example 2.
Case (i) *Suppose X is known to be normally distributed with unknown mean μ and unknown variance σ^2 (we write this as $X \sim \mathcal{N}(\mu, \sigma^2)$). The parameter space is then the collection of 2-dimensional parameters $\theta := (\mu, \sigma^2)$. If one is only interested in estimating the mean μ, one lets $g(\mu, \sigma^2) = \mu$. The second parameter σ^2 is then called a nuisance parameter.*
Case (ii) *If actually the distribution of X is completely unknown, we may take*

$$\mathcal{P} := \{\text{all distributions on } \mathbb{R}\}.$$

We can let $\mathcal{P}$ itself be the parameter space, and the parameter of interest is written as function $g(P)$ of the probability measure P. For example, with $\mu = EX$ being the parameter interest, we have $g(P) := \int x dP(x)$.

How to Construct Estimators?

From a mathematical point of view, the construction of an estimator as function of the data $X_1, \ldots, X_n$ can be based on *loss* and *risk*. Let $g(\theta)$ be the parameter of interest, and $T = T(X_1, \ldots, X_n)$ be an estimator. With this estimator, we associate the *loss* $L(g(\theta), T)$, where L is a given ▶loss function. As T is a random variable, the loss is generally random as well. The *risk* of the estimator T is now defined as

$$R(\theta, T) := E_\theta L(g(\theta), T),$$

where the expectation E_θ is with respect to the probability measure of an i.id. sample $X_1, \ldots, X_n$ from P_θ. When the parameter of interest is real-valued, an important special case is quadratic loss

$$L(g(\theta), T) = |T - g(\theta)|^2.$$

The risk is then the mean square error

$$MSE_\theta(T) = E_\theta |T - g(\theta)|^2.$$

The mean square error can be separated into a squared bias term and a variance term

$$MSE_\theta(T) = \text{bias}_\theta^2(T) + \text{var}_\theta(T),$$

where

$$\text{bias}_\theta(T) := E_\theta T - g(\theta),$$

and

$$\text{var}_\theta(T) := E_\theta T^2 - (E_\theta T)^2.$$

An estimator T is called *unbiased* if

$$E_\theta T = g(\theta), \ \forall\ \theta.$$

It is called *uniform minimum variance unbiased* (UMVU) if it has the smallest variance among all unbiased estimators, for all values of the parameter.

Once the loss function $L(g(\theta), T)$ is specified, one may try to find the estimator T which has smallest risk $R(\theta, T)$. However, the risk depends on θ, which is unknown! This generally means that estimators are not directly comparable. One way to overcome this problem is to require the estimator to be the best one in the worst possible case:

$$\min_{\text{estimators } T} \max_{\theta\in\Theta} R(\theta, T).$$

This is called the *minimax approach*. Another way to treat the dependence on θ is to assign a priori weights to the various parameter values. This is called the Bayesian approach. Formally, let Π be some probability measure on Θ, the so-called prior. The Bayes' risk of the estimator T is then defined as

$$R(T) := \int R(\vartheta, T) d\Pi(\vartheta).$$

In other words, the unknown parameter is integrated out. The minimizer T_{bayes} of $R(T)$ over all estimators $T = T(X_1, \ldots, X_n)$ is called Bayes' estimator.

The (minimax, Bayes) risk generally heavily depends on the model class $\mathcal{P}$. This means that if the model is misspecified, the estimator may not have the optimality properties one hoped for. A related problem is the robustness of an estimator: how much does it change if some of the data points in the sample are perturbed? One often decides to stay on the conservative side, i.e. instead of believing in the model and aiming at mathematical optimality, one prefers to be sure to be doing something reasonable. And, last but not least, there may be practical cost considerations that prevent one from applying a particular estimator. Here, cost can also be computation time, e.g., if one needs online answers.

The asymptotic approach is to try to construct estimators that are "approximately" "optimal" under mild assumptions. For example, unbiased estimators often do not even exist. However, for large sample size n, many estimators are "approximately" unbiased. One then looks for the one with the smallest asymptotic variance, i.e., the highest asymptotic efficiency. Rigorous asymptotic theory can be mathematically involved, as a certain *uniformity* in the parameter θ is required.

The Plug in Principle

In this section, we assume that the sample size allows for an *asymptotic* approach, i.e., that n is large enough to base ideas on e.g. ▶laws of large numbers and ▶central limit theorems. We then see $X_1, \ldots, X_n$ as the first n of an infinite sequence. The *plug in* principle is mainly based on the law of large numbers. Consider for example a subset $A \subset \mathcal{X}$. The probability of this set is $P(X \in A)$, or shortly $P(A)$. As, by the law of large numbers, probabilities can be approximated by frequencies, a sensible estimator of $P(A)$ is the proportion of observations that fall into A:

$$\hat{P}_n(A) := \frac{1}{n}\#\Big\{i \in \{1, \ldots, n\} :\ X_i \in A\Big\}.$$

Note that $\hat{P}_n$ corresponds to a probability measure that puts mass $1/n$ at each observation. One calls $\hat{P}_n$ the *empirical distribution*.

Consider now a parameter of interest $\gamma = g(\theta)$. We write it as

$$\gamma := Q(P),$$

where Q is a given function on the probability measures $P \in \mathcal{P}$. In other words, $g(\theta) = Q(P_\theta)$. The plug in principle is now to use the estimator

$$\hat{\gamma}_n := Q(\hat{P}_n),$$

i.e., to replace the unknown probability measure P by the empirical measure. We remark however that is may happen that $Q(\hat{P}_n)$ is not defined (as generally $\hat{P}_n$ is not in the model class $\mathcal{P}$). In that case, one takes

$$\hat{\gamma}_n := Q_n(\hat{P}_n),$$

where

$$Q_n(P) \approx Q(P).$$

Example 3. *Suppose* $X \in \mathbb{R}$. *Let* $\mu = EX = \int x dP(x)$ *be the parameter of interest. The sample mean is*

$$\hat{\mu}_n = \int x d\hat{P}_n(x) = \frac{1}{n}\sum_{i=1}^n X_i.$$

Example 4. *Let the sample space again be the real line. The distribution function of* X *is*

$$F(x) := P(X \le x), \qquad x \in \mathbb{R}.$$

The empirical distribution function is

$$\hat{F}_n(x) = \frac{1}{n}\#\Big\{i \in \{1, \ldots, n\} :\ X_i \le x\Big\}.$$

The Glivenko–Cantelli Theorem tells us that the law of large numbers hold, uniformly in x (In fact, by Donsker's Theorem, $\sqrt{n}(\hat{F}_n - F)$ converges in distribution to $B \circ F$, where B is a Brownian bridge.)

$$\sup_x |\hat{F}_n(x) - F(x)| \to 0, \qquad n \to \infty,$$

with probability one. Suppose we know that F has a density f with respect to Lebesgue measure, and that we aim at estimating f at a fixed point x. Then

$$Q(F) = f(x) = \lim_{h \to 0} \frac{F(x+h) - F(x-h)}{2h}.$$

Note that $Q(\hat{F}_n)$ does not make sense in this case. Instead, we take

$$Q_n(\hat{F}_n) := \frac{\hat{F}_n(x+h_n) - \hat{F}_n(x-h_n)}{2h_n},$$

where the *bandwidth* h_n is "small." The choice of h_n can theoretically be based on a trade-off between bias and variance.

Maximum Likelihood

Suppose that $\mathcal{P} = \{P_\theta : \theta \in \Theta\}$ is a dominated family, i.e., there exists a σ-finite dominating measure ν, such that the densities

$$p_\theta := \frac{dP_\theta}{d\nu}, \qquad \theta \in \Theta$$

exist. The *maximum likelihood estimator* (MLE) $\hat{\theta}_n$ of θ is then defined as

$$\hat{\theta}_n := \arg\max_{\vartheta \in \Theta} \sum_{i=1}^n p_\vartheta(X_i),$$

where "arg" is "argument," i.e, the location where the maximum is achieved. It is to be checked in particular cases that the maximum actually exists.

Example 5. Suppose the densities w.r.t. Lebesgue measure are

$$p_\theta(x) = \theta(1+x)^{-\theta+1}, \ x > 0,$$

where $\theta \in \Theta = (0, \infty)$. Then

$$\log p_\vartheta(x) = \log \vartheta - (\vartheta + 1)\log(1+x).$$

We denote the derivative w.r.t. ϑ by

$$s_\vartheta(x) := \frac{d}{d\vartheta} \log p_\vartheta(x) = \frac{1}{\vartheta} - \log(1+x).$$

We put the derivative $\sum_{i=1}^n s_\vartheta(X_i)$ to zero:

$$\frac{n}{\hat{\theta}_n} - \sum_{i=1}^n \log(1+X_i) = 0.$$

This gives $\hat{\theta}_n = 1/\left[\sum_{i=1}^n \log(1+X_i)/n\right]$.

When Θ is finite-dimensional, say $\Theta \subset \mathbb{R}^p$, then under general regularity conditions, the MLE is approximately unbiased and each component has the smallest asymptotic variance. In fact, then $\sqrt{n}(\hat{\theta}_n - \theta)$ is approximately normally distributed, with mean zero and covariance matrix $I(\theta)^{-1}$, where $I(\theta)$ is the $p \times p$ Fisher information matrix

$$I(\theta) = E_\theta s_\theta(X) s_\theta^T(X),$$

with s_θ the *score function*

$$s_\theta := \frac{\partial}{\partial \theta} \log p_\theta.$$

Moreover, $I(\theta)$ can be approximated by the matrix of second derivatives

$$-\frac{\partial^2}{\partial \vartheta \partial \vartheta^T} \sum_{i=1}^n \log p_\vartheta(X_i)/n \Big|_{\vartheta = \hat{\theta}_n}.$$

These results however are not for free as they do rely on regularity conditions.

The MLE can be seen as plug in estimator:

$$\hat{\theta}_n = \arg\max_\vartheta \int \log p_\vartheta d\hat{P}_n,$$

and

$$\theta = \arg\max_\vartheta \int \log p_\vartheta dP_\theta.$$

M-Estimators

An M-estimator is of the form

$$\hat{\gamma}_n := \arg\min_{c \in \Gamma} \frac{1}{n} \sum_{i=1}^n \rho_c(X_i).$$

Here, for each $c \in \Gamma$, $\rho_c : \mathcal{X} \to \mathbb{R}$, $c \in \Gamma$ is a given function, called a *loss function* (generally to be distinguished from the loss function considered in Section ►"How to Construct Estimators?"). The M-estimator targets at the parameter

$$\gamma := \arg\min_{c \in \Gamma} E\rho_c(X).$$

This is indicated by the plug-in principle: the mean $E\rho_c(X)$ is approximated by the average $\sum_{i=1}^n \rho_c(X_i)/n$.

Example 6. Let $\mathcal{X} = \mathbb{R}$ and also $\Gamma = \mathbb{R}$. The sample mean $\hat{\mu} = \sum_{i=1}^n X_i/n$ is an M-estimator with $\rho_c(x) = (x-c)^2$, the squared error. In other words, the sample mean is the least squares estimator. In the same spirit, the sample median (the middle observation) can be seen as an M-estimator with $\rho_c(x) = |x-c|$. More generally, the empirical $(1-\alpha)$-quantile $\hat{F}_n^{-1}(1-\alpha)$ is an M-estimator with

$$\rho_c(x) = \rho(x-c), \ \rho(x) = \alpha|x|\{x > 0\} + (1-\alpha)|x|\{x < 0\}.$$

Example 7. The MLE is an M-estimator, with $\Gamma = \Theta$, and

$$\rho_\vartheta = -\log p_\vartheta.$$

Non-Parametric and High-Dimensional Problems

The non-parametric case is the situation where the parameter space Θ is infinite-dimensional. Closely related is the case where $\Theta \subset \mathbb{R}^p$ with $p > n$ (or $p \gg n$). Construction of estimators in high-dimensional or nonparametric models often - but not always - requires some complexity regularization. This is because a famous statistical rule-of-thumb, which says that the number of parameters should not exceed the number of observations, is violated.

Example 8. *Consider a linear regression model* (see ▶Linear Regression Models)

$$Y = \sum_{j=1}^{p} Z_j \beta_j + \epsilon,$$

where Y is a real-valued response variable, $Z_1, \ldots, Z_p$ are p co-variables, and where ϵ is mean-zero measurement error. The coefficients $\beta = (\beta_1, \ldots, \beta_p)^T$ form a p-dimensional unknown parameter. Let $Z = (Z_1, \ldots, Z_p)$ be the p-dimensional co-variable. Suppose we observe n independent copies $\{(Y_i, Z_i)\}_{i=1}^n$ of (Y, Z). Ideally, we would like $n \gg p$, in order to estimate the p parameters. If however $p \geq n$, one generally needs a regularization penalty. For example, when one believes that only a few of the variables are relevant, one may use the so-called Lasso

$$\hat{\beta}_n = \arg\min_{\beta} \frac{1}{n} \sum_{i=1}^{n} |Y_i - (Z\beta)_i|^2 + \lambda_n \sum_{j=1}^{p} |\beta_j|,$$

where $\lambda_n > 0$ is a tuning parameter.

Note that we used the standard quadratic loss function here. Other choices may also be applied, for instance quantile regression:

$$\hat{\beta}_n = \arg\min_{\beta} \frac{1}{n} \sum_{i=1}^{n} \rho(Y_i - (Z\beta)_i) + \lambda_n \sum_{j=1}^{p} |\beta_j|,$$

where, as in Example 6

$$\rho(x) = \alpha |x| \{x > 0\} + (1 - \alpha)|x| \{x < 0\}.$$

Example 9. *The estimator*

$$\hat{f}_n(x) := \frac{\hat{F}_n(x + h_n) - \hat{F}_n(x - h_n)}{2h_n},$$

considered in Example 4 is a nonparametric estimator of the density f at the point x. In this case, the bandwidth h_n is the tuning parameter. More generally, one may apply kernel estimators

$$\hat{f}_n(x) = \frac{1}{nh_n} \sum_{i=1}^{n} K\left(\frac{x - X_i}{h_n}\right),$$

where K is a given kernel. Another possibility is to use a regularized M-estimator. For example, when $\mathcal{X} = [0,1]$, one may consider using

$$\hat{f}_n = \arg\min_{\mathrm{f}} \left\{ \int_0^1 \mathrm{f}^2(x)dx - 2\sum_{i=1}^{n} \mathrm{f}(X_i)/n + \lambda_n \int_0^1 |\ddot{\mathrm{f}}(x)|^2 dx \right\},$$

where λ_n is again a tuning parameter.

Regularization is not always necessary, it can often be replaced by qualitative constraints such as monotonicity or convexity.

Example 10. *Suppose X has density f with respect to Lebesgue measure, and suppose we know that f is increasing. Let $\hat{f}_n$ be the Grenander estimator, i.e., the maximum likelihood estimator*

$$\hat{f}_n = \arg\max_{\mathrm{f\ increasing}} \frac{1}{n} \sum_{i=1}^{n} \log \mathrm{f}(X_i).$$

Then under moderate conditions, $\hat{f}_n$ is a good approximation of f for large sample size n.

Further Reading

Estimation is a very broad area is statistics. Classical books covering this area are Bickel and Doksum (2001) and Rice (1994), and for Bayesian methods, Berger (1985). The details for the asymptotic approach (also non- and semi-parametric) are in van der Vaart (2000). In van de Geer (2000) one finds a treatment of M-estimators, mostly in a nonparametric context. One can read more about density estimation in Wand and Jones (1995), and Silverman (1986). The Lasso is explained in Hastie et al. (2001), and the estimator of a monotone density is handled in Grenander (1981).

About the Author

Dr. Sara Ana van de Geer obtained her PhD in 1987 under supervision of Prof. R.D. Gill and Prof. W.R. van Zwet. She is Full Professor at the ETH Zürich (since 2005). She was Chair of Probability and Mathematical Statistics, Leiden University (1999–2005), and currently is Chair of the Seminar for Statistics, ETH Zürich. Dr. van de Geer is Elected Fellow of the Institute of Mathematical Statistics, Elected member of the International Statistical Institute, and Correspondent of the Dutch Royal Academy of Sciences. She was Associate Editor of *Bernoulli* (2004–2008), *Annals of Statistics* (1997–2007), *Statistica Sinica* (2005–2008), and *Statistica Neerlandica* (1996–2000). Currently, she is Editor

of Collections Volume (Springer, 2010) and Associate Editor of *The Scandinavian Journal of Statistics* (2010–). Professor van de Geer has (co-)authored over 40 papers and three books, including *Empirical Processes in M-Estimation* (Cambridge University Press, 2000). She was awarded the Medallion Lecturer at the Joint Statistical Meetings, San Francisco (August 2003) and the International Statistical Institute Award.

Eurostat

Walter J. Radermacher
Chief Statistician of the European Union and
Director-General of Eurostat
Luxembourg

Eurostat is the Statistical Office of the European Union. Established in 1953 and based in Luxembourg, it is part of the European Commission. Its role is to provide the European Union with high-quality statistics that enable comparisons between countries and regions.

Responsibilities

Eurostat has two main areas of responsibility. Firstly, in close cooperation with the national statistical authorities of the EU Member States, it develops harmonized methods for the production of statistics.

Secondly, Eurostat calculates and publishes total figures, aggregates, for the European Union and the euro area. As Eurostat does not conduct its own surveys in EU Member States, statistics from specific areas are transmitted to Eurostat by individual countries.

The methodology applied by EU Member States in the data collection as well as the delivery deadlines for transmission to Eurostat are regulated to a large degree by EU legislation.

Eurostat's statistics enable straightforward comparisons between European countries and regions and are crucial for politicians, economists and business people active at European, country and local government levels.

Increasingly, statistics made available by Eurostat are also consulted by members of the European public and media.

The Eurostat website gives access to a huge selection of statistical information. Over 300 million figures are available in its data base, around 4,500 Eurostat publications; many of them in English, German and French, and 1,000 tables can be accessed online and free of charge.

Internal Organization

Eurostat is part of the European Commission. It is headed by Director-General Walter Radermacher, the Chief Statistician of the European Union. Eurostat reports to the European Commissioner for Economic and Monetary Affairs.

In 2009, Eurostat had 900 staff. It is divided into seven directorates. They are:

- Cooperation in the European Statistical System; Resources
- Quality, methodology and information systems
- National and European Accounts
- External cooperation, communication and key indicators
- Sectoral and regional statistics (agriculture, fisheries, environment, transport, energy and regional statistics)
- Social and information society statistics (population, labor market, living conditions and social protection, education, science, culture, health and food safety, crime, information society and tourism statistics)
- Business statistics (business statistics, international trade and price statistics)

European Statistical System

Eurostat does not work alone. Together with the national statistical authorities of the EU-27 Member States (national statistical institutes, or NSIs, ministries, central banks etc.) it forms the European Statistical System (ESS). Its legal basis is the Regulation on European Statistics which came into force in April 2009, replacing older legislation.

The main decision-making body of the ESS is the European Statistical System Committee (ESSC), chaired by the Director-General of Eurostat. The ESSC is made up of Heads of the NSIs. It develops the ESS strategy, in accordance with the so-called European Statistics Code of Practice from 2005.

In 2008, the European Statistical Governance Advisory Board, or ESGAB, was created. Its role is to enhance the professional independence, integrity and accountability of the European Statistical System as well as to improve the quality of European statistics.

Also created in 2008, the European Statistical Advisory Committee (ESAC) consists of 24 representatives of institutional and private statistics users, who give their opinion on various statistical projects developed by the ESS.

Short History

The origins of Eurostat go back to the early 1950s, when a "statistical service" of the Coal and Steel Community was created in 1952, charged with conducting "a continuous study of market and price trends."

Over the next few years the responsibilities of the Statistical Division, renamed in 1954, diversified and, when the European Community was founded in 1958, it became a separate Directorate-General of the European Commission. Eurostat received its present name in 1959.

Today, Eurostat's key role is to supply the EU institutions and policy makers as well as the research community and all European citizens with a wide range of statistics, instrumental for planning, development and implementation of joint European Community policies.

About the Author

Walter Radermacher was born in Walheim (near Aachen) on 10 June 1952. From 1970 to 1975 he studied business administration in Aachen and in Münster. After obtaining the academic degree of Diplom-Kaufmann (economist), he worked as member of academic staff at the University of Münster from 1975 to 1977. At the beginning of 1978, Walter Radermacher joined the Federal Statistical Office. Mr Radermacher has held a wide variety of posts at the German Statistical Office during his thirty-year career there, notably in the fields of environmental and economic statistics. He has been Vice-President of the German Federal Statistical Office (2003–2006), and President since 2006. During the 2007 German Presidency, he was Chair of the Council's working group on statistics. He has also chaired the UN Committee on Environmental–Economic Accounting. During his career, Mr. Radermacher has had teaching assignments in statistics and environmental economy at the specialised college of higher education (Fachhochschule) in Wiesbaden and the University of Lüneburg in Germany. As of 2008, he was appointed Director General of Eurostat and chief statistician of the European Union.

Event History Analysis

Hans-Peter Blossfeld
Professor
Otto-Friedrich-Universität Bamberg, Bamberg, Germany

Introduction

Event history analysis studies a collection of units, each moving among a finite (usually small) number of states. An example is individuals who are moving from unemployment to employment. In this article various examples of event history applications are presented, the concepts and advantages of event history analysis are demonstrated, and practical complications are addressed.

Examples of Continuous-Time, Discrete-State Processes

Event history analysis is the study of processes that are characterized in the following general way: (1) there is a collection of units (which may be individuals, organizations, societies, etc.), each moving among a *finite* (usually small) *number of states*; (2) these changes (or *events*) may *occur at any point in time* (i.e., they are not restricted to predetermined points in time); and (3) there are *time-constant and/or time-varying factors* influencing the timing of events. Examples are workers who move between unemployment and employment; men and women who enter into consensual unions or marriages; companies that are founded or closed down; governments that break down; people who are mobile between different regions or nation states; consumers who switch from one brand to another; prisoners who are released and commit another crime; people who show certain types of verbal and non-verbal behaviors in social interactions; students who drop out of school; incidences of racial and ethnic confrontation, protest, riot, and attack; people who show signs of psychoses or neuroses; patients who switch between the states "healthy" and "diseased," and so on. In event history analysis, the central characteristics of the underlying stochastic process are mirrored in the specific way theoretical and mathematical models are built, data are collected, and the estimation and evaluation of models is done.

Different Observation Plans

In event history analysis the special importance of broader research design issues has been stressed. In particular, different observation plans have been used to collect information on the *continuous-time, discrete-state substantive process*. These various schemes produce different types of data that constrain the statistical analysis in different ways: cross-sectional data, event count data, event sequence data, ►panel data, and event history data.

The *cross-sectional observation design* is still the most common form of data collection in many fields. A cross-sectional sample is only a "snapshot" taken on the continuous-time, discrete-state substantive process (e.g., the jobs of people at the time of the interview). Event history analysis has shown that one must be very cautious in drawing inferences about explanatory variables on the basis of such data because, implicitly or explicitly, social researchers have to assume that the process under study is in some kind of *equilibrium*. Equilibrium means that the *state probabilities* are fairly trendless and the relationships among the variables are quite stable over time. Therefore, an equilibrium of the process requires that the inflows to and the outflows from each of the discrete states be equal over time to a large extent. This is a strong assumption that is not very often justified in the social and behavioral sciences (see Blossfeld and Rohwer 2002; Blossfeld et al. 2007).

A comparatively rare type of data on changes of the process are *event count data*. They record the number of different types of events for each unit in an interval (e.g., the number of racial and ethnic confrontations, protests, riots, or attacks in a period of 10 years). *Event sequence data* provide even more information. They record the sequence of specific states occupied by each unit over time. Today, the temporal data most often available to the scientist are *panel data*. They provide information on the same units of analysis at a series of discrete points in time. In other words, there is only information on the states of the units at predetermined survey points and the course of the process between the survey points remains unknown. Panel data certainly contain more information than cross-sectional data, but involve well-known distortions created by the method itself (e.g., panel bias, attrition of sample). In addition, causal inferences based on panel approaches are much more complicated than has been generally acknowledged (Blossfeld and Rohwer 2002; Blossfeld et al. 2007). With regard to the continuous-time, discrete-state substantive process, panel analysis is particularly sensitive

to the length of the time intervals between the waves relative to the speed of the process. They can be too short, so that very few state transitions will be observed, or too long, so that it is difficult to establish a time-order between the events.

The *event oriented observation design* records the complete sequence of states occupied by each unit and the timing of changes among these states. For example, an event history of job mobility consists of more or less detailed information about each of the jobs and the exact beginning and ending dates of each job. Thus this is the most complete information one can get on the continuous-time, discrete-state substantive process. Such *event history data* are often collected retrospectively with *life history studies*. Life history studies are normally cheaper than panel studies and have the advantage that they code the data into one framework of codes and meaning. But retrospective studies also suffer from several limitations (see Blossfeld and Rohwer 2002; Blossfeld et al. 2007). In particular, data concerning motivational, attitudinal, cognitive, or affective states are difficult (or even impossible) to collect retrospectively because the respondents can hardly recall the timing of changes in these states accurately. Also the retrospective collection of behavioral data has a high potential for bias because of its strong reliance on autobiographic memory. To reduce these problems of data collection, modern panel studies (e.g., the PSID in the US, the BHPS in the UK, or the SOEP in Germany) use a mixed design that provides traditional panel data and retrospectively collects event history data for the period before the first panel wave and between the successive panel waves.

Event History Analysis

Event history analysis, originally developed as independent applications of mathematical probability theory in ►demography (e.g., the *classical life table analysis* and the *product-limit estimator*), reliability engineering, and ►biostatistics (e.g., the path-breaking *semiparametric regression* model for ►*survival data*), has gained increasing importance in the social and behavioral sciences (see Tuma and Hannan 1984; Blossfeld et al. 1989; Lancaster 1990; Blossfeld and Rohwer 2002; Blossfeld et al. 2007) since the 1980s. Due to the development and application of these methods in various disciplines, the terminology is normally not easily accessible to the user. Central definitions are therefore given first.

Basic Terminology

Event history analysis studies *transitions* across a set of discrete states, including the length of *time intervals* between entry to and exit from specific states. The basic analytical framework is a state space and a time axis. The choice of the *time axis* or *clock* (e.g., age, experience, and marriage duration) used in the analysis must be based on theoretical considerations and affects the statistical model. Dependent on practical and theoretical reasons, there are event history methods using a *discrete-* (Yamaguchi 1991; Vermunt 1997) or *continuous-time axis* (Tuma and Hannan 1984; Blossfeld et al. 1989; Lancaster 1990; Courgeau and Lelièvre 1992; Blossfeld and Rohwer 2002; Blossfeld et al. 2007). Discrete-time event history models are, however, special cases of continuous-time models, and are therefore not further discussed here. *An episode, spell, waiting time, or duration* – terms that are used interchangeably in the literature – is the time span a unit of analysis (e.g., an individual) spends in a specific state. The *states are discrete* and usually small in number. The definition of a set of possible states, called the *state space*, is also dependent on substantive considerations. Thus, a careful, theoretically driven choice of the time axis and design of state space are crucial because they are often serious sources of misspecification.

The most restricted event history model is based on a process with only a *single episode* and two *states* (an *origin state* j and a *destination state* k). An example may be the duration of first marriage until the end of the marriage, for whatever reason (separation, divorce, or death). In the *single episode* case each unit of analysis that entered into the origin state is represented by one episode. Event history models are called *multistate models*, if more than one destination state exists. Models for the special case with a single origin state but two or more destination states are also called *models with competing events or risks*. For example, a housewife might become "unemployed" (meaning entering into the state "looking for work"), or start being "full-time" or "part-time employed." If more than one event is possible (i.e., if there are repeated events or transitions over the observation period), the term *multi-episode modes* is used. For example, an employment career normally consists of a series of job shifts.

Censoring

Observations of event histories are often *censored*. Censoring occurs when the information about the duration in the origin state is incompletely recorded. An episode is *fully censored on the left*, if starting and ending times of a spell are located before the beginning of an observation period (e.g., before the first panel wave) and it is *partially censored on the left*, if the length of time a unit has already spent in the origin state is unknown. This is typically the case in panel studies, if individuals' job episodes at the time of a first panel wave are known but no further information about the history of the job is collected. Left censoring is

normally a difficult problem because it is not possible to take the effects of the unknown episodes into account. It is only without problems if the assumption of a *Markov process* (see ►Markov Processes) is justified (i.e., if the transition rates do not depend on the duration in the origin state).

The usual kind of censoring, however, is *right censoring*. In this case the end of the episode is not observed but the observation of the episode is terminated at an arbitrary point in time. This type of censoring typically occurs in life course studies at the time of the retrospective interviews or in panel studies at the time of the last panel wave. Because the timing of the end of the observation window is normally determined independently from the substantive process under study, this type of right censoring is unproblematic and can easily be handled with event history methods. Finally, episodes might be *completely censored on the right*. In other words, entry into and exit from the duration occurs after the observation period. This type of censoring normally happens in retrospective life history studies in which individuals of various birth cohorts can only be observed over very different spans of life. To avoid sample selection bias, such models have to take into account variables controlling for the selection, for example, by including birth cohort dummy variables (see Yamaguchi 1991).

The Transition Rate

The central concept of event history analysis is the *transition rate*. Because of the various origins of event history analysis in the different disciplines, the transition rate is also called the *hazard rate, intensity rate, failure rate, transition intensity, risk function, or mortality rate*:

$$r(t) = \lim_{t' \to t} Pr\left(t \le T < t' | T \ge t\right) / \left(t' - t\right).$$

The transition rate provides a local, time-related description of how the process evolves over time. It can be interpreted as the propensity (or *intensity*) to change from an origin state to a destination state, at time t. But one should note that this propensity is defined in relation to a *risk set* $(T \ge t)$ at t, i.e., the set of units that still can experience the event because they have not yet had the event before t.

Statistical Models

The central idea in event history analysis is to make the transition rate, which describes a process evolving in time, dependent on time (t) and on a set of covariates, x:

$$r(t) = g(t, x).$$

The causal interpretation of the transition rate requires that we take the temporal order in which the processes evolve very seriously. In other words, at any given point in time t, the transition rate $r(t)$ can be made dependent on conditions that happened to occur in the past (i.e., before t), but not on what is the case at t or in the future after t.

There are several possibilities to specify the functional relationship $g(.)$ (see Blossfeld and Rohwer 2002; Blossfeld et al. 2007). For example, the *exponential model*, which normally serves a baseline model, assumes that the transition rate can vary with different constellations of covariates x, but that the rates are time constant. The *piecewise-constant exponential model* allows the transition rate to vary across fixed time periods with period-specific effects of covariates. There are also different parametric models that are based on specific shapes of the time dependence (e.g., the *Gompertz-Makeham*, *Weibull*, *Sickle*, *Log-logistic*, *Log-normal*, or *Gamma model*). If the time shape of the *baseline hazard rate* is unspecified, and only possible effects of covariates x are estimated, the model is called a *semi-parametric or partial likelihood model*. Finally, there are also *models of unobserved heterogeneity* in which the transition rate can be made dependent on the observed covariates x, the duration t, and a stochastic error term.

Parallel and Interdependent Processes

The most important scientific progress permitted by event history analysis is based on the opportunity to include explicitly measured *time-varying covariates* in transition rate models (see Blossfeld and Rohwer 2002; Blossfeld et al. 2007). These covariates can change their values over process time in an analysis. Time-varying covariates can be qualitative or quantitative, and may stay constant for finite periods of time or change continuously. From a substantive point of view, time-varying covariates can be conceptualized as observations of the sample path of parallel processes. These processes can operate at different levels. In sociology, for example, (1) there can be parallel processes at the level of the individual's different domains of life (e.g., one may ask how upward and downward moves in an individual's job career influence his/her family trajectory), (2) there may be parallel processes at the level of some few individuals interacting with each other (e.g., one might study the effect of the career of the husband on his wife's labor force participation), (3) there may be parallel processes at the intermediate level (e.g., one can analyze how organizational growth influences career advancement or changing household structure determines women's labor force participation), (4) there may be parallel processes at the macro level (e.g., one may be interested in the effect of changes in the business cycle on family formation or career

advancement), and (5) there may be any combination of such processes of type (1) to (4). For example, in the study of life course, cohort, and period effects, time-dependent covariates at different levels (see below) must be included simultaneously (►*multilevel analysis*).

In dealing with such systems of parallel processes, the issue of *reverse causation* is often addressed in the methodological literature (see, e.g., Tuma and Hannan 1984; Blossfeld et al. 1989; Yamaguchi 1991). Reverse causation refers to the (direct or indirect) effect of the dependent process on the independent covariate process(es). Reverse causation is often seen as a problem because the effect of a time-dependent covariate on the transition rate is confounded with a feedback effect of the dependent process on the values of the time-dependent covariate. However, Blossfeld and Rohwer (2002) have developed a *causal approach* to the analysis of interdependent processes that also works in the case of interdependence. For example, if two interdependent processes, $Y_t{}^A$ and $Y_t{}^B$, are given, a change in $Y_t{}^A$ at any (specific) point in time t' may be modeled as being dependent on the history of both processes up to, but not including t'. Or stated in another way: What happens with $Y_t{}^A$ at any point in time t' is conditionally independent of what happens with $Y_t{}^B$ at t', conditional on the history of the joint process $Y_t = \left(Y_t{}^A, Y_t{}^B\right)$ up to, but not including, t ("*principle of conditional independence*"). Of course, the same reasoning can be applied if one focuses on Y_t^B instead of Y_t^A as the "dependent variable." Beginning with a transition rate model for the joint process, $Y_t = \left(Y_t^A, Y_t^B\right)$, and assuming the principle of conditional independence, the likelihood for this model can then be factorized into a product of the likelihood's for two separate models: a transition rate model for $Y_t{}^A$, which is dependent on $Y_t{}^B$ as a time-dependent covariate, and a transition rate model for $Y_t{}^B$, which is dependent on $Y_t{}^A$ as a time-dependent covariate. From a technical point of view, there is therefore no need to distinguish between *defined, ancillary, and internal covariates* because all of these time-varying covariate types can be treated in the estimation procedure. Estimating the effects of time-varying processes on the transition rate can easily be achieved by applying the *method of episode splitting* (see Blossfeld and Rohwer 2002; Blossfeld et al. 2007).

Unobserved Heterogeneity

Unfortunately, researchers are not always able to include all the important covariates into an event history analysis. These unobserved differences between subpopulations can lead to *apparent time dependence* at the population level and additional identification problems. There exists a fairly large literature on misspecified models in general. In particular, there have been several proposals to deal with *unobserved heterogeneity* in transition rate models (so-called *frailty models*) (see, e.g., Blossfeld and Rohwer 2002; Blossfeld et al. 2007).

About the Author

Dr. Hans-Peter Blossfeld is Professor of Sociology at Bamberg University. He is also Director of the Institute of Longitudinal Studies in Education (Institut für bildungswissenschaftliche Längsschnittstudien – INBIL), Principal Investigator of the National Educational Panel Study (NEPS), and Director of the State Institute for Family Research at Bamberg University (Staatsinstitut für Familienforschung - ifb). He is an Elected member of the German Academy of Sciences (Leopoldina), the Bavarian Academy of Sciences and the Berlin-Brandenburg Academy of Sciences. He is also a Elected member of the European Academy of Sociology, London, and Elected Chairman of the European Consortium of Sociological Research (ECSR). He serves as member of the Steering Committees of the European Science Foundation (ESF) Programes "Quantitative Methods in the Social Sciences II" and "TransEurope". He is also member of the ESRC National Strategy Committee on Longitudinal Studies in the UK. He has authored and co-authored more than 200 papers, mostly in refereed journals, and has written as well as edited 22 books, including *Techniques of Event History Modeling: New Approaches to Causal Analysis* (with G. Rohwer, Lawrence Erlbaum Associates, 2002). Professor Blossfeld has received the Descartes award for his Globalife project (European Commission, 2007). He is Editor of the following journals: *European Sociological Review*, *Zeitschrift für Erziehungswissenschaft*, and *Zeitschrift für Familienforschung*. Currently, he is also an Associate editor of *International Sociology*.

Exact Goodness-of-Fit Tests Based on Sufficiency

Federico J. O'Reilly, Leticia Gracia-Medrano
Professors
IIMAS, UNAM, México City, México

Introduction and Simple Case

In the univariate continuous goodness-of-fit problem, the probability integral transformation (PIT) is used to transform the sample observations into the unit interval when the distribution to be tested is completely specified (the simple case); thus reducing the problem to that of testing uniformity of the transforms. The asymptotic theory for the induced empirical process in (0,1) is well known and so, that of functionals of it, including the so called EDF tests that are based on the Empirical Distribution Function (see ►Tests of fit based on the empirical distribution function).

The empirical process (see ►Empirical Processes), labeled with the original x is the process

$$\psi_n(x) = \sqrt{n}\{F_n(x) - F_0(x)\},$$

for $x \in R$, with F_n being the empirical distribution function constructed from the observed sample $x_1, \cdots, x_n$ and with F_0 the known distribution function to be tested. This process is in a 1:1 correspondence with the corresponding process labeled with $u \in (0,1)$,

$$\eta_n(u) = \sqrt{n}\{G_n(u) - u\},$$

with $u = F_0(x)$, where G_n stands for the empirical distribution function of the transformed sample $u_1, \cdots, u_n$ with the u_i's given by $u_i = F_0(x_i)$.

Functionals of the empirical process, that appeared in literature (mostly) for the continuous goodness-of-fit problem are Kolmogorov's statistic, D_n, Cramér-von Mises, $W^2{}_n$, Anderson-Darling's, $A^2{}_n$ and others like Kuiper's V_n, Watson's $U^2{}_n$, and Pearson's chi square, χ^2.

These may be described in the $(0,1)$ transformed range as:

$$D_n = sup_u|\eta_n(u)|$$
$$W^2{}_n = \int_0^1 (\eta_n(u))^2 du$$
$$A^2{}_n = \int_0^1 (\eta_n(u))^2 \frac{1}{u(1-u)} du,$$

having well known computable formulas in terms of the $u_{(i)}$'s, the now ordered transformed u_i's, from smallest to largest, with $u_{(0)} = 0$ and $u_{(n+1)} = 1$, if needed.

$$D_n = max\{D^+{}_n, D^-{}_n\},$$
$$D^+{}_n = max_i\left\{G_n(u_{(i)}) - u_{(i)}\right\},$$
$$D^-{}_n = max_i\{u_{(i)} - G_n(u_{(i-1)})\}, G_n(u_{(i)}) = i/n,$$
$$W^2{}_n = \sum_{i=1}^{n}[u_{(i)} - (2i-1)/(2n)]^2 + 1/(12n),$$
$$A^2{}_n = -n - \frac{1}{n}\sum_{i=1}^{n}(2i-1)[log(u_{(i)}) + log(1 - u_{(n+1-i)})],$$

with similar expressions for the other EDF tests (like Kuiper's $V_n = D^+{}_n + D^-{}_n$).

If the continuous distribution to be tested, has unknown parameters, the established procedure (using asymptotics) is to estimate first and substitute them in place of the parameters before employing the PIT, to transform to the unit interval. Under quite general conditions, asymptotics for the resulting empirical process in $(0,1)$ have been reported in literature for many distributions (see Durbin 1973; D'Agostino and Stephens 1986 and references given there).

If the distribution is discrete, the above approach using asymptotics, has not been followed much. To start, in the simple case, the PIT does not yield uniform transforms. There are however several proposed tests for the discrete case; some based on the empirical characteristic function, others on the empirical probability generating function and others. See for example Kocherlakota and Kocherlakota (1986), Rueda et al. (1991), Nakamura and Pérez-Abreu (1993), Rueda and O'Reilly (1999), Gurtler and Henze (2000) and references therein. In Spinelli and Stephens (1997) discrete versions of EDF tests are studied. All these procedures, yield tests related to the "observed and expected counts." Further mention of the discrete case is made only for "on site" evaluation of ►*p*-values.

With fast computers available now, the *simple* goodness-of-fit problem, either continuous or discrete, may be solved by computing the *p*-value of the selected statistic to test the fit, simply by simulating many independent samples from

the null hypothetical distribution. This is done by observing first the value of the test statistic with the initial sample and then looking the corresponding simulated values of the test statistic, then finding the proportion of simulated values exceeding the initial value of the test statistic. That is the p-value.

This procedure is easier than having to use tables, and possible finite-n corrections. Moreover, this simulation procedure applies to the continuous as well as the discrete case, because the inverse of the PIT (IPIT) is a proper generator for any distribution.

The IPIT maps a uniformly distributed random variable U with the "inverse" of a distribution function F^{-1} yielding a new random variable $X = F^{-1}(U)$, whose distribution function is precisely, F. With the inverse $F^{-1}(u)$, say, taken as the *supremum* of the x-values such that $F(x) \leq u$.

So in *any* simple goodness-of-fit problem (continuous or discrete), given

$$\underline{x} = (x_1, x_2, \cdots, x_n),$$

a sample of independent identically distributed random variables with common distribution function F, to test the null hypothesis,

$$H_0 : F = F_0,$$

with F_0 totally known, one proceeds as follows:

For $S_n(\underline{x}) = S_n(x_1, \cdots, x_n)$ the test statistic to be used for testing H_0, evaluated at the observed sample, simulate from the null distribution F_0, say 10,000 samples $(\underline{x}_j, j = 1, \cdots, 10{,}000)$ of the same size n and with each, compute $S_n(\underline{x}_j)$. Finally look at the proportion of simulated values (the $S_n(\underline{x}_j)$'s) exceeding $S_n(\underline{x})$. This is the p-value obtained with the 10,000 simulations.

Composite Case: Group Model

Many "composite" goodness-of-fit problems may be tackled with a strikingly similar Monte-Carlo simulation. Those problems arise when the null hypotheses corresponds to a parametric family with a group structure, where the test statistic S_n is invariant; typically, most families with location and/or scale parameters only. It was noticed that when finding the limiting distribution of the "empirical process with estimated parameters," the limiting process was a zero mean Gaussian process, whose covariance function did not depend on the parameter values (generally depends on the particular family to be tested). This result allowed the use of the limiting distribution for the EDF test statistic; perhaps using some finite-n correction (see e.g., Chap. 4 in D'Agostino and Stephens 1986). This is the case of most location/scale families.

Under a group model, not only the asymptotic, but the finite-n distributions of invariant tests S_n are independent of the value of the parameters, so one may simply assign any arbitrary value to them, and simulate tens of thousands of samples and repeat as in the simple case to evaluate an exact p-value in situ.

Composite Case: Non-Group Model

There are important parametric families where there is no group structure, and limiting distributions depend also on the parameter values. These include those where a "shape" parameter is present, as in the case of the ▶gamma distribution, the inverse-Gaussian and is the case of most discrete distributions with unknown parameters. For these, an attempt has been made to compute *not* the p-value, since in general that quantity depends on the parameter, but rather use the conditional distribution of the test statistic S_n given some suitable sufficient statistic to compute a *conditional* p-value. This is explained next.

Assume that in the setting $H_0 : F(\cdot) = F_0(\cdot; \theta)$, where $\theta \in \Theta$, T_n is the minimal sufficient statistic. Not being a group model the test statistic S_n will have a distribution, under H_0, that will in general depend on θ. But having T_n sufficient means that the conditional distribution of S_n given T_n, will not depend on θ, so in order to base the procedure in a simulation, it will be enough to have a simulator of samples which are *conditionally to* T_n, independent identically distributed. One way to simulate in that fashion appears in O'Reilly and Gracia-Medrano (2006), and is illustrated for the ▶inverse Gaussian distribution. In González-Barrios et al. (2006), the results provide means to simulate for the Poisson, binomial and negative binomial, with unknown parameters (besides the test derived there that uses enumeration for the conditional distribution). In Lockhart et al. (2007) a simulator is provided for the two parameter gamma distribution. The first reference bases the simulator on the explicit use of the Rao-Blackwell estimator of the distribution $F_0(\cdot; \theta)$. The third reference uses the Gibbs sampler to achieve an exact simulation method.

The inverse-Gaussian simulator is sketched to illustrate. Let the null hypothesis correspond to the inverse-Gaussian distribution, $F_0(x; \mu, \lambda)$. Denote the Rao-Blackwell distribution estimate, based on the sample $\underline{x}$, by $\check{F}_n(x)$, which is a function of the minimal sufficient statistic,

$$T_n(\underline{x}) = \left(\sum_i x_i, \sum_i \left(\frac{1}{x_i} \right) \right),$$

and exists for $n > 2$. Its expression appears (corrected) in Chhikara and Folks (1977).

Observe that the statistic T_n has the property of double transitivity, which means that the pair (T_n, X_n) is in a 1:1 correspondence with (T_{n-1}, X_n). It implies in particular that knowing the value of the statistic with a sample of size n and knowledge of, say, the last observation, one can find the value of the statistic with the corresponding smaller sample of size $(n-1)$.

After observing the sample, denote by s the value of the goodness of fit test and by t_n the value of the minimal sufficient statistic; that is, $S_n(\underline{x}) = s$ and $T_n(\underline{x}) = t_n$. In order to simulate, conditionally to $T_n = t_n$, a conditional sample (denoted a $*$-sample) proceed as follows:

Obtain randomly u_n from the $U(0,1)$ distribution and set $x^\star{}_n = \tilde{F}_n^{-1}(u_n)$, then compute $t^\star_{n-1}$ from the knowledge of t_n and taking away form its evaluation the (imposed) n-th value $x^\star{}_n$, i.e., obtain $t^\star_{n-1}$ from the pair $\left(t_n, x^\star{}_n\right)$. Next with an independently selected u_{n-1} from the $U(0,1)$, use the Rao-Blackwell estimate given $t^\star_{n-1}$ and define $x^\star{}_{n-1} = \tilde{F}_{n-1}^{-1}(u_{n-1})$. Continue finding $t^\star_{n-2}$ from $\left(t^\star_{n-1}, x^\star{}_{n-1}\right)$, then looking at the Rao-Blackwell estimate given $t^\star_{n-2}$, use its inverse to get $x^\star{}_{n-2}$ with an independently selected u_{n-2}; and so on until finding $x^\star{}_3$.

Finally, get $x^\star{}_2$ and $x^\star{}_1$ as the solution to yield the same value for T_n when evaluated at the new $*$-sample (that is t_n).

The procedure is repeated for tens of thousands of times getting tens of thousands of $*$-samples which in turn produces the desired simulated values of the statistic S_n. The proportion of simulated values that exceed the original s is the conditional p-value, and is exact. With 10,000 $*$-samples and $n = 20$, evaluation of the p-value takes around 13 s on a conventional PC.

Parametric Bootstrap

Simulations based on parametric bootstrap to get a p-value, provide an *exact* procedure in the case of a group model. In the non-group model, bootstrapping is not theoretically exact but very good. Ongoing research is being done on the closeness of the conditional p-value and the one found with bootstrap (see ▶Bootstrap Methods). Articles where bootstrap has been proposed to evaluate the p-value for particular distributions, show that for large n, the procedure provides a very good approximation.

Exact Inference for Categorical Data

Roshini Sooriyarachchi
Professor
University of Colombo, Colombo, Sri Lanka

In practice statistical inference for categorical data is based mainly on large sample approximations of test statistics.

This asymptotic theory is valid only if the sample sizes are reasonably large and well balanced across populations. To make valid inferences in the presence of small, sparse or unbalanced data, exact p-values and confidence intervals, based on the permutational distribution of the test statistic (Good 1993) needs to be computed. The most common approach to exact inference for categorical data has been a conditional one (Agresti, 1992) thus this approach is mainly discussed here. This utilizes the distribution of the sufficient statistic for the parameter of interest, conditional on the sufficient statistics for the other model parameters (Agresti 2001). The sufficiency principle used here is explained in more detail in Mehta (1998).

Settings and Notation

The rest of the article presents a variety of exact methods for categorical data. The required settings and notation are defined in this section. Consider a two-way contingency table having I rows and J columns cross–classifying a row variable X and a column variable Y. Let $\{n_{ij}\}$ correspond to the cell counts $n_{i+} = \sum_j n_{ij}$, $n_{+j} = \sum_i n_{ij}$, and $n = \sum_{i,j} n_{ij}$. Agresti (1992) and Mehta (1998) list three sampling schemes (settings) that can give rise to cross-classified categorical data. These schemes are namely:

1. Full multinomial sampling scheme where the cell counts $\{n_{ij}\}$ have a ▶multinomial distribution generated by n independent trials with IJ cell probabilities $\{\pi_{ij}\}$.
2. Product multinomial sampling where counts $\{n_{ij}\}$ in row I have a multinomial distribution for all j, with counts in different rows being independent. Here $n_{i+} = \sum_j n_{ij}$, $i = 1, \ldots, I$ are fixed.
3. Poisson sampling, where $\{n_{ij}\}$ have a Poisson distribution with expected value $E(n_{ij}) = m_{ij}$ where $n = \sum_{i,j} n_{ij}$ is random.

As Agresti (1992) indicates that all three sampling models lead to the same inference, for the sake of simplicity the following results are based on sampling scheme (2). Under this scheme, the conditional probability of belonging to the jth column given that observation is in the ith row is denoted by $\pi_{j|i} = P(Y = j|X = i)$ for $i = 1, \ldots, I$ and $j = 1, \ldots, J$.

2 × 2 Table

Let π_1 and π_2 denote "success" probabilities associated with row 1 and row 2 respectively. Then the odds ratio is given by

$$\theta = \frac{\pi_1/(1-\pi_1)}{\pi_2/(1-\pi_2)}.$$

Several authors (Mehta, 1998; Agresti, 1992, 2001) showed that

$$P(n_{11} = k \mid n, n_{1+}, n_{+1}; \theta) = \frac{\binom{n_{1+}}{k}\binom{n-n_{1+}}{n_{+1}-k}\theta^k}{\sum_u \binom{n_{1+}}{u}\binom{n-n_{1+}}{n_{+1}-u}\theta^u}. \quad (1)$$

Under the null hypothesis of independence ($\theta = 1$) the conditional distribution given in (1) is hypergeometric. To test $H_0 : \theta = 1$ versus $H_1 : \theta > 1$ the p-value is given by $P = \sum_S P(t \mid n, n_{1+}, n_{+1}; \theta = 1)$ where $S = \{t; t \geq n_{11}\}$. This test is called the ▶*Fisher's Exact test* (Fisher, 1935).

$I \times J$ Tables

For $I \times J$ tables, statistical independence of X and Y (H_0) corresponds to the log-linear model (Bishop et al., 1975)

$$\log(m_{ij}) = \mu + \lambda_i^X + \lambda_j^Y. \quad (2)$$

To test H_0, model (2) has to be compared with the saturated model

$$\log(m_{ij}) = \mu + \lambda_i^X + \lambda_j^Y + \lambda_{ij}^{XY}. \quad (3)$$

Cornfield (1956) showed that the distribution of $\{n_{ij}\}$ given $\{n_{i+}\}$ and $\{n_{+j}\}$ depends only on the odds ratios (α_{ij}) such that

$$P(n_{ij} \mid \{n_{i+}\}, \{n_{+j}\}; \alpha_{ij}) = \frac{\prod_{i=1}^{I-1}\prod_{j=1}^{J-1}\alpha_{ij}^{n_{ij}}}{\prod_{i=1}^{I-1}\prod_{j=1}^{J-1} n_{ij}!} \ldots\ldots \quad (4)$$

where

$$\alpha_{ij} = \frac{\pi_{ij}/\pi_{IJ}}{\pi_{iJ}/\pi_{Ij}}.$$

Under H_0, $\alpha_{ij} = 1$ for all i and j thus the conditional distribution of n_{ij} given $\{n_{i+}\}$ and $\{n_{+j}\}$ under H_0 is multiple hypergeometric and is given by

$$P(n_{ij} \mid \{n_{i+}\}, \{n_{+j}\}) = \frac{\left(\prod_i n_{i+}!\right)\left(\prod_j n_{+j}!\right)}{n!\prod_{i=1}^{I}\prod_{j=1}^{J} n_{ij}!}.$$

The methods for $I \times J$ tables can be extended to multiway tables (Agresti, 1992).

Exact Inference for Logistic Models

Consider the case of a single binary response variable (Y) and several explanatory variables $X_1, \ldots, X_k$. In this situation a logistic model (Hosmer and Lemeshow (2000)) is preferred to a log-linear model. This model is expressed as $\log\left(\frac{\pi_i}{1-\pi_i}\right) = \sum_{j=0}^{k}\beta_j x_{ij}$ where π_i is the probability of belonging to the research category of interest for the ith subject, $x_{i1}, \ldots, x_{ik}$ are the values of the k explanatory variables observed for the ith subject and $x_{i0} = 1$ for all i. When $\{y_i\}$ are independent Bernoulli outcomes, Cox (1970) showed that the sufficient statistics for β_j are $T_j = \sum_i y_i x_{ij}$; $j = 0, \ldots, k$ and illustrated how to conduct inference for β_j using the conditional distribution of T_j given $\{T_i, i \neq j\}$.

Other Topics and Available Software

Agresti (1992) discusses less common topics such as exact confidence intervals, exact goodness of fit tests, controversies regarding the exact conditional approach, exact unconditional approach and Bayesian approach. Software support for exact inference for categorical data are available in SAS, Stata, R, SPSS, StatXact and LogXact.

About the Author

Dr Sooriyarachchi is Professor of Statistics at the University of Colombo Sri Lanka. She has written several papers both in international and local journals on methodological developments for categorical data. She has received several awards (Presidential award and University of Colombo Award). She has been a visiting Research Fellow at the University of Reading UK for three years.

Exchangeability

Sander Greenland[1], David Draper[2]
[1]Professor
University of California-Los Angeles, Los Angeles, CA, USA
[2]Professor
University of California-Santa Cruz, Santa Cruz, CA, USA

In probability theory, the random variables $Y_1, \ldots, Y_N$ are said to be *exchangeable* (or *permutable* or *symmetric*) if their joint distribution $F(y_1, \ldots, y_N)$ is a symmetric function; that is, if F is invariant under permutation of its arguments, so that $F(z_1, \ldots, z_N) = F(y_1, \ldots, y_N)$ whenever $z_1, \ldots, z_N$ is a permutation of $y_1, \ldots, y_N$. There is a related epidemiologic usage described in the article on ►*confounding*.

Exchangeable random variables are identically distributed, and iid variables are exchangeable. In many ways, sequences of exchangeable random variables play a role in subjective Bayesian theory analogous to that played by independent identically distributed (iid) sequences in frequentist theory. In particular, the assumption that a sequence of random variables is exchangeable allows the development of inductive statistical procedures for inference from observed to unobserved members of the sequence (Bernardo and Smith 1994; De Finetti 1937, 1974; Draper 1995; Draper et al. 1993; Lindley and Novick 1981).

Now suppose that $Y_1, \ldots, Y_N$ are iid given an unknown parameter θ that indexes their joint distribution. Such variables will not be unconditionally independent when θ is a random variable, but will be exchangeable. Suppose, for example, $Y_1, \ldots, Y_N$ have a joint density. The

unconditional density of $Y_1, \ldots, Y_N$ will be

$$f(y_1, \ldots, y_N) = \int_\theta f(y_1, \ldots, y_N|\theta) dF(\theta)$$
$$= \int \prod_i f(y_i|\theta) dF(\theta).$$

Exchangeability of $Y_1, \ldots, Y_N$ follows from the identity of the marginal densities in the product.

However, given that these densities depend on θ, the integral and product cannot be interchanged, so that $f(y_1, \ldots, y_N) \neq \prod_i f(y_i)$. We thus have that a mixture of iid sequences is an exchangeable sequence, but not iid except in trivial cases.

One consequence of this result is that the usual procedures for generating a sequence $Y_1, \ldots, Y_N$ of iid random variables for inference on an unknown parameter (such as Bernoulli trials of binary data with unknown success probability) generate an exchangeable sequence when the parameter is generated randomly and the sequence is considered unconditionally. From a Bayesian perspective, this means that, when your uncertainty about the parameter is integrated with your uncertainty about the realizations of $Y_1, \ldots, Y_N$, the latter are (for you) exchangeable but dependent even if the realizations are physically independent. This subjective dependence is immediately clear if you consider (say) a sequence of 99 iid (but possibly biased) coin tosses, with Y_i the indicator of heads on toss i. Then, starting from a uniform prior distribution for the chance of heads θ, you should have $\Pr(Y_{99} = 1) = {}^1/_2$ before seeing any toss, but $\Pr(Y_{99} = 1 | Y_i = 1 \text{ for } i = 1, \ldots, 98) = 0.99$ after seeing the first 98 tosses come up heads (Good 1983).

A generalization important for statistical modeling is *partial* or *conditional* exchangeability (De Finetti, 1937, 1974). For example, suppose that the sequence $Y_1, \ldots, Y_N$ is partitioned into disjoint subsequences. Then the sequence is said to be partially exchangeable given the partition if each subsequence can be permuted without changing the joint distribution. For example, if the Y_i represent survival times within a cohort of male stroke patients, then a judgment of unconditional exchangeability of the Y_i would be unreasonable if the patient ages were known, because age is a known predictor of survival time. Nonetheless, one might regard the survival times as partially exchangeable, given age, if no further prognostically relevant partitioning was possible based on the available data.

While exchangeability is weaker than iid, finite subsequences of an infinite exchangeable sequence of Bernoulli (binary) variates have representations as mixtures of iid Bernoulli sequences – a partial converse of the fact that any mixture of iid sequences is an exchangeable sequence. More precisely, suppose that $Y_1, Y_2, \ldots$ is an infinite sequence of exchangeable Bernoulli variates (that is, every finite subsequence of the sequence is exchangeable), and that θ is the limit of $(Y_1 + \cdots + Y_n)/n$ as n goes to infinity. De Finetti [1974, Chapter 11] showed that there exists a distribution function $P(\theta)$ for θ such that, for all n,

$$\Pr(Y_1 = y_1, \ldots, Y_n = y_n) \equiv \Pr(y_1, \ldots, y_n)$$
$$= \int_\theta \theta^s (1-\theta)^{n-s} dP(\theta),$$

where $s = y_1 + \cdots + y_n$. Many Bayesian statisticians find this theorem helpful, because it partially specifies the form of the predictive probability $\Pr(y_1, \ldots, y_n)$ when $Y_1, \ldots, Y_n$ can be modeled as a subsequence of an infinite exchangeable sequence. In this representation, $P(\theta)$ is recognizable as a *prior distribution* for θ, a distribution that may be developed from what is known about θ before the Y_i are observed. As noted in (Freedman 1995), however, the strength of the theorem's conclusion is easy to overstate: it does *not* imply that all binary data must be analyzed using the representation; it merely says that if you judge $Y_1, Y_2, \ldots$ to be an exchangeable sequence, then there is a prior $P(\theta)$ that allows you to use to specify $\Pr(y_1, \ldots, y_n)$ as a mixture of iid variables over that prior.

Finite versions of De Finetti's theorem exist (Diaconis and Freedman 1980). If $Y_1, \ldots, Y_n$ is the start of an exchangeable Bernoulli sequence $Y_1, \ldots, Y_N$ and n/N is small enough, then $\Pr(y_1, \ldots, y_n)$ may be approximately represented by the mixture in the theorem, with the approximation improving as n/N approaches zero. There are further generalizations to exchangeable sequences of polytomous variates, as well as to exchangeable sequences of continuous variates (Diaconis and Freedman 1980). The latter generalization requires a prior distribution on the space of continuous distributions, however, which can be much harder to specify than a prior for a vector of multinomial parameters, and which may lead to intractable computational problems (Draper 1995).

About the Authors

For Dr. Greenland's biography *see* the entry ▶Confounding and Confounder Control.

David Draper is a Professor of Statistics in the Department of Applied Mathematics and Statistics (in the Baskin School of Engineering) at the University of California, Santa Cruz (UCSC). He was President of the International

Society for Bayesian Analysis in 2001. From 2001 to 2007 he served as the Founding Chair of the Applied Mathematics and Statistics Department at UCSC. He is a Fellow of the American Association for the Advancement of Science, the American Statistical Association, the Institute of Mathematical Statistics and the Royal Statistical Society. He is the author or co-author of 92 contributions to the research literature. Since 1993 he has given 63 invited, special invited or plenary talks at major research conferences and leading statistics departments in 21 countries worldwide. He has been an Associate Editor for 6 leading journals (including *Journal of the American Statistical Association* and the *Journal of the Royal Statistical Society*), and has organized or co-organized 6 international research conferences.

Expected Value

Czesław Stępniak
Professor
Maria Curie-Skłodowska University, Lublin, Poland
University of Rzeszów, Rzeszów, Poland

Synonyms

Expectation, First usual moment, Mean value

Genesis

The origin of this notion is closely related with so called *problem of points*. It may be explained by the simplest two-person game based on tossing a coin according the following rules. In each toss, if the coin comes up heads then the player A gets a point; otherwise the point goes to the player B. The first to get 10 points wins 100 Francs. Suppose the game is interrupted in the moment when A reached 8 while B 7 points. How to divide the winnings?

This problem was posed in 17th century by a French man Antoine Gombaud (who named himself Chevalier de Méré, although he was not a nobleman) and was undertaken by Blaise Pascal and Luis de Fermat in a series of letters. Fermat noted that the game would over after four more tosses with possible $2^4 = 16$ equally likely outcomes and the fewer ratio is 11:5 for player A. Thus the player A should receive 68.75 Francs and B 31.25 Francs.

Formal Definition and Equivalent Expressions

Let $X = X(\omega)$ be a random variable defined on a set Ω of outcomes endowed with a family $A=\{A : A \subseteq \Omega\}$ of random events and let $P = P(A)$ be a probability measure on (Ω, A). *Expected value* of the r.v. X [notation: EX] is defined as the Lebesgue's integral of the function $X = X(\omega)$ w.r.t. probability measure P, i.e.

$$EX = \int_{\Omega} X(\omega) dP(\omega).$$

(if such integral exists). The expected value EX may also be expressed in terms of the distribution of X, i.e. by the measure P_X on (R, B), where B is the family of Borel sets on the real line R, defined by $P_X(B) = P(\{\omega : X(\omega) \in B\})$ for $B \in B$. Namely, EX is the Lebesgue's integral of the form

$$EX = \int_{R} x dP_X(x). \tag{1}$$

If $E|X| < \infty$, then Eq. (1) may be expressed as the Riemann–Stielties integral $EX = \int_{-\infty}^{+\infty} x dF(x)$ w.r.t. the cumulative distribution function $F(\alpha) = P(X \le \alpha)$.

Computing Rules

If X is a discrete r.v. taking values x_i with probabilities p_i, $i = 1, 2, \ldots$, then (1) reduces to

$$EX = \sum_i x_i p_i,$$

and if X is a continuous r.v. with density function $f(x)$ then (1) reduces to the Riemann integral

$$EX = \int_{-\infty}^{+\infty} x f(x) dx.$$

Moreover, if X is nonnegative, then

$$EX = \int_0^\infty [1 - F(x)]dx.$$

Caution Expected value may do not exist. Example: Cauchy random variable with density $f(x) = \frac{\lambda}{\pi[\lambda^2+(x-\theta)^2]}$ for $x \in R$.

An attribute of the expected value If $EX = \mu$ then $E(X-\mu)^2 \le E(X-c)^2$ for any $c \in R$ with the strict inequality if $c \neq \mu$.

Moments of a Random Variable It is worth to add that if $X = X(\omega)$ is a random variable and f is a Borel function, i.e. a real function of a real variable such that $\{x : f(x) \le c\} \in \mathcal{B}$ for all $c \in R$ then the composition $f[X(\omega)]$ is also random variable. Special attention is given to random variables of the form $Y(\omega) = f[X(\omega)]$, where f is a polynomial of type $f(x) = x^k$ or $(x-EX)^k$. The expectation of the form EX^k and $E(X-EX)^k$ is called, respectively, the k-th usual and central moment of the initial random variable X. If EX^k (or $E(X-EX)^k$) exists then there exist also all i-th (both usual and central) moments for $i \le k$.

Basic Properties

1. If $X(\omega) = c$ for all $\omega \in \Omega$ then $EX = c$.
2. If X is bounded then EX is finite.
3. If $X_1(\omega) \le X_2(\omega)$ for all $\omega \in \Omega$ then $EX_1 \le EX_2$.
4. $E(\alpha X_1 + \beta X_2) = \alpha EX_1 + \beta EX_2$ for all $\alpha, \beta \in R$.
5. $E\left(\sum_{n=1}^\infty X_n\right) = \sum_{n=1}^\infty EX_n$, providing $\sum E|X_n| < \infty$.
6. $E\left(\prod_{i=1}^n X_i\right) = \prod_{i=1}^n EX_i$, providing $X_1, \ldots, X_n$ are independent
7. $g(EX) \le E(g(X))$ for any convex function g.
8. *Markov's inequality*: $P[f(X) \ge c] \le \frac{E[f(X)]}{c}$ for any nonnegative function g and positive scalar c.
9. *Weak law of large numbers*: For any sequence $\{X_n\}$ of independent identically distributed random variables X_n with finite expectation $EX_n = \mu$ and for any $c > 0$, $\lim_{n\to\infty} P\left(\left|\frac{X_1+\ldots+X_n}{n} - \mu\right| < c\right) = 1$
10. *Strong law of large numbers:* For any sequence $\{X_n\}$ of independent identically distributed random variables X_n with finite expectation $EX_n = \mu$, $P\left(\lim_{n\to\infty} \frac{X_1+\ldots+X_n}{n} = \mu\right) = 1$.

Expected Values of Some Well Known Discrete and Continuous Distributions

1. Zero-one distribution. It corresponds to a random variable X taking only two values: 0 and 1 with corresponding probabilities $P(X = 1) = p$ and $P(X = 0) = 1 - p$, where $0 < p < 1$. In this case $EX = p$.
2. Binomial (or Bernoulli) distribution with parameters n and p, where n is a positive integer while $0 < p < 1$. It corresponds to the sum $X = X_1 + \ldots + X_n$ of n independent zero-one random variables with $P(X = 1) = p$. In this case $P(X = k) = \binom{n}{k} p^k (1-p)^{n-k}$ for $k = 0, 1, \ldots, n$ and $EX = np$.
3. Geometric distribution with parameter p. It corresponds to the time $X = n$ of the first success ($X_n = 1$ while $X_i = 0$ for all $i < n$) in the sequence $\{X_i\}$ of independent zero-one random variables X_i with the same probability $P(X_i = 1)$. In this case $P(X = n) = p(1-p)^{n-1}$ for $n = 1, 2, \ldots$ and $EX = \frac{1}{p}$.
4. Poisson distribution with a positive parameter λ. It corresponds to a discrete random variable X being the limit of the sequence $\{X_i\}$ of Bernoulli distributions with parameters (n_i, p_i) where $\lim_{i\to\infty} n_i = \infty$ and $\lim_{i\to\infty} n_i p_i = \lambda$. Formally $P(X = k) = e^{-\lambda}\frac{\lambda^k}{k!}$ for $k = 0, 1, \ldots$ In this case $EX = \lambda$.
5. Uniform distribution on the interval $< a, b >$. It corresponds to a continuous random variable X with the density function

$$f(x) = \begin{cases} \frac{1}{b-a} & \text{if} \quad a \le x \le b \\ 0 & \text{if} \quad \text{not.} \end{cases}.$$

   In this case $EX = \frac{a+b}{2}$.
6. Exponential distribution with a parameter $\lambda > 0$. It corresponds to a continuous random variable X with density

$$f(x) = \begin{cases} \lambda e^{-\lambda x} & \text{if} \quad x \ge 0 \\ 0 & \text{if} \quad x < 0 \end{cases}.$$

   In this case $EX = \frac{1}{\lambda}$.
7. Normal distribution with parameters $\mu \in R$ and $\sigma^2 > 0$. It corresponds to a continuous random variable X with density

$$f(x) = \frac{1}{\sigma\sqrt{2\pi}} e^{-\frac{(x-\mu)^2}{2\sigma^2}} \quad \text{for all } x \in R.$$

   In this case $EX = \mu$.

Experimental Design: An Introduction

Klaus Hinkelmann
Professor Emeritus
Virginia Polytechnic Institute and State University, Blacksburg, VA, USA

Experimental sciences and industrial research depend on data to draw inferences and make recommendations. Data are obtained in essentially two ways: from observational studies or from experimental; i.e., interventional, studies. The distinction between these two types of studies is important, because only experimental studies can lead to causal inferences. In order to ensure that proper inferences can be drawn, any such experiment has to be planned carefully subject to certain principles of *design of experiments*.

Steps of Designed Investigations

Any investigation begins with the formulation of a question or research hypothesis in the context of a particular subject matter area, such as agriculture, medicine, industry, etc. For a given situation the researcher has to identify and characterize the experimental units to be used in the experiment. The experimental units are then subjected to different treatments, which are the objective of the study and about which statistical and scientific inferences should be drawn. These treatments are employed in a suitable error-control design adhering to the three important principles of experimental design as exposited by R.A. Fisher (1926, 1935): ▶Randomization, replication, and local control (blocking). Randomization of the treatment assignment is performed over the entire set or suitable subsets (blocks) of the experimental units in order to eliminate any bias. Replication of the treatments is essential to assess the experimental error that is needed to formally draw any statistical inference, such as testing of hypotheses or estimating confidence intervals in order to assess the efficacy of the treatments. The randomization procedure is also used to derive linear models on which the statistical analysis of the observations is based, usually some form of ▶analysis of variance (see Hinkelmann and Kempthorne 2008). Based on the analysis of the data, the results need to be interpreted in the context of the originally posed research hypothesis. This may lead to further investigations of new hypotheses in subsequent experiments.

Components of Experimental Design

Each experimental design consists of three components: treatment design, error-control design, and sampling or observational design. The *treatment design* determines the number and types of treatments to be included in the experiment. The treatments may be quantitative or qualitative. They may have a factorial structure in that each treatment is determined by a combination of different levels of two or more treatment factors. The most common factorial structure has each treatment occurring at two levels, especially for screening experiments. Even that may lead to a number of treatments too large for practical purposes. In that case a fractional factorial may have to be considered, where only a suitable subset of all level combinations is included. Once the appropriate treatment design has been determined, one must consider how to assign the treatments to the available experimental units; i.e., one must choose a suitable *error-control design*. For example, if the experimental units are essentially uniform, then a completely randomized design is appropriate, which means that each treatment is randomly assigned to, say, r experimental units, where r is the number of replications for each treatment. If, however, the experimental units are characterized by different extraneous factors, such as locations in an agricultural experiment or age and gender in a psychological experiment or type of raw material and type of machine in an industrial setting, then some form of block design has to be used. Each combination of different "levels" of the extraneous factors forms a set of essentially uniform experimental units to which the treatments are then randomly assigned. The most common block design is the randomized complete block design, where each block has as many experimental units as there are treatments, and each treatment is randomly assigned to one unit in each block. Other types of block designs are ▶incomplete block designs, where not every treatment can occur in each block. This poses a number of combinatorial problems. Still other error-control designs

employ blocking in two directions, such as subjects and periods in the form of a Latin square in a psychological experiment. The aim of blocking is to generate sets with uniform experimental units which will result in reduction of error and, hence, in a more efficient design. The third component of an experimental design is the *sampling* or *observational design*. Its function is to determine what the observational units are. In most experiments only one observation is obtained from each experimental unit, in which case experimental and observational units are identical. On other occasions several observations are obtained from each experimental unit, for example several items from an industrial production lot. This is referred to as subsampling. In this case experimental and observational units are not identical. In connection with the error-control design this then allows the separate estimation of experimental and observational (measurement) errors.

Modeling Observations

In most cases it is clear what the observations should be, but in other cases this may need careful consideration in order to arrive at a useful type of measurement which will be most meaningful in the context of the formulated research hypothesis. Following the choice of measurement, a model for the observations can, in general terms, be expressed as follows:

$$\text{Response} = f(\text{explanatory variables}) + \text{error},$$

where f is an unknown function and the explanatory variables refer to treatment and blocking factors as employed in the treatment and error-control designs, respectively. More specifically, however, using the notion of experimental unit-treatment additivity and randomization theory one can derive a linear model of the form

$$\text{Response} = \text{overall mean} + \text{block effect}(s) + \text{treatment effect} + \text{error},$$

where the distributional properties of the error term are determined essentially by the randomization process (see Hinkelmann and Kempthorne 2008). This model may be enlarged, where appropriate, by including certain block-treatment interaction terms depending on the blocking structure (see Cox 1984).

Analysis of Data

The analysis of the observations from a designed experiment is based on the model given above using analysis of variance techniques. The analysis of variance table is used to estimate the error variance component (including experimental and observational error) or, in the case of subsampling, the experimental and observational error variance components. The F-test based on the ratio (treatment mean square/error mean square) or, in case of subsampling, (treatment mean square/experimental error mean square) serve as approximation to the randomization test that there are no differences among the treatment effects. Other tests may have to be performed to more fully investigate differences among treatments by considering specific comparisons among the treatments or treatment effect trends or interactions between treatment factors or block × treatment interactions. The possibilities are being dictated essentially by the treatment and error-control designs employed and the research hypothesis postulated at the beginning of the experiment.

About the Author

Dr. Klaus Hinkelmann is Professor Emeritus of Statistics, Virginia Polytechnic Institute and State University (Virginia Tech), where he has served as Director of Graduate Studies (1976–1982) and Head of Department (1982–1993). He served as Associate Editor of *Biometrics* (1975–1984) and the *Biometrical Journal* (1995–1999), Editor of *Biometrics* (1990–1993) and the *Current Index to Statistics* (1995–1999), Book Review Editor of *Journal of Statistical Planning and Inference* (1995–1997), Member of Editorial Board *Selected Tables in Mathematical Statistics* (1974–1990). He was President of the Virginia Chapter of the American Statistical Association (1983–1984), Vice-President of Mu Sigma Rho (American Statistical Honor Society) (1994–1996), Member, Council of the International Biometric Society (1982–1985, 1988–1989). He was elected Fellow of the American Statistical Association (1983), Member of the International Statistical Institute (1985), Fellow of the American Association for the Advancement of Science (1987). Dr. Hinkelmann is the author/co-author of more than 50 articles in statistical and subject-matter journals. He is the author/editor of three books. With Oscar Kempthorne as co-author he wrote *Design and Analysis of Experiments, Vol.1: Introduction to Experimental Design* (1994, 2nd edition 2008) and *Vol.2: Advanced Experimental Design* (John Wiley and Sons 2005).

Expert Systems

Ali S. Hadi
Professor and Vice Provost
The American University in Cairo, Cairo, Egypt
Emeritus Professor
Cornell University, Ithaca, NY, USA

The area of artificial intelligence (AI) is concerned with the design and implementation of computer systems that exhibit the abilities associated with the human intelligence (e.g., the ability to memorize, learn, think, etc.). The AI area has seen a great surge of research and rapid development during the past three or so decades; see, e.g., Luger (2009) and the references therein. As a result many branches of AI (e.g., automatic game playing, automated reasoning and theorem proving, robotics, artificial vision, natural language processing (see ►Statistical Natural Language Processing), pattern recognition (see ►Pattern Recognition, Aspects of and ►Statistical Pattern Recognition Principles), expert systems, etc.) have evolved. Expert systems are one of the successful branches of AI and most AI branches include an expert system component in them.

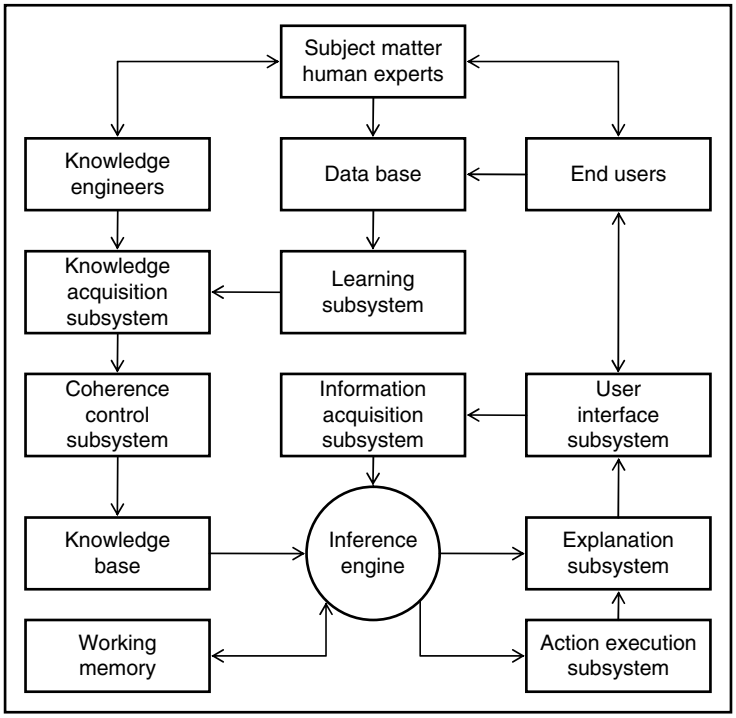
Several definitions of expert systems have evolved over time (see, e.g., Stevens 1984; Durkin, 1994; Castillo et al. 1997). These definitions, however, can be summarized as follows: An expert system is a computer system (hardware and software) that emulates human experts in a given area of specialization. As such, an expert system attempts to either completely replace the human experts (e.g., Automated Teller Machines), help the human experts become even better experts by providing them with fast answers to complex problems (e.g., Medical Expert Systems), or provide decision makers quick answers that enables them to make wise decisions in the face of uncertainty (e.g., Automating the Underwriting of Insurance Applications; Aggour and Cheetham, 2005).

Successful expert systems are usually domain specific. One of the earliest expert systems is DENDRAL, developed in the late 1960s (Shortliffe, 1976) to infer the structure of organic molecules from information about their chemical characteristics. MYCIN is another example of domain specific (medicine) expert systems. It was developed in the 1970s to diagnose and prescribe treatment for spinal meningitis and bacterial infections of the blood (Buchanan and Shortliffe, 1984). Today expert systems have varied applications in many fields such as medicine, education, business, design, and science (Waterman, 1985; Feigenbaum et al., 1988; Durkin, 1994). Dozens of commercial software packages with easy interfaces are now available which are used to develop expert systems in these fields of applications. Several books and papers have been written about the subject; see, e.g., Neapolitan (1990), Ignizio (1991), Jensen (1996), Schneider et al. (1996), Castillo et al. (1997), Jackson (1999), Pearl (1988, 2009), Russell and Norvig (2003), Giarratano and Riley (2005), Cowell et al. (2007), and Darwiche (2009).

The development of an effective and successful expert system requires team-work and collaboration of humans from different fields. First, domain experts (e.g., doctors, lawyers, business managers, etc.) provide knowledge about the specific domain. For example, medical doctors can provide information about the relationships among symptoms and diseases. Second, *knowledge engineers* translate the knowledge provided by the subject-matter specialists into a language that the expert system can understand. Third, during the design, development, and implementation of an expert system, it is important that the needs of the end-users are kept in mind and that their input be taken into consideration throughout the process.

The information provided by the domain experts is stored in one of the components of expert systems known as the *Knowledge Base*. A knowledge base can consist of two types of knowledge: deterministic and stochastic. Deterministic knowledge typically consists of a set of crisp *rules*. The simplest rule takes the form "*If A Then B*," where *A* is a logical expression, known as the *premise* or *antecedent* of the rule, which is related to input variable(s), and *B* is a logical expression, known as the *conclusion* or *consequent* of the rule, which is related to an output variable. An example of a rule is "*If* PassWord = Correct *Then* Access = Permitted," where the input variable PassWord can take one of two values (Correct or Incorrect) and Access is an output variable that can take one of two or more values (e.g., Permitted or Denied).

Stochastic knowledge usually involves some elements of uncertainty. For example, the relationships among symptoms and diseases are not one-to-one. A disease can cause many symptoms and the same symptom can be caused by a number of different diseases. It is therefore necessary to develop some means for dealing with the



Expert Systems. Fig. 1 A typical architecture of an expert system

uncertainty and imprecision in the knowledge we receive. Expert systems that involve only deterministic knowledge are referred to as *deterministic* or *rule-based* expert systems. Two types of expert systems that can deal with stochastic or imprecise knowledge are *fuzzy* expert systems and *probabilistic* expert systems.

Fuzzy systems, first introduced by Zadeh (1965), are based on fuzzy logic instead of Boolean logic. The knowledge base of a fuzzy expert system consists of a set of *fuzzy rules* and a set of *membership functions* defined on the input variables. Fuzzy rules are similar in form to the crisp rules except that the premise of the fuzzy rule describes the degree of truth for the rule and the membership functions are applied to their actual values to determine the degree of truth for each rules conclusion. The edited book by Siler and Buckley (2005) is a good source of many papers and references on fuzzy expert systems.

In probabilistic expert system, the uncertainty is measured in terms of probabilities. Thus, the knowledge base of a probabilistic expert system consists of the joint probability distribution function (pdf) of all variables. This joint pdf, however, can be specified by a set of conditional probability distributions, one for each variable. Each conditional pdf gives the probability for each value of the variable given the values of a set of associated variables known as its *parents*. The specifications of these conditional distributions can be either given by the domain experts and/or learned from the available data.

To emulate the performance of the human experts in a given domain of application, expert systems consist of several components and sub components. A typical architecture of an expert system is depicted in Fig. 1, which is adapted from Castillo et al. (1997), and explained below. Knowledge can be provided directly by the subject-matter experts, but it can also be learned from historical data. The data, when available, are stored in a *data base* and the knowledge learned from data is done by the *learning subsystem*. The flow of knowledge from either source is controlled by the *knowledge acquisition* subsystem. Before the knowledge is added to the *knowledge base*, it must be checked for consistency by the *coherence control* subsystem to prevent incoherent knowledge from reaching the knowledge base.

Through the *User Interface* subsystem, *Information Acquisition* subsystem collects information or inquiries from the end-users. This information together with the knowledge in the knowledge base are used by the *Inference Engine* to draw conclusions. The inference engine and knowledge base are then the most important components of an expert system.

The inference engine is the brain of an expert system. It contains the decision-making logic of the expert system which allows the expert system to draw conclusions and provide expert answers (e.g., diagnose a disease). In deterministic expert systems, the inference is made based on *Boolean* or classic logic. In advanced expert systems, the inference engine can also enhance the knowledge base by adding a set of *concluded* rules using various inference strategies such as *Modus Ponens*, *Modus Tollens*, *Rule Chaining*, etc.

In fuzzy expert systems, the inference is made based on *fuzzy* logic; see, e.g., Schneider et al. (1996). Given realizations of a specified set of variables, the inference engine of probabilistic expert systems computes the conditional probabilities for each values of the other variables given the realization of specified set of variables. This is known as the *propagation* of uncertainty.

In the process of drawing conclusions, the inference engine may need to store temporary information, which is stored in the *Working Memory*. Finally, if actions are needed, they are specified by the inference engine through the *Action Execution* subsystem and the actions and conclusions are explained to the users through the *Explanation* subsystem.

Explaining Paradoxes in Nonparametric Statistics

Anna E. Bargagliotti[1], Donald G. Saari[2]
[1]University of Memphis, Memphis, TN, USA
[2]Distinguished Professor, Director
University of California-Irvine, Irvine, CA, USA

Introduction

Nonparametric statistical methods based on ranks are commonly used to test for differences among alternatives and to extract overall rankings. But depending on the method used to analyze the ranked data, inconsistencies can occur and different conclusions can be reached. Recent advances (Bargagliotti and Orrison 2009; Bargagliotti and Saari 2009; Haunsperger and Saari 1991; Haunsperger 1992; Saari 2008) prove that all possible inconsistencies among

outcomes for these methods are caused by hidden symmetries within the data.

To analyze how methods utilize and interpret different data configurations, decompose a nonparametric method into a two step process. The first step is where the method uses a uniquely defined procedure to convert ranked data into an overall ranking. The second step uses a test statistic (based on the procedure ranked outcome) to determine whether there are significant differences among alternatives. Differences and even conflicting results can occur at each step when analyzing the same ranked data set. These peculiarities can complicate the choice of an appropriate method in a given situation.

To demonstrate, consider the general setting in which ranked performance data are collected on a set of three alternatives where larger values indicate a better performance:

A	B	C
15	14	13
10	12	11
8	7	9
6	5	4
1	2	3

(1)

With the Kruskal–Wallis procedure (Kruskal and Wallis 1952), which computes the rank-sum for each alternative, these data define the tied ranking $A \sim B \sim C$. In contrast, Bhapkar's V procedure (Bhapkar 1961) analyzes ranked data by considering all possible 3-tuples of the form (a_i, b_j, c_m) for $i, j, m = 1, \ldots, 5$. For each 3-tuple, the V procedure assigns a point to the alternative with the highest rank; the tally for each alternative is the sum of the assigned points and the V procedure ranking is based on these tallies. With the Eq. 1 data, the V procedure yields the $A > B > C$ ranking, which conflicts with the Krusal–Wallis ranking.

A still different outcome arises with pairwise comparison procedures such as the Mann–Whitney (Whitney 1947) or Wilcoxon (Wilcoxon 1945) (see ▶Wilcoxon–Mann–Whitney Test). These rules also are based on all possible tuples, but now, for a specified pair, an alternative receives a point for each tuple where it is ranked above its opponent. The Eq. 1 data lead to the $A > B, B > C, C > A$ cyclic rankings, which conflict with those from the earlier approaches.

In this article, we show that subtle symmetry structures hidden within the data explain why different outcomes can be obtained by different nonparametric ranking procedures for the same data set. Namely, we show how and why different nonparametric methods interpret data structures differently and why this causes the inconsistencies experienced by different methods.

Same Data, Different Methods, Different Outcomes

Two forms of ranked data can be constructed: full ranked data and block ranked data. An entry in a full ranked data set describes the datum's ranking relative to all others in the set; an entry in a block ranked data set describes the datum's ranking relative to all others within the block. For example, Eq. 2 illustrates a full ranked data set with the overall ordering of all the entries:

A	B	C
1	2	3
5	6	4
9	8	7

(2)

while Eq. 3 ranks the entries within each row, so a row is considered a block:

A	B	C
1	2	3
2	3	1
3	2	1

(3)

Standard methods of analysis for the full ranked data set include, but are not limited to, the Kruskal–Wallis, Mann–Whitney, and Bhapkar's V tests. When analyzing the block ranked data, the Friedman (Friedman 1937) or Anderson tests (Anderson 1959) are commonly employed. Each of these nonparametric methods is susceptible to ranking and statistical paradoxes. We explain how certain data configurations cause either ranking or statistical significance paradoxes.

For the purpose of clarity, our examples and analysis emphasize the three-sample setting with the three alternatives A, B, and C. All symmetries for the three samples thus come from S_3 – the space of all ways to permute these alternatives. Two natural symmetries, the $\mathbb{Z}_3$ orbit and the $\mathbb{Z}_2$ orbit of a triplet, are what cause the differences among nonparametric procedures.

The set of permuted rankings defined by the $\mathbb{Z}_3$ orbit of the ranking $A > B > C$ is:

$$\{A > B > C, \quad B > C > A, \quad C > A > B\}. \tag{4}$$

while the other *"rotational symmetry"* set is generated with the ranking $A \succ C \succ B$:

$$\{A \succ C \succ B, \quad C \succ B \succ A, \quad B \succ A \succ C\}. \tag{5}$$

Either configuration is constructed by moving the top ranked alternative in one triplet to be bottom ranked in the next triplet. Thus each alternative is in first, second, and third place precisely once over the triplet of rankings.

Data sets that feature one of these $\mathbb{Z}_3$ structures (but not the $\mathbb{Z}_2$ structure described below) require combining three rotational parts:

A	B	C
27	26	25
22	24	23
20	19	21

,

A	B	C
16	18	17
14	13	15
12	11	10

,

A	B	C
8	7	9
6	5	4
1	3	2

(6)

The first array arranges the row data in the expected $A \succ B \succ C$, $B \succ C \succ A$, $C \succ A \succ B$ order of a $\mathbb{Z}_3$ orbit. Notice how the top defining row of the next two sets also manifest this cycle; e.g., the top rows also define the $A \succ B \succ C$, $B \succ C \succ A$, $C \succ A \succ B$ order. The rest of each block array continues the $\mathbb{Z}_3$ cyclic structure. Thus each set of three rows reflects the $\mathbb{Z}_3$ symmetry, and the three sets are connected with a $\mathbb{Z}_3$ symmetry.

The importance of the rotational symmetry is captured by Theorem 1.

Theorem 1 *Bargagliotti and Saari (2009) Let A, B, C represent the three alternatives. For a data component that introduces a rotational symmetry (Eq. 4 or 5), all three-sample procedures yield a completely tied outcome. The pairwise procedure outcomes for such a component, however, form a cycle where, for each pair, the tally of tuples is the same. Such a component is strictly responsible for all non-transitive paired comparison behavior.*

To illustrate with the Eq. 6 pure rotational data, the Kruskal–Wallis and V procedures have the ranking $A \sim B \sim C$, but the paired comparisons yield the $A \succ B$, $B \succ C$, $C \succ A$ cycle. Components within a data set yielding these rotational configurations are totally responsible for all possible paired comparison paradoxes (for methods such as the Mann–Whitney and the Wilcoxon) including cyclic effects and all possible disagreements with the three-sample Kruskal–Wallis test. All three-sample procedures essentially ignore rotation configurations present in data and consider the alternatives as tied.

The *"inversion symmetry"* of the $\mathbb{Z}_2$ orbit consists of the ranking of a triplet and its inverted version. As an illustration, the $\mathbb{Z}_2$ orbit of the ranking $A \succ B \succ C$ is the set:

$$\{A \succ B \succ C, \; C \succ B \succ A\} \tag{7}$$

The two other sets generated by the $\mathbb{Z}_2$ orbit are

$$\{A \succ C \succ B, \; B \succ C \succ A\}, \quad \{B \succ A \succ C, \; C \succ A \succ B\} \tag{8}$$

An example capturing the inversion structure with no rotational symmetry is:

A	B	C
12	11	10
7	9	8
6	4	5
1	2	3

(9)

In this example, the rows have opposing rankings, while the first and fourth rows and the second and third rows reverse each other. (See Bargagliotti and Saari (2009) for examples that do not have the same number of rows with one ranking as with its reversal.)

The following theorem captures the importance of the inversion symmetry for ranking procedures.

Theorem 2 *Bargagliotti and Saari (2009) Consider the three alternatives A, B, C. For a data component that creates a inversion symmetry (e.g., Eqs. 7, 8), the Kruskal–Wallis and the pairwise procedures yield a tied outcome, but the ranking for all other three-sample procedures is not a tie. All possible differences among three-sample procedures are caused by this inversion symmetry.*

To illustrate with the pure inversion data in Eq. (9), the Kruskal–Wallis and pairwise procedures have the $A \sim B \sim C$ ranking, while the V procedure outputs $A \sim B \succ C$. For any data set, components causing an inversion symmetry are treated as a tie by the Kruskal–Wallis and paired comparison methods, but they influence, and can even change the rankings, of all other three-sample procedures. Indeed, the rotational and inversion symmetries are responsible for all possible differences in this class of nonparametric procedures. Thus components causing rotational symmetries create differences between paired comparison and three-sample approaches, while inversion symmetries cause all possible differences among three-sample procedures; only the Kruskal–Wallis test is immune to these symmetries Bargagliotti and Saari (2009).

These symmetries also cause significant differences when testing among alternatives with block ranked data; we illustrate this behavior with the Friedman and the Anderson tests. The Friedman test statistics is given by

$$Q = \frac{n\sum_{j=1}^{k}(\bar{r}_{\cdot j} - \bar{r})^2}{\frac{1}{n(k-1)}\sum_{i=1}^{n}\sum_{j=1}^{k}(r_{ij} - \bar{r})^2} \tag{10}$$

where n is the number of blocks, k is the number of alternatives, $\bar{r}_{\cdot j}$ is the mean of the rankings for alternative j, r_{ij} is the *ith* ranking for alternative j, and $\bar{r}$ is the grand mean of the rankings. The Anderson statistic is defined as

$$A = \frac{k-1}{n}\sum_{i=1}^{n}\sum_{j=1}^{k}\left(n_{ij} - \frac{n}{k}\right)^2 \tag{11}$$

where n_{ij} is the number of times alternative j was assigned rank i by the respondents, n is the number of blocks, and k is the number of alternatives. Both statistics follow a χ^2 distribution with $k-1$ and $(k-1)^2$ degrees of freedom respectively.

As both tests are over three-samples, the above theorems assert that all differences are displayed by the inversion, $\mathbb{Z}_2$ symmetries that are embedded within data sets. As this suggests examining difference over a pure inversion block set, consider the following data set where the number of rows with a given ranking equals the number of rows with the inverted ranking.

Ranking	*Number of Voters*
$A \succ B \succ C$	12
$C \succ B \succ A$	12
$B \succ A \succ C$	10
$C \succ A \succ B$	10
$A \succ C \succ B$	3
$B \succ C \succ A$	3

(12)

The effects of this inversion symmetry on tests is reflected by the following statement:

Example 1 *For the data set in Eq. 12, the Anderson test statistic, A, equals* 10.72 *resulting in a p-value of* .029 *while the Friedman statistic, Q, equals* 0 *with associated p-value of* 1. *At the* .05 *significance level, the Anderson test considers the three alternatives significantly different but the Friedman test does not.*

It is the inversion symmetry structures embedded within data that can cause these tests to yield conflicting outcomes. This is because the Friedman test is based on the average ranks of each alternative while the Anderson statistic is more sensitive to inversion symmetry structures as its outcome is based on how often each alternative is in first, second, and third place. The tests disagree when the block data reports similar means but vastly different marginal distributions for each alternative caused by the inversion symmetries. In Eq. 3, each alternative receives an average weighted score of 2 overall but the data has the following distribution:

Alternative	First Place	Second Place	Third Place
A	15	13	22
B	20	24	6
C	15	13	22

(13)

As this table displays, although the average score for each alternative is the same, the distribution of rankings (caused by the inversion symmetry) is quite different. With this relatively small data set of 50 observations, the Anderson test "picks up" on this difference in distribution while the Friedman test does not (see Bargagliotti and Orrison (2009) for a mathematical characterization of these types of paradoxes).

These examples illustrate how different nonparametric methods interpret the specific data configurations. Different tests and procedures emphasize or deemphasize certain symmetry configurations in the data, which can lead to conflicting outcomes. But by decomposing the data space in terms of the relevant symmetry configurations, it becomes possible to determine how different nonparametric methods interpret specific sets of data (see Bargagliotti and Saari (2009) for the full data decomposition and Marden (1995) and Bargagliotti and Orrison (2009) for the block data decomposition). Depending on the situation, certain methods may be more desirable to use than others. For instance, if a certain data structure that is not viewed as being important influences the outcomes of a specified method, then the method may not be an appropriate choice. Conversely, if a method ignores a type of data structure that is accepted as being valuable while another method does not, then this information provides support for adopting the second method.

Conclusion

Although nonparametric statistical methods based on ranks are commonly used to test for differences among alternatives and to extract overall rankings, different methods can lead to different conclusions. These paradoxes and inconsistencies can occur at both the ranking procedure

step or the test statistic step; they are based on how the methods ignore, or react, to certain data structures. For three alternatives, these structures are completely captured by the rotational and inversion symmetries (Bargagliotti and Saari 2009; Saari 2008).

By understanding what types of data cause statistical methods to have different outcomes, we have better understanding of how different methods work. This provides insight about which nonparametric method should be applied in a given situation and offers guidelines for the construction of new methods that utilize desired data structures.

About the Authors

Dr. Bargagliotti is an Assistant Professor of Mathematics and Statistics at the University of Memphis. Since finishing her doctorate in 2007, she has published several articles related to nonparametric statistics as well as mathematics and statistics education. In addition, she has received several education related grants as PI, co-PI, or Senior Personnel totaling in over 6 million in external funding from the U.S. Department of Education, Tennessee Department of Education, and the National Science Foundation.

Professor Saari was elected to the United States National Academy of Sciences (2001). He was named a Fellow of the American Academy of Arts and Sciences (2004). He holds four honorary doctorates. Professor Saari was awarded the Lester R. Ford Award (1985), Chauvenet Prize (1995) and Allendoerfer Award (1999). He holds the Pacific Institute for the Mathematical Sciences Distinguished Chair at the University of Victoria in British Columbia, Canada. He has published 11 books and about 180 papers on topics ranging from dynamical systems, celestial mechanics, mathematical economics, decision analysis (in engineering and elsewhere) and voting theory. In 2009, Professor Saari was elected to the Finnish Academy of Science and Letters.

Exploratory Data Analysis

Kate Smith-Miles
Professor, Head
Monash University, Melbourne, VIC, Australia

Exploratory data analysis (EDA) is a term first utilized by John Tukey (1977), and is intended to contrast with the more traditional statistical approach to data analysis that starts with hypothesis testing and model building. Instead of using confirmatory data analysis (CDA) methods to verify or refute suspected hypotheses, Tukey (1977) advocated the use of basic descriptive statistics and visualization methods to generate information that would lead to the development of hypotheses to test. The objectives of EDA (see Velleman and Hoaglin 1981) are therefore to provide statistical summaries of the data as a pre-processing step before building a model or testing hypotheses. The EDA phase enables new hypotheses to be suggested about the causes of the relationships in the data, and provides an opportunity to determine whether the assumption that various models rely upon are valid for the particular dataset. It provides us with a very rapid feel for the data: the shape of its distributions, the presence of ►outliers (which may represent errors in the data which need to be corrected prior to hypothesis testing and model building, or may be accurate exceptions), and the measures of central tendency and spread that are so critical for understanding the character of the data.

The most common methods employed in EDA are the five-number summaries of the data, consisting of the minimum and maximum value of each variable, the median,

Exploratory Data Analysis. Table 1 Basic graphical methods of Exploratory Data Analysis

Box Plot (Box-and-Whiskers plot)	Graphical display of five number summaries of data, showing quartiles, as well as minimum and maximum values. The graphical representation shows the distribution as well as existence of outliers.
Stem Plot (Stem-and-leaf display)	Graphical display showing the distribution of the data created by sorting the data, and then using the leading digits from each data value as the "stems" and the subsequent digits as the "leaves." A vertical line separates the leaves from each stem. The digits to the right of the vertical line each represent one observation. The stems should be selected so that they create evenly distributed "bins" for the resulting histogram.
Bubble Charts	Graphical display of showing colored bubbles of different sizes in a 2-dimensional space. A bubble chart is therefore able to represent four variables simultaneously, with two variables represented by the *x* and *y* axes, one (nominal) variable represented by the color of a bubble, and one (ordinal) variable represented by the size of the bubble.
Radar/Spider Plots	Graphical display of multivariate data with each variable represented as an axis stemming from a central origin at an angle given by $360/n$ for n variables ($n \geq 3$). A multivariate data point is usually represented in a unique color and shown as a "spider web" woven through the relevant points of each axis.
Scatterplot matrices	Graphical display of multivariate data with the cell in row *i* and column *j* of the matrix containing a scatterplot of variable *i* versus variable *j*.

and the first and third quartiles, often represented as a box-plot (see ►Summarizing Data with Boxplots). Other plots of the data are also commonly employed, such as histograms, scatter plots, stem-and-leaf plots, all designed to explore the relationships that might exist in the data, and the distributions of the variables, including the presence of outliers. A number of graphical EDA methods are summarized in Table 1.

In addition to graphing of variables, simple statistical measures such as the correlations between variables, as well as multi-way frequency tables are often constructed to explore the dependence between variables and explore possible causal effects. Tukey (1977) proposed a number of other useful measures to characterize a data sample, including the median polish (see Emerson and Hoaglin, 1983) which sweeps out row and column medians from a two-way table to expose each datum composed of a common median plus individual row and column effects. Tukey (1977) also proposed methods for estimating the linear relationships in the data that are robust in the presence of ►outliers by fitting regression lines through the median points of three bins for example, as well as methods for smoothing noisy time series to expose the underlying trends. These methods aim to reveal the true nature of the underlying data, counteracting the effect of outliers, and therefore providing a more robust and accurate picture of the data prior to model building and hypothesis testing.

Beyond the basic EDA methods advocated by Tukey (1977), which pre-dated the current era of powerful computational methods, in recent years a greater arsenal of EDA methods have become available to assist with the exploration of a dataset and to reveal the relationships that may lead to a more successful model development phase. These methods include cluster analysis (Hair 2006), ►multidimensional scaling (Borg and Groenen 2005), and methods such as self-organizing feature maps (Kohonen 1988; Deboeck and Kohonen 1998) that reduce high dimensional data to low dimensional maps of the most prominent features.

The approach that Tukey proposed in 1977 seems commonsense nowadays – before building a model or testing hypotheses, take the time to understand the data, to verify its accuracy, and to explore it with a view to generating the right questions to ask a model. At the time though, it was a significant departure from the prevailing statistical practices of confirmatory data analysis. These days, it is a philosophy that is underscored in more recent developments in ►data mining (Maimon and Rokach 2005), where the importance of EDA as a pre-processing steps is seen as critical to avoid the "garbage in – garbage out" consequences of blindly developing models (see Pyle 1999).

About the Author

Kate Smith-Miles is a Professor and Head of the School of Mathematical Sciences at Monash University in Australia.

Prior to commencing this role in January 2009, she held a Chair in Engineering at Deakin University (where she was Head of the School of Engineering and Information Technology from 2006–2008, and a Chair in Information Technology at Monash University, where she worked from 1996–2006). She has published 2 books on neural networks and data mining applications, and over 200 refereed journal and international conference papers in the areas of neural networks, combinatorial optimization, intelligent systems and data mining. She has been a member of the organizing committee for over 50 international data mining and neural network conferences, including several as chair. Professor Smith-Miles was Chair of the IEEE Technical Committee on Data Mining (2007–2008).

Exponential and Holt-Winters Smoothing

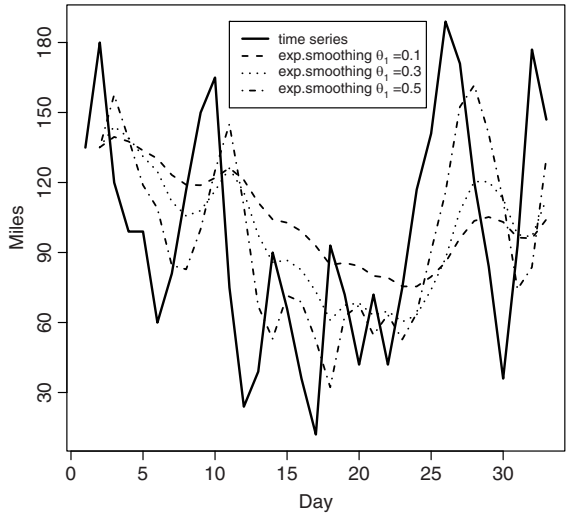
Roland Fried[1], Ann Cathrice George[2]
[1]Professor
TU Dortmund University, Dortmund, Germany
[2]TU Dortmund University, Dortmund, Germany

Exponential smoothing techniques are simple tools for smoothing and forecasting a time series (that is, a sequence of measurements of a variable observed at equidistant points in time). Smoothing a time series aims at eliminating the irrelevant noise and extracting the general path followed by the series. Forecasting means prediction of future values of the time series. Exponential smoothing techniques apply recursive computing schemes, which update the previous forecasts with each new, incoming observation. They can be applied online since they only use past observations which are already available at the corresponding point in time. Although exponential smoothing techniques are sometimes regarded as naive prediction methods, they are often used in practice because of their good performance, as illustrated e.g. in Chapter 4 of Makridakis et al. (1998). We speak of exponential smoothing techniques in plural because different variants exist which have been designed for different scenarios.

Suppose we observe a variable y at equidistant points in time, which are denoted by $t \in \mathbb{N}$. The sequence of measurements of y is called a time series and denoted by $(y_t : t \in \mathbb{N})$. *Simple exponential smoothing* computes the smoothed value $\tilde{y}_t$ at time t according to the following recursive scheme:

$$\tilde{y}_t = \alpha y_t + (1-\alpha)\tilde{y}_{t-1}, \qquad (1)$$

where $\alpha \in (0,1)$ is a *smoothing parameter*. The smaller we choose the value of α, the less weight is given to the most recent observation and the more weight is given to the smoothed value $\tilde{y}_{t-1}$ at the previous time $t-1$. As a



Exponential and Holt-Winters Smoothing. Fig. 1 Daily sea miles covered by Columbus on his first passage to America in 1492 and outputs of simple exponential smoothing with different smoothing parameters

consequence, the series $(\tilde{y}_t : t \in \mathbb{N})$ will be smoother. This is illustrated in Fig. 1, which depicts the number of sea miles covered by Columbus on each day of his first passage to America, as well as the results of exponential smoothing for several values of the smoothing parameter $\alpha \in \{0.1, 0.3, 0.5\}$. Obviously, the smaller we choose the weight α of the most recent observation, the less variable (smoother) is the resulting sequence of smoothed values.

Recursion (1) needs a starting value $\tilde{y}_k$, which can be obtained for instance as the average of the first k observations $y_1, \ldots, y_k$, where $k \geq 1$ is the length of a period used for initialization. Recursion (1) is run for the times $t = k+1, \ldots$ thereafter.

Successive replacement of $\tilde{y}_{t-1}$ by $\alpha y_{t-1} + (1-\alpha)\tilde{y}_{t-2}$, of $\tilde{y}_{t-2}$ by $\alpha y_{t-2} + (1-\alpha)\tilde{y}_{t-3}$, etc., in (1) allows to express $\tilde{y}_t$ as a weighted average of the previous observations $y_{t-1}, \ldots, y_{k+1}$ and the starting value $\tilde{y}_k$:

$$\tilde{y}_t = \alpha y_t + \alpha(1-\alpha) y_{t-1} + \ldots + \alpha(1-\alpha)^{t-k-1} y_{k+1} + (1-\alpha)^{t-k} \tilde{y}_k \,. \tag{2}$$

Note that the weights $\alpha, \alpha(1-\alpha), \ldots, \alpha(1-\alpha)^{t-k-1}, (1-\alpha)^{t-k}$ sum to 1. Equation 2 shows that the weight of the preceding observation y_{t-h} is $\alpha(1-\alpha)^h$ and thus decreases geometrically in the time lag h, which stands in the exponent. This explains the name exponential smoothing.

Simple exponential smoothing can be justified by the assumption that the mean level of the time series is locally almost constant at neighboring points in time. Applying weighted least squares for estimation of the level at time t from the observations y_{t-h}, $h = 0, 1, \ldots$, available at time t (and the starting value) with geometrically decreasing weights $\alpha(1-\alpha)^h$ leads to the above Eqns. 1 and 2. The assumption of an almost constant level also explains how to use recursion (1) to predict future values $y_{t+1}, \ldots$. The h-step ahead forecast $\hat{y}_{t+h|t}$ of y_{t+h} from the observations up to time t, which can be derived from simple exponential smoothing, equals the smoothed value at time t,

$$\hat{y}_{t+h|t} = \tilde{y}_t, \qquad h = 1, 2, \ldots \,. \tag{3}$$

This simple prediction does not depend on the forecast horizon h. This is reasonable for a time series with a constant level, but it will result in bad forecasts for series with a trend. *Double exponential smoothing* incorporates a trend variable b_t representing the local slope of the trend at time t into the recursions to overcome this deficiency:

$$\begin{aligned} \tilde{y}_t &= \alpha\, y_t + (1-\alpha)\,(\tilde{y}_{t-1} + b_{t-1}) \\ b_t &= \beta\,(\tilde{y}_t - \tilde{y}_{t-1}) + (1-\beta)\, b_{t-1}. \end{aligned} \tag{4}$$

b_t can be regarded as an estimate of the local slope of the trend at time t. Now this slope is assumed to be locally almost constant at neighboring points in time. The increment $\tilde{y}_t - \tilde{y}_{t-1}$ of the estimated level is a simple and highly variable estimate of the slope at time t. The parameters $\alpha \in (0,1)$ and $\beta \in (0,1)$ are smoothing parameters regulating the amount of smoothing applied for the calculation of the smoothed slope b_t and the smoothed level $\tilde{y}_t$ at time t.

Starting values $\tilde{y}_k$ and b_k for the recursions (4) can be obtained by fitting an ordinary least squares regression line to an initial period, as described by Bowerman et al. (2005). Regressing y_t versus the time t, for $t = 1, \ldots, k$, yields an intercept $\hat{a}_0$ and a slope $\hat{b}_0$ resulting in

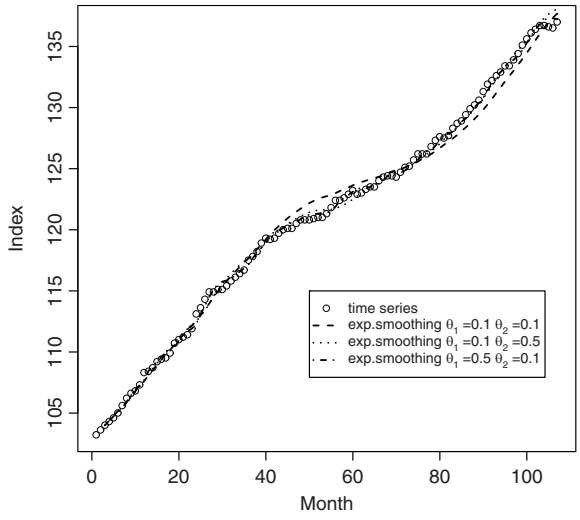
$$\begin{aligned} \tilde{y}_k &= \hat{a}_0 + \hat{b}_0 k\,, \\ b_k &= \hat{b}_0. \end{aligned}$$

An h-step-ahead forecast of y_{t+h} given the data up to time t can be obtained from recursion (4) as

$$\hat{y}_{t+h|t} = \tilde{y}_t + h b_t, \qquad h = 1, 2, \ldots \,. \tag{5}$$

These forecasts form a straight line, starting at $\tilde{y}_t$ and with slope equal to the most recent estimate b_t.

Figure 2 illustrates the results of double exponential smoothing applied to a time series representing the monthly consumer price index in Spain from January 1993 till December 2001, as well as the results of double exponential smoothing using several combinations of smoothing parameters. If values of α and β about 0.5 are chosen for these data, we get quite good 1-step ahead predictions,



Exponential and Holt-Winters Smoothing. Fig. 2 Monthly consumer price index in Spain from 1/1993 till 12/2001 and outputs of double exponential smoothing with different smoothing parameters

whereas the sequence of predictions is too stiff and does not adapt quickly to the bends of this time series if both α and β are small.

The *seasonal Holt-Winters method* is a further extension of the above procedure to incorporate periodic seasonality. For this we decompose the smoothed values $\tilde{y}_t$ into the sum of a trend component ℓ_t and a seasonal component s_t,

$$\tilde{y}_t = \ell_t + s_t.$$

The trend - consisting of the local level ℓ_t and the local slope b_t - and the seasonal component s_t are smoothed separately by the recursions

$$\begin{aligned} \ell_t &= \alpha\,(y_t - s_{t-m}) + (1-\alpha)\,(\ell_{t-1} + b_{t-1}) \\ b_t &= \beta\,(\ell_t - \ell_{t-1}) + (1-\beta)\,b_{t-1} \\ s_t &= \gamma\,(y_t - \ell_t) + (1-\gamma)\,s_{t-m}, \end{aligned} \tag{6}$$

with m being the period of the seasonality. Note that ℓ_t is calculated from the observations corrected for seasonality. h-step ahead forecasts are obtained by means of

$$\hat{y}_{t+h|t} = \ell_t + hb_t + s_{t-m+i}, \qquad h = jm + i,$$
$$i = 1, 2, \ldots, m, \quad j = 0, 1, \ldots.$$

The performance of all these exponential smoothing techniques depends on the smoothing parameters α, β and γ, which are sometimes set arbitrarily to values between 0.05 and 0.3. Alternatively, they can be chosen by minimizing the sum of the squared 1-step ahead prediction errors $\sum_{t=k+1}^{n}(y_t - \hat{y}_{t-1|1})^2$ or another error criterion.

Many modifications and improvements of exponential smoothing schemes have been suggested in the literature. Robustness against aberrant values (►outliers) is an important issue because these have large effects on the outcome of exponential smoothing. Gelper et al. (2010) modify the recursions and replace the incoming observations by a cleaned value whenever it lies outside some prediction bounds, using the Huber function.

There is a direct relation between exponential smoothing techniques and certain ARIMA models and state space models, like local constant or local linear models, for which an appropriately designed exponential smoothing technique leads to optimum forecasts in the mean square error sense. This connection can be used for selecting an adequate exponential smoothing scheme, see Ord et al. (1997) or Hyndman et al. (2002). Model selection procedures are important in the context of exponential smoothing since besides the schemes for additive seasonal and trend components outlined above there are also schemes for multiplicative components and for combinations of both, see Hyndman and Khandakar (2008). Gardner (2008) provides an overview on recent work in the field of exponential smoothing, see also Hyndman et al. (2008).

Exponential Family Models

Rolf Sundberg
Professor of Mathematical Statistics
Stockholm University, Stockholm, Sweden

An exponential family is a parametric model for a data set y whose distribution can be expressed by a density (or for discrete data: probability function) of type

$$f(y;\,\theta) = e^{\theta'\,t(y)}\,h(y)\,/C(\theta)$$

where $\theta'\,t$ is the scalar product of a k-dimensional *canonical parameter* vector θ and a k-dimensional *canonical statistic* $t = t(y)$, that is

$$\theta'\,t = \sum_{j=1}^{k} \theta_j\,t_j(y),$$

and the two factors C and h are two functions, the former interpretable as a norming constant (integral or sum). As a first simple example, consider a sample $y = (y_1, \ldots, y_n)$

from an exponential distribution with intensity parameter $\theta > 0$, whose density is

$$f(y;\theta) = \theta^n \, e^{-\theta \sum y_i}, \qquad \text{all } y_i > 0$$

and which is essentially already in exponential family form, with $t(y) = -\sum y_i$, $h(y) = 1$ if all $y_i \geq 0$, else $h(y) = 0$, and $C(\theta) = \theta^{-n}$. As a second simple example, let y be the number of successes in n Bernoulli trials with a probability $0 < p < 1$ for success, The probability for $y = 0, 1, \ldots, n$ is

$$f(y;p) = \binom{n}{y} p^y \, (1-p)^{n-y} = e^{\theta y} \binom{n}{y} / (1+e^{\theta})^n,$$

when parametrized by $\theta = \log \frac{p}{1-p}$ (the logit transform of p) instead of p. A sample from the Gaussian (Normal) distribution, with its two parameters, is an example with $k = 2$. Its canonical statistic has the components $\sum y_i$ and $\sum y_i^2$ (except for constant factors).

Very many statistical models have these features in common. Other distributions providing basic examples of exponential families are the Poisson, the Geometric, the Multinomial, the Multivariate normal, the Gamma and the Beta families. Of more statistical importance, however, are all those statistical models which can be constructed with these building blocks without leaving the exponential families: the Gaussian linear models (i.e. Linear regression models and ANOVA type models), Logistic regression models (see ►Logistic Regression), Multinomial or Poisson-based log-linear models for contingency tables, Graphical models (discrete or Gaussian, specified by conditional independencies), and the basic setting for ►Generalized linear models. Somewhat more specialized examples are Rasch's models for item analysis (in education testing), some basic models for spatial ►Poisson processes, without or with spatial interaction, and exponential random graph models (ERGM) for social networks.

We think of the vector t and the parameter θ as both in effect k-dimensional (not less). This implies that t is minimal sufficient for θ. To some extent, the importance of these models is explained by a general characterization of a distribution family with a minimal sufficient statistic of dimension independent of the sample size, when the latter increases (and satisfying a couple of other regularity conditions), as necessarily being an exponential family.

We say that the family is *full* if the canonical parameter space is maximal, that is if it contains all possible θ-values. A full exponential family in its canonical parametrization has several nice properties. Some families with pathological properties at the boundary of the parameter space are excluded by the (not quite necessary) requirement that the canonical parameter space be open. Such families are called *regular*, and most families in practical use satisfy this demand. Here is a selection of properties of full or regular exponential families:

- $\log C$ is strictly convex and infinitely differentiable, and its first and second derivatives are the mean value vector $\mu_t(\theta)(= E_\theta(t))$ and the variance-covariance matrix $V_t(\theta)$ for t.
- The parameter space for θ is a convex subset of R^k.
- The log-likelihood function $\log L(\theta)$ is a strictly concave function.
- The maximum likelihood estimate is the unique root of the likelihood equation system (when a maximum exists – a concave function can have an infinite supremum).
- The likelihood equation has the simple form $t = \mu_t(\theta)$.
- The observed and expected (Fisher) informations in θ are the same, namely $V_t(\theta)(= \mathrm{Var}_\theta(t))$, and its inverse is the large sample variance of the MLE of θ.
- An equivalent alternative parametrization of the model is by the mean value vector μ_t.
- If u and v are subvectors of t, which together form t, then the conditional model for v given u is also an exponential family, for each u, and with the canonical parameter θ_v (the subvector of θ corresponding to v).
- An equivalent alternative parametrization of the original family is the *mixed* parametrization, formed by $\mu_u(\theta)$ and θ_v together. This parametrization is information orthogonal, that is the information matrix is block diagonal.
- A parametric model having an unbiased efficient estimator, in the sense of equality in the ►Cramér–Rao inequality, is necessarily an exponential family in mean value parametrization, with its mean value parameter $\mu_t(\theta)$ estimated by the corresponding canonical statistic t.
- Exponential families are well suited for the saddle point approximation of the density of the maximum likelihood estimator (also called the p* formula or the magical formula). This approximation is typically quite efficient even for small samples. For the MLE $\hat{\theta}$ of the canonical parameter, with true value θ_0, the approximation is

$$f(\hat{\theta};\theta_0) \approx \frac{\sqrt{\det\{V_t(\hat{\theta})\}}}{\sqrt{2\pi}} \frac{L(\theta_0)}{L(\hat{\theta})},$$

  where $\det\{\}$ denotes the determinant of the information matrix (that was V_t for θ).

The properties listed above indicate that full exponential families form nice statistical models. In some applications, however, we need to go a bit outside this model class. One type of such situations goes under the natural name Curved exponential families. In this case, the family

is not full, but the canonical parameter is specified to lie in a curved subspace of the canonical parameter space. Important examples are the Behrens–Fisher model (two normal samples with the mean values prescribed to be the same, but not their variances), and the model called Seemingly unrelated regressions (the SUR model, popular in econometrics). To some extent the nice properties of the full family remain, but in important respects they do not. The minimum sufficient statistic is of a higher dimension than the parameter of the curved model, and this typically causes problems. For example, the likelihood equations do not always have a unique root in the models mentioned above.

The number of parameters in a multivariate Gaussian distribution model may be reduced by setting to zero a correlation or covariance between two of the variables. However, this would only seemingly be a simplification, because the model would turn into a curved family, and the minimal sufficient statistic would not be reduced. Instead, for a real simplification the zero should be inserted among the canonical parameters, that is in the inverse of the covariance matrix, corresponding to the specification of a conditional independence (so-called covariance selection modeling).

Another type of situation is when an exponential family is thought of as a model for some data x, but these data are not observable in the form desired. Instead, only some function $y = y(x)$ is observed, implying a loss of information. Such situations are known as incomplete data. Examples are grouped and censored data, data from a mixture of two or more distributions, non-Gaussian distributed x observed with Gaussian noise, missing data in multivariate analysis. Some specific distributions can be described in this way, for example the Negative binomial, the Cauchy and the t distributions. The theory starts from the observation that the conditional distribution of x given y is an exponential family that only differs from that for x in its norming constant, say $C_y(\theta)$ instead of $C(\theta)$. It follows that the density for y can be written $f(y, \theta) = C_y(\theta)/C(\theta)$, and next that the likelihood equations are $E_\theta(t|y) = \mu_t(\theta)$, which means that the complete data statistic t has been replaced by its conditional expected value, given the observed data y. Similarly, the Fisher information is now $\mathrm{Var}_\theta(E_\theta(t|y))$, instead of the complete data formula $\mathrm{Var}_\theta(t)$.

The unique root property does not hold for the incomplete data likelihood equations. Typically an iterative method of solution is needed. The EM algorithm is often well suited for this, and is particularly simple for incomplete data from exponential families: Given $\theta^{(i)}$ after i steps, calculate $E_{\theta^{(i)}}(t|y)$, insert its value in the likelihood equation (left hand side above, as a replacement for t), and solve for θ, to get $\theta^{(i+1)}$. The rate of convergence is determined by the loss of information relative to the complete data, as calculated from the information matrices.

Exponential families with $t(y_i) = y_i$ for an individual observation i are called linear. Examples are the Binomial, the Poisson, the Exponential, and the Gaussian with known variance. Such families play a basic role in the class of *Generalized Linear Models*. In such a model, the observations y_i follow a linear exponential family, with varying parameter θ_i. The form of the family relates θ_i with the mean value μ_{y_i}. Furthermore, μ_{y_i} is described by some predictor or regressor variables, via a link function.

- Some jointly observed explanatory (continuous or class) variables, x_i say, are tried to explain (linearly) the systematic part of the variability in y, via a linear predictor function $\eta(x) = \beta^T x$ with unknown coefficients β.
- The mean value μ_y need not be the linear predictor (as in a linear Gaussian model), but the mean value is linked to the predictor η by a specified *link function* g, $\eta = g(\mu)$.
- The observations y_i follow a linear exponential family, with varying parameter θ_i. The form of the family relates θ_i with the mean value μ_{y_i}.

When the link is the *canonical link* the model is a full exponential family, otherwise it is a curved family. Sometimes an additional variance parameter must be introduced (as with the Gaussian). In that case, the model will at least be a (full or curved) exponential family for each fixed value of the variance parameter.

Extreme Value Distributions

Isabel Fraga Alves[1], Cláudia Neves[2]
[1]Associate Professor, CEAUL, DEIO Faculty of Sciences University of Lisbon, Lisbon, Portugal
[2]Assistant Professor, UIMA University of Aveiro, Aveiro, Portugal

Introduction

Extreme Value distributions arise as limiting distributions for maximum or minimum (*extreme values*) of a sample of independent and identically distributed random variables, as the sample size increases. Extreme Value Theory (EVT) is the theory of modelling and measuring events which occur with very small probability. This implies its usefulness in risk modelling as risky events per definition happen with low probability. Thus, these distributions are important in statistics. These models, along with the Generalized Extreme Value distribution, are widely used in risk management, finance, insurance, economics, hydrology, material sciences, telecommunications, and many other industries dealing with extreme events. The class of Extreme Value Distributions (EVD's) essentially involves three types of extreme value distributions, types I, II and III, defined below.

Definition 1 (Extreme Value Distributions *for maxima*). *The following are the standard Extreme Value distribution functions:*

(i) Gumbel (type I): $\Lambda(x) = \exp\{-\exp(-x)\}$, $x \in \mathbb{R}$;

(ii) Fréchet (type II): $\Phi_\alpha(x) = \begin{cases} 0, & x \le 0; \\ \exp\{-x^{-\alpha}\}, & x > 0,\ \alpha > 0; \end{cases}$

(iii) Weibull (type III):

$$\Psi_\alpha(x) = \begin{cases} \exp\{-(-x)^{\alpha}\}, & x \le 0,\ \alpha > 0; \\ 1, & x > 0. \end{cases}$$

The EVD families can be generalized with the incorporation of location (λ) and scale (δ) parameters, leading to

$$\Lambda(x;\lambda,\delta) = \Lambda((x-\lambda)/\delta),$$
$$\Phi_\alpha(x;\lambda,\delta) = \Phi_\alpha((x-\lambda)/\delta),$$
$$\Psi_\alpha(x;\lambda,\delta) = \Psi_\alpha((x-\lambda)/\delta), \quad \lambda \in \mathbb{R}, \delta > 0.$$

Among these three families of distribution functions, the type I is the most commonly referred in discussions of extreme values. Indeed, the Gumbel distribution $\{\Lambda(x;\lambda,\delta) = \Lambda((x-\lambda)/\delta); \lambda \in \mathbb{R}, \delta > 0\}$, is often coined "*the*" extreme value distribution.

Proposition 1 (Moments and Mode of EVD). *The mean, variance and mode of the EVD as in definition 1 are, respectively:*

(i) Gumbel – Λ: $E[X] = \gamma = 0.5772\ldots =$ *Euler's constant;* $Var[X] = \pi^2/6$; *Mode* $= 0$;

(ii) Fréchet – Φ_α: $E[X] = \Gamma(1-1/\alpha)$, *for* $\alpha > 1$; $Var[X] = \Gamma(1-2/\alpha) - \Gamma^2(1-1/\alpha)$, *for* $\alpha > 2$; *Mode* $= (1+1/\alpha)^{-1/\alpha}$;

(iii) Weibull – Ψ_α: $E[X] = -\Gamma(1+1/\alpha)$; $Var[X] = \Gamma(1+2/\alpha) - \Gamma^2(1+1/\alpha)$; *Mode* $= -(1-1/\alpha)^{-1/\alpha}$, *for* $\alpha > 1$, *and Mode* $= 0$, *for* $0 < \alpha \le 1$;

here Γ *denotes the gamma function* $\Gamma(s) := \int_0^\infty x^{s-1}e^{-x}dx$, $s > 0$.

Definition 2 (Extreme Value Distributions *for minima*). *The standard converse EVD's for minima are defined as:* $\Lambda^*(x) = 1 - \Lambda(-x)$, $\Phi^*_\alpha(x) = 1 - \Phi_\alpha(-x)$ *and* $\Psi^*_\alpha(x) = 1 - \Psi_\alpha(-x)$.

Emil Gumbel

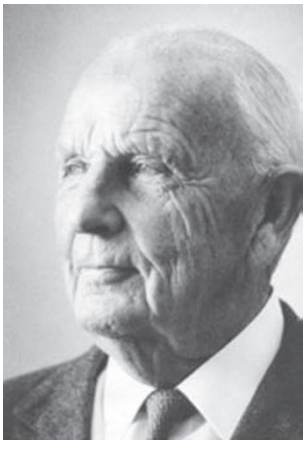
The Gumbel distribution, named after one of the pioneer scientists in practical applications of the Extreme

Value Theory (EVT), the German mathematician Emil Gumbel (1891–1966), has been extensively used in various fields including hydrology for modeling extreme events. Gumbel applied EVT on real world problems in engineering and in meteorological phenomena such as annual flood flows (Gumbel 1958):

> *"It seems that the rivers know the theory. It only remains to convince the engineers of the validity of this analysis."*

Maurice Fréchet

The EVD of type II was named after Maurice Fréchet (1878–1973), a French mathematician who devised one possible limiting distribution for a sequence of maxima, provided convenient scale normalization (Fréchet 1927). In applications to finance, the Fréchet distribution has been of great use apropos to the adequate modeling of market-returns which are often heavy-tailed.



Waloddi Weibull

The EVD of type III was named after Waloddi Weibull (1887–1979), a Swedish engineer and scientist well-known for his work on strength of materials and fatigue analysis (Weibull 1939). Even though the ▶Weibull distribution was originally developed to address the problems for minima arising in material sciences, it is widely used in many other areas thanks to its flexibility. If $\alpha = 1$, the Weibull distribution function for *minima*, Ψ_α^*, in Definition 2, reduces to the Exponential model, whereas for $\alpha = 2$ it mimics the Rayleigh distribution which is mainly used in the telecommunications field. Furthermore, Ψ_α^* resembles the Normal distribution when $\alpha = 3.5$.

Owing to the equality for a random sample $(X_1, \ldots, X_n)$

$$\min(X_1, \ldots, X_n) = -\max(-X_1, \ldots, -X_n)$$

it suffices to consider henceforth only the EVD's for maxima featuring in Definition 1. In probability theory and statistics, the Generalized Extreme Value (GEV) distribution is a family of continuous probability distributions developed under the extreme value theory in order to combine the Gumbel, Fréchet and Weibull families. The GEV distribution arises from the extreme value theorem (Fisher-Tippett 1928 and Gnedenko 1943) as the limiting distribution of properly normalized maxima of a sequence of independent and identically distributed (i.i.d.) random variables. Because of this, the GEV distribution is fairly used as an approximation to model the maxima of long (finite) sequences of random variables. In some fields of application the GEV distribution is in fact known as the Fisher-Tippett distribution, named after Sir Ronald Aylmer Fisher (1890–1962) and Leonard Henry Caleb Tippett (1902–1985) who recognized the only three possible limiting functions outlined above in Definition 1.

Extreme Value Theory and Max-Stability

Richard von Mises (1883–1953) studied the EVT in 1936, giving in particular the von Mises sufficient conditions on the hazard rate (assuming the density exists) in order to give a situation in which EVT behavior occurs, leading to one of the above three types of limit laws that is, giving an extremal domain of attraction $\mathcal{D}(G)$ for the extreme-value distribution G. Later on, and motivated by a storm surge in the North Sea (31 January–1 February 1953) which caused extensive flooding and many deaths, the Netherlands Government gave top priority to understanding the causes of such tragedies with a view to risk mitigation. Since it is the maximum sea level which is the danger, EVT became a Netherlands scientific priority. A relevant work in the field is the doctoral thesis of Laurens de Haan in 1970.

The fundamental extreme value theorem (Fisher-Tippett 1928; Gnedenko 1943) ascertains the Generalized

Extreme Value distribution in the von Mises-Jenkinson parametrization (von Mises 1936; Jenkinson 1955) as an unified version of all possible non-degenerate weak limits of partial maxima of sequences comprising i.i.d. random variables $X_1, X_2, \ldots$. That is:

Theorem 1 (Fisher-Tippett 1928; Gnedenko 1943). *If there exist normalizing constants $a_n > 0$ and $b_n \in \mathbb{R}$ such that*

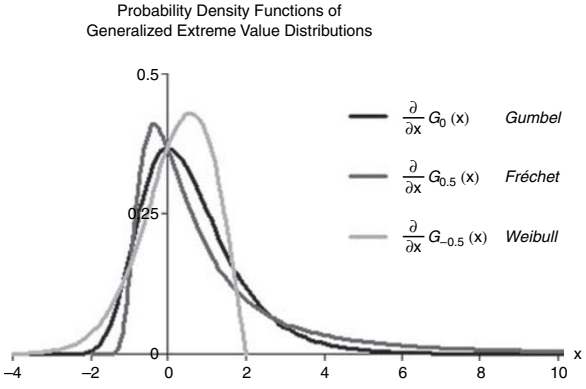
$$\lim_{n\to\infty} P\left\{a_n^{-1}\left(\max(X_1,\ldots,X_n) - b_n\right) \le x\right\} = G(x),$$

for some non-degenerate distribution function G, then it is possible to redefine the normalizing constants in such a way that

$$G(x) = G_\xi(x) := \exp\left(-(1+\xi x)^{-1/\xi}\right),$$

for all x such that $1+\xi x > 0$, with extreme value index $\xi \in \mathbb{R}$. Taking $\xi \to 0$, then $G_\xi(x)$ reduces to $\Lambda(x)$ for all $x \in \mathbb{R}$ (cf. Definition 1). Thus the distribution function F belongs to the domain of attraction of G_ξ, which is denoted by $F \in \mathcal{D}(G_\xi)$.

Remark 1 Note that, as $n \to \infty$, the $\max(X_1,\ldots,X_n)$ detached of any normalization converges in distribution to a degenerate law assigning probability one to the right endpoint of F, $x_F := \sup\{x : F(x) < 1\}$.



For $\xi < 0$, $\xi = 0$ and $\xi > 0$, the G_ξ distribution function reduces to Weibull, Gumbel and Fréchet distributions, respectively. More precisely,

$$\Lambda(x) \equiv G_0(x),$$
$$\Phi_\alpha(x) \equiv G_{1/\alpha}(\alpha(x-1)),$$

and

$$\Psi_\alpha(x) \equiv G_{-1/\alpha}(\alpha(1+x)).$$

For exhaustive details on EVD see Chapter 22 of Johnson et al. (1995).

Proposition 2 (Moments and Mode of GEV). *The mean, variance and mode of the GEV as in Theorem 1 are, respectively:*

$$E[X] = -\frac{1}{\xi}[1-\xi(1-\xi)], \text{for } \xi < 1; Var[X] = \frac{1}{\xi^2}[\Gamma(1-2\xi) - \Gamma^2(1-\xi)], \text{for } \xi < 1/2;$$
$$\text{Mode} = \frac{1}{\xi}[(1+\xi)^{-\xi} - 1], \text{for } \xi \neq 0.$$

Proposition 3 (Skewness of GEV). *The skewness coefficient of GEV distribution, defined as $skew_{G_\xi} := E[\{X - E[X]\}^3]/\{Var[X]\}^{3/2}$, is equal to zero at $\xi_0 \simeq -2.8$. Moreover, $skew_{G_\xi} > 0$, for $\xi > \xi_0$, and $skew_{G_\xi} < 0$, for $\xi < \xi_0$. Furthermore, for the Gumbel distribution, $skew_{G_0} \simeq 1.14$.*

The Fréchet domain of attraction contains distributions with polynomially decay tails. All distribution functions belonging to Weibull domain of attraction are light-tailed with finite right endpoint. The intermediate case $\xi = 0$ is of particular interest in many applied sciences where extremes are relevant, not only because of the simplicity of inference within the Gumbel domain $D(G_0)$ but also for the great variety of distributions possessing an exponential tail whether having finite right endpoint or not. In fact, separating statistical inference procedures according to the most suitable domain of attraction for the sampled distribution has become an usual practice. In this respect we refer to Neves and Fraga Alves (2008) and references therein.

Definition 3 (Univariate Max-Stable Distributions). *A random variable X with distribution function F is max-stable if there are normalizing sequences $\{a_n > 0\}$ and $\{b_n \in \mathbb{R}\}$ such that the independent copies $X_1, X_2, \cdots, X_n$ satisfy the equality in distribution $\max(X_1, \cdots, X_n) \stackrel{d}{=} a_n X + b_n$. Equivalently, F is a max-stable distribution function if $[F(x)]^n = F((x-b_n)/a_n)$, all $n \in \mathbb{N}$.*

The class GEV, up to location and scale parameters, $\{G_\xi(x;\lambda,\delta) = G_\xi((x-\lambda)/\delta), \lambda \in \mathbb{R}, \delta > 0\}$, represents the only possible max-stable distributions.

Additional information can be found in Kotz and Nadarajah (2000), a monograph which describes in an organized manner the central ideas and results of probabilistic extreme-value theory and related extreme-value distributions – both univariate and multivariate – and their applications, and it is aimed mainly at a novice in the field. De Haan and Ferreira (2006) constitutes an excellent introduction to EVT at the graduate level, however requiring some mathematical maturity in regular variation, ▶point processes, empirical distribution functions, and Brownian motion. Extremes of Gaussian Processes

Sinisa Stamatovic
Professor
University of Montenegro, Podgorica, Montenegro

One of the oldest, most difficult, and most important problems in the theory of random processes has been the precise calculation of the probability

$$\mathbb{P}\left(\sup_{t\in[0,T]} X(t) > u\right) \tag{1}$$

where $X(t)$ is a random process. This problem is especially attractive for a Gaussian process. Even today, there is no explicit formula of the probability (1) in the general Gaussian situation, despite the fact that the set of finite dimensional distributions of a Gaussian process has a simple form. Because of this, there are multitudes of approximations and techniques of deriving approximations to (1), particularly when u is large. ►Gaussian processes appear in various fields (finance, hydrology, climatology, etc.) and finding the probability of attaining high level is particularly significant.

Extremes of Gaussian processes are well established in probability theory and mathematical statistics. Furthermore, besides the already mentioned problem, this theory addresses the following problems, among others: prediction of extremes, the moments of the number of crossings, and limit theorems for high excursions. The ruin probability with Gaussian process as input and the extremes of Gaussian process in random environment are two contemporary directions in the theory of extremes. To acquaint the reader with extremes of Gaussian processes we recommend monographs (Leadbetter et al., 1983; Lifshits 1995; Piterbarg 1996) and review articles (Alder 2000; Albeverio and Piterbarg 2006; Piterbarg and Fatalov 1995).

We will focus on one important part of the theory. J. Pickands III suggested a natural and elegant way of computing the asymptotic behavior of the probability (1) when $u \to \infty$, see Pickands (1969), Piterbarg and Fatalov (1995), Piterbarg (1996). Today his method is generalized for a wide class of Gaussian processes and fields. Approximation is based on the Bonferroni inequality, so Pickands' method is known as a double sum method. We will extract two central theorems. First, we will consider a stationary, centered Gaussian process $X(t),\ t \geq 0$. Assume also that its covariance function $r(t)$ satisfies the conditions

$$r(t) = 1 - |t|^{\alpha} + o(|t|^{\alpha}),\ t \to 0$$

for some $0 < \alpha \leq 2$ and

$$r(t) < 1, t > 0.$$

Let $\chi(t)$ be a fractional Brownian motion with a shift,

$$\mathbb{E}\chi(t) = -|t|^{\alpha}$$

and

$$cov(\chi(t), \chi(x)) = |t|^{\alpha} + |s|^{\alpha} - |t-s|^{\alpha}.$$

Theorem 1

$$\mathbb{P}\left(\sup_{t\in[0,p]} X(t) > u\right) = H_{\alpha} p u^{\frac{2}{\alpha}} \Psi(u)(1+o(1)),$$

as $u \to \infty$, *where*

$$\Psi(u) = \frac{1}{\sqrt{2\pi}} \int_u^{\infty} \exp\left(-\frac{z^2}{2}\right) dz,$$

$$H_{\alpha} = \lim_{T\to\infty} \frac{H_{\alpha}(T)}{T}, H_{\alpha}(T) = \mathbb{E}\exp\left(\sup_{t\in[0,T]} \chi(t)\right).$$

Let $X(t),\ t \in [0,T]$ be a centered Gaussian process with continuous trajectories. Denote by $\sigma^2(t)$ and $r(t,s)$ corresponding variance and correlation functions. Suppose that variance function attains its maximum at a unique point $t_0,\ t_0 \in (0,T)$. We introduce the following assumptions:

$\mathbb{D}1$ For some positive numbers a and β,

$$\sigma(t) = 1 - a|t-t_0|^{\beta}(1+o(1)), t - t_0 \to 0.$$

$\mathbb{D}2$ For the correlation function $r(t,s)$

$$r(t,s) = 1 - |t-s|^{\alpha}(1+o(1)), t \to t_0,\ s \to t_0,$$

where $0 < \alpha \leq 2$.

$\mathbb{D}3$ For some G and $\gamma > 0$

$$\mathbb{E}(X(t) - X(s))^2 \leq G|t-s|^{\gamma}.$$

Theorem 2 Assume that the conditions $\mathbb{D}1, \mathbb{D}2, \mathbb{D}3$ hold. Under these conditions:

$\mathbb{A}$. if $\beta > \alpha$, then

$$\mathbb{P}\left(\sup_{t\in[0,T]} X(t) > u\right) = \frac{2H_{\alpha}\Gamma(1/\beta)}{\beta a^{\frac{1}{\beta}}} u^{\frac{2}{\alpha}-\frac{2}{\beta}} \Psi(u)(1+o(1)),$$
$$u \to \infty,$$

$\mathbb{B}$. if $\beta = \alpha$, then

$$\mathbb{P}\left(\sup_{t\in[0,T]} X(t) > u\right) = 2H_{\alpha}^{a} \Psi(u)(1+o(1)),\ u \to \infty,$$

where

$$H_{\alpha}^{a}(S) = \mathbb{E}\exp\left(\sup_{t\in[-S,S]} (\chi(t) - a|t|^{\alpha})\right), H_{\alpha}^{a} = \lim_{S\to\infty} H_{\alpha}^{a}(S),$$

$\mathbb{C}$. if $\beta < \alpha$, then

$$\mathbb{P}\left(\sup_{t\in[0,T]} X(t) > u\right) = \Psi(u)(1+o(1)),\ u \to \infty.$$

Theorem 2 gives us asymptotic formulas for distributions of Kolmogorov-Smirnov type statistics that appear in goodness-of-fit tests for parameter families of distributions $F(x;\theta)$. Let θ_N be the maximum likelihood estimate for θ. It is well known that the empirical process

$$\zeta_N(x) = \sqrt{N}(F_N(x) - F_N(x,\theta_N))$$

weakly converges (under some regularity conditions) to some Gaussian centered process $\zeta(t)$ with a covariance function

$$cov(\zeta(x),\zeta(y)) = F^0(x) \wedge F^0(y) - F^0(x)F^0(y)$$
$$- \left(\int_{-\infty}^{x} G(z)dz\right)^T J^{-1} - \left(\int_{-\infty}^{y} G(z)dz\right)^T.$$

Here $F_0(x) = F(x,\theta_0),\ \theta_0$ is the true value of the parameter, vector $G(z)$ is of the form

$$G(z) = \left(\frac{\partial}{\partial\theta_i} \ln f(z,\theta_0), i = 1,2,\ldots,q\right)^T,$$

q is the dimension of the parameter θ, f is the density of F with respect to the Lebesgue measure,

$$J = \left(\int_{-\infty}^{\infty} \frac{\partial}{\partial \theta_i} \ln f(z, \theta_0) \frac{\partial}{\partial \theta_j} \ln f(z, \theta_0) dz, \; i, j = 1, 2, \ldots, q \right)$$

is the Fisher's information matrix. By Theorem 2 we can find the asymptotic behavior of $\mathbb{P}\left(\sup_{x \in \mathbb{R}} \zeta(x) > u \right)$ and $\mathbb{P}\left(\sup_{x \in \mathbb{R}} |\zeta(x)| > u \right)$ as $u \to \infty$ if we know the behavior of variance and covariance of the process $\zeta(x)$ near the maximum point of the variance. We will present an asymptotic formula obtained by V. Fatalov, for testing hypothesis

$$H_1 : F(x) \in \left\{ \Phi\left(\frac{x - a}{\sigma} \right), |a| < \infty, 0 < \sigma < \infty \right\},$$

both parameters are unknown. Suppose H_1 is true. Then the covariance function of the process $\zeta(x)$ is equal to

$$r(t, s) = t \wedge s - ts - \varphi(\Phi^{-1}(t))(\varphi(\Phi^{-1}(s)) \\ (1 + 0,5\Phi^{-1}(t)\Phi^{-1}(s)),$$

where $t = F(x), s = F(y)$, $\Phi(t)$ is the standard normal distribution function and $\varphi(t)$ is the standard normal density function. Thanks to the Theorem 2,

$$\mathbb{P}\left(\sup_{t \in [0,1]} |\zeta(t)| > u \right) = 2\sqrt{\frac{2\pi}{\pi - 2}} \exp\left(-\frac{2\pi}{\pi - 2} u^2 \right) \\ (1 + o(1)), \; u \to \infty.$$

F

F Distribution

Enrique M. Cabaña
Professor
Universidad de la República, Monterideo, Uruguay

George W. Snedecor (1882–1974) promoted the development of statistics in the USA by contributing to the foundation of a department of statistics at Iowa State University, reputed to be the first one in the country, and helping with his writings the diffusion and application of Sir Ronald A. Fisher's (1890–1962) work on the ►analysis of variance and covariance (Fisher 1950, 1971).

Snedecor named "F" the distribution of the ratio of independent estimates of the variance in a normal setting as a tribute to Fisher, and now that distribution is known as the *Snedecor F*. It is a continuous skew probability distribution with range $[0, +\infty)$, depending on two parameters denoted ν_1, ν_2 in the sequel. In statistical applications, ν_1 and ν_2 are positive integers.

Definition of the F Distribution

Let Y_1 and Y_2 be two independent random variables distributed as chi-square, with ν_1 and ν_2 degrees of freedom, respectively (abbreviated $Y_i \sim \chi^2_{\nu_i}$). The distribution of the ratio $Z = \dfrac{Y_1/\nu_1}{Y_2/\nu_2}$ is called the F distribution with ν_1 and ν_2 degrees of freedom.

The notation $Z \sim \mathrm{F}_{\nu_1,\nu_2}$ expresses that Z has the F distribution with ν_1 and ν_2 degrees of freedom. The role of ν_1 and ν_2 in this definition is often emphasized by saying that ν_1 are the degrees of freedom of the numerator, and ν_2 are the degrees of freedom of the denominator.

Remark 1 Let $s^2 = \frac{1}{n-1}\sum_{i=1}^n (X_i - \bar{X})^2$ denote the usual estimator of the variance σ^2 obtained from $X_1, X_2, \ldots, X_n$ i.i.d. Normal(μ, σ^2), $\bar{X} = \frac{1}{n}\sum_{i=1}^n X_i$. Since s^2 is distributed as $\sigma^2\chi^2_{n-1}/(n-1)$ (this means that $(n-1)s^2/\sigma^2 \sim \chi^2_{n-1}$), then the ratio of two such independent estimators of the same variance has the F distribution that, for this reason, is often referred to as *the distribution of the variance ratio*.

This leads to an immediate application of the F distribution: Assume that s_1^2 and s_2^2 are the estimators of the variances of two normal populations with variances σ_1^2 and σ_2^2 respectively, computed from independent samples of sizes n_1 and n_2 respectively. Then the ratio $F = s_1^2/s_2^2$ is distributed as $\frac{\sigma_1^2}{\sigma_2^2} F_{n_1-1,n_2-1}$.

When $\sigma_1^2 = \sigma_2^2$, $F \sim F_{n_1-1,n_2-1}$. On the other hand, when $\sigma_1^2 > \sigma_2^2$ or $\sigma_1^2 < \sigma_2^2$, F is expected to be respectively larger or smaller than a random variable with distribution F_{n_1-1,n_2-1}, and this suggests the use of F to test the null hypothesis $\sigma_1^2 = \sigma_2^2$: the null hypothesis is rejected when F is significantly large or small.

Remark 2 The joint probability density of the i.i.d. Normal$(0,1)$ variables $X_1, X_2, \ldots, X_n$ in $\boldsymbol{x} = (x_1, x_2, \ldots, x_n)$ is $\prod_{i=1}^n \frac{1}{\sqrt{2\pi}} e^{-x_i^2/2} = \frac{1}{(2\pi)^{n/2}} e^{-\|\boldsymbol{x}\|^2/2}$, with $\|\boldsymbol{x}\|^2 = \sum_{i=1}^n x_i^2$ equal to the Euclidean norm of $\boldsymbol{x}$. Since it depends on $\boldsymbol{x}$ only through its norm, it follows that the new coordinates $X_1^*, X_2^*, \ldots, X_n^*$ of $\boldsymbol{X} = (X_1, X_2, \ldots, X_n)$ in any orthonormal basis of $\mathbf{R}^n$ have the same joint density and therefore are i.i.d. Normal$(0,1)$.

If $\mathcal{R}$ denotes the subspace generated by the first p vectors of the new basis, and $\mathcal{R}^\perp$ is its orthogonal complement, then the angle Ψ of $\boldsymbol{X}$ with $\mathcal{R}^\perp$ has tangent

$$\tan\Psi = \sqrt{\frac{Y_1^*}{Y_2^*}}, \text{ with } Y_1^* = \sum_{i=1}^p \left(X_i^*\right)^2 \sim \chi^2_p, Y_2^* = \sum_{i=p+1}^n \left(X_i^*\right)^2 \sim \chi^2_{n-p},$$

and hence

$$Z := \frac{n-p}{p}\tan^2\Psi \sim \mathrm{F}_{p,n-p}.$$

This geometrical interpretation of the F distribution is closely related to the F test in the analysis of variance (Scheffe 1959).

Important applications of F distribution include: F test for testing equality of two population variances, F test for fit of regression models, and Scheffe's method of multiple comparison.

Miodrag Lovric (ed.), *International Encyclopedia of Statistical Science*, DOI 10.1007/978-3-642-04898-2,

The Density and Distribution Function of F_{ν_1,ν_2}

Let $Y_i \sim \chi^2_{\nu_i}, i = 1,2$. In order to compute the probability density of $Z = \frac{Y_1/\nu_1}{Y_2/\nu_2} \sim F_{\nu_1,\nu_2}$, introduce the random angle Ψ by $Z = \frac{\nu_2}{\nu_1}\tan^2\Psi$, and start by computing the distribution of $C = \cos^2\Psi = (1+\tan^2\Psi)^{-1} = \frac{\nu_2}{\nu_1 Z+\nu_2} = \frac{Y_2}{Y_1+Y_2}$:

$$\begin{aligned}\mathbf{P}\{C \le c\} &= \mathbf{P}\left\{Y_1 \ge \left(\tfrac{1}{c}-1\right)Y_2\right\}\\ &= \int_0^\infty f_2(y_2)\int_{\left(\frac{1}{c}-1\right)y_2}^\infty f_1(y_1)dy_1dy_2,\end{aligned}$$

where $f_i(t) = \frac{e^{-t/2}t^{\nu_i/2-1}}{2^{\nu_i/2}\Gamma(\nu_i/2)}$ is the density of the χ^2 distribution with ν_i degrees of freedom.

By replacing the analytical expressions of the χ^2 densities in

$$f_C(c) := \frac{d}{dc}\mathbf{P}\{C \le c\} = \int_0^\infty f_2(t)\frac{t}{c^2}f_1\left(\left(\tfrac{1}{c}-1\right)t\right)dt$$

one gets

$$\begin{aligned}f_C(c) &= \int_0^\infty \frac{e^{-t/2}t^{\nu_2/2-1}}{2^{\nu_2/2}\Gamma(\nu_2/2)}\\ &\quad\times\frac{t}{c^2}\frac{e^{-(1/c-1)t/2}(1/c-1)^{\nu_1/2-1}t^{\nu_1/2-1}}{2^{\nu_1/2}\Gamma(\nu_1/2)}dt\\ &= \frac{(1/c-1)^{\nu_1/2-1}}{c^2 2^{(\nu_1+\nu_2)/2}\Gamma(\nu_1/2)\Gamma(\nu_2/2)}\\ &\quad\times\int_0^\infty e^{-t/2c}t^{(\nu_1+\nu_2)/2-1}dt\\ &= c^{\nu_2/2-1}(1-c)^{\nu_1/2-1}\frac{\Gamma((\nu_1+\nu_2)/2)}{\Gamma(\nu_1/2)\Gamma(\nu_2/2)}\\ &= \frac{c^{\nu_2/2-1}(1-c)^{\nu_1/2-1}}{B(\nu_1/2,\nu_2/2)}.\end{aligned}$$

This last expression, obtained by using the well-known relation $B(x,y) = \frac{\Gamma(x)\Gamma(y)}{\Gamma(x,y)}$ between Euler's Beta and Gamma functions, shows that $\cos^2\Psi$ has the ▶Beta distribution with parameters $(\nu_2/2, \nu_1/2)$ and consequently $\sin^2\Psi = 1-\cos^2\Psi$ has the Beta distribution with parameters $(\nu_1/2, \nu_2/2)$ and density $f_S(s) = \frac{s^{\nu_1/2-1}(1-s)^{\nu_2/2-1}}{B(\nu_1/2,\nu_2/2)}$.

The distribution function of $Z \sim F_{\nu_1,\nu_2}$ is

$$\begin{aligned}F_{\nu_1,\nu_2}(z) &= \mathbf{P}\{Z \le z\} = \mathbf{P}\left\{\tan^2\Psi \le \frac{\nu_1}{\nu_2}z\right\}\\ &= \mathbf{P}\left\{\cos^2\Psi \ge \frac{\nu_2}{\nu_1 z+\nu_2}\right\}\\ &= \mathbf{P}\left\{\sin^2\Psi \le \frac{\nu_1 z}{\nu_1 z+\nu_2}\right\} = \int_0^{\frac{\nu_1 z}{\nu_1 z+\nu_2}} f_S(s)ds\\ &= \frac{B\left(\frac{\nu_1 z}{\nu_1 z+\nu_2};\frac{\nu_1}{2},\frac{\nu_2}{2}\right)}{B\left(\frac{\nu_1}{2},\frac{\nu_2}{2}\right)},\end{aligned}$$

where $B(t;a,b) = \int_0^t s^{a-1}(1-s)^{b-1}ds$ denotes the incomplete Beta function with parameters a, b evaluated in t. It may be noticed that the distribution function of F_{ν_1,ν_2} evaluated at z is the same as the distribution function of a $\text{Beta}(\nu_1/2, \nu_2/2)$ random variable evaluated at $\frac{\nu_1 z}{\nu_1 z+\nu_2}$.

By differentiating the c.d.f. the density of the F distribution is obtained:

$$\begin{aligned}f_{\nu_1,\nu_2}(z) &= \frac{\nu_1\nu_2}{(\nu_1 z+\nu_2)^2}f_S\left(\frac{\nu_1 z}{\nu_1 z+\nu_2}\right)\\ &= \frac{\sqrt{\nu_1^{\nu_1}\nu_2^{\nu_2}}}{zB(\nu_1/2,\nu_2/2)}\sqrt{\frac{z^{\nu_1}}{(\nu_1 z+\nu_2)^{\nu_1+\nu_2}}}.\end{aligned}$$

Figures 1 and 2 show graphs of f_{ν_1,ν_2} for several values of the parameters.

Some Properties of F Distribution

The moments of $Y \sim \chi^2_\nu$ are $\mathbf{E}Y^k = 2^k\frac{\Gamma(\frac{\nu}{2}+k)}{\Gamma(\frac{\nu}{2})}$ for $k > -\frac{\nu}{2}$, and infinite otherwise. Therefore, from the expression of $Z = \frac{\nu_2 Y_1}{\nu_1 Y_2}$ as the ratio of independent random variables $Y_i \sim \chi^2_{\nu_i}$ we get $\mathbf{E}Z^k = \left(\frac{\nu_2}{\nu_1}\right)^k \mathbf{E}Y_1^k\mathbf{E}Y_2^{-k} = \left(\frac{\nu_2^k}{\nu_1^k}\right)2^k\frac{\Gamma(\frac{\nu_1}{2}+k)}{\Gamma(\frac{\nu_1}{2})} \times 2^{-k}\frac{\Gamma(\frac{\nu_2}{2}-k)}{\Gamma(\frac{\nu_2}{2})} = \left(\frac{\nu_2}{\nu_1}\right)^k\frac{\Gamma(\frac{\nu_1}{2}+k)\Gamma(\frac{\nu_2}{2}-k)}{\Gamma(\frac{\nu_1}{2})\Gamma(\frac{\nu_2}{2})}$, provided $k < \nu_2/2$. If this last restriction does not hold, the moment is infinite. In particular,

$$\mathbf{E}Z = \frac{\nu_2}{\nu_2-2} \text{ for } \nu_2 > 2,$$

$$\mathbf{Var}Z = \frac{2(\nu_1+\nu_2-2)\nu_2^2}{\nu_1(\nu_2-2)^2(\nu_2-4)} \text{ for } \nu_2 > 4.$$

Other descriptive parameters are the mode $\frac{(\nu_1-2)\nu_2}{\nu_1(\nu_2+2)}$ for $\nu_1 > 2$, the skewness coefficient

$$\frac{2\sqrt{2}(2\nu_1+\nu_2-2)\sqrt{\nu_2-4}}{\sqrt{\nu_1(\nu_1+\nu_2-2)}(\nu_2-6)}$$

for $\nu_2 > 6$ and the kurtosis

$$\frac{3(\nu_2-4)\left(4(\nu_2-2)^2+\nu_1^2(\nu_2+10)+\nu_1(\nu_2-2)(\nu_2+10)\right)}{\nu_1(\nu_2-8)(\nu_2-6)(\nu_1+\nu_2-2)} - 3$$

for $\nu_2 > 8$.

On Numerical Computations

There exist many tables of the F distribution, but the simpler way to obtain the numerical values of the density, the distribution function or its inverse, is to use the facilities provided by statistical software. The pictures here included and the numerical computations required by them were made by using the free software "R" (R Development Core Team 2008).

Factor Analysis and Latent Variable Modelling

David J. Bartholomew
Professor Emeritus of Statistics
London School of Economics and Political Science, London, UK

Background

Factor analysis was invented in 1904 by Professor Charles Spearman at University College London. Spearman was a psychologist and, for half century, factor analysis largely

remained the preserve of psychologists. Latent class analysis was developed by Paul Lazarsfeld at Columbia University in New York in the nineteen fifties and was designed for use by sociologists. Yet both of these techniques, and others like them, are essentially statistical and are now recognized as sharing a common conceptual framework which can be used in a wide variety of fields. It was not until the late nineteen thirties that statisticians, such as M. S. Bartlett, made serious contributions to the field.

Both factor analysis and latent class analysis are examples of the application of what would now be called latent variable models. Statistics deals with things that vary and in statistical theory such quantities are represented by random variables. In most fields these variables are observable and statistical analysis works with the observed values of such variables. But there are some important applications where we are interested in variables which cannot be observed. Such variables are called *latent* variables. In practice these often arise in the social sciences and include such things as human intelligence and political attitudes.

A latent variable model provides the link between the latent variables, which cannot be observed, and the manifest variables which can be observed. The purpose of the analysis is to determine how many latent variables are needed to explain the correlations between the manifest variable, to interpret them and, sometimes, to predict the values of the latent variables which have given rise to the manifest variables.

The Linear Factor Model

The basic idea behind factor analysis and other latent variable models is that of regression, or conditional expectation. We may regress each of the manifest (observed) variables on the set of latent variables (or factors). Thus, if we have p manifest variables, denoted by $x_1, x_2, \ldots x_p$ and q factors, denoted by $f_1, f_2, \ldots f_q$, the model may be written

$$x_i = \alpha_0 + \alpha_1 f_1 + \alpha_2 f_2 + \ldots \alpha_q f_q + e_i \qquad (i = 1, 2, \ldots, p) \quad (1)$$

where, without loss of generality, the fs are assumed to have zero means and unit standard deviations. The error term e_i is also assumed to have zero mean and standard deviation, σ_i. We often assume that all distributions are normal, in which case we refer to this as the *normal linear factor model*.

There are p linear equations here but the model cannot be fitted like the standard linear regression model (see ►Linear Regression Models) because the number of factors is unknown and the values of the f_s are not known, by definition. We, therefore, have to use indirect methods which depend on the fact that the correlation coefficients between the xs depend only on the αs and the σs. In practice, efficient computer programs are available which take care of the fitting.

The Latent Class Model

In a latent class model the manifest and latent variables are both categorical, often binary, instead of continuous. Thus the xs may consist of binary answers to a series of questions of the YES/NO variety. These are often coded 0 and 1 so that the manifest variable, x_i takes one of the two values 0 and 1. On the basis of these data we may wish to place individuals into one of several categories. In such cases the model is usually expressed in terms of probabilities. For example, for the ith manifest variable we may specify that

$$\Pr[x_i = 1] = \frac{\exp - \alpha_{i0} - \alpha_{i1} f}{1 + \exp - \alpha_{i0} - \alpha_{i1} f} \quad (2)$$

Because x_i is binary, the left hand side of the equation may also be written, $E(x_i)$ The reason for this somewhat strange expression is that probabilities necessarily lie between 0 and 1. The link with the linear expression of the previous section is made clearer if we write it in terms of the logit function. In that case we have

$$\text{logitE}[x_i] = \alpha_{i0} + \alpha_{i1} f. \quad (3)$$

This becomes a latent class model if we let f be a binary variable; this is a way of letting the probability on the left hand side of the equation take just two values.

Other Latent Variable Models

Prior to the last step, we actually had a latent profile model with one continuous factor, f. Further latent variables could have been added to the right hand side in exactly the same way as with the general linear factor model. Similarly, we could have had a continuous variable on the left hand side with discrete variables on the right hand side. Beyond this, in principle, there could be mixtures of continuous and/or categorical variables on both sides of the equation.

Much recent work is on what are called linear structural relations models where the interest is in the assumed (linear) relationships among the latent variables.

The Literature

There is an enormous literature on factor analysis and latent variable models, much of it very old and difficult to follow. This is not helped by the fact that much of the work has been published in books or journals appropriate to the disciplinary origins of the material and the level of mathematical expertise expected of the readers. One of the very few broad treatments from a statistical angle is given in:

Bartholomew, D.J. and Knott, M. (2011) *Latent Variable Models and Factor Analysis*, 2nd edition, Kendall's Library of Statistics 7, Arnold.

The references given there will lead on to many other aspects of the field, some of which have been touched on above.

About the Author

Past President of the Royal Statistical Society (1993–1995), David Bartholomew, was born in England in 1931. After undergraduate and postgraduate study at University College London, specializing in statistics, he worked for two years in the operational research branch of the National Coal Board. In 1957 he began his academic career at the University of Keele and then moved to the University College of Wales, Aberystwyth as lecturer, then senior lecturer in statistics. This was followed by appointment to a chair in statistics at the University of Kent in 1967. Six years later he moved to the London School of Economics as Professor of Statistics where he stayed until his retirement in 1996. During this time at the LSE he also served as Pro-Director for three years. He is a Fellow of the British Academy, a Member of the International Statistical Institute, and a Fellow of the Institute of Mathematical Statistics, He has authored, co-authored or edited about 20 books and about 120 research papers and articles, including the text *Latent Variable Models and Factor Analysis* (1987, Griffin; 2nd edition (with Martin Knott), Edward Arnold, 1999).

Factorial Experiments

Kalina Trenevska Blagoeva
Associate Professor, Faculty of Economics
University "Ss. Cyril and Methodius", Skopje, Macedonia

Statistically designed experiments are an important tool in data analysis. The objective of such experimentation is to estimate the effect of each experimental factor on a response variable and to determine how the effect of one factor varies over the levels of other factors. Each measurement or observation is made on an item denoted as an *experimental unit*. Although some ideas of the several varying factors simultaneously appeared in England in the nineteenth century, the first major systematic discussion on factorial designs was given by Sir Ronald Fisher in his seminal book The Design of Experiments (Chap. 6) in 1935.

A *factorial experiment* is an experiment in which several factors (such as fertilizers or antibiotics) are applied to each experimental unit and each factor is applied at two, or more, levels. The levels may be quantitative (as with amounts of some ingredient) or qualitative (where the level refers to different varieties of wheat) but in either case are represented by elements of a finite set, usually by $0, 1, 2, \ldots, k_i - 1$ where the ith factor occurs at k_i levels. A factorial experiment in which t independent factors are tested, and in which the ith factor has k_i levels is labeled a $k_1 \times k_2 \times \cdots \times k_t$ factorial experiment. If $k_1 = k_2 = \cdots = k_t = k$, then the experiment is designated as a k^t *symmetrical factorial experiment*. An important feature of a complete factorial experiment is that all possible factor-level combinations are included in the design of the experiment.

Each controllable experimental variable, such as temperature or diet, in a factorial experiment is termed a *factor*. The *effect* of a factor on the response variable is the change in the average response between two experimental conditions. When the effect is computed as the difference between the average response at a given level of one factor and the overall average based on all of its levels after averaging over the levels of all the other factors, it is labeled the *main effect* of that factor. The difference in the effects of factors at different levels of other factors represents the *interaction* between factors. We can estimate the effect of each factor, independently of the others (the main effect), and the effect of the interaction of two (or more) factors (the interaction effect).

A factorial experiment allows for estimation of experimental error in two ways. The experiment can be replicated, or the sparsity-of-effects principle can often be

exploited. Replication is more common for small experiments and is a very reliable way of assessing experimental error. When the number of factors is large, replication of the design can become operationally difficult. In these cases, it is common to only run a single replicate of the design and to assume that factor interactions of more than a certain order (say, between three or more factors) are negligible. A *single replicate factorial design* is a factorial experiment in which every treatment combination appears precisely once in the design. As with any statistical experiment, the experimental runs in a factorial experiment should be randomized to reduce the impact that bias could have on the experimental result. In practice, this can be a large operational challenge.

Factorial experiments also can be run in block designs, where blocks refer to groups of experimental units or test runs (such as batches of raw material) that are more homogeneous within a block than between blocks. Combinations of the levels of two or more factors are defined as *treatment combinations*. If the number of treatment combinations is not too large, it is often possible to run the experiment in block designs in which some information is available within blocks on all factorial effects (i.e., main effects and interactions). Such effects are said to be partially confounded with blocks. However, factorial experiments with many factors, or with factors at many levels, involve large numbers of treatment combinations. The use of designs that require a number of replicates of each treatment combination then becomes impractical. To overcome this problem, designs using a single replicate are frequently used. Information on all or part of some of the factorial effects will consequently no longer be available from comparisons within blocks; these effects, or some components of them, will be said to be totally confounded with blocks.

Any number of factor levels can be used in a factorial experiment provided there is an adequate number of experimental units. However, the number of experimental runs required for three-level (or more) factorial designs will be considerably greater than for their two-level counterparts. Factorial designs are therefore less attractive if a researcher wishes to consider more than two levels. When the number of test runs required by a complete factorial experiment cannot be run due to time or cost constraints, a good alternative is to use fractional factorial experiments. These types of designs reduce the number of test runs.

False Discovery Rate

John D. Storey

Multiple Hypothesis Testing

In hypothesis testing, *statistical significance* is typically based on calculations involving ►p-values and Type I error rates. A p-value calculated from a single statistical hypothesis test can be used to determine whether there is statistically significant evidence against the null hypothesis. The upper threshold applied to the p-value in making this determination (often 5% in the scientific literature) determines the Type I error rate; i.e., the probability of making a Type I error when the null hypothesis is true. *Multiple hypothesis testing* is concerned with testing several statistical hypotheses simultaneously. Defining statistical significance is a more complex problem in this setting.

A longstanding definition of statistical significance for multiple hypothesis tests involves the probability of making one or more Type I errors among the family of hypothesis tests, called the *family-wise error rate*. However, there exist other well established formulations of statistical significance for multiple hypothesis tests. The Bayesian framework for classification naturally allows one to calculate the probability that each null hypothesis is true given the observed data (Efron et al. 2001; Storey 2003), and several frequentist definitions of multiple hypothesis testing significance are also well established (Shaffer 1995).

Soric (1989) proposed a framework for quantifying the statistical significance of multiple hypothesis tests based on

the proportion of Type I errors among all hypothesis tests called statistically significant. He called statistically significant hypothesis tests *discoveries* and proposed that one be concerned about the rate of false discoveries when testing multiple hypotheses. (A false discovery, Type I error, and false positive are all equivalent. Whereas the false positive rate and Type I error rate are equal, the false discovery rate is an entirely different quantity.) This false discovery rate is robust to the false positive paradox and is particularly useful in exploratory analyses, where one is more concerned with having mostly true findings among a set of statistically significant discoveries rather than guarding against one or more false positives. Benjamini and Hochberg (1995) provided the first implementation of false discovery rates with known operating characteristics. The idea of quantifying the rate of false discoveries is directly related to several pre-existing ideas, such as Bayesian misclassification rates and the positive predictive value (Storey 2003).

Applications

In recent years, there has been a substantial increase in the size of data sets collected in a number of scientific fields, including genomics, astrophysics, neurobiology, and epidemiology. This has been due in part to an increase in computational abilities and the invention of various technologies, such as high-throughput biological devices. The analysis of high-dimensional data sets often involves performing simultaneous hypothesis tests on each of thousands or millions of measured variables. Classical multiple hypothesis testing methods utilizing the family-wise error rate were developed for performing just a few tests, where the goal is to guard against any single false positive occurring. However, in the high-dimensional setting, a more common goal is to identify as many true positive findings as possible, while incurring a relatively low number of false positives. The false discovery rate is designed to quantify this type of trade-off, making it particularly useful for performing many hypothesis tests on high-dimensional data sets.

Hypothesis testing in high-dimensional genomics data sets has been particularly influential in increasing the popularity of false discovery rates (Storey and Tibshirani 2003). For example, DNA microarrays measure the expression levels of thousands of genes from a single biological sample. It is often the case that microarrays are applied to samples collected from two or more biological conditions, such as from multiple treatments or over a time course. A common goal in these studies is to identify genes that are differentially expressed among the biological conditions, which involves performing a hypothesis tests on each gene. In addition to incurring false positives, failing to identify truly differentially expressed genes is a major concern, leading to the false discovery rate being in widespread use in this area. In a notably different area of application, the false discovery rate was utilized in an astrophysics study to detect acoustic oscillations on the distribution of matter in present time, which had implications towards confirming the Big Bang theory of the creation of the universe (Lindsay et al. 2004). The body of scientific problems to which the false discovery rate is applied continues to grow.

Mathematical Definitions

Although multiple hypothesis testing with false discovery rates can be formulated in a very general sense (Storey 2007; Storey et al. 2007), it is useful to consider the simplified case where m hypothesis tests are performed with corresponding p-values $p_1, p_2, \ldots, p_m$. The typical procedure is to call hypotheses statistically significant whenever their corresponding p-values are less than or equal to some threshold t, where $0 < t \leq 1$. This threshold can be fixed or data-dependent, and the procedure for determining the threshold involves quantifying a desired error rate.

Table 1 describes the various outcomes that occur when applying this approach to determining which of the m hypothesis tests are statistically significant. Specifically, V is the number of Type I errors (equivalently false positives or false discoveries) and R is the total number of hypothesis tests called significant (equivalently total discoveries). The *family-wise error rate* (FWER) is defined to be

$$\text{FWER} = \mathbf{Pr}(V \geq 1),$$

and the *false discovery rate* (FDR) is usually defined to be (Benjamini and Hochberg 1995):

$$\text{FDR} = \mathbf{E}\left[\frac{V}{R \vee 1}\right] = \mathbf{E}\left[\frac{V}{R}\middle| R > 0\right]\mathbf{Pr}(R > 0).$$

The effect of "$R \vee 1$" in the denominator of the first expectation is to set $V/R = 0$ when $R = 0$. As demonstrated by Benjamini and Hochberg (1995), the FDR offers a less strict

False Discovery Rate. Table 1 Possible outcomes from m hypothesis tests based on applying a significance threshold $t \in (0,1]$ to their corresponding p-values

	Not significant (p-value $> t$)	Significant (p-value $\leq t$)	Total
Null true	U	V	m_0
Alternative true	T	S	m_1
	W	R	m

multiple testing criterion than the FWER, allowing it to be more appropriate for some applications.

Two other false discovery rate definitions have been proposed in the literature, where the main difference is in how the $R = 0$ event is handled. These quantities are called the *positive false discovery rate* (pFDR) and the *marginal false discovery rate* (mFDR), and they are defined as follows (Storey 2003, 2007):

$$\text{pFDR} = \mathbf{E}\left[\frac{V}{R}\middle| R > 0\right],$$
$$\text{mFDR} = \frac{\mathbf{E}[V]}{\mathbf{E}[R]}.$$

Note that pFDR = mFDR = 1 whenever all null hypotheses are true, whereas FDR can always be made arbitrarily small because of the extra term $\mathbf{Pr}(R > 0)$. Some have pointed out that this extra term in the FDR definition may lead to misinterpreted results, and pFDR or mFDR offer more scientifically relevant values (Storey 2003; Zaykin et al. 1998), while others have argued that FDR is preferable because it allows for the traditional "strong control" criterion to be met (Benjamini and Hochberg 1995). All three quantities can be utilized in practice, and they are all similar when the number of hypothesis tests is particularly large.

Control and Estimation

There are two approaches to utilizing false discovery rates in a conservative manner when determining multiple testing significance. One approach is to fix the acceptable FDR level beforehand, and find a data-dependent thresholding rule so that the expected FDR of this rule over repeated studies is less than or equal to the pre-chosen level. This property is called *FDR control* (Benjamini and Hochberg 1995; Shaffer 1995). Another approach is to fix the p-value threshold at a particular value and then form a point estimate of the FDR whose expectation is greater than or equal to the true FDR at that particular threshold (Storey 2002). The latter approach has been useful in that it places multiple testing in the more standard context of point estimation, whereas the derivation of algorithms in the former approach may be less tractable. Indeed, it has been shown that the point estimation approach provides a comprehensive and unified framework (Storey et al. 2004).

For the first approach, (Benjamini and Hochberg 1995) proved that the algorithm below for determining a data based p-value threshold controls the FDR at level α when the p-values corresponding to true null hypotheses are independent and identically distributed (i.i.d.) Uniform(0,1). Other p-value threshold determining algorithms for FDR control have been subsequently studied (e.g., Benjamini and Liu 1999). This algorithm was originally introduced by Simes (1986) to control the FWER when all p-values are independent and all null hypotheses are true, although it also provides control of the FDR for any configuration of true and false null hypotheses.

FDR Controlling Algorithm (Simes, 1986; Benjamini and Hochberg, 1995)
1. Let $p_{(1)} \le \ldots \le p_{(m)}$ be the ordered, observed p-values.
2. Calculate $\widehat{k} = \max\{1 \le k \le m : p_{(k)} \le \alpha \cdot k/m\}$.
3. If $\widehat{k}$ exists, then reject null hypotheses corresponding to $p_{(1)} \le \ldots \le p_{(\widehat{k})}$. Otherwise, reject nothing.

To formulate the point estimation approach, let $\text{FDR}(t)$ denote the FDR when calling null hypotheses significant whenever $p_i \le t$, for $i = 1, 2, \ldots, m$. For $t \in (0,1]$, we define the following ▶stochastic processes based on the notation in Table 1:

$$V(t) = \#\{\text{true null } p_i : p_i \le t\},$$
$$R(t) = \#\{p_i : p_i \le t\}.$$

In terms of these, we have

$$\text{FDR}(t) = \mathbf{E}\left[\frac{V(t)}{R(t) \vee 1}\right].$$

For fixed t, Storey (2002) provided a family of conservatively biased point estimates of $\text{FDR}(t)$:

$$\widehat{\text{FDR}}(t) = \frac{\widehat{m}_0(\lambda) \cdot t}{[R(t) \vee 1]}.$$

The term $\widehat{m}_0(\lambda)$ is an estimate of m_0, the number of true null hypotheses. This estimate depends on the tuning parameter λ, and it is defined as

$$\widehat{m}_0(\lambda) = \frac{m - R(\lambda)}{(1 - \lambda)}.$$

It can be shown that $\mathbf{E}[\widehat{m}_0(\lambda)] \ge m_0$ when the p-values corresponding to the true null hypotheses are Uniform(0,1) distributed (or stochastically greater). There is an inherent bias/variance trade-off in the choice of λ. In most cases, when λ gets smaller, the bias of $\widehat{m}_0(\lambda)$ gets larger, but the variance gets smaller. Therefore, λ can be chosen to try to balance this trade-off. Storey and Tibshirani (2003) provide an intuitive motivation for the $\widehat{m}_0(\lambda)$ estimator, as well as a method for smoothing over the $\widehat{m}_0(\lambda)$ to obtain a tuning parameter free $\widehat{m}_0$ estimator. Sometimes instead

of m_0, the quantity $\pi_0 = m_0/m$ is estimated, where simply $\widehat{\pi}_0(\lambda) = \widehat{m}_0(\lambda)/m$.

To motivate the overall estimator $\widehat{\text{FDR}}(t) = \widehat{m}_0(\lambda) \cdot t/[R(t) \vee 1]$, it may be noted that $\widehat{m}_0(\lambda) \cdot t \approx V(t)$ and $[R(t) \vee 1] \approx R(t)$. It has been shown under a variety of assumptions, including those of Benjamini and Hochberg (1995), that the desired property $\mathbf{E}\left[\widehat{\text{FDR}}(t)\right] \geq \text{FDR}(t)$ holds.

Storey et al. (2004) have shown that the two major approaches to false discovery rates can be unified through the estimator $\widehat{\text{FDR}}(t)$. Essentially, the original FDR controlling algorithm can be obtained by setting $\widehat{m}_0 = m$ and utilizing the p-value threshold $t^*_\alpha = \max\left\{t : \widehat{\text{FDR}}(t) \leq \alpha\right\}$. By allowing for the different estimators $\widehat{m}_0(\lambda)$, a family of FDR controlling procedures can be derived in this manner. In the asymptotic setting where the number of hypothesis tests m is large, it has also been shown that the two approaches are essentially equivalent.

Q-Values

In single hypothesis testing, it is common to report the p-value as a measure of significance. The "q-value" is the FDR based measure of significance that can be calculated simultaneously for multiple hypothesis tests. Initially it seems that the q-value should capture the FDR incurred when the significance threshold is set at the p-value itself, $\text{FDR}(p_i)$. However, unlike Type I error rates, the FDR is not necessarily strictly increasing with an increasing significance threshold. To accommodate this property, the q-value is defined to be the minimum FDR (or pFDR) at which the test is called significant (Storey 2002, 2003):

$$\text{q-}value(p_i) = \min_{t \geq p_i} \text{FDR}(t) \quad \text{or}$$
$$\text{q-}value(p_i) = \min_{t \geq p_i} \text{pFDR}(t).$$

To estimate this in practice, a simple plug-in estimate is formed, for example:

$$\widehat{\text{q}}\text{-}value(p_i) = \min_{t \geq p_i} \widehat{\text{FDR}}(t).$$

Various theoretical properties have been shown for these estimates under certain conditions, notably that the estimated q-values of the entire set of tests are simultaneously conservative as the number of hypothesis tests grows large (Storey et al. 2004).

Bayesian Derivation

The pFDR has been shown to be exactly equal to a Bayesian derived quantity measuring the probability that a significant test is a true null hypothesis. Suppose that (a) $H_i = 0$ or 1 according to whether the ith null hypothesis is true or not, (b) $H_i \overset{i.i.d.}{\sim} \text{Bernoulli}(1-\pi_0)$ so that $\mathbf{Pr}(H_i = 0) = \pi_0$ and $\mathbf{Pr}(H_i = 1) = 1-\pi_0$, and (c) $P_i|H_i \overset{i.i.d.}{\sim} (1-H_i)\cdot G_0 + H_i \cdot G_1$, where G_0 is the null distribution and G_1 is the alternative distribution. Storey (2001, 2003) showed that in this scenario

$$\text{pFDR}(t) = \mathbf{E}\left[\frac{V(t)}{R(t)} \middle| R(t) > 0\right] = \mathbf{Pr}(H_i = 0 | P_i \leq t),$$

where $\mathbf{Pr}(H_i = 0|P_i \leq t)$ is the same for each i because of the i.i.d. assumptions. Under these modeling assumptions, it follows that $\text{q-value}(p_i) = \min_{t \geq p_i} \mathbf{Pr}(H_i = 0|P_i \leq t)$, which is a Bayesian analogue of the p-value – or rather a "Bayesian posterior Type I error rate." Related concepts were suggested as early as 1955 (Morton 1955). In this scenario, it also follows that $\text{pFDR}(t) = \int \mathbf{Pr}(H_i = 0|P_i = p_i) dG(p_i|p_i \leq t)$, where $G = \pi_0 G_0 + (1-\pi_0)G_1$. This connects the pFDR to the posterior error probability $\mathbf{Pr}(H_i = 0|P_i = p_i)$, making this latter quantity sometimes interpreted as a *local false discovery rate* (Efron et al. 2001; Storey 2001).

Dependence

Most of the existing procedures for utilizing false discovery rates in practice involve assumptions about the p-values being independent or weakly dependent. An area of current research is aimed at performing multiple hypothesis tests when there is dependence among the hypothesis tests, specifically at the level of the data collected for each test or the p-values calculated for each test. Recent proposals suggest modifying FDR controlling algorithms or extending their theoretical characterizations (Benjamini and Yekutieli 2001), modifying the null distribution utilized in calculating p-values (Devlin and Roeder 1999; Efron 2004), or accounting for dependence at the level of the originally observed data in the model fitting (Leek and Storey 2007, 2008).

About the Author

Dr. John D. Storey is Associate Professor of Genomics and Molecular Biology at Princeton University, with associated appointments in the Program in Applied and Computational Mathematics and the Department of Operations Research and Financial Engineering. He is currently an Associate editor of the *Annals of Applied Statistics* and *PLoS Genetics*, and has previously served on the editorial boards of *Biometrics*, *Biostatistics*, and *PLoS ONE*. He has published over 40 articles, including several highly cited articles on multiple hypothesis testing. He was recently recognized by Thomson Reuters as one of the top ten most cited mathematicians in the last decade.

Farmer Participatory Research Designs

Kaku Sagary Nokoe
Professor
University for Development Studies, Navrongo, Ghana

Introduction

Multilocation trials often follow classical on-station agronomic and breeding trials to test developed varieties under varying local conditions. Often these trials are imposed on farmer fields or set up as demonstration trials only to be viewed and ultimately to be adopted by rural poor farmers. On-farm trials involving the participation or use of farmers' fields have been applied in various studies, including: taungya and intercropping trials; mother–baby breeding trials aimed at selecting for specific traits in breed; augmented block designs (ABD) with emphasis on technology or selection of best or adaptable variety of crop under conditions of urgency and insufficient quantities of planting materials; crop livestock systems involving farmer management practices and animal preferences; and in the evaluation of adaptation and adoption of technologies. These trials are characterized by a high degree of variability within and between farmer fields (Mutsaers et al. 1997; Nokoe 1999; Odong 2002). Statistical issues of primary concern embrace the need for trial locations under farmer conditions, and why and how farmers may be involved to ensure acceptability and analyzability of selected designs.

From an intuitive but nonstatistical point of view, the involvement of all stakeholders (end user, researcher, community, donor) in the design of a trial, and the testing of trials under real-farm conditions utilizing options including maximum farmer management, is a sure way of enhancing adaptability and adoption. For breeders, there is a considerable advantage in time as duration from on-station to on-farm and then release is considerably shortened and results made more certain and output acceptable. On-farm research (OFR) has been variously classified, but generally could be grouped according to the level of farmer involvement. The class of interest in this entry is that involving the active participation of the farmer right from the design to the execution phases.

As an example, a participatory on-farm trial involving a crop–livestock system involved the following steps:

- Farmers and research institutions established formal collaborative linkages.
- Farmers discussed needs and prevailing cultural practices with researchers.

- Researchers and farmers evaluated intervention strategies.
- Statisticians guided selection of farmers and treatment allocations.
- Farmers randomly assigned inferior treatments allowed to change over time.

Arising from the above that is relevant from the point of view of designs is the fact that farmers are involved in the choice of treatments, blocks, and consequently the sampling or experimental designs. The implication is that block sizes are rarely of the same size or homogeneous, while considerable variability in some factors (such as variation in planting times) is common. In addition, it is common practice to have several standard controls (farmer practices), while in crop yield assessments the entire (not net or inner) plots are observed. Since, farmer differences are confounded in treatment, comparison of on-farm trials extend beyond differences in treatment effects. Mutsaers et al. (1997) point out that testing under farmer-field conditions and with their involvement provides a realistic assessment of the technologies or innovations under evaluation. Furthermore, the large number of farmers required is essential for capturing the expectedly high variation among farmer practices and sites. This large number should not be seen as a disadvantage, as the trade-off is the potentially high rate of adaptation and adoption of promising technologies (Nokoe 1999, 2000).

We shall consider general approaches aimed at the effective construction and analysis of farmer participatory designs.

The Design

Basic experimental principles (►randomization, replication, blocking, scope, and experimental error minimization) hold for participatory designs. The enforcement of these principles enables objectivity, estimation of standard errors, and effective comparison of treatment effects.

Identifying the Blocks

On-farm trials expectedly involve the use of block designs. The usual practice is to assume as blocks villages/communities (singly or cluster) and farm sites. This practice of assigning or identifying blocks is not very appropriate, though convenient. A preferred procedure would involve the use of statistical methods such as principal component and cluster analysis for constructing clusters. Classification variables must be relevant to the principal objectives of the study and would include socioeconomic, demographic, agronomic, and historical variables among others. It is emphasized that clusters are based on nontreatment characteristics that have the potential of influencing yields. As expected, the resulting blocks would not necessarily be contiguous, and that several farm sites from different villages, possibly distant-apart, may belong to the same block. Examples include classification of farm sites in an agroforestry and socioeconomic study and classification of farmers on the basis of soil type and cultural practices adopted. An alternative procedure, the post-model-based approach, would involve fitting a model (including discriminant functions) and then creating groups on the basis of limits of expected values, to which individuals may then be assigned.

Standard Block Structures

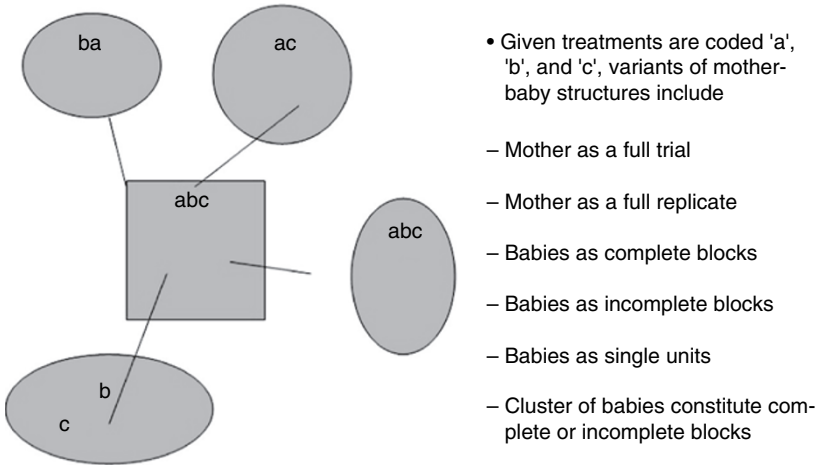
The block sizes may be equal (with each block receiving the same number of treatments) or balanced/unbalanced incomplete. Balanced complete block structure would generally imply treatments and pairs appear the same number of times in the experiment, and are present in all blocks. For incomplete block structures, several variants are available. These include alpha and cyclic incomplete block structures, and may be balanced with pairs of treatments appearing the same number of times in the experiment. Discussions on such designs are well documented (see, e.g., Cox and Reid 2000; and basic texts on designs). When block sizes are unequal, a fully balanced structure is not imaginable. Expectedly, in participatory designs, natural block structures are usually of the unequal and unbalanced type.

Augmented Block Structures

In recent times, block structures augmented with additional treatments, which are usually not replicated, are common in use. Augmented block designs (ABD) involve enlargement of blocks of a design (with treatments already assigned) to accommodate new treatments which appear usually once in the entire experiment (Federer 1955). The design allows for a wide range of technologies to be tested without necessarily straining resources or stifling farmers' interest [e.g., "1000 lines" in an on-farm situation is feasible]. Pinney (1991) provides an illustrated example for participatory agroforestry research.

Mother–Baby Structures

These block structures involve several blocks of varying sizes (Figure 1), with usually the larger sized one (the mother) having all or accommodating more treatments than the other blocks (baby/babies). The mother could also constitute a full trial with necessary replicates, and



Farmer Participatory Research Designs. Fig. 1 Treatment and Allocation to Blocks in Mother–Baby Trial

could represent an on-station or researcher-managed component of the trial. Babies may also be complete or incomplete blocks or as single experimental units with clusters of babies constituting blocks. The final block structure is arrived at after determining the number and sizes of the clusters.

Choice, Number of Treatments and Treatment Structures

The choice and number of treatments are made by consensus and on factors involved. The number need not be small as popularized in earlier works on OFR. However, the guiding principles are wide coverage (in the allocation of the treatments to the blocks), the willingness of the participating farmers, and availability of resources for the trial at the farmer/site level. The structure could be a single factor (say already packaged technologies or crop variety), factorial, or nested involving two or more factors. For factorial treatment structures, an alternative is the sequential or stepwise (step-up or step-down) arrangements. Stepwise allocation of treatments enable fewer number of treatments constituted from a number of factors, but the order of factor levels is crucial and needs to be well determined with all stakeholders. An example of factorial and corresponding stepwise is given in Table 1, where only four out of eight treatments are required for the stepwise (step-up and step-down options).

It is recommended that the decision to include a level of a factor, and at what step in the stepwise structure, must be determined jointly with all stakeholders. The sequence of factor levels affects and restricts the type of contrasts or comparisons that could reasonably be made (see, e.g., Mutsaers et al. 1991). It is also important the inability to estimate interactions is a major drawback of stepwise structures.

Observations and Measurements

Each farmer site represents different environments. Observations or measurements should therefore cover all other variables likely to account for the expectedly high variability. In crop trials with the response variable of interest being yield per hectare, there may be a need to include as many covariates (e.g., stand at establishment at plot level; soil depth, slope at field level; rainfall and labor cost at village level) and regressors (e.g., shade, labor size) as possible. In addition it is the gross and not the net plot that is observed. One basic advantage of such measurements from gross instead of usually uniform micro-net plot (as in on-station trials) is that yields are more likely to be realistic. Studies have shown that conversion of yield from micro to farmer level on the basis of small uniform on-station plot sizes considerably overestimates the real or farmer yield (Odulaja and Nokoe 1997).

Analytical Options

Several analytical options may be adapted from conventional ►analysis of variance and regression modeling. The particular option to use will be influenced by the desired objective, the hypotheses of interests, and the nature of the response variables. The response variables may be continous (normally or non-normally distributed) or discrete

Farmer Participatory Research Designs. Table 1 Breakdown of treatment structure using factorial and stepwise procedures

3	Recommended	Local	Farmers own	3
4	Local	Local	Farmers own	4

(counts, ordinal, binary outcomes) or nominal outcomes. The options are briefly outlined.

Simple Analysis (Adjusted by Local Controls)

Treatments in farmer/village blocks are adjusted by farmer/village's own treatment (control) either directly (e.g., difference in response) or used as covariate (especially in situations where the farmer site is not a block).

Stability Analysis

Adaptability (stability) analysis made popular by Hildebrand in the 1980s for genotype by environment interaction can readily be adapted. This is a regression-based method used initially in genotype by environment interaction studies, where the treatment response is fitted to site mean and the estimated slope examined (see Example of output in Table 2). In the example, Variety differences were small; while high yields were associated with Fertilizer input. In particular, tropical zea streak resistance (TZSR) with Fertilizer input should be recommended – stable yields (with slope close to 1) imply same yield may be expected across all sites for this treatment combination. It may also be noted that Local/300 associated with certain sites (i.e., high yields of local with 300L fertilizer expected at some locations).

An alternative and enhanced procedure is through the use of *biplot and AMMI (additive main effect multiplicative analysis) models* (See, e.g., text of Milliken and Johnson 1987 or notes on Matmodel Software by Gauch). AMMI involves the partitioning of variance. For data presented in a contingency table format, biplot may also be obtained via the method of ►correspondence analysis which involves the partitioning of the chi-square.

Analysis of variance (ANOVA) with mixed models, where the error structure is adequately catered for and Contrasts, can be effectively used. In the mixed model scenario blocks, farmers, sites, etc., are usually treated as random effects being respectively a random sample from a large bulk. In particular, mixed modeling is most appropriate for augmented block designs (ABDs) and mother baby trials (MBTs) (Nokoe 1999), as it enables recovery of both inter-block and inter-treatment variation (Wolfinger et al. 1997). In ABDs, replicated lines are treated as fixed while non-replicated lines are considered as random.

Regression modeling is recommended for several situations where the design is not balanced, and/or when several auxiliary variables are available. These covariates or regressors, when included in the model, lead to considerable improvement in fit (Mutsaers et al. 1997; Carsky et al. 1998) and reduction of experimental error.

Categorical response variables, which constitute a substantial percentage of response variables, have not been modeled appropriately in several studies. These are better fitted by appropriate categorical modeling procedures, including the logistic and loglinear models (Bellon and Reeves 2002; Agresti 1990). An example of a trial with categorical responses is given in Table 3 (experimental setting and results) and Table 4 (partial data). In Table 4, the reader is to note the different types of response variables in the same data set – nominal (site history, indicating previous crop on farm site), ordinal (size of finger of plantains coded 1–3), and binary (size of plantain bunch and acceptability of product). It is important to indicate that a mixture of categorical and continuous variables is common in participatory design analysis.

Farmer Participatory Research Designs. Table 4 A summary of the plantain on-farm trial with categorical response variables

The experimental setting and variables	Models fitted and conclusions
Four Agro-Ecological zones across West/ Central/Eastern Africa involved Six plantain cultivars A, B, C, D, E, and F evaluated against local cultivar Only four cultivars allocated to farmers; each farmer provided four sites, one for each of the four allocated cultivars. Farmers local planted along with each cultivar or separately (as they wished) Previous field history recorded as: Fal – Fallow prior to trial Maz – Maize planted previous year Pla – Field already with plantain Weevil history (previous year when plantain had been cultivated): H – High Weevil population M – Medium Weevil population L – Low Medium population Response variables (assessed against local variety by farmers and chief) Bunch size: Binary - normal, small Finger size: Ordinal - 1 (least) to 4 (highest) Marketabilty: Binary - accept(able), not	*Logistic model* for bunch size, marketability as function of field history, weevil history, and other covariates, and regressors that may be available *Cumulative logit* model fitted to finger size Main conclusions: 1. Weevil history is the most important determinant of marketability 2. For bunch size, only finger size was significant at $p = 0.0434$. At 10% level of significance, study identified Weevil history and finger size as significant determinants of bunch size.

Conclusion

Participatory research designs can be planned and executed with scientifically verifiable results as outcome. It is emphasized that the understanding and active involvement of the farmer or end user are nontrivial considerations that need to be strictly adhered to for a successful research design aimed at addressing the needs of the usually poor rural farmer in developing countries. Adoption and adaptation of improved technologies are enhanced if all stakeholders are involved in the entire process. Blocking is a key ingredient in participatory designs, while the use of several regressors and covariates facilitate proper handling of the expectedly large variation between and within farm sites and farmer practices. The cocktail of analytical options requires adequate knowledge of statistical designs and the use of appropriate statistical software.

Federal Statistics in the United States, Some Challenges

Edward J. Spar
Executive Director
Council of Professional Associations on Federal Statistics, Alexandria, VA, USA

The Current Status

Are the federal statistical agencies in the United States meeting their mandates? Overall, the answer is yes. Surveys that are required for policy purposes in health, education, labor, and other areas are being conducted with well-tested statistical designs that so far have reasonable margins of error. The decennial census, even with an under and over count meets the needs of the Constitution and thousands of federal, state and local data users. Measures, including labor force data, gross domestic product, the system of national accounts, health, education, and income estimates are excellently covered by the federal statistical agencies. Estimates of the population are reasonable even in situations where high immigration and/or internal migration, that have disproportionate influence, take place. The agencies are very sensitive of the need to maintain the confidentiality of respondents. Based on the above, it sounds as if the federal statistical system in the United States is healthy and on track; yet what about the future?

Ongoing and Upcoming Issues

Many new problems are facing the statistical agencies in the United States, and it will take enormous effort to solve them. Indeed, the agencies are fully aware of them and understand that there is a need for innovative thinking. An example of the type of innovation that has already taken place is the U.S. Census Bureau's American Community Survey. This is a replacement for the decennial census long form, and at the same time as an ongoing annual survey of about three million housing units, is unique. The ability to have data available every year for national, state, and local geographies is an important step for a dynamic country such as the United States. Another innovative set of data is the U.S. Census Bureau's Longitudinal Employer–Household Employer Dynamic. Using a mathematical model to insure non-disclosure, data are available for detailed employment statistics at very local geographic levels.

An issue that is becoming critical and is being looked at closely is the declining response rates in key federal surveys that measure employment, income, consumer expenditures, health and education, for example. Surveys that were achieving rates in the middle to high 90% range are now attaining response rates well below that. Clearly, the continuing decline in non-response will have serious effects on the usefulness of data collected. Either the statistical error will become so high so as to make the estimates of limited value, or, perhaps even worse, with biases due to non-response, the data may lose most of its value. Clearly the statistical agencies are aware of the problem and much research is being conducted to determine if address-listing techniques, for example, can be of use in conjunction with telephone interviewing. Some work has been accomplished in the areas of non-response and statistical and non-statistical biases but much more is required. The issue of conducting telephone surveys (see ►Telephone Sampling: Frames and Selection Techniques), given the elimination of land lines on the part of households and their turning to the increasing use of cell phones, must be addressed.

The data retrieval world has been transformed by the world-wide-web. The concept of charging for governmental data is no longer realistic given the assumption on the part of users that all data should be free on-line. Also, search engines such as Google have enabled users to retrieve diverse information as an integrated "package."

However, data integration across federal statistical agencies is for the most part limited. For example, there is no way to analyze and reconcile the many different measures of income between and sometimes even within an agency. Each agency creates its own web site and its own data dissemination system with little or no regard to the fact that the user has to go to a over a dozen sites and learn a dozen approaches to data retrieval to get a complete review of the socio-economic data of the United States. Indeed, if the user wants to integrate the data, it's much easier, but more expensive to go to a private sector vendor to do the work for you. At a time when the web is there for the specific purpose to retrieve information easily, freely, and comprehensively, this approach is outdated. The time has come for an integration of data processing and retrieval systems. This should be accomplished even though the structure of the federal statistical system in the United States is highly decentralized. The concept of a single system in the case of the United States, and probably most countries, is misleading. In reality what you have is a confederation of agencies for the most part reporting to different jurisdictions and quite independent of each other. In the United States, there is very limited administrative record data sharing and with separate Internet sites mentioned above, little integration of tabulated data sets. Each agency has its own budget and except for the purchasing of surveys from the U.S. Census Bureau, little in the way of financial interaction. Unfortunately, because of this lack of centralization, the agencies don't have great influence with the Congress. (This is not the case during the decennial census cycle where the apportionment of Congressional seats can impact a member of the House of Representatives. Other data series such as employment and inflation are also closely looked at.) This lack of influence can be a problem for an agency that each year must request funding for its programs. Would a centralized single agency help solve this? An agency large enough to be noticed by Congress and the Administration as being critical to the overall health of the nation would have a better opportunity of receiving the needed resources to implement innovative statistical techniques.

To perhaps overstate the case, the days of taking censuses and surveys may soon be coming to an end. We may be at the crossroads of having to rely, for the very most part, on administrative records. The use of administrative record data brings up issues of confidentiality on the part of agencies and the sensitivity to the privacy needs of the public. Yet these data may have to become the basis for measuring health, education, employment, expenditure, transportation, energy use and many more statistical needs on the part of the federal government. Using administrative data will call for public/private sector coordinated analyses and the allocation of talent and research dollars. If the use of administrative data becomes the norm, it is not too outré to see a time when no data will be real – put another way, they will be modeled estimates based on the original data series. As previously mentioned, we already see such a transformation in the U.S. Census Bureau's Longitudinal Employer-Household Employer Dynamic program produced at the local level. Indeed, once the block group level data from the American Community Survey are analyzed, we may also see some move in the same direction.

Over the next few years, much of the senior staffs of statistical agencies will be of retirement age. At the same time, it's difficult for agencies to hire new personnel and hold on to talented statisticians and economists that have entered the federal statistical system. The private sector offers both higher salaries and the opportunity to diversify. Indeed, the problem of "stove-piping" within statistical agencies, where talented people are expected to stay in one place for an overly extended period of time, is counter-productive. There is a need to develop a system whereby people can move not only within an agency, but also across agencies. Such a system of diverse training will be required so that personnel can develop the skills needed to address the concerns that have been mentioned in this review.

The challenges reviewed above are only the beginning. In order to properly measure the effects of the current and probably future economic crises in the United States, timely and relevant data are needed for those who have to make informed decisions affecting all Americans.

Fiducial Inference

Jan Hannig[1], Hari Iyer[2], Thomas C. M. Lee[3]

Introduction

The origin of Generalized Fiducial Inference can be traced back to R. A. Fisher (Fisher 1930, 1933, 1935) who introduced the concept of a fiducial distribution for a

parameter, and proposed the use of this fiducial distribution, in place of the Bayesian posterior distribution, for interval estimation of this parameter. In the case of a one-parameter family of distributions, Fisher gave the following definition for a fiducial density $f(\theta|x)$ of the parameter based on a single observation x for the case where the cdf $F(x|\theta)$ is a monotonic decreasing function of θ:

$$f(\theta/x) = -\frac{\partial F(x|\theta)}{\partial \theta}. \tag{1}$$

In simple situations, especially in one parameter families of distributions, Fisher's fiducial intervals turned out to coincide with classical confidence intervals. For multiparameter families of distributions, the fiducial approach led to confidence sets whose frequentist coverage probabilities were close to the claimed confidence levels but they were not exact in the frequentist sense. Fisher's proposal led to major discussions among the prominent statisticians of the 1930's, 40's and 50's (e.g., Dempster 1966, 1968; Fraser 1961a, b, 1966, 1968; Jeffreys 1940; Lindley 1958; Stevens 1950). Many of these discussions focused on the nonexactness of the confidence sets and also nonuniqueness of fiducial distributions. The latter part of the 20th century has seen only a handful of publications Barnard (1995); Dawid and Stone (1982); Dawid et al. (1973); Salome (1998); Wilkinson (1977) as the fiducial approach fell into disfavor and became a topic of historical interest only.

Recently, the work of Tsui and Weerahandi (1989, 1991) and Weerahandi (1993, 1994, 1995) on generalized confidence intervals and the work of Chiang (2001) on the *surrogate variable method* for obtaining confidence intervals for variance components, led to the realization that there was a connection between these new procedures and fiducial inference. This realization evolved through a series of works (Hannig 2009b; Hannig et al. 2006b; Iyer and Patterson 2002; Iyer et al. 2004; Patterson et al. 2004). The strengths and limitations of the fiducial approach is becoming to be better understood, see, especially, Hannig (2009b). In particular, the asymptotic exactness of fiducial confidence sets, under fairly general conditions, was established in Hannig et al. (2006b); Hannig (2009a,b).

Subsequently Hannig et al. (2003); Iyer et al. (2004); McNally et al. (2003); Wang and Iyer (2005, 2006a,b) applied this fiducial approach to derive confidence procedures in many important practical problems. Hannig (2009b) extended the initial ideas and proposed a Generalized Fiducial Inference procedure that could be applied to arbitrary classes of models, both parametric and nonparametric, both continuous and discrete. These applications include Bioequivalence Hannig et al. (2006a), Variance Components Lidong et al. (2008), Problems of Metrology Hannig et al. (2007, 2003); Wang and Iyer (2005, 2006a, b), Interlaboratory Experiments and International Key Comparison Experiments Iyer et al. (2004), Maximum Mean of a Multivariate Normal Distribution Wandler and Hannig (2009), Mixture of a Normal and Cauchy Glagovskiy (2006), Wavelet Regression Hannig and Lee (2009), ▶Logistic Regression and LD_{50} Lidong et al. (2009). Recently, other authors have also contributed to research on fiducial methods and related topics (e.g., Berger and Sun 2008; Wang 2000; Xu and Li 2006).

Generalized Fiducial Distribution

The idea underlying Generalized Fiducial Inference comes from an extended application of Fisher's fiducial argument, which is briefly described as follows. Generalized Fiducial Inference begins with expressing the relationship between the data, $\mathbf{X}$, and the parameters, $\boldsymbol{\theta}$, as

$$\mathbf{X} = G(\boldsymbol{\theta}, \mathbf{U}), \tag{2}$$

where $G(\cdot,\cdot)$ is termed structural equation, and $\mathbf{U}$ is the random component of the structural equation whose distribution is completely known. The data $\mathbf{X}$ are assumed to be created by generating a random variable $\mathbf{U}$ and plugging it into the structural equation (2).

For simplicity, this section only considers the case where the structural relation (2) can be inverted and the inverse $G^{-1}(\cdot,\cdot)$ always exists. Thus, for any observed $\mathbf{x}$ and for any arbitrary $\mathbf{u}$, $\boldsymbol{\theta}$ is obtained as $\boldsymbol{\theta} = G^{-1}(\mathbf{x}, \mathbf{u})$. Fisher's *Fiducial Argument* leads one to define the fiducial distribution for $\boldsymbol{\theta}$ as the distribution of $G^{-1}(\mathbf{x}, \mathbf{U}^\star)$ where $\mathbf{U}^\star$ is an independent copy of $\mathbf{U}$. Equivalently, a sample from the fiducial distribution of $\boldsymbol{\theta}$ can be obtained by generating $\mathbf{U}_i^\star$, $i = 1, \ldots, N$ and using $\boldsymbol{\theta}_i = G^{-1}\left(\mathbf{x}, \mathbf{U}_i^\star\right)$. Estimates and confidence intervals for $\boldsymbol{\theta}$ can be obtained based on this sample.

Hannig (2009b) has generalized this to situations where G is not invertible. The resulting fiducial distribution is called a Generalized Fiducial Distribution. To explain the idea we begin with Eq. 2 but do not assume that G is invertible with respect to $\boldsymbol{\theta}$. The inverse $G^{-1}(\cdot,\cdot)$ may not exist for one of the following two reasons: for any particular $\mathbf{u}$, either there is no $\boldsymbol{\theta}$ satisfying (2), or there is more than one $\boldsymbol{\theta}$ satisfying (2).

For the first situation, Hannig (2009b) suggests removing the offending values of $\mathbf{u}$ from the sample space and then re-normalizing the probabilities. Such an approach has also been used by Fraser (1968) in his work on structural inference. Specifically, we generate $\mathbf{u}$ conditional on the event that the inverse $G^{-1}(\cdot,\cdot)$ exists. The rationale

for this choice is that we know our data $\mathbf{x}$ were generated with some $\boldsymbol{\theta}_0$ and $\mathbf{u}_0$, which implies there is at least one solution $\boldsymbol{\theta}_0$ satisfying (2) when the "true" $\mathbf{u}_0$ is considered. Therefore, we restrict our attention to only those values of $\mathbf{u}$ for which $G^{-1}(\cdot,\cdot)$ exists. However, this set has probability zero in many practical situations leading to non-uniqueness due to the Borel paradox (Casella and Berger 2002, Section 4.9.3). The Borel paradox is the fact that when conditioning on an event of probability zero, one can obtain any answer.

The second situation can be dealt with either by selecting one of the solutions or by the use of the mechanics underlying Dempster-Shafer calculus Dempster (2008). In any case, Hannig (2009a) proved that this non-uniqueness disappears asymptotically under very general assumptions.

Hannig (2009b) proposes the following formal definition of the generalized fiducial recipe. Let $\mathbf{X} \in \mathbb{R}^n$ be a random vector with a distribution indexed by a parameter $\boldsymbol{\theta} \in \boldsymbol{\Theta}$. Recall that the data generating mechanism for $\mathbb{X}$ is expressed by (2) where G is a jointly measurable function and $\mathbf{U}$ is a random variable or vector with a completely known distribution independent of any parameters. We define for any measurable set $A \in \mathbb{R}^n$ a set-valued function

$$Q(A,\mathbf{u}) = \{\boldsymbol{\theta} : G(\boldsymbol{\theta},\mathbf{u}) \in A\}. \tag{3}$$

The function $Q(A,\mathbf{u})$ is the generalized inverse of the function G. Assume $Q(A,\mathbf{u})$ is a measurable function of $\mathbf{u}$.

Suppose that a data set was generated using (2) and it has been observed that the sample value $\mathbf{x} \in A$. Clearly the values of $\boldsymbol{\theta}$ and $\mathbf{u}$ used to generate the observed data will satisfy $G(\boldsymbol{\theta},\mathbf{u}) \in A$. This leads to the following definition of a generalized fiducial distribution for $\boldsymbol{\theta}$:

$$Q(A,\mathbf{U}^\star) \mid \{Q(A,\mathbf{U}^\star) \neq \emptyset\}, \tag{4}$$

where $\mathbf{U}^\star$ is an independent copy of $\mathbf{U}$.

The object defined in (4) is a random set of parameters (such as an interval or a polygon) with distribution conditioned on the set being nonempty. It is well-defined provided that $P(Q(A,\mathbf{U}^\star) \neq \emptyset) > 0$. Otherwise additional care needs to be taken to interpret this distribution (c.f., Hannig 2009b). In applications, one can define a distribution on the parameter space by selecting one point out of $Q(A,\mathbf{U}^\star)$.

Examples

The following examples provide simple illustrations of the definition of a generalized fiducial distribution.

Example 1 Suppose $\mathbf{U} = (U_1,U_2)$ where U_i are i.i.d. $N(0,1)$ and $\mathbb{X} = (X_1,X_2) = G(\mu,\mathbf{U}) = (\mu+U_1,\mu+U_2)$ for some $\mu \in \mathbb{R}$. So X_i are iid $N(\mu,1)$. Given a realization $\mathbf{x} = (x_1,x_2)$ of $\mathbb{X}$, the set-valued function Q maps $\mathbf{u} = (u_1,u_2) \in R^2$ to a subset of $\mathbb{R}$ and is given by

$$Q(\mathbf{x},\mathbf{u}) = \begin{cases} \{x_1 - e_1\} & \text{if} \quad x_1 - x_2 = u_1 - u_2, \\ \emptyset & \text{if} \quad x_1 - x_2 \neq u_1 - u_2. \end{cases}$$

By definition, a generalized fiducial distribution for μ is the distribution of $x_1 - U_1^\star$ conditional on $U_1^\star - U_2^\star = x_1 - x_2$ where $\mathbf{U}^\star = \left(U_1^\star, U_2^\star\right)$ is an independent copy of $\mathbf{U}$. Hence a generalized fiducial distribution for μ is $N(\bar{x},1/2)$ where $\bar{x} = (x_1+x_2)/2$.

Example 2 Suppose $\mathbf{U} = (U_1,\ldots,U_n)$ is a vector of i.i.d. uniform $(0,1)$ random variables U_i. Let $p \in [0,1]$. Let $X = (X_1,\ldots,X_n)$ be defined by $X_i = I(U_i < p)$. So X_i are iid Bernoulli random variables with success probability p. Suppose $x = (x_1,\ldots,x_n)$ is a realization of X. Let $s = \sum_{i=1}^n x_i$ be the observed number of 1's. The mapping $Q : [0,1]^n \to [0,1]$ is given by

$$Q(x,\mathbf{u}) = \begin{cases} [0,u_{1:n}] & \text{if} \quad s = 0, \\ (u_{1:n},1] & \text{if} \quad s = n, \\ (u_{s:n},u_{s+1:n}] & \text{if} \quad s = 1,\ldots,n-1 \text{ and} \\ & \sum_{i=1}^n I(x_i = 1)I(u_i \leq u_{s:n}) = s, \\ \emptyset & \text{otherwise.} \end{cases}$$

Here $u_{r:n}$ denotes the rth order statistic among $u_1,\ldots,u_n$. So a generalized fiducial distribution for p is given by the distribution of $Q(x,\mathbf{U}^\star)$ conditional on the event $Q(x,\mathbf{U}^\star) \neq \emptyset$. By the exchangeability of $U_1^\star,\ldots,U_n^\star$ it follows that the stated conditional distribution of $Q(x,\mathbf{U}^\star)$ is the same as the distribution of $\left[0,U_{1:n}^\star\right]$ when $s = 0$, $\left(U_{s:n}^\star,U_{s+1:n}^\star\right]$ for $0 < s < n$, and $\left(U_{n:n}^\star,1\right]$ for $s = n$.

Next, we present a general recipe that is useful in many practical situations.

Example 3 Let us assume that the observations $X_1,\ldots,X_n$ are i.i.d. univariate with distribution function $F(x,\xi)$ and density $f(x,\xi)$, where ξ is a p-dimensional parameter. Denote the generalized inverse of the distribution function by $F^{-1}(\xi,u)$ and use the structural equation

$$X_i = F^{-1}(\xi,U_i) \qquad \text{for} \quad i = 1,\ldots,n. \tag{5}$$

If all the partial derivatives of $F(x,\xi)$ with respect to ξ are continuous and the Jacobian

$$\det\left(\frac{\mathbf{d}}{\mathbf{d}\xi}\left(F(x_{i_1},\xi),\ldots,F(x_{i_p},\xi)\right)\right) \neq 0$$

for al distinct $x_1, \ldots, x_p$, then Hannig (2009b) shows that the generalized fiducial distribution (4) is

$$r(\xi) = \frac{f_{\mathbf{X}}(\mathbf{x}|\xi) J(\mathbf{x}, \xi)}{\int_{\Xi} f_{\mathbf{X}}(\mathbf{x}|\xi') J(\mathbf{x}, \xi')\, d\xi'}, \tag{6}$$

where

$$J(\mathbf{x}, \xi) = \sum_{\mathbf{i}=(i_1,\ldots,i_p)} \left| \frac{\det\left(\frac{\mathbf{d}}{\mathbf{d}\xi}\left(F(x_{i_1}, \xi), \ldots, F(x_{i_p}, \xi)\right)\right)}{f(x_{i_1}, \xi) \cdots f(x_{i,p}, \xi)} \right|. \tag{7}$$

This provides a form of generalized fiducial distribution that is usable in many practical applications, see many of the papers mentioned in introduction. Moreover, if $n = p = 1$ (6) and (7) simplify to the Fisher's original definition (1).

Equation 6 is visually similar to Bayes posterior. However, the role of the prior is taken by the function $J(\mathbf{x}, \xi)$. Thus unless $J(\mathbf{x}, \xi) = k(\mathbf{x})l(\xi)$ where k and l are measurable functions, the generalized fiducial distribution is not a posterior distribution with respect to any prior. A classical example of such a situation is in Grundy (1956).

Moreover, $\binom{n}{p}^{-1} J(\mathbf{x}, \xi)$ is a ►U-statistic and therefore it often converges a.s. to

$$\pi_{\xi_0}(\xi) = E_{\xi_0} \left| \frac{\det\left(\frac{\mathbf{d}}{\mathbf{d}\xi}\left(F(X_1, \xi), \ldots, F(X_p, \xi)\right)\right)}{f(X_1, \xi) \cdots f(X_p, \xi)} \right|$$

At first glance $\pi_{\xi_0}(\xi)$ could be viewed as an interesting non-subjective prior. Unfortunately, this prior is not usable in practice, because the expectation in the definition of $\pi(\xi)$ is taken with respect to the true parameter ξ_0 which is unknown. However, since $\binom{n}{p}^{-1} J(\mathbf{x}, \xi)$ is an estimator of $\pi_{\xi_0}(\xi)$, the generalized fiducial distribution (6) could be interpreted as an empirical Bayes posterior.

Financial Return Distributions

Matthias Fischer
University of Erlangen-Nürnberg, Erlangen, Germany

Describing past and forecasting future asset prices has been attracting the attention of several generations of researchers. Rather than analyzing the asset prices P_t at times $t = 1, \ldots, T$ themselves, one usually focusses on the corresponding log-returns defined by $R_t^c = \log(P_t) - \log(P_{t-1})$ for $t = 2, \ldots, T$. Considering prices (and consequently log-returns) as realizations of random variables, it seems natural to identify the underlying data-generating probability distribution. The search for an adequate model for the distribution of stock market returns dates back to the beginning of the twentieth century: Following Courtault et al. (2000), "*The date March 29, 1900, should be considered as the birthdate of mathematical finance. On that day, a French postgraduate student, Louis Bachélier, successfully defended at the Sorbonne his thesis Théorie de la Spéculation. […] This pioneering analysis of the stock and option markets contains several ideas of enormous value in both finance and probability. In particular, the theory of Brownian motion (see* ►*Brownian Motion and Diffusions*), *was initiated and used for the mathematical modelling of price movements and the evaluation of contingent claims in financial markets*".

Whereas Bachélier (1900) rests upon normally distributed return distributions, the history of heavy tails in finance began in 1963: Assuming independence of successive increments and the validity of the principle of scaling invariance, Mandelbrot (1963) advocates the (Lévy) stable distributions for price changes, supported by Fama (1965) and Fielitz (1976). In fact, tails of stable distributions are very heavy, following a power-law distribution with an exponent $\alpha < 2$. In contrast, empirical studies indicate that tails of most financial time series have to be modeled with $\alpha > 2$ (see, e.g., Lau et al. 1990 or Pagan 1996). In particular,

Akgiray et al. (1989) support this conjecture for German stock market returns. Rejecting the stable hypothesis, several proposals came up in the subsequent years: Praetz (1972), Kon (1984) or Akgiray and Booth (1987) favour finite mixtures of normal distributions, whereas, e.g., Ball and Torous (1983) propose an infinite number of normal distributions mixtures with Poisson probabilities.

Since the early seventies of the last century, the Student-*t* distribution increases in popularity (see, e.g., Blattberg and Gonedes 1974). Depending on the shape and tail parameter ν, moments of the Student-*t* distribution exist only up to a certain order depending on ν, whereas the ►moment-generating function doesn't exist. In order to increase its flexibility regarding ►skewness, peakedness and tail behavior, several generalized Student-*t* versions followed up within the past years (see, e.g., McDonald and Newey 1988; Theodossiou 1998; Hansen et al. 2003 or Adcock and Meade 2003). Finally, if both (semi-)heavy tails and existence of the corresponding moment-generating function are required, different multi-parametric distribution families with exponential tail behavior were successfully applied to financial returns: Among them, the generalized logistic distribution family (see, e.g., Bookstaber and McDonald 1987; McDonald 1991 or McDonald and Bookstaber 1991), the generalized hyperbolic secant distribution families (see, e.g., Fischer 2004, 2006) and the generalized hyperbolic distribution family (see, e.g., Eberlein and Keller 1995; Barndorff-Nielsen 1995; Küchler et al. 1999 and Prause 1999) which in turn includes a subfamily (in the limit) where one tail has polynomial and the other exponential tails, see Aas and Haff (2006).

Selecting a suitable probability distribution for a given return data sample is by far not an easy task. In general, there is no information about the tail behavior of the unknown distribution or, conversely, about the order up to which the corresponding moments exit. Discussions as to whether moments, in particular variances, do exist or not, have a long tradition in financial literature (see, for instance, Tucker 1992). In order to check whether certain moments do exist or not, Granger and Orr (1972) introduced the so-called running-variance plot. Alternatively, the test statistic of Yu (2000) – which is determined by the range of the sample interquartile and the sample standard deviation – may come to application. Recently, Pisarenko and Sornette (2006) came up with a test statistic to discriminate between exponential and polynomial tail behavior.

First Exit Time Problem

Christos H. Skiadas[1], Charilaos Skiadas[2]
[1]Professor, Director of the Data Analysis and Forecasting Laboratory
Technical University of Crete, Chania, Greece
[2]Hanover College, Hanover, IN, USA

The first exit time distribution for a stochastic process is the distribution of the times at which particles following this process cross a certain (often linear) barrier. It is often referred to also as hitting time. It is closely related to the probability density function $p(x_t, t)$ of a stochastic process x_t over time t.

For a linear horizontal barrier located at a, the first exit time density function relation is given by: $g(t) = \frac{|a|}{t} p(a, t)$.

For other types barriers (e.g., quadratic), a tangent approximation may be used to obtain a satisfactory estimate as is presented below.

The probability density function may be computed in some cases using the Fokker-Planck equation. In particular in the one-dimensional diffusion problem expressed by a stochastic differential equation of the form:

$$dx_t = \sigma dw_t,$$

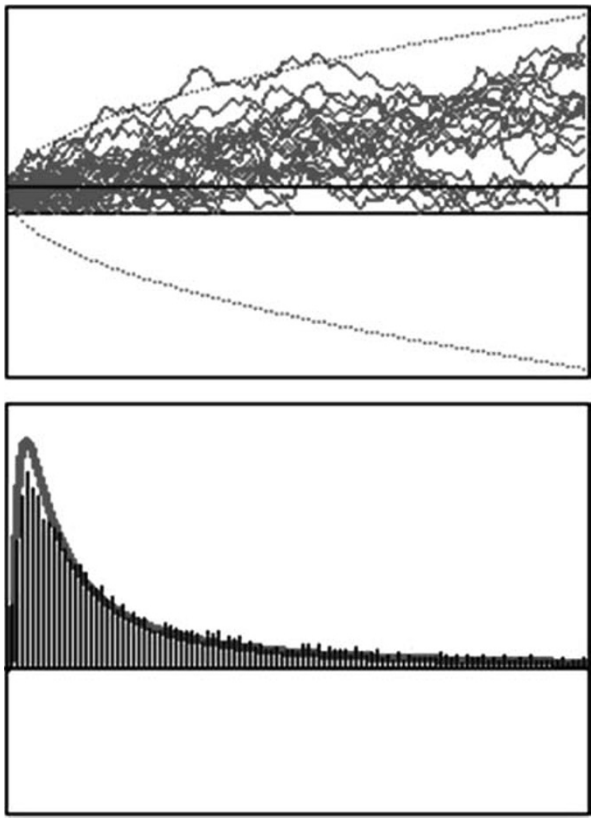
where σ is the variance and w_t is the standard Wiener process, the corresponding Fokker-Planck equation for the probability density function $p(x_t, t)$ associated to the above stochastic differential equation has the form:

$$\frac{\partial p(x_t, t)}{\partial t} = \frac{\sigma^2}{2} \frac{\partial^2 p(x_t, t)}{\partial x_t^2}$$

This partial differential equation form is also known as the one-dimensional heat equation first solved by Joseph Fourier (1822). Later on Fick (1855a; 1855b) applied this equation to express one-dimensional diffusion in solids. Albert Einstein (1905) proposed the same form for the one-dimensional diffusion for solving the Brownian motion process (see ►Brownian Motion and Diffusions). It was the first derivation and application of a probabilistic-stochastic theory to the classical Brownian motion problem that is the movement of a particle or a molecule into a liquid. He resulted in giving the development over space and time of this particle. One year later Smoluchowski (1906) proposed also a theory for solving the Brownian motion problem.

Solving this partial differential equation with the boundary conditions, $p(x_t, 0 : 0, 0) = \delta(x_t, 0)$ and $\frac{\partial p(x_t, t : 0, t)}{\partial x} = 0$ as $x_t \to \infty$ the probability density function p_t for the stochastic process results:

$$p(x_t, t) = \frac{1}{\sigma\sqrt{2\pi t}} e^{-\frac{x_t^2}{2\sigma^2 t}}.$$



First Exit Time Problem. Fig. 1 Linear barrier

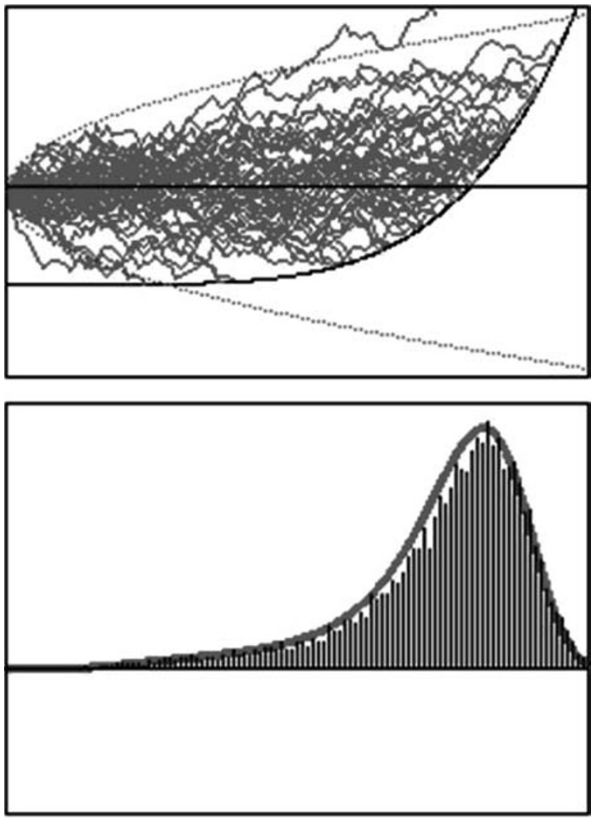
The First Exit Time Density Function

The finding of a density function expressing the distribution of the first exit time of particles escaping from a boundary is due to Schrödinger (1915) and Smoluchowski (1915) in two papers published in the same journal issue. Later on Siegert (1951) gave an interpretation closer to our modern notation whereas Jennen (1985), Lerche (1986) and Jennen and Lerche (1981) gave the most interesting first exit density function form. For the simple case presented earlier the proposed form is:

$$g(t) = \frac{|a|}{t} p(a,t) = \frac{|a|}{\sigma\sqrt{2\pi t^3}} e^{-\frac{a^2}{2\sigma^2 t}}.$$

Jennen (1985) proposed a more general form using a tangent approximation of the first exit density. Application of this theory to the mortality modeling leads to the following form (earlier work can be found in Janssen and Skiadas (1995) and Skiadas and Skiadas (2007):

$$g(t) = \frac{|H_t - tH_t'|}{t} p(t) = \frac{|H_t - tH_t'|}{\sigma\sqrt{2\pi t^3}} e^{-\frac{(H_t)^2}{2\sigma^2 t}}.$$



First Exit Time Problem. Fig. 2 Curved barrier

The last form is associated to the following stochastic process Skiadas (2010):

$$dx_t = \mu_t dt + \sigma dw_t$$

where μ_t is a function of time and there exists a function H_t related to μ_t with the differential equation: $\mu_t = dH_t/dt$.

The associated Fokker–Planck equation is:

$$\frac{\partial p(x_t,t)}{\partial t} = -\mu_t \frac{\partial p(x_t,t)}{\partial x_t} + \frac{\sigma^2}{2} \frac{\partial^2 p(x_t,t)}{\partial x_t^2}$$

and the solution is given by:

$$p(t) = \frac{1}{\sigma\sqrt{2\pi t^3}} e^{-\frac{(H_t)^2}{2\sigma^2 t}}.$$

Two realizations are provided in Figs. 1 and 2. In the first case the first exit time probability density function is provided and stochastic simulations are done for a linear barrier located at α. Figure 2 illustrates the case when a curved barrier is present.

First-Hitting-Time Based Threshold Regression

Xin He[1], Mei-Ling Ting Lee[2]
[1]Assistant Professor
University of Maryland, College Park, MD, USA
[2]Professor, Director, Biostatistics and Risk Assessment Center (BRAC)
University of Maryland, College Park, MD, USA

First-hitting-time (FHT) based threshold regression (TR) model is a relatively new methodology for analyzing ►survival data where the time-to-event is modeled as the first time the stochastic process of interest hits a boundary threshold. FHT models have been applied in analyzing the failure time of engineering systems, the length of hospital stay, the survival time of AIDS patients, and the duration of industrial strikes, etc.

First-Hitting-Time (FHT) Model

A first-hitting-time (FHT) model has two basic components, namely a stochastic process $\{Y(t), t \in \mathcal{T}, y \in \mathcal{Y}\}$ with initial value $Y(0) = y_0$, where $\mathcal{T}$ is the time space and $\mathcal{Y}$ is the state space of the process; and a boundary set $\mathcal{B}$, where $\mathcal{B} \subset \mathcal{Y}$. Assume that the initial value of the process y_0 lies outside the boundary set $\mathcal{B}$, then the first hitting time can be defined by the random variable

$$S = \inf\{t : Y(t) \in \mathcal{B}\},$$

where S is the first time the sample path of the stochastic process reaches the boundary set $\mathcal{B}$. In a medical context, the stochastic process $\{Y(t)\}$ may describe a subject's latent health condition or disease status over time t. The boundary set $\mathcal{B}$ represents a medical end point, such as death, or disease onset. Although the boundary set $\mathcal{B}$ is set to be fixed in time in basic FHT models, it may vary with time in some applications. The stochastic process $\{Y(t)\}$ in the FHT model may take many forms. The most commonly used process is a Wiener diffusion process with a positive initial value and a negative drift parameter. Alternative processes including the gamma process, the Ornstein-Uhlenbeck (OU) process, and the semi-Markov process have also been investigated. For a review, see Lee and Whitmore (2006) and Aalen et al. (2008).

Threshold Regression

Threshold regression (TR) is an extension of the first-hitting-time model by adding regression structures to it so as to accommodate important covariates. The threshold regression model does not required the proportional hazards assumption and hence it provides an alternative model for analyzing time-to-event data. The unknown parameters in the stochastic process $\{Y(t)\}$ and the boundary set $\mathcal{B}$ are connected to covariates using suitable regression link functions. For example, the initial state y_0 and the drift parameter μ of a Wiener diffusion process $\{Y(t)\}$ can be linked to covariates using general link functions of the form

$$y_0 = g_1(\mathbf{x})$$

and

$$\mu = g_2(\mathbf{x}),$$

where $\mathbf{x}$ is the vector of covariates (Lee et al. 2000; Lee and Whitmore 2006). Pennell et al. (2010) proposed a TR model with Bayesian random effects to account for unmeasured covariates in both the initial state and the drift. Yu et al. (2009) incorporated penalized regression and regression splines to TR models to accommodate semi-parametric nonlinear covariate effects.

Analytical Time Scale

In stead of calendar time, in many applications involving time-dependent cumulative effects, an alternative time scale can be better used in describing the stochastic process. Let $r(t|\mathbf{x})$ denote a monotonic transformation of calendar time t to analytical time r (or referred to as process time) with $r(0|\mathbf{x}) = 0$. In a medical context, the analytical time may be some time-dependent measure to describe cumulative toxic exposure or the progression of disease. The process $\{Y(r)\}$ defined in terms of analytical time r can be expressed as a subordinated process $\{Y[r(t)]\}$ in terms of calendar time t. Lee and Whitmore (1993, 2004) examined the connection between subordinated stochastic processes and analytical time.

Whitmore et al. (1998) proposed a bivariate Wiener model in which failure is governed by a latent process while auxiliary readings are available from a correlated marker process. Lee et al. (2000) extended this model to bivariate threshold regression by including CD4 cell counts as a marker process in the context of AIDS clinical trials.

Tong et al. (2008) generalized the bivariate TR model to current status data. Using Markov decomposition methods, Lee et al. (2010) generalized threshold regression to include time-dependent covariates. Lee and Whitmore (2010) discussed the connections between TR and proportional hazard regressions and demonstrated that proportional hazard functions can be generated by TR models.

About the Author

Professor Lee was named the Mosteller Statistician of the Year in 2005 by the American Statistical Association, Boston Chapter. She is Elected member of the International Statistical Institute (1995), and Elected Fellow of: Royal Statistical Society (1998), American Statistical Association (1999) and the Institute of Mathematical Statistics (2005). Professor Lee is the Founding Editor and Editor-in-Chief of the international journal *Lifetime Data Analysis*.

Fisher Exact Test

Peter Sprent
Emeritus Professor
University of Dundee, Dundee, UK

The Fisher Exact test was proposed by Fisher (1934) in the fifth edition of *Statistical Methods for Research Workers*. It is a test for independence as opposed to association in 2×2 contingency tables.

A typical situation where such tables arise is where we have counts of individuals categorized by each of two dichotomous attributes, e.g., one attribute may be religious affiliation dichotomized into Christian and non-Christian and the other marital status recorded as married or single.

Another example is that where one of the attributes that are dichotomized corresponds to treatments, e.g., Drug A prescribed, or Drug B prescribed, and the other attribute is the responses to those treatments, e.g., patient condition improves or patient condition does not improve.

In the latter situation if 9 patients are given Drug A and 12 patients are given drug B we might observe the following counts in cells of a 2×2 table:

	Improvement	No improvement	Row total
Drug A	8	1	9
Drug B	3	9	12
Column totals	11	10	21

Fisher pointed out that if we assume row and column totals are fixed then once we know the entry in any cell of the table (e.g., here 8 in the top left cell) then the entries in the remaining three cells are all fixed by the constraint that the marginal totals are fixed. This is usually expressed by saying the table has one degree of freedom. What Fisher noted is that under the hypothesis of independence, if we assume the marginal totals fixed then the distribution of the numbers in the first cell (or any other cell) has a hypergeometric distribution under independence for any of the common models associated with such a table as described, for example in Agresti (2002) or Sprent and Smeeton (2007). These common models are (1) that responses to each drug, for example, are binomially distributed with a common value for the binomial parameter p or (2) have a common Poisson distribution, or (3)

the four cell counts are a sample from a ►multinomial distribution.

If a general a 2×2 contingency table has cell entries n_{ij} $(i, j = 1, 2)$ and row totals n_{i+} and column totals n_{+j} and grand total of all 4 cell entries is n, then the hypergeometric distribution for the observed cell values has an associated probability

$$\frac{(n_{1+})!(n_{2+})!(n_{+1})!(n_{+2})!}{(n_{11})!(n_{12})!(n_{21})!(n_{22})!n!}$$

To perform the test one calculates these probabilities for all possible n_{11} consistent with the fixed marginal totals and computes the P-value as the sum of all such probabilities that are less than or equal to that associated with the observed configuration. For the numerical example given above n_{11} may take any integral value between 0 and 9 and the following table gives the corresponding hypergeometric probabilities:

n_{11}	Hypergeometric probability
0	0.00003
1	0.00168
2	0.02245
3	0.11788
4	0.28295
5	0.33008
6	0.18862
7	0.05052
8	0.00561
9	0.00019

From this table we see that the observed $n_{11} = 8$ has associated probability $p = 0.00561$ and the only other outcomes with this or a lower probability correspond to $n_{11} = 0, 1$ or 9. Thus the test P-value is $P = 0.00561 + 0.00168 + 0.00019 + 0.00003 = 0.00751$.

This low P-value provides very strong evidence of association, i.e., that the drugs differ in effectiveness.

In practice, except for very small samples appropriate statistical software is required to compute P. When the expected numbers in each cell assuming independence are not too small the standard chi-squared test for contingency tables gives a close approximation to the exact test P-value especially if Yates's correction (*see* Sprent and Smeeton 2007) is used.

The exact test procedure was extended by Freeman and Halton (1951) to tables with any specified numbers of rows and columns.

Some statisticians have argued that it is inappropriate to condition the test statistics on fixed marginal totals, but it is now widely accepted that in most, though not perhaps in all, situations arising in practice such conditioning is appropriate.

Fisher-Tippett Theorem

Bojan Basrak
University of Zagreb, Zagreb, Croatia

In 1928, Fisher and Tippett presented a theorem which can be considered as a founding stone of the *extreme value theory*. They identified all ►*extreme value distributions*, which means all possible nondegenerate limit laws for properly centered and scaled partial maxima $M_n = \max\{X_1, \ldots, X_n\}$, where (X_n) is a sequence of independent and identically distributed random variables. More precisely, if there exist real sequences (a_n) and (b_n) where $a_n > 0$ for all n, such that the random variables

$$\frac{M_n - b_n}{a_n} \quad \text{as } n \to \infty,$$

converge in distribution to a nondegenerate random variable with a distribution function G, then G is called an extreme value distribution. The theorem states that G (permitting centering and scaling) necessarily belongs to one of the following three classes: *Fréchet, Gumbel*, and *Weibull distributions*.

Rigorous proofs of the theorem appearing in contemporary literature are due to Gnedenko in 1943, and works of de Haan and Weissman in 1970s. The class of ►extreme value distributions coincides with the class of *max–stable distributions*, i.e. those distributions of the random variable X_1, for which there exist real constants $c_n > 0$ and d_n for each $n \geq 1$, such that $(M_n - d_n)/c_n$ has the same distribution as X_1.

To determine whether partial maxima of a given family of random variables, after scaling and centering, has asymptotically one of those distributions is one of the main tasks of extreme value analysis. Many of such questions are answered using the notion of regular variation which was introduced in mathematical analysis by Karamata, a couple of years after the publication of Fisher–Tippett theorem.

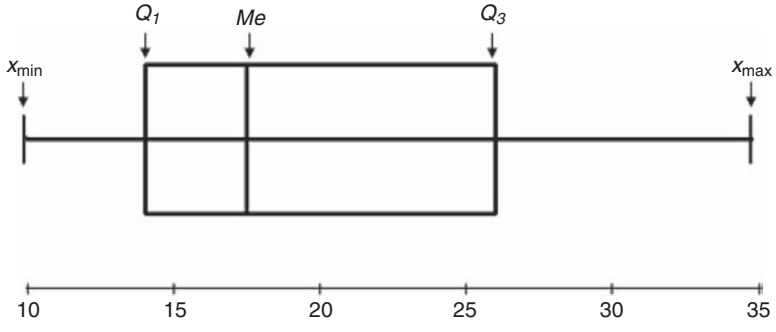
Five-Number Summaries

Mirjana Čižmešija
Professor, Faculty of Economics and Business
University of Zagreb, Zagreb, Croatia

The five-number summary $(5'S)$ is a technique of exploratory data analyses developed with the aim of investigating one or more data sets. It consists of five descriptive measures (Anderson 2007): minimum value $(x_{\min})$, first quartile (Q_1), median (Me), third quartile (Q_3), and maximum value $(x_{\max})$. The graphical presentation of the five-number summary is the box-and-whisker plot (box-plot) developed by John Tukey (Levine 2008). In determining the $5'S$, the data set of observations on a single variable must be arranged from the smallest to the largest value, and therefore the $5'S$ are arranged as follows: $x_{\min} \leq Q_1 \leq Me \leq Q_3 \leq x_{\max}$. Each of these five parameters is important in descriptive statistics for providing information about the dispersion and skew of data sets. ►Outliers in the data set may be detected in the box-plot. In measuring dispersion, the distance between the minimum and maximum value is important (particularly in financial analyses).

The difference between the first and third quartile is the range of the middle 50% of the data in the data set (interquartile range). These differences and the differences between quartiles and the median are important in detecting the shape of the data set. In a symmetrical distribution, the difference between the first quartile and the minimum value is the same as the difference between the maximum value and the third quartile, and the difference between the median and the first quartile is the same as the difference between the third quartile and the median. In a right-skewed distribution, the difference between the first quartile and the minimum value is smaller than the



Five-Number Summaries. Fig. 1 Box-plot

difference between the maximum value and the third quartile, and the difference between the median and the first quartile is smaller than the difference between the third quartile and the median. In a left-skewed distribution, the difference between the first quartile and the minimum value is greater than the difference between the maximum value and the third quartile and the difference between the median and the first quartile is greater than the difference between the third quartile and the median. The five-number summary is a useful tool in comparing the dispersion of two or more data sets.

For example, the following data set

$$10, 11, 14, 15, 17, 18, 20, 26, 26, 35$$

can be described as $5'S$:

$$x_{\min} = 10, \quad Q_1 = 14, \quad Me = 17,5, \quad Q_3 = 26, \quad x_{\max} = 35$$

and graphically displayed by the box-plot in the Fig. 1.

Forecasting Principles

Kesten C. Green[1], Andreas Graefe[2], J. Scott Armstrong[3]
[1]Associate Professor
University of South Australia, Adelaide, SA, Australia
[2]Karlsruhe Institute of Technology, Karlsruhe, Germany
[3]Professor of Marketing
University of Pennsylvania, Philadelphia, PA, USA

Introduction

Forecasting is concerned with making statements about the as yet unknown. There are many ways that people go about deriving forecasts. This entry is concerned primarily with procedures that have performed well in empirical studies that contrast the accuracy of alternative methods.

Evidence about forecasting procedures has been codified as condition-action statements, rules, guidelines or, as we refer to them, *principles*. At the time of writing there are 140 principles. Think of them as being like a safety checklist for a commercial airliner – if the forecast is important, it is important to check all relevant items on the list. Most of these principles were derived as generalized findings from empirical comparisons of alternative forecasting methods. Interestingly, the empirical evidence sometimes conflicts with common beliefs about how to forecast.

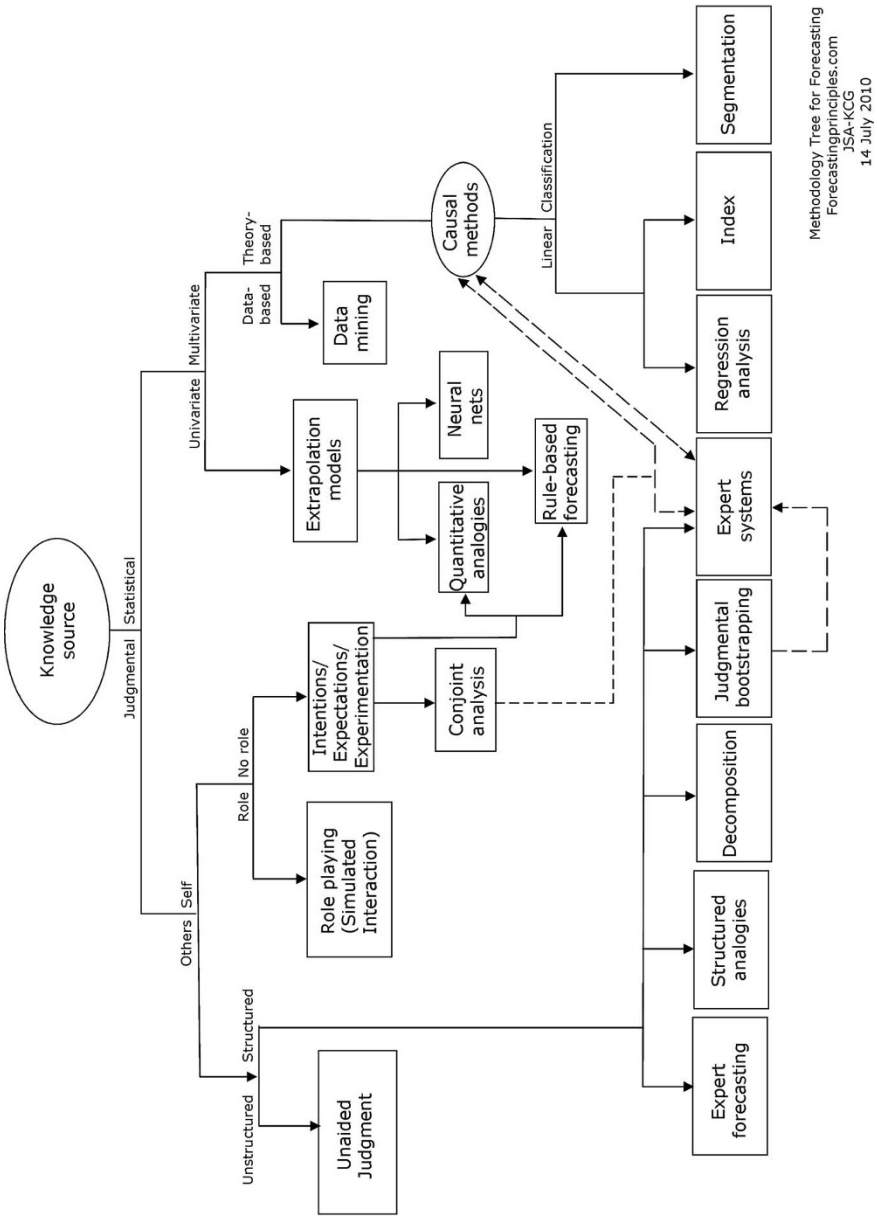
Primarily due to the strong emphasis placed on empirical comparisons of alternative methods, researchers have made many advances in forecasting since 1980. The most influential paper in this regard is the M-competition paper (Makridakis et al. 1982). This was based on a study in which different forecasters were invited to use what they thought to be the best method to forecast many time series. Entry into the competition required that methods were fully disclosed. Entrants submitted their forecasts to an umpire who calculated the errors for each method. This was only one in a series of M-competition studies, the most recent being Makridakis and Hibon (2000). For a summary of the progress that has been made in forecasting since 1980, see Armstrong (2006).

We briefly describe valid forecasting methods, provide guidelines for the selection of methods, and present the *Forecasting Canon* of nine overarching principles. The *Forecasting Canon* provides a gentle introduction for those who do not need to become forecasting experts but who nevertheless rightly believe that proper knowledge about forecasting would help them to improve their decision making. Those who wish to know more can find what they seek in *Principles of Forecasting: A Handbook for Practitioners and Researchers*, and at the Principles of Forecasting Internet site (ForPrin.com).

Forecasting Methods

As shown in Fig. 1, the *Forecasting Methodology Tree*, forecasting methods can be classified into those that are based primarily on judgmental sources of information and those that use statistical data. There is overlap between some judgmental and statistical approaches.

If available data are inadequate for quantitative analysis or qualitative information is likely to increase the accuracy, relevance, or acceptability of forecasts, one way to make forecasts is to ask experts to think about a situation and predict what will happen. If experts' forecasts are not derived using structured forecasting methods, their forecasting method is referred to as *unaided judgment*. This is the most commonly used method. It is fast, inexpensive



Forecasting Principles. Fig. 1 Methodology tree

when few forecasts are needed, and may be appropriate when small changes are expected. It is most likely to be useful when the forecaster knows the situation well and gets good feedback about the accuracy of his forecasts (e.g., weather forecasting, betting on sports, and bidding in bridge games).

Expert forecasting refers to forecasts obtained in a structured way from two or more experts. The most appropriate method depends on the conditions (e.g., time constraints, dispersal of knowledge, access to experts, expert motivation, need for confidentiality). In general, diverse experts should be recruited, questions should be chosen carefully and tested, and procedures for combining across experts (e.g., the use of medians) should be specified in advance.

The *nominal group technique* (NGT) tries to account for some of the drawbacks of traditional meetings by imposing a structure on the interactions of the experts. This process consists of three steps: First, group members work independently and generate individual forecasts. The group then conducts an unstructured discussion to deliberate on the problem. Finally, group members work independently and provide their final individual forecasts. The NGT forecast is the mean or median of the final individual estimates.

Where group pressures are a concern or physical proximity is not feasible, the *Delphi method,* which involves at least two rounds of anonymous interaction, may be useful. Instead of direct interaction, individual forecasts and arguments are summarized and reported as feedback to participants after each round. Taking into account this information, participants provide a revised forecast for the next round. The Delphi forecast is the mean or median of the individual forecasts in the final round. Rowe and Wright (2001) found that Delphi improved accuracy over unstructured groups in five studies, harmed accuracy in one, and the comparison was inconclusive in two. Delphi is most suitable if experts are expected to possess different information, but it can be conducted as a simple one-round survey for situations in which experts possess similar information. A free version of the Delphi software is available at ForPrin.com.

In situations where dispersed information frequently becomes available, *prediction markets* can be useful for providing continuously updated numerical or probability forecasts. In a prediction market, mutually anonymous participants reveal information by trading contracts whose prices reflect the aggregated group opinion. Incentives to participate in a market may be monetary or nonmonetary. Although prediction markets seem promising, to date there has been no published ▶meta-analysis of the method's accuracy. For a discussion of the relative advantages of prediction markets and Delphi, see Green et al. (2007).

With *structured analogies*, experts identify situations that are analogous to a target situation, identify similarities and differences to the target situation, and determine an overall similarity rating. The outcome or decision implied by each expert's top-rated analogy is used as the structured analogies forecast. Green and Armstrong (2007) analyzed structured analogies for the difficult problem of forecasting decisions people will make in conflict situations. When experts were able to identify two or more analogies and their closest analogy was from direct experience, 60% of structured analogies forecasts were accurate compared to 32% of experts' unaided judgment forecasts, the latter being little better than guessing.

Decomposition involves breaking down a forecasting problem into components that are easier to forecast. The components may either be multiplicative (e.g., to forecast a brand's sales, one could estimate total market sales and market share) or additive (estimates could be made for each type of product when forecasting new product sales for a division). Decomposition is most likely to be useful in situations involving high uncertainty, such as when predicting large numbers. MacGregor (2001) summarized results from three studies involving 15 tests and found that judgmental decomposition led to a 42% reduction in error under high levels of uncertainty.

Judgmental bootstrapping derives a model from knowledge of experts' forecasts and the information experts used to make their forecasts. This is typically done by regression analysis. It is useful when expert judgments have validity but data are scarce (e.g., forecasting new products) and outcomes are difficult to observe (e.g., predicting performance of executives). Once developed, judgmental bootstrapping models are a low-cost forecasting method. Armstrong (2001a) found judgmental bootstrapping to be more accurate than unaided judgment in 8 of 11 comparisons. Two tests found no difference, and one found a small loss in accuracy.

Expert systems are based on rules for forecasting that are derived from the reasoning experts use when making forecasts. They can be developed using knowledge from diverse sources such as surveys, interviews of experts, protocol analysis in which the expert explains what he is doing as he makes forecasts, and research papers. Collopy et al. (2001) summarized evidence from 15 comparisons that included expert systems. Expert systems were more accurate than unaided judgment in six comparisons, similar in one, and less accurate in another. Expert systems were less accurate than judgmental bootstrapping in two

comparisons and similar in two. Expert systems were more accurate than econometric models in one comparison and as accurate in two.

It may be possible to ask people directly to predict how they would behave in various situations. However, this requires that people have valid *intentions* or *expectations* about how they would behave. Both are most useful when (1) responses can be obtained from a representative sample, (2) responses are based on good knowledge, (3) people have no reason to lie, and (4) new information is unlikely to change behavior. Intentions are more limited than expectations in that they are most useful when (5) the event is important, (6) the behavior is planned, and (7) the respondent can fulfill the plan (e.g., their behavior is not dependent on the agreement of others). Better yet, in situations in which it is feasible to do so, conduct an experiment by changing key causal variables in a systematic way, such that the independent variables are not correlated with one another. Estimate relationships from responses to the changes and use these estimates to derive forecasts.

Role playing involves asking people to think and behave in ways that are consistent with a role and situation described to them. Role playing for the purpose of predicting the behavior of people with different roles who are interacting with each other is called *simulated interaction*. Role players are assigned roles and asked to act out prospective interactions in a realistic manner. The decisions are used as forecasts of the actual decision. Green (2005) found that 62% of simulated interaction forecasts were accurate for eight diverse conflict situations. By comparison, 31% of forecasts from the traditional approach – expert judgments unaided by structured techniques – were accurate. Game theory experts' forecasts were no better, also 31%, and both unaided judgment and game theory forecasts were little better than chance at 28% accurate.

Conjoint analysis is a method for eliciting people's preferences for different possible offerings (e.g., for alternative mobile phone designs or for different political platforms) by using combinations of features (e.g., size, camera, and screen of a mobile phone.) The possibilities can be set up as experiments where each variable is unrelated to the other variable. Regression-like analyses are then used to predict the most desirable design.

Extrapolation models use time-series data on the situation of interest (e.g., data on automobile sales from 1940–2009) or relevant cross-sectional data. For example, exponential smoothing, which relies on the principle that more recent data is weighted more heavily, can be used to extrapolate over time. Quantitative extrapolation methods do not harness people's knowledge about the data but assume that the causal forces that have shaped history will continue. If this assumption turns out to be wrong, forecast errors can be large. As a consequence, one should only extrapolate trends when they correspond to the prior expectations of domain experts. Armstrong (2001b) provides guidance on the use of extrapolation.

Quantitative analogies are similar to structured analogies. Experts identify analogous situations for which time-series or cross-sectional data are available, and rate the similarity of each analogy to the data-poor target situation. These inputs are used to derive a forecast. This method is useful in situations with little historical data. For example, one could average data from cinemas in suburbs identified by experts as similar to a new (target) suburb in order to forecast demand for cinema seats in the target suburb.

Rule-based forecasting is an expert system for combining expert domain knowledge and statistical techniques for extrapolating time series. Most series features can be identified automatically, but experts are needed to identify some features, particularly causal forces acting on trends. Collopy and Armstrong (1992) found rule-based forecasting to be more accurate than extrapolation methods.

If data are available on variables that might affect the situation of interest, causal models are possible. Theory, prior research, and expert domain knowledge provide information about relationships between the variable to be forecasted and explanatory variables. Since causal models can relate planning and decision-making to forecasts, they are useful if one wants to create forecasts that are conditional upon different states of the environment. More important, causal models can be used to forecast the effects of different policies.

Regression analysis involves estimating causal model coefficients from historical data. Models consist of one or more regression equations used to represent the relationship between a dependent variable and explanatory variables. Regression models are useful in situations with few variables and many reliable observations where the causal factors vary independently of one another. Important principles for developing regression (econometric) models are to (1) use prior knowledge and theory, not statistical fit, for selecting variables and for specifying the directions of effects (2) use simple models, and (3) discard variables if the estimated relationship conflicts with theory or prior evidence.

Real-world forecasting problems are, however, more likely to involve few observations and many relevant variables. In such situations, the *index method* can be used. Index scores are calculated by adding the values of the explanatory variables, which may be assessed subjectively,

for example as zero or one, or may be normalized quantitative data. If there is good prior domain knowledge, explanatory variables may be weighted relative to their importance. Index scores can be used as forecasts of the relative likelihood of an event. They can also be used to predict numerical outcomes, for example by regressing index scores against historical data.

Segmentation is useful when a heterogeneous whole can be divided into homogenous parts that act in different ways in response to changes, and that can be forecasted more accurately than the whole. For example, in the airline industry, price has different effects on business and personal travelers. Appropriate forecasting methods can be used to forecast individual segments. For example, separate regression models can be estimated for each segment. Armstrong (1985:287) reported on three comparative studies on segmentation. Segments were forecasted either by extrapolation or regression analysis. Segmentation improved accuracy for all three studies.

Selection of Methods

The Forecasting Method Selection Tree, shown in Fig .2, provides guidance on selecting the best forecasting method for a given problem. The Tree has been derived from evidence-based principles. Guidance is provided in response to the user's answers to questions about the availability of data and state of knowledge about the situation for which forecasts are required. The first question is whether sufficient objective data are available to perform statistical analyses. If not, the forecaster should use judgmental methods.

In deciding among judgmental procedures, one must assess whether the future is likely to be substantially different from the past, whether the situation involves decision makers who have conflicting interests, and whether policy analysis is required. Other considerations affecting the selection process are whether forecasts are made for recurrent and well-known problems, whether domain knowledge is available, and whether information about similar types of problems is available.

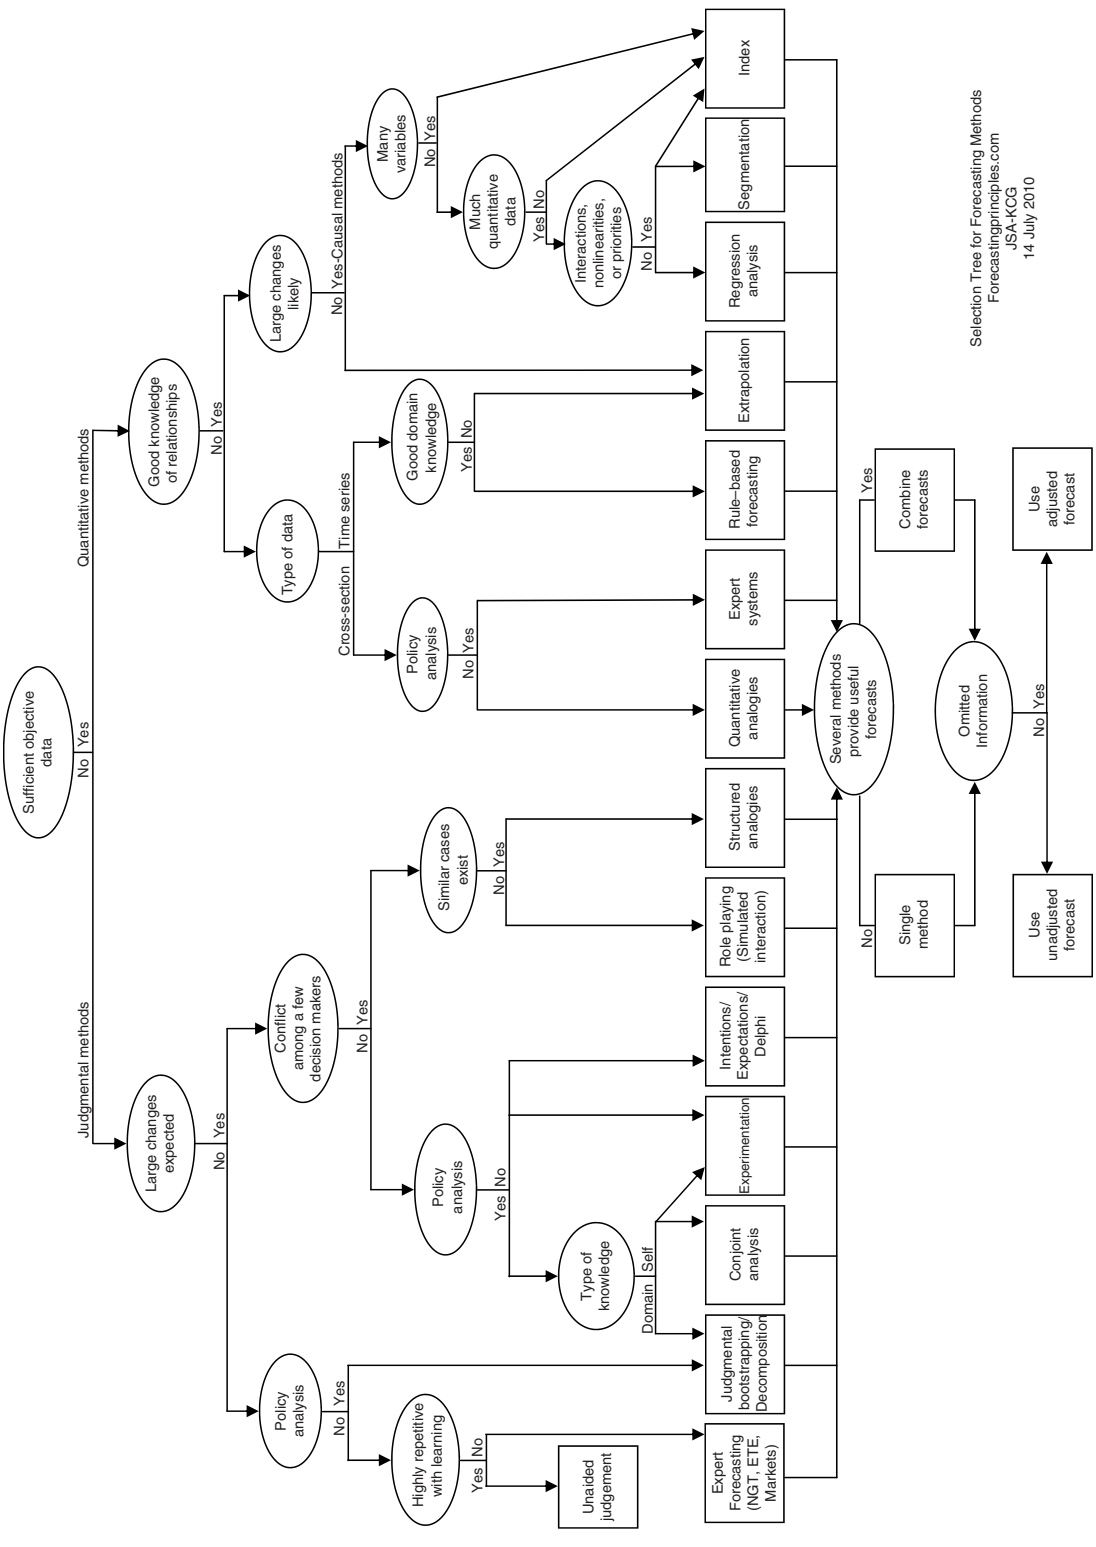
If, on the other hand, much objective data are available and it is possible to use quantitative methods, the forecaster first has to assess whether there is useful knowledge about causal relationships, whether cross-sectional or time-series data are available, and whether large changes are involved. In situations with little knowledge about empirical relationships, the next issues are to assess whether policy analysis is involved and whether there is expert domain knowledge about the situation. If there is good prior knowledge about empirical relationships and the future can be expected to substantially differ from the past, the number of variables and presence or absence of intercorrelation between them, and the number of observations determine which causal method to use. For example, regression models that rely on non-experimental data can typically use no more than three or four variables – even with massive sample sizes. For problems involving many causal variables, variable weights should not be estimated from the dataset. Instead it is useful to draw on independent sources of evidence (such as empirical studies and prior expert knowledge) for assessing the impact of each variable on the situation.

The Forecasting Method Selection Tree provides guidance but on its own, the guidance is not comprehensive. Forecasters may have difficulty identifying the conditions that apply. In such situations, one should use different methods that draw on different information and combine their forecasts according to pre-specified rules. Armstrong (2001c) conducted a meta-analysis of 30 studies and estimated that the combined forecast yielded a 12% reduction in error compared to the average error of the components; the reductions of forecast error ranged from 3% to 24%. In addition, the combined forecasts were often more accurate than the most accurate component. Studies since that meta-analysis suggest that under favorable conditions (many forecasts available for a number of different valid methods and data sources when forecasting for an uncertain situation), the error reductions from combining are much larger. Simple averages are a good starting point but differential weights may be used if there is strong evidence about the relative accuracy of the method. Combining forecasts is especially useful if the forecaster wants to avoid large errors and if there is uncertainty which method will be most accurate.

The final issue is whether there is important information that has not been incorporated in the forecasting methods. This includes situations in which recent events are not reflected in the data, experts possess good domain knowledge about future events or changes, or key variables could not be included in the model. In the absence of these conditions, one should not adjust the forecast. If important information has been omitted and adjustments are needed, one should use a structured approach. That is, provide written instructions, solicit written adjustments, request adjustments from a group of experts, ask for adjustments to be made prior to seeing the forecast, record reasons for the revisions, and examine prior forecast errors.

Forecasting Canon

The Forecasting Canon provides a summary of evidence-based forecasting knowledge, in this case in the form of



Forecasting Principles. Fig. 2 Selection tree

nine overarching principles that can help to improve forecast accuracy. The principles are often ignored by organizations, so attention to them offers substantial opportunities for gain.

Match the Forecasting Method to the Situation

Conditions for forecasting problems vary. No single best method works for all situations. The Forecasting Method Selection Tree (Fig. 2) can help identify appropriate forecasting methods for a given problem. The recommendations in the Selection Tree are based on expert judgment grounded in research studies. Interestingly, generalizations based on empirical evidence sometimes conflict with common beliefs about which forecasting method is best.

Use Domain Knowledge

Managers and analysts typically have useful knowledge about situations. While this domain knowledge can be important for forecasting, it is often ignored. Methods that are not well designed to incorporate domain knowledge include exponential smoothing, stepwise regression, ►data mining and ►neural networks.

Managers' expectations are particularly important when their knowledge about the direction of the trend in a time series conflicts with historical trends in the data (called "contrary series"). If one ignores domain knowledge about contrary series, large errors are likely.

A simple rule can be used to obtain much of the benefit of domain knowledge: when one encounters a contrary series, do not extrapolate a trend. Instead, extrapolate the latest value – this approach is known as the naive or no-change model.

Structure the Problem

One of the basic strategies in management research is to break a problem into manageable pieces, solve each piece, then put them back together. This decomposition strategy is effective for forecasting, especially when there is more knowledge about the pieces than about the whole. Decomposition is particularly useful when the forecasting task involves extreme (very large or very small) numbers.

When contrary series are involved and the components of the series can be forecasted more accurately than the global series, using causal forces to decompose the problem increases forecasting accuracy. For example, to forecast the number of people who die on the highways each year, forecast the number of passenger miles driven (a series that is expected to grow) and the death rate per million passenger miles (a series that is expected to decrease) and then multiply these forecasts.

Model the Experts' Forecasts

Expert systems represent forecasts made by experts and can reduce the costs of repetitive forecasts while improving accuracy. However, expert systems are expensive to develop.

An inexpensive alternative to expert systems is judgmental bootstrapping. The general proposition borders on the preposterous; it is that a simple model of the man will be more accurate than the man. The reasoning is that the model applies the man's rules more consistently than the man can.

Represent the Problem Realistically

Start with the situation and develop a realistic representation. This generalization conflicts with common practice, in which one starts with a model and attempt to generalize to the situation. Realistic representations are especially important when forecasts based on unaided judgment fail. Simulated interaction is especially useful for developing a realistic representation of a problem.

Use Causal Models When You Have Good Information

Good information means that the forecaster (1) understands the factors that have an influence on the variable to forecast and (2) possesses enough data to estimate a regression model. To satisfy the first condition, the analyst can obtain knowledge about the situation from domain knowledge and from prior research. Thus, for example, an analyst can draw upon quantitative summaries of research (meta-analyses) on price or advertising elasticities when developing a sales-forecasting model. An important advantage of causal models is that they reveal the effects of alternative decisions on the outcome, such as the effects of different prices on sales. Index models are a good alternative when there are many variables and insufficient data for regression analysis.

Use Simple Quantitative Methods

Complex models are often misled by noise in the data, especially in uncertain situations. Thus, using simple methods is important when there is much uncertainty about the situation. Simple models are easier to understand than complex models, and are less prone to mistakes. They are also more accurate than complex models when forecasting for complex and uncertain situations – which is the typical situation for the social sciences.

Be Conservative When Uncertain

One should make conservative forecasts for uncertain situations. For cross-sectional data, this means staying close to

the typical behavior (often called the "base rate"). In time series, one should stay close to the historical average. If the historical trend is subject to variations, discontinuities, and reversals, one should be cautious with extrapolating the historical trend. Only when a historical time series show a long steady trend with little variation should one extrapolate the trend into the future.

Combine Forecasts

Combining is especially effective when different forecasting methods are available. Ideally, one should use as many as five different methods, and combine their forecasts using a predetermined mechanical rule. Lacking strong evidence that some methods are more accurate than others, one should use a simple average of forecasts.

Conclusion

This entry gives an overview of methods and principles that are known to reduce forecast error. The Forecasting Method Selection Tree provides guidance for which method to use under given conditions. The Forecasting Canon can be used as a simple checklist to improve forecast accuracy. Further information and support for evidence-based forecasting is available from the *Principles of Forecasting* handbook and from the ForecastingPrinciples.com Internet site.

About the Authors

Dr. Green is a developer of the simulated interactions and structured analogies methods, which have been shown to provide more accurate forecasts of decisions in conflicts than does expert judgment, including the judgments of game theorists. He has been consulted by the U.S. Department of Defense and National Security Agency on forecasting matters. He is co-director of the Forecasting Principles site (ForPrin.com).

Dr. Graefe is the prediction markets editor of *Foresight - The International Journal of Applied Forecasting*. He is currently developing and testing the index method as an alternative to regression analysis, with applications to election forecasting.

Dr. Armstrong has been involved in forecasting since 1960. He has published *Long-Range Forecasting* (1978, 1985) and *Principles of Forecasting* (2001). He is a co-founder of the *Journal of Forecasting* (1982), the *International Journal of Forecasting* (1985), and the *International Symposium on Forecasting* (1981). He is a developer of new forecasting methods including: rule-based forecasting and causal forces for extrapolation. His book, *Persuasive Advertising* was published in 2010.

Forecasting with ARIMA Processes

William W. S. Wei
Professor
Temple University, Philadelphia, PA, USA

One of the most important objectives in the analysis of a time series is to forecast its future values. Let us consider

the time series Z_t from the general ARIMA(p,d,q) process

$$\phi(B)(1-B)^d \dot{Z}_t = \theta(B)a_t, \tag{1}$$

where $\dot{Z}_t = (Z_t - \mu)$ if $d = 0$ and $\dot{Z}_t = Z_t$ when $d \neq 0$, $\phi(B) = (1-\phi_1 B - \cdots - \phi_p B^p)$, $\theta(B) = (1-\theta_1 B - \cdots - \theta_q B^q)$, $\phi(B) = 0$ and $\theta(B) = 0$ share no common roots that lie outside of the unit circle, and the series a_t is a Gaussian $N\left(0, \sigma_a^2\right)$ white noise process.

Minimum Mean Square Error Forecasts and Forecast Limits

Our objective is to derive a forecast with as small an error as possible. Thus, our optimum forecast will be the forecast that has the minimum mean square forecast error. Let us consider the case when $d = 0$ in Eq. (1), and express the process in the moving average representation

$$\dot{Z}_t = \psi(b)a_t = \sum_{j=0}^{\infty} \psi_j a_{t-j}, \tag{2}$$

where $\psi(B) = \sum_{j=0}^{\infty} \psi_j B^j = \theta(B)/\phi(B)$, and $\psi_0 = 1$. More specifically, the ψ_j can be obtained from equating the coefficients of B^j on the both sides of

$$\begin{aligned}(1-\phi_1 B - \cdots - \phi_p B^p)(1+\psi_1 B + \psi_2 B^2 + \cdots)\\ = (1-\theta_1 B - \cdots - \theta_q B^q).\end{aligned} \tag{3}$$

For $t = n + \ell$, we have $\dot{Z}_{n+\ell} = \sum_{j=0}^{\infty} \psi_j a_{n+\ell-j}$. Suppose that at time $t = n$ we have the observations $\dot{Z}_n, \dot{Z}_{n-1}, \dot{Z}_{n-2}, \ldots$ and wish to forecast ℓ-step ahead future values of $\dot{Z}_{n+\ell}$ as a linear combination of the observations $\dot{Z}_n, \dot{Z}_{n-1}, \dot{Z}_{n-2}, \ldots$. Since $\dot{Z}_t$ for $t \leq n$ can all be written in the form of (2), we can let the minimum mean square error forecast $\hat{\dot{Z}}_n(\ell)$ of $\dot{Z}_{n+\ell}$ be

$$\hat{\dot{Z}}_n(\ell) = \psi^*_\ell a_n + \psi^*_{\ell+1} a_{n-1} + \psi^*_{\ell+2} a_{n-2} + \cdots \tag{4}$$

where the ψ^*_j are to be determined. The mean square error of the forecast is

$$E\left[\dot{Z}_{n+\ell} - \hat{\dot{Z}}_n(\ell)\right]^2 = \sigma_a^2 \sum_{j=0}^{\ell-1} \psi_j^2 + \sigma_a^2 \sum_{j=0}^{\infty} \left[\psi_{\ell+j} - \psi^*_{\ell+j}\right]^2,$$

which is easily seen to be minimized when $\psi^*_{\ell+j} = \psi_{\ell+j}$. Hence,

$$\hat{\dot{Z}}_n(\ell) = \psi_\ell a_n + \psi_{\ell+1} a_{n-1} + \psi_{\ell+2} a_{n-2} + \cdots = E(\dot{Z}_{n+\ell} | \dot{Z}_t, t \leq n). \tag{5}$$

$\hat{\dot{Z}}_n(\ell)$ is usually read as the ℓ-*step* ahead forecast of $\dot{Z}_{n+\ell}$ at the forecast origin n.

The forecast error is

$$e_n(\ell) = \dot{Z}_{n+\ell} - \hat{\dot{Z}}_n(\ell) = \sum_{j=0}^{\ell-1} \psi_j a_{n+\ell-j}. \tag{6}$$

Because $E(e_n(\ell)) = 0$ the forecast is unbiased with the error variance

$$Var(e_n(\ell)) = \sigma_a^2 \sum_{j=0}^{\ell-1} \psi_j^2. \tag{7}$$

For a normal process, the $100(1-\alpha)\%$ forecast limits are

$$\hat{\dot{Z}}_n(\ell) \pm N_{\alpha/2} \left[1 + \sum_{j=0}^{\ell-1} \psi_j^2\right]^{1/2} \sigma_a, \tag{8}$$

where $N_{\alpha/2}$ is the standard normal deviate such that $P(N > N_{\alpha/2}) = \alpha/2$.

For a general ARIMA model in (1) with $d \neq 0$ the moving average representation does not exist because when we obtain the ψ_j from equating the coefficients of B^j on the both sides of

$$\begin{aligned}(1-\phi_1 B - \cdots - \phi_p B^p)(1-B)^d (1+\psi_1 B + \psi_2 B^2 + \cdots)\\ = (1-\theta_1 B - \cdots - \theta_q B^q),\end{aligned} \tag{9}$$

the resulting series of ψ_j coefficients is not convergent. However, for practical purposes, one can use Eq. (9) to find a finite number of the ψ_j coefficients. The minimum mean square error forecast is also given by $E(\dot{Z}_{n+\ell} | \dot{Z}_t, t \leq n)$ directly through the use of Eq. (1), and Eqs. (6), (7), and (8) hold also for the general ARIMA process. The main difference between the ARMA and ARIMA processes is that $\lim_{\ell \to \infty} \sum_{j=0}^{\ell-1} \psi_j^2$ exists for a stationary ARMA process but does not exist for a nonstationary ARIMA process. Hence, the eventual forecast limits for a stationary process approach two horizontal lines. For a nonstationary process since $\sum_{j=0}^{\ell-1} \psi_j^2$ increases as ℓ increases, the forecast limits become wider and wider. It implies that the forecaster becomes less certain about the result as the forecast lead time gets larger.

Computation of Forecasts

The general ARIMA process in Eq. (1) can be written as

$$(1-\Psi_1 B - \cdots - \Psi_{p+d} B^{p+d})\dot{Z}_t = (1-\theta_1 B - \cdots - \theta_q B^q)a_t, \tag{10}$$

where $(1-\Psi_1 B - \cdots - \Psi_{p+d} B^{p+d}) = \phi(B)(1-B)^d$. For $t = n+\ell$ we have

$$\begin{aligned}\dot{Z}_{n+\ell} = \Psi_1 Z_{n+\ell-1} + \cdots + \Psi_{p+d} Z_{n+\ell-p-d} + a_{n+\ell}\\ - \theta_1 a_{n+\ell-1} - \cdots - \theta_q a_{n+\ell-q}.\end{aligned}$$

Taking the conditional expectation at time origin n, we get

$$\begin{aligned}\hat{\dot{Z}}_n(\ell) = \Psi_1 \hat{\dot{Z}}_n(\ell-1) + \cdots + \Psi_{p+d} \hat{\dot{Z}}_n(\ell-p-d) + \hat{a}_n(\ell)\\ - \theta_1 \hat{a}_n(\ell-1) - \cdots - \theta_q \hat{a}_n(\ell-q),\end{aligned} \tag{11}$$

where

$$\hat{\dot{Z}}_n(j) = E(\dot{Z}_{n+j}|\dot{Z}_t, t \le n), \qquad j \ge 1,$$
$$\hat{\dot{Z}}_n(j) = \dot{Z}_{n+j}, \qquad j \le 0,$$
$$\hat{a}_n(j) = 0, \qquad j \ge 1,$$

and

$$\hat{a}_n(j) = \dot{Z}_{n+j} - \hat{\dot{Z}}_{n+j-1}(1) = a_{n+j}, \quad j \le 0.$$

Updating Forecasts

Note that from Eq. (6), we have

$$\begin{aligned} e_n(\ell+1) &= \dot{Z}_{n+\ell+1} - \hat{\dot{Z}}_n(\ell+1) \\ &= \sum_{j=0}^{\ell} \psi_j a_{n+\ell+1-j} = e_{n+1}(\ell) + \psi_\ell a_{n+1} \\ &= \dot{Z}_{n+\ell+1} - \hat{\dot{Z}}_{n+1}(\ell) + \psi_\ell a_{n+1}. \end{aligned}$$

Hence, we obtain the equation for updating forecasts,

$$\hat{\dot{Z}}_{n+1}(\ell) = \hat{\dot{Z}}_n(\ell+1) + \psi_\ell[\dot{Z}_{n+1} - \hat{\dot{Z}}_n(1)]. \tag{12}$$

Eventual Forecast Functions

When $\ell > q, \hat{\dot{Z}}_n(\ell)$ in Eq. (11) becomes

$$\Psi(B)\hat{\dot{Z}}_n(\ell) = 0, \tag{13}$$

where $\Psi(B) = \phi(B)(1-B)^d = 1 - \Psi_1 B - \cdots - \Psi_{p+d}B^{p+d}$, and $B\hat{\dot{Z}}_n(\ell) = \hat{\dot{Z}}_n(\ell-1)$. Thus, we can use the difference equation result to obtain the eventual forecast function. That is, if $\Psi(B) = \prod_{i=1}^{K}(1-R_iB)^{m_i}$ with $\sum_{i=1}^{K} m_i = (p+d)$, then

$$\hat{\dot{Z}}_n(\ell) = \sum_{i=1}^{K}\Big(\sum_{j=0}^{m_i-1} c_{ij}\ell^j\Big)R_i^\ell, \tag{14}$$

for $\ell \ge (q-p-d+1)$ where c_{ij} are constants that are functions of time origin n and known data.

An illustrative example: $(1-\phi_1B)(Z_t-\mu) = (1-\theta_1B)a_t$.

a. Computation of $\hat{Z}_n(\ell)$

For $t = n+\ell, Z_{n+\ell} = \mu + \phi_1(Z_{n+\ell-1}-\mu) + a_{n+\ell} - \theta_1 a_{n+\ell-1}$.

Hence

$$\hat{Z}_n(1) = E(Z_{n+1}|Z_t, t \le n) = \mu + \phi_1(Z_n - \mu) - \theta_1 a_t,$$

and

$$\begin{aligned} \hat{Z}_n(\ell) &= E(Z_{n+\ell}|Z_t, t \le n) \\ &= \mu + \phi_1[\hat{Z}_n(\ell-1) - \mu] \\ &= \mu + \phi_1^\ell(Z_n - \mu) - \phi_1^{\ell-1}\theta_1 a_n, \ell \ge 2. \end{aligned}$$

b. The Forecast Error Variance and Forecast Limits

From Eq. (3), $(1-\phi_1B)(1+\psi_1B+\psi_2B^2+\cdots) = (1-\theta_1B)$, and equating the coefficients of B^j on both sides, we get $\psi_j = \phi_1^{j-1}(\phi_1-\theta_1), j \ge 1$. So

$$\hat{Z}_n(\ell) \pm N_{\alpha/2}\left[1 + \sum_{j=0}^{\ell-1}\left[\phi_1^{j-1}(\phi_1-\theta_1)\right]^2\right]^{1/2}\sigma_a.$$

defines the forecast limits.

c. The Eventual Forecast Function

Since $(1-\phi_1B)(\hat{Z}_n(\ell)-\mu) = 0, \ell \ge 1$, and $|\phi_1| < 1$ we have $\hat{Z}_n(\ell) = \mu + c_1\phi_1^\ell \to \mu$ as $\ell \to \infty$. For more detailed discussions and illustrative examples on time series forecasting, we refer readers to Box, Jenkins, and Reinsel (2008), and Wei (2006).

Forecasting: An Overview

Rob J. Hyndman
Professor of Statistics
Monash University, Melbourne, VIC, Australia

What Can Be Forecast?

Forecasting is required in many situations: deciding whether to build another power generation plant in the next 5 years requires forecasts of future demand; scheduling staff in a call centre next week requires forecasts of call volume; stocking an inventory requires forecasts of stock requirements. Forecasts can be required several years in advance (for the case of capital investments), or only a few minutes beforehand (for telecommunication routing). Whatever the circumstances or time horizons involved, forecasting is an important aid in effective and efficient planning.

Some things are easier to forecast than others. The time of the sunrise tomorrow morning can be forecast very precisely. On the other hand, currency exchange rates are very difficult to forecast with any accuracy. The predictability of an event or a quantity depends on how well we understand the factors that contribute to it, and how much unexplained variability is involved.

Forecasting situations vary widely in their time horizons, factors determining actual outcomes, types of data patterns, and many other aspects. Forecasting methods can be very simple such as using the most recent observation as a forecast (which is called the "naïve method"), or highly complex such as ►neural networks and econometric systems of simultaneous equations. The choice of method depends on what data are available and the predictability of the quantity to be forecast.

Forecasting Methods

Forecasting methods fall into two major categories: quantitative and qualitative methods.

Quantitative forecasting can be applied when two conditions are satisfied:

1. numerical information about the past is available;
2. it is reasonable to assume that some aspects of the past patterns will continue into the future.

There is a wide range of quantitative forecasting methods, often developed within specific disciplines for specific purposes. Each method has its own properties, accuracies, and costs that must be considered when choosing a specific method.

Qualitative forecasting methods are used when one or both of the above conditions does not hold. They are also used to adjust quantitative forecasts, taking account of information that was not able to be incorporated into the formal statistical model. These are not purely guesswork – there are well-developed structured approaches to obtaining good judgmental forecasts. However, as qualitative methods are non-statistical, they will not be considered further in this article.

Explanatory Versus Time Series Forecasting

Quantitative forecasts can be largely divided into two classes: time series and explanatory models. Explanatory models assume that the variable to be forecasted exhibits an explanatory relationship with one or more other variables. For example, we may model the electricity demand (ED) of a hot region during the summer period as

$$\mathrm{ED} = f(\text{current temperature, strength of economy, population, time of day, day of week, error}). \quad (1)$$

The relationship is not exact – there will always be changes in electricity demand that can not be accounted for by the variables in the model. The "error" term on the right allows for random variation and the effects of relevant variables not included in the model. Models in this class include regression models, additive models, and some kinds of neural networks.

The purpose of the explanatory model is to describe the form of the relationship and use it to forecast future values of the forecast variable. Under this model, any change in inputs will affect the output of the system in a predictable way, assuming that the explanatory relationship does not change.

In contrast, time series forecasting uses only information on the variable to be forecast, and makes no attempt to discover the factors affecting its behavior. For example,

$$\mathrm{ED}_{t+1} = f(\mathrm{ED}_t, \mathrm{ED}_{t-1}, \mathrm{ED}_{t-2}, \mathrm{ED}_{t-3}, \ldots, \text{error}), \quad (2)$$

where t is the present hour, $t+1$ is the next hour, $t-1$ is the previous hour, $t-2$ is two hours ago, and so on. Here, prediction of the future is based on past values of a variable and/or past errors, but not on explanatory variables which may affect the system. Time series models used for forecasting include ARIMA models, exponential smoothing and structural models.

There are several reasons for using a time series forecast rather than an explanatory model for forecasting. First, the system may not be understood, and even if it was understood it may be extremely difficult to measure the relationships assumed to govern its behavior. Second, it is necessary to predict the various explanatory variables in order to be able to forecast the variable of interest, and this may be too difficult. Third, the main concern may be only to predict what will happen and not to know why it happens.

A third type of forecasting model uses both time series and explanatory variables. For example,

$$\mathrm{ED}_{t+1} = f(\mathrm{ED}_t, \text{current temperature, time of day, day of week, error}). \quad (3)$$

These types of models have been given various names in different disciplines. They are known as dynamic regression models, panel data models, longitudinal models, transfer function models, and linear system models (assuming f is linear).

The Basic Steps in a Forecasting Task

There are usually five basic steps in any forecasting task.

Step 1: Problem definition. Often this is most difficult part of forecasting. Defining the problem carefully requires

an understanding of how the forecasts will be used, who requires the forecasts, and how the forecasting function fits within the organization requiring the forecasts. A forecaster needs to spend time talking to everyone who will be involved in collecting data, maintaining databases, and using the forecasts for future planning.

Step 2: Gathering information. There are always at least two kinds of information required: (a) statistical data, and (b) the accumulated expertise of the people who collect the data and use the forecasts. Often, a difficulty will be obtaining enough historical data to be able to fit a good statistical model. However, occasionally, very old data will not be so useful due to changes in the system being forecast.

Step 3: Preliminary (exploratory) analysis. Always start by graphing the data. Are there consistent patterns? Is there a significant trend? Is seasonality important? Is there evidence of the presence of business cycles? Are there any ▶outliers in the data that need to be explained by those with expert knowledge? How strong are the relationships among the variables available for analysis?

Step 4: Choosing and fitting models. Which model to use depends on the availability of historical data, the strength of relationships between the forecast variable and any explanatory variables, and the way the forecasts are to be used. It is common to compare two or three potential models.

Step 5: Using and evaluating a forecasting model. Once a model has been selected and its parameters estimated, the model is to be used to make forecasts. The performance of the model can only be properly evaluated after the data for the forecast period have become available. A number of methods have been developed to help in assessing the accuracy of forecasts as discussed in the next section.

Forecast Distributions

All forecasting is about estimating some aspects of the conditional distribution of a random variable. For example, if we are interested in monthly sales denoted by y_t for month t, then forecasting concerns the distribution of y_{t+h} conditional on the values of $y_1, \ldots, y_t$ along with any other information available. Let $\mathcal{I}_t$ denote all other information available at time t. Then we call the distribution of $(y_{t+h} \mid y_1, \ldots, y_t, \mathcal{I}_t)$ the *forecast distribution*.

Typically, a forecast consists of a single number (known as a "point forecast"). This can be considered an estimate of the mean or median of the forecast distribution. It is often useful to provide information about forecast uncertainty as well in the form of a prediction interval. For example, if the forecast distribution is normal with mean $\hat{y}_{t+h}$ and variance σ^2_{t+h}, then a 95% prediction interval for y_{t+h} is $\hat{y}_{t+h} \pm 1.96\sigma^2_{t+h}$. Prediction intervals in forecasting are sometimes called "interval forecasts."

For some problems, it is also useful to estimate the forecast distribution rather than assume normality or some other parametric form. This is called "density forecasting."

Evaluating Forecast Accuracy

It is important to evaluate forecast accuracy using genuine forecasts. That is, it is invalid to look at how well a model fits the historical data; the accuracy of forecasts can only be determined by considering how well a model performs on new data that were not used when fitting the model. When choosing models, it is common to use a portion of the available data for testing, and use the rest of the data for fitting the model. Then the testing data can be used to measure how well the model is likely to forecast on new data.

The issue of measuring the accuracy of forecasts from different methods has been the subject of much attention. We summarize some of the approaches here. A more thorough discussion is given by Hyndman and Koehler (2006). In the following discussion, $\hat{y}_t$ denotes a forecast of y_t. We only consider the evaluation of point forecasts. There are also methods available for evaluating interval forecasts and density forecasts (Corradi and Swanson 2006).

Scale-Dependent Errors

The forecast error is simply $e_t = y_t - \hat{y}_t$ which is on the same scale as the data. Accuracy measures that are based on e_t are therefore scale-dependent and cannot be used to make comparisons between series that are on different scales.

The two most commonly used scale-dependent measures are based on the absolute error or squared errors:

$$\text{Mean absolute error (MAE)} = \text{mean}(|e_t|),$$

$$\text{Mean squared error (MSE)} = \text{mean}\left(e_t^2\right).$$

When comparing forecast methods on a single series, the MAE is popular as it is easy to understand and compute.

Percentage Errors

The percentage error is given by $p_t = 100e_t/y_t$. Percentage errors have the advantage of being scale-independent, and so are frequently used to compare forecast performance between different data sets. The most commonly used measure is:

$$\text{Mean absolute percentage error (MAPE)} = \text{mean}(|p_t|)$$

Measures based on percentage errors have the disadvantage of being infinite or undefined if $y_t = 0$ for any t in the period of interest, and having an extremely skewed distribution when any y_t is close to zero. Another problem with percentage errors that is often overlooked is that they assume a meaningful zero. For example, a percentage error makes no sense when measuring the accuracy of temperature forecasts on the Fahrenheit or Celsius scales.

They also have the disadvantage that they put a heavier penalty on positive errors than on negative errors. This observation led to the use of the so-called "symmetric" MAPE proposed by Armstrong (1985, p. 348), which was used in the M3 forecasting competition (Makridakis and Hibon 2000). It is defined by

$$\text{Symmetric mean absolute percentage error (sMAPE)} = \text{mean}\left(200\,|y_t - \hat{y}_t|/(y_t + \hat{y}_t)\right).$$

However, if y_t is zero, $\hat{y}_t$ is also likely to be close to zero. Thus, the measure still involves division by a number close to zero. Also, the value of sMAPE can be negative, so it is not really a measure of "absolute percentage errors" at all. Hyndman and Koehler (2006) recommend that the sMAPE not be used.

Scaled Errors

The MASE was proposed by Hyndman and Koehler (2006) as an alternative to the MAPE or sMAPE when comparing forecast accuracy across series on different scales. They proposed scaling the errors based on the *in-sample* MAE from the naïve forecast method. Thus, a scaled error is defined as

$$q_t = \frac{e_t}{\frac{1}{n-1}\sum_{i=2}^{n}|y_i - y_{i-1}|},$$

which is independent of the scale of the data. A scaled error is less than one if it arises from a better forecast than the average one-step naïve forecast computed in-sample. Conversely, it is greater than one if the forecast is worse than the average one-step naïve forecast computed in-sample. The *mean absolute scaled error* is simply

$$\text{MASE} = \text{mean}(|q_t|).$$

About the Author

Rob Hyndman is Professor of Statistics and Director of the Business and Economic Forecasting Unit at Monash University, Australia. He has published extensively in leading statistical and forecasting journals. He is co-author of the highly regarded international text on business forecasting, *Forecasting: methods and applications* (Wiley, 3rd edition 1998), and more recently *Forecasting with exponential smoothing: a state space approach* (Springer, 2008). Professor Hyndman is Editor-in-Chief of the *International Journal of Forecasting* and was previously Theory and Methods Editor of the *Australian and New Zealand Journal of Statistics* (2001–2004). He was elected to the International Statistical Institute in 2005. In 2007 he was awarded the prestigious Moran Medal from the Australian Academy of Science, for his contributions to statistical research.

Forensic DNA: Statistics in

Wing Kam Fung[1], Yuk Ka Chung[2]
[1]Chair Professor
University of Hong Kong, Hong Kong, China
[2]University of Hong Kong, Hong Kong, China

Introduction

Since its introduction by Sir Alec Jeffreys in 1985, deoxyribonucleic acid (DNA) profiling, or DNA fingerprinting,

has become one of the most important tools in forensic human identification. DNA contains unique genetic information of each organism and can be found in blood, semen, hair/hair root, bone, and body fluids such as saliva and sweat. Theoretically, every individual except for identical twins can be identified by one's unique DNA sequence. However, due to technical limitations, current human identification is not based on fully sequencing the whole genome. Instead, only a number of genetic markers are used, and so the identification cannot be established without any doubt. Statistics thereby plays an important role in assessing the uncertainty in forensic identification and evaluating the weight of DNA evidence.

Random Match Probability

Suppose a crime was committed and a blood stain has been found in the crime scene and a suspect has been identified. The DNA profiles obtained from the crime stain and the blood specimen of the suspect will be compared. A DNA profile is a set of numbers representing the genetic characteristics of the forensic sample, often at nine or more DNA regions called loci. If a perfect match is found between the two DNA profiles, the suspect would not be excluded as a possible contributor to the crime stain. To evaluate the weight of the DNA evidence, the probability that another person would have the same DNA profile will be computed and reported in the courtroom. The smaller the random match probability, the stronger is the evidence to convict the suspect.

A common assumption adopted in the evaluation of the random match probability is that the population is in Hardy–Weinberg equilibrium (HWE), which means the two alleles of a genotype at a particular locus are statistically independent of each other. For example, suppose at a particular locus the alleles found in the profiles of the crime stain and the suspect are in common, say, A_iA_j. The random match probability at this particular locus can be obtained using the product rule as $2p_ip_j$ for $i \neq j$ and p_i^2 for $i = j$, where p_i and p_j are the allele frequencies of A_i and A_j, respectively. Under the assumption of linkage equilibrium, i.e., independence of alleles across all loci, multiplying the individual probabilities over all loci will give the overall random match probability, which is often found as small as one in a million or one in a billion in practice.

In some cases, the suspect is unavailable for typing and a close relative of the suspect is typed instead. In some other cases, the suspect is typed, but the prosecution about who left the crime stain involves a close relative of the suspect. Extensions of the formulas to handle these situations as well as the violation of Hardy–Weinberg and linkage equilibrium are extensively discussed in the literature.

Paternity Determination

Another application of DNA profiling is in kinship determination, which refers to the confirmation of a specific biological relationship between two individuals. In particular, a paternity test determines whether a man is the biological father of an individual. For a standard trio case in which the mother, her child, and the alleged father are typed with DNA profiles denoted by M, C, and AF respectively, the weight of evidence that the alleged father is the biological father of the child is often expressed as a likelihood ratio (LR) of the following hypotheses:

H_p : Alleged father is the biological father of the child.

H_d : The biological father is a random unrelated man.

The LR, also termed as the paternity index (PI) in the context of paternity testing, takes the form

$$LR = PI = \frac{P\left(Evidence|H_p\right)}{P\left(Evidence|H_d\right)} = \frac{P\left(M, C, AF|H_p\right)}{P\left(M, C, AF|H_d\right)}.$$

Using some results on conditional probability and the fact that the genotypes of the mother and the alleged father are not affected by the hypotheses, the index can be simplified to

$$PI = \frac{P\left(C|M, AF, H_p\right)}{P\left(C|M, H_d\right)}.$$

Suppose the genotypes at a particular locus are obtained as $C = A_1A_2$, $M = A_2A_3$, and $AF = A_1A_4$. Since the mother has half chance to pass the allele A_2 to the child and the alleged father also has half chance to pass the allele A_1 to the child under H_p, the numerator of the PI is given by $P\left(C|M, AF, H_p\right) = (1/2)\,(1/2) = 1/4$. Similarly, the denominator can be obtained as $P\left(C|M, H_d\right) = p_1\,(1/2) = p_1/2$ and as a result, $PI = 1/(2p_1)$. The overall paternity index can then be obtained by multiplying the individual PIs over all loci.

It may sometimes be argued that the alleged father is not the biological father of the child, but his relative (say, brother) is, thereby resulting in the following hypotheses:

H_p : Alleged father is the biological father of the child.

H_d : A relative (brother) of the alleged father is the biological father of the child.

The PI can still be computed by using the formula $PI = 1/[2F + 2\,(1 - 2F)\,p_1]$, where F is the kinship coefficient between the alleged father and his relative. The kinship coefficient is a measure of the relatedness between two individuals, representing the probability that two randomly sampled genes from each of them are identical. In particular, $F = 1/4$ for full siblings and, therefore, in this case, $PI = 2/(1 + 2p_1)$, which is substantially smaller

than $1/(2p_1)$, indicating that DNA profiling performs less effective in distinguishing paternity among relatives.

DNA Mixture

In practical crime cases, it is not uncommon that the biological traces collected from the crime scene are obtained as mixed stains, especially in rape cases. In general, the evaluation and interpretation of the mixed DNA sample can be very complicated due to many factors including unknown number of contributors and missing alleles. Here, we consider a simple two-person mixture problem in which the DNA mixture is assumed to be contributed by the victim and only one perpetrator. Suppose that, at a particular locus, the mixture sample contains alleles $M = \{A_1, A_2, A_3\}$, the victim has genotype $V = A_1A_2$, and the suspect has genotype $S = A_3A_3$. The following two competing hypotheses, the prosecution and defense hypotheses, about who contributes to the crime stain are considered:

H_p : The victim and the suspect are the contributors.

H_d : The victim and an unknown person are the contributors.

The weight of the evidence can be evaluated by

$$LR = \frac{P(Evidence|H_p)}{P(Evidence|H_d)} = \frac{P(M,V,S|H_p)}{P(M,V,S|H_d)} = \frac{P(M|V,S,H_p)}{P(M|V,H_d)}$$

where the last expression is obtained after some simplifications. Obviously in this case, $P(M|V,S,H_p) = 1$ as the mixture M is contributed by the victim and the suspect under H_p. Under H_d, the unknown person must have at least one A_3 allele but cannot have alleles not present in the mixture $M = \{A_1, A_2, A_3\}$. Therefore, there are only three possible genotypes for the unknown person at this locus: A_1A_3, A_2A_3, and A_3A_3. Under HWE, $P(M|V,H_d) = 2p_1p_3 + 2p_2p_3 + p_3^2$ and therefore the LR is obtained as

$$LR = \frac{1}{2p_1p_3 + 2p_2p_3 + p_3^2}$$

In the above example, the LR can be easily computed because there are only three possible genotypes for the only unknown person. In general for multiple perpetrator cases, the following general defense hypothesis may be considered:

H_d : The contributors are the victim and x unknown individuals.

For $x = 2$, there are 27 possible genotype configurations of the two unknown individuals and it is cumbersome to list them all. Over the years, general method and formulas for evaluating the LR have been developed in the literature to deal with complicated mixture problems, including situations with the presence of relatives or population substructures.

Foundations of Probability

Thomas Augustin, Marco E. G. V. Cattaneo
Ludwig Maximilian University, Munich, Germany

Introduction

Probability theory is that part of mathematics that is concerned with the description and modeling of random phenomena, or in a more general – but not unanimously accepted – sense, of any kind of uncertainty. Probability is assigned to random events, expressing their tendency to occur in a random experiment, or more generally to propositions, characterizing the degree of belief in their truth.

Probability is the fundamental concept underlying most statistical analyses that go beyond a mere description of the observed data. In statistical inference, where conclusions from a random sample have to be drawn about the properties of the underlying population, arguments based on probability allow to cope with the sampling error and therefore control the inference error, which is necessarily present in any generalization from a part to the whole. Statistical modeling aims at separating regularities (structure explainable by a model) from randomness. There, the sampling error and all the variation that is not explained by the chosen optimal model are comprised in an error probability as a residual category.

Different Interpretations and Their Consequences for Statistical Inference

The concept of probability has a very long history (see, e.g., Vallverdú 2010). Originally, the term had a more philosophical meaning, describing the degree of certainty or the persuasive power of an argument. The beginnings of a more mathematical treatment of probability are related to considerations of symmetry in games of chance (see, e.g., Hald 2003). The scope of the theory was extended by Bernoulli (1713), who applied similar symmetry considerations in the study of epistemic probability in civil, moral, and economic problems. In this connection he proved his "law of large numbers," which can be seen as the first theorem of mathematical statistics, and as a cornerstone of the *frequentist* interpretation of probability, which understands the probability of an event as the limit of its relative frequency in an infinite sequence of independent repetitions of a random experiment. Typically, the frequentist (or aleatoric) point of view is *objectivist* in the sense that it relates probability to random phenomena only and perceives probability as a property of the random experiment (e.g., rolling a dice) under consideration.

In contrast, the second of the two most common interpretations (see, e.g., Peterson (2010), for more details), the *subjective*, personalistic, or epistemic viewpoint, perceives probability as a property of the subject confronted with uncertainty. Consequently, here probability can be assigned to anything the very subject is uncertain about, and the question of whether or not there is an underlying random process vanishes. For the interpretation, in the tradition of Savage (1954) a fictive scenario is used where preferences between actions are described. In particular, the probability of an event is understood as the price at which the subject is indifferent between buying and selling a security paying 1 when the event occurs (and 0 otherwise).

The interpretation of probability predetermines to a considerable extent the choice of the statistical inference methods to learn the unknown parameters ϑ of a statistical model from the data. The frequentist perceives ϑ as an unknown but fixed quantity and seeks methods that are optimal under fictive infinite repetitions of the statistical experiment, while for the subjectivist it is straightforward to express his or her uncertainty about ϑ by a (*prior*) probability distribution, which is then, in the light of new data, updated by the so-called Bayes' rule to obtain the (*posterior*) probability distribution describing all her/his knowledge about ϑ (*Bayesian inference*).

Kolmorgorov's Axioms

While the interpretation of probability is quite important for statistical applications, the mathematical theory of probability can be developed almost independently of the interpretation of probability. The foundations of the modern theory of probability were laid by Kolmogorov (1933) in measure theory: Probability is axiomatized as a normalized measure.

More specifically (see, e.g., Merkle (2010) and Rudas (2010) for more details), let Ω be the set of elementary events under consideration (Ω is usually called *sample space*). The events of interest are described as sets of elementary events: it is assumed that they build a σ-algebra $\mathcal{A}$ of subsets of Ω (i.e., $\mathcal{A} \subseteq \mathcal{P}(\Omega)$ is nonempty and closed under complementation and countable union). A probability measure on $(\Omega, \mathcal{A})$ is a function $P : \mathcal{A} \to [0,1]$ such that $P(\Omega) = 1$ and

$$P\left(\bigcup_{n=1}^{\infty} E_n\right) = \sum_{n=1}^{\infty} P(E_n) \tag{1}$$

for all sequences of pairwise disjoint events $E_1, E_2, \ldots \in \mathcal{A}$. When Ω is uncountable, a Borel σ-algebra is usually selected as the set $\mathcal{A}$ of events of interest, because the natural choice $\mathcal{A} = \mathcal{P}(\Omega)$ would place too strong limitations

on the probability measure P, at least under the axiom of choice (see, e.g., Solovay (1970)).

Kolmogorov supplemented his axioms by two further basic definitions: the definition of *independence* of events and the definition of *conditional probability* $P(A|B)$ (i.e., the probability of event A given an event B).

From the axioms, fundamental theorems with a strong impact on statistics have been derived on the behavior of independent repetitions of a random experiment (see, e.g., Billingsley (1995) and Schervish (1995) for more details). They include different ►*laws of large numbers* (see above), the *central limit theorem* (see ►Central Limit Theorems), distinguishing the Gaussian distribution as a standard distribution for analyzing large samples, and the *Glivenko–Cantelli theorem* (see ►Glivenko-Cantelli Theorems), formulating convergence of the so-called empirical distribution function to its theoretical counterpart, which means, loosely speaking, that the true probability distribution can be rediscovered in a large sample and thus can be learned from data.

Current Discussion and Challenges

In statistical methodology, for a long time Kolmogorov's measure-theoretic axiomatization of probability theory remained almost undisputed: only countable additivity (1) was criticized by some proponents of the subjective interpretation of probability, such as De Finetti (1974–1975). If countable additivity is replaced by the weaker assumption of finite additivity (i.e., $P(E_1 \cup E_2) = P(E_1) + P(E_2)$ for all pairs of disjoint events $E_1, E_2 \in \mathcal{A}$), then it is always possible to assign a probability to any set of elementary events (i.e., the natural choice $\mathcal{A} = \mathcal{P}(\Omega)$ does not pose problems anymore). However, without countable additivity many mathematical results of measure theory are not valid anymore.

In recent years, the traditional concept of probability has been questioned in a more fundamental way, especially from the subjectivist point of view. On the basis of severe problems encountered when trying to model uncertain expert knowledge in artificial intelligence, the role of probability as the exclusive methodology for handling uncertainty has been rejected (see, e.g., the introduction of Klir and Wierman (1999)). It is argued that traditional probability is only a one-dimensional, too reductionistic view on the multidimensional phenomenon of uncertainty. Similar conclusions (see, e.g., Hsu et al. (2005)) have been drawn in economic decision theory following Ellsberg's seminal experiments (Ellsberg 1961), where the extent of ambiguity (or non-stochastic uncertainty) has been distinguished as a constitutive component of decision making.

Such insights have been the driving force for the development of the theory of *imprecise probability* (see, e.g., Coolen et al. (2010) for a brief survey), comprising approaches that formalize the probability of an event A as an interval $[\underline{P}(A), \overline{P}(A)]$, with the difference between $\overline{P}(A)$ and $\underline{P}(A)$ expressing the extent of ambiguity. Here $\underline{P}$ and $\overline{P}$ are non-additive set-functions, often called *lower* and *upper probabilities*. In particular, Walley (1991) has partially extended De Finetti's framework (De Finetti 1974–1975) to a behavioral theory of imprecise probability, based on an interpretation of probability as possibly differing buying and selling prices, while Weichselberger (2001) has developed a theory of *interval-probability* by generalizing Kolmogorov's axioms.

Frailty Model

Paul Janssen[1], Luc Duchateau[2]
[1]Professor, President of the Belgian Statistical Society (2008–2010), Vice-rector of research at UHasselt (2008–2012)
Hasselt University, Diepenbeek, Belgium
[2]Professor and Head, President of the Quetelet Society (Belgian branch of IBS) (2010–2012)
Ghent University, Ghent, Belgium

►Survival data are often clustered; it follows that the independence assumption between event times does not hold. Such survival data occur, for instance, in cancer clinical trials, where patients share the same hospital environment. The shared frailty model can take such clustering in the data into account and provides information on the within cluster dependence. In such a model, the frailty is a measure for the relative risk shared by all observations in the same cluster. The model, a conditional hazard model, is given by

$$h_{ij}(t) = h_0(t)u_i \exp\left(\boldsymbol{x}_{ij}^t\boldsymbol{\beta}\right) = h_0(t)\exp\left(\boldsymbol{x}_{ij}^t\boldsymbol{\beta} + w_i\right)$$

where $h_{ij}(t)$ is the conditional (on u_i or w_i) hazard function for the jth observation ($j=1,\ldots,n_i$) in the ith cluster ($i=1,\ldots,s$): $h_0(t)$ is the baseline hazard, $\boldsymbol{\beta}$ is the fixed effects vector of dimension p, $\boldsymbol{x}_{ij}$ is the vector of covariates and w_i (u_i) is the random effect (frailty) for the ith cluster. The w_i's (u_i's) are the actual values of a sample from a density $f_W(.)$ ($f_U(.)$). Clustered survival data will be denoted by the observed (event or censoring) times $\boldsymbol{y} = (y_{11},\ldots,y_{sn_s})^t$ and the censoring indicators $(\delta_{11},\ldots,\delta_{sn_s})^t$. Textbooks references dealing with shared frailty models include Hougaard (2000) and Duchateau and Janssen (2008).

The one-parameter gamma density function $f_U(u) = \frac{u^{1/\theta-1}\exp(-u/\theta)}{\theta^{1/\theta}\Gamma(1/\theta)}$ (with mean one and variance θ) is often used as frailty density as it simplifies model fitting, especially if a parametric baseline hazard (parameterized by $\boldsymbol{\xi}$) is assumed. The marginal likelihood for the ith cluster of the gamma frailty model can easily be obtained by first writing the conditional likelihood for the ith cluster and by then integrating out the gamma distributed frailty. With $\boldsymbol{\zeta} = (\boldsymbol{\xi}, \theta, \boldsymbol{\beta})$, we have

$$L_{marg,i}(\boldsymbol{\zeta}) = \int_0^\infty \prod_{j=1}^{n_i} \left(h_0(y_{ij})u_i \exp\left(\boldsymbol{x}_{ij}^t\boldsymbol{\beta}\right)\right)^{\delta_{ij}} \exp\left(-H_0(y_{ij})u_i \exp\left(\boldsymbol{x}_{ij}^t\boldsymbol{\beta}\right)\right) \times \frac{u_i^{1/\theta-1}}{\theta^{1/\theta}\Gamma(1/\theta)} \exp\left(-u_i/\theta\right) du_i$$

There exists a closed form for this expression. Taking the logarithm and summing over the s clusters we obtain (Klein 1992; Duchateau and Janssen 2008, Chap. 2)

$$l_{marg}(\boldsymbol{\zeta}) = \sum_{i=1}^{s}\left[d_i\log\theta - \log\Gamma(1/\theta) + \log\Gamma(1/\theta + d_i) - (1/\theta + d_i)\log\left(1 + \theta\sum_{j=1}^{n_i} H_{ij,c}(y_{ij})\right) + \sum_{j=1}^{n_i}\delta_{ij}\left(\boldsymbol{x}_{ij}^t\boldsymbol{\beta} + \log h_0(y_{ij})\right)\right] \quad (1)$$

where $H_{ij,c}(y_{ij}) = H_0(y_{ij})\exp\left(\boldsymbol{x}_{ij}^t\boldsymbol{\beta}\right)$ and $d_i = \sum_{j=1}^{n_i}\delta_{ij}$, the number of events in the ith cluster. The marginal loglikelihood does no longer contain the frailties and can therefore be maximized to obtain parameters estimates $\hat{\boldsymbol{\zeta}}$. The asymptotic variance-covariance matrix can also be obtained using the marginal loglikelihood expression. The preferred model in survival analysis is a (conditional) hazards model with unspecified baseline hazard (a semiparametric model, a Cox model). Leaving $h_0(.)$ and $H_0(.)$ in (1) unspecified we obtain a semiparametric gamma frailty model. For such model direct maximization of the marginal likelihood is not possible. Both the EM-algorithm (Klein 1992) and penalized likelihood maximization (Therneau et al. 2003) have been proposed to fit such models; both approaches use the fact that closed form expressions can be obtained for the expected values of the frailties.

An alternative representation of the marginal likelihood (1) for the parametric gamma frailty model is based on the Laplace transform of the gamma frailty density

$\mathcal{L}(s) = \mathrm{E}(\exp(-Us)) = (1+\theta s)^{-1/\theta}$. With $\boldsymbol{t}_{n_i} = (t_1, \ldots, t_{n_i})$ and $H_{i,c}(\boldsymbol{t}_{n_i}) = \sum_{j=1}^{n_i} H_{ij,c}(t_i)$, the joint survival function for the ith cluster is given by

$$S_{i,f}(\boldsymbol{t}_{n_i}) = \int_0^\infty \exp(-u_i H_{i,c}(\boldsymbol{t}_{n_i})) f_{U_i}(u_i) du_i$$
$$= \mathcal{L}(H_{i,c}(\boldsymbol{t}_{n_i})) = (1+\theta H_{i,c}(\boldsymbol{t}_{n_i}))^{-1/\theta}$$

The likelihood contribution of the ith cluster, with $\boldsymbol{y}_{n_i} = (y_{i1}, \ldots, y_{in_i})$ and the first l observations uncensored, is then

$$(-1)^l \frac{\partial^l}{\partial t_1 \ldots \partial t_l} S_{i,f}(\boldsymbol{y}_{n_i}) = (-1)^l \mathcal{L}^{(l)}(H_{i,c}(\boldsymbol{y}_{n_i}))$$
$$\prod_{j=1}^{l} h_0(y_{ij}) \exp(\boldsymbol{x}_{ij}^t \boldsymbol{\beta}) \qquad (2)$$

For the gamma frailty model the explicit form of (2) is

$$\prod_{j=1}^{n_i} h_{\boldsymbol{x}_{ij},c}^{\delta_{ij}}(y_{ij}) (1+\theta H_{i,c}(\boldsymbol{y}_{n_i}))^{-1/\theta - d_i} \prod_{l=0}^{d_i-1} (1+l\theta)$$

with $\prod_{l=0}^{d_i-1}(1+l\theta) = 1$ for $d_i = 0$.

For frailty densities different from the gamma frailty density, for which the Laplace transform exists, expression (2) is the key to obtain the appropriate marginal loglikelihood expression. Frequently used frailty densities, such as the inverse Gaussian and the positive stable densities (Hougaard 1986a), have indeed simple Laplace transforms. More complex two-parameter frailty densities are the power variance function densities (Hougaard 1986b) and the compound Poisson densities (Aalen 1992). Although the lognormal density is also used as frailty density, it does not have a simple Laplace transform; its use mainly stems from mixed models ideas (McGilchrist and Aisbett 1991), and different techniques, such as ▶numerical integration, have to be used to fit this model (Bellamy et al. 2004).

The choice of the frailty density determines the type of dependence between the observations within a cluster. A global dependence measure is Kendall's τ (Kendall 1938). For two randomly chosen clusters i and k of size two with event times (T_{i1}, T_{i2}) and (T_{k1}, T_{k2}) and no covariates, τ is defined as $\mathrm{E}[\mathrm{sign}((T_{i1}-T_{k1})(T_{i2}-T_{k2}))]$ where $\mathrm{sign}(x) = -1, 0, 1$ for $x < 0, x = 0, x > 0$. Kendall's τ can be expressed as a function of the Laplace transform. Global dependence measures do not allow us to investigate how dependence changes over time. An important local dependence measure is the cross ratio function (Clayton 1978). An interesting feature of this function is its relation with a local version of Kendall's τ (see Duchateau and Janssen 2008, Chap. 4). The positive stable distribution and the ▶gamma distribution characterize early and late dependence respectively, with the ▶inverse Gaussian distribution taking a position in between the two.

So far we discussed the shared frailty model, which is the most simple model to handle within cluster dependence. The shared frailty model can be extended in different ways. First, a frailty term can be assigned to each subject, resulting in a univariate frailty model which can be used to model overdispersion (Aalen 1994). Another extension is the correlated frailty model in which the subjects in a cluster do not share the same frailty term although their respective frailties are correlated (Yashin and Iachine 1995). Finally the model can be extended to multifrailty and multilevel frailty models. In a multifrailty model, two different frailties occur in one and the same cluster. A good example is the study of the heterogeneity of a prognostic index over hospitals in cancer clinical trials, with each hospital (cluster) containing a frailty term for the hospital effect and a frailty term for the prognostic index effect (Legrand et al. 2007). Multilevel frailty models have two or more nesting levels, with a set of smaller clusters contained in a large cluster. Fitting such models is discussed in Ripatti and Palmgren (2000) and Rondeau et al. (2006).

Fraud in Statistics

Vassiliy Simchera
Director of Rosstat's Statistical Research Institute
Moscow, Russia

Fraud is an intentional distortion of the truth, whether it is a deliberate omission or false elimination, or an exaggeration or fabrication.

The aim of one who commits fraud is always self-benefit and self-interest. The main reasons for fraud are immorality, impunity, and anarchy, and the methods are deception and betrayal. From these it gives rise to the gravest of crimes – violation of law, murder, mutinies and wars. The tools to overcome fraud are law and order, auditing and control, morals, science, prosecution, and adequate punishment.

Fraud is a man-made phenomenon. The substance of fraud is unknown in the natural world. A lack of knowledge or limited knowledge, unpremeditated actions as well as unobserved phenomena (including deliberate, but legal and justified by jury's verdict, but still obviously criminal actions and perjuries) on the modern level of social mentality do not belong to the substance of fraud, and they are definitely not a subject for a scientific research.

Science, as opposed to jurisprudence, is much more liberal (despite some exceptions for genius of Galileo Galilei, Giordano Bruno, Jan Hus and Nicolaus Copernicus).

The most efficient tool for not only revealing but also overcoming fraud in economy (and further in socio-economic activity) is statistics. Its accurate methods of observation and auditing, powerful databases and knowledge bases, advanced software, and technical provision, as well as the intellectual culture verified by hundreds of years of qualitative data collection and data processing, allow the guarantee of controlled completeness, credibility, and accessibility for a wide range of people.

Being the world's most powerful information system with regulated branches in center and local areas controlled by hundred of quality criteria including those provided by IMF, the modern statistics is by its nature, as any other meter device is free from necessity to lie but at the same time it is surrounded by various kinds of lies and in turn reflects them, and as any other domain of empirical knowledge cannot be free of it.

Fraud in statistics is distortion of data, resulting from two different types of causes: 1) distortion of random errors, caused by poor observation and calculation, the characteristics of which are analyzed in another chapter in this text 2) deliberate (premeditated) distortion of data, resulting from different kinds of systematic causes and giving rise to effects beyond the statistics domain; these cannot be eliminated by methods or techniques.

The main sources of the data distortions (or in simple words – improper data reflections) are unknown, unobservable, and immeasurable phenomena. Such phenomena are not and cannot be discussed due to the objective reasons by observed phenomena; they are actually published and reflected in an incomplete and distorted form and thus they rather characterize themselves but do not reflect the real situation.

The most widespread sources of distortion in modern statistics are:

- evasion from participation in the preparation and submission of the obligatory current statistical reports;
- failure of respondents to answer ▶questionnaire for periodical and random statistical samplings;
- use of obsolete registers of individuals as well as legal entities, omissions, including deliberate omissions of the observed units and the reports units;
- underestimation (or overestimation) of the statistical data registration and reporting.

The particular type of data distortion in modern statistics, statistical estimates, connected with substitution of concepts or estimates obtained with use of inadequate techniques and algorithms that cannot be verified by the existing criteria of their credibility or with the application of other control methods, which are suitable for solving similar class of problems.

The biggest domains of fraud in statistics today are activities that cannot be prohibited and there is little means to prevent these activities. They are as follows:

- all types of illegal activities, including terrorism, counterfeiting, money laundering, corruption, smuggling, drug dealing, arms trafficking, illegal mining of rare metals, trafficking of toxic agents illegal organ transplants, and child abduction;
- illegal activity of individuals and legal entities;
- illegal business of unregistered organizations, institutions, and individuals;
- production and rendering services for self-consumption by households and individuals;
- unrecorded and omitted by statistical observations types of activities, statistical errors, rounding, errors and discrepancies, underestimated or overestimated estimates;
- second-hand activity, tolling, venture enterprises, intellectual activity; intermediate consumption, subsidies for production; offshore activity;
- transactions charges, fees, tips, VAT return, barter, payment in goods for labour, single payments, taxes, losses, including anthropogenic impacts;
- doctoring, imputed value, royalty, goodwill, repeat count of raw materials, commodities, services and capitals;
- other reasons, their identification is imposed and acceptable within the limits of standards and methods of effective statistical reporting and accounts.

The demonstrative example of fraud is fictitious estimates of capitalization of the world markets which, against the background of their real assets estimates (2008) would not exceed $70 trillion USD, and today account for over $700 trillion of USD.

The phantom of fraud in the modern world is also represented by estimates of banks assets. According to these estimates by US Statistics on Banking, 2007 (table 1136) which is considered as the most reliable one, the aggregate assets of all 730,000 of American banks in 2007 were estimated for $14.0 trillion USD (the precise sum is $13,792.5 billion of USD), whilst according to public information the allied assets of JP Morgan Bank solely at the same year were estimated for $97.5 trillion USD, Goldman and Sachs – $50 trillion USD, and HSBC – $108 trillion USD, which exceeded their accounted real equity capital by 30–40 times or more.

Another example of fraud is tax evasion, in particular VAT, the size of which reaches one-third of its total volume in the world, including over $20 billion USD per year in England or $50 billion USD in the United States.

However, there are no ideal measurements or absolutely precise estimations in science and life. Even those which seem to be absolutely accurate values obtained from the variables such as lengths, speed, weight, and temperature (degrees), are just conventional but not the absolute truth itself.

On the other hand, not all inaccurate values (estimates) are distorted ones and hence not all distorted values are false. In accordance with existing criteria in statistics, the inaccurate estimates are such and only distorted estimates that deteriorate the true core of measured phenomena and turn it into its opposite, that is to say, a lie. Inaccurate and reasonably distorted estimates, which by the way prevail in modern statistics (actually they prevailed in the past, too), are called approximated and they are widely used with reserve of some errors as acceptable asymptotic or approximations estimates.

Frequentist Hypothesis Testing: A Defense

Shlomo Sawilowsky
Professor and Assistant Dean
Wayne State University, Detroit, MI, USA

John Graunt, William Petty, René Déscartes, Blaise Pascal, Pierre Fermat, James Gregory, Christiaan Huygens,

Isaac Newton, Gottfried Leibniz, Jakob Bernoulli, Johann Bernoulli, Abraham DeMoivre, Daniel Bernoulli, Leonhard Euler, Joseph Lagrange, Pierre Laplace, Siméon Poisson, Jean Fourier, Friedrich Bessel, Carl Jacobi, Carl Gauss, Augustin Cauchy, Gustav Dirichlet, Georg Riemann, Michel Chasles, Augustus DeMorgan, Lambert Quetelet, Joseph Liouville, Pafnuty Chebyshev, Charles Hermite, and Andrei Markov. It was the work of these men, among others, that led to the development of the grand theorems, the mathematical inerrancies.

True, they were initially prompted by real world problems, such as winning games of chance or determining actuarial odds; and esoteric problems, such as proving the existence of a Divine plan by confirming a slightly greater proportion of male births to ensure the survival of the species. However, the grand theorems ascended to their elevated place in history because they are elegant, not because they were particularly useful in solving the problems for which they were created.

Moreover, they dictated the types of problems that are considered worthy, relegating those not subsumed under the cleverness of what mankind can solve as being intractable and designated as an eternal mystery of the universe. Their importance was buttressed by their utility for the few problems that they could solve, not for the problems that needed to be solved. Nunnally (1978) wrote mathematics "is purely an abstract enterprise that need have nothing to do with the real world… Thus the statement *iggle wug drang flous* could be a legitimate mathematical statement in a set of rules stating that when any *iggle* is *wugged* it *drang* a *flous*…Of course … [this] might not be of any practical use" (p. 9–10).

Woodward (1906) observed "since the beginning of the eighteenth century almost every mathematician of note has been a contributor to or an expositor of the theory of probability" (p. 8). But the focus on probability eventually moved away from populations and the grand theorems, and settled on just very large samples, such as, e.g., the work of Charles Darwin and Francis Galton.

Darwin collected his data between December 26, 1831 and February 27, 1832 while on the Cherokee class ten gun brig-sloop H. M. S. Beagle, sailing under the command of Captain Robert Fitzroy. Most of Darwin's data were obtained in St. Jago (Santiago) in the Cape Verde Islands from January 16 – February 7. Galton (1885) collected 17 discreet data points on 9,337 people. They were measured in a cubicle 6 feet wide and 36 feet long with the assistance of Serjeant Williams, Mr. Gammage the optician, and a doorkeeper who made himself useful. The data were obtained in the anthropometric laboratory at the International Health Exhibition and subsequently deposited at the South Kensington Museum.

Darwin's and Galton's lack of mathematical training limited their ability to quantify and analyze their trophies, but that limitation was resolved with the brilliance of Karl (née Carl) Pearson. With their data in hand, and the more immediate problem of huge data sets from the biologist/zoologist Walter Weldon, Pearson set to work. By 1900, he provided the rigor that had eluded his colleagues with the discovery of both r and χ^2, and the world was at peace. Well, at least scholars, the intelligencia, and their paparazzi were comforted.

K. Pearson (1978) assuredly knew the limitations of the grand theorems. After all, he quipped

> "As I understand De Moivre the 'Original Design' is the mean occurrence on an indefinite number of trials…The Deity fixed the 'means' and 'chance' provided the fluctuations…There is much value in the idea of the ultimate laws of the universe being statistical laws… [but] it is not an exactly dignified conception of the Deity to suppose him occupied solely with first moments and neglecting second and higher moments!" (p. 160)

But, alas and alack, as the first champion of statistics, K. Pearson was the inheritor of the grand theorems. As a co-founding editor of *Biometrika* he strove to stay above controversy by minimizing, if not ignoring, ordinary problems. And indeed there are those who still pine for the days of yore with its grand theorems, as Tukey (1954) nostalgically noted "Once upon a time the calculation of the first four moments was an honorable art in statistics" (p. 717).

But the ordinary person readily intuited that real world problems are not asymptotic in nature. William Gosset's Monte Carlo study published in 1908 with numbers written on pieces of poster board was conducted because he wasn't sure mathematicians could help him with real, small samples problems.

How could the recipe of his employer, Arthur Guinness, be improved? How many barrels of malt or hops are needed to approximate a population, or at least a large number? 2? 3? Are 4 barrels close to infinity? This chemist (whose sole credential was his undergraduate dual major in chemistry and mathematics from New College, Oxford) sounded all the great mathematical minds of his day, who assured him that he could rely on the grand theorems, and that he need not trouble himself with matters above his pay grade. Daydreams, it seems he was told, were more profitable than the time spent fretting on how large is large.

Gosset ("Student") neither wrote the t formula in the form that it appears in undergraduate textbooks today, nor

did he create the experimental design in which it would be applied. Ronald Fisher provided both the design and the null hypothesis that brought Gosset's Monte Carlo experiments and intuitive mathematics to fruition. Then, Pearson, Gosset, and Fisher became a quintet with the addition of Jerzy Neyman and Egon Pearson, who cemented the frequentist approach to hypothesis testing with the creation of an alternative hypothesis. Not satisfied, Neyman later re-expressed frequentist hypothesis testing into confidence intervals based on the same theory of probability.

Doubts were immediately raised, such as Bowley (1934), who asked and answered, "I am not at all sure that the 'confidence' is not a 'confidence trick'… Does it really take us any further?... I think it does not" (p. 609). Many scholars have adopted the shortcut to notoriety by rushing to follow in Bowley's footsteps, proclaiming the sky is falling on hypothesis testing.

But K. Pearson's development of the χ^2 test is surely listed among the greatest practical achievements of three millennia of mathematical inquiry. He captured the ability, regardless of the direct object, to quantify the difference between human observation and expectation. Remarkable! Was it wrong? Of course. Fisher had to modify the degrees of freedom. Again, remarkable! Was it still wrong? Of course. Frank Yates had to modify the method for small values of expectation. Once again, remarkable! Was it nevertheless wrong? Of course. The correction was found to sap statistical power. Where does the χ^2 test stand today? Statistical software can produce exact p values regardless of how small the expectation per cell. Remarkable!

Has society, therefore, improved with advent of the evolution of the χ^2 test? Most assuredly not:

- We live in a χ^2 society due to political correctness that dictates equality of outcome instead of equality of opportunity. The test of independence version of this statistic is accepted *sans voire dire* by many legal systems as the single most important arbiter of truth, justice, and salvation. It has been asserted that any statistical difference between (often even nonrandomly selected) samples of ethnicity, gender, or other demographic as compared with (often even inaccurate, incomplete, and outdated) census data is *primae faciea* evidence of institutional racism, sexism, or other ism. A plaintiff allegation that is supportable by a significant χ^2 is often accepted by the court (judges and juries) *praesumptio iuris et de iure*. (Sawilowsky 2010).

But is this really the fault of the χ^2 test? Any device can be lethal in the hands of a lunatic, as Mosteller (1968) warned, "I fear that the first act of most social scientists upon seeing a contingency table is to compute a chi-square for it" (p. 1).

What discipline has not followed an evolutionary path? Has agriculture, archeology, architecture, anthropology, biology, botany, chemistry, computer science, education, engineering, genetics, medicine, nursing, pharmacology, physics, psychology, sociology, and zoology always been as they exist today? Do we blame statistics for its ignoble development more so because the content disciplines were dependent on it?

There have been antagonists of Fisher–Neyman/Pearson hypothesis testing for three quarters of a century since Bowley. And it is understandable with the following analogy:

I had a summer job in 1972, working in Florida for a major manufacturer of fiberglass yachts. The hulls of the larger boats were made by laminating two 1/2 hull pieces together. The exterior paint was sprayed inside the two molds and set to dry. Next, fiberglass chop mixed with resin and methyl ethyl ketone peroxide was sprayed into the mold, laminators worked out the air bubbles, and it was set to harden.

The two 1/2 hull shells were then aligned, and held in place with many C clamps with the aid of a powerful air compressor. This was necessary because over time the molds changed in shape and they no longer matched. A small, temporary seam was laminated inside the hull to keep the two parts together. When the clamps were released, one could almost see the two 1/2 hulls trembling, working against the thin fiberglass seam to separate and go their separate ways.

My job was to be lowered inside the hull, and lay down a successively wider series of fiberglass mats and resign/catalyst, to strengthen the seam. On one boat I had laminated perhaps five or six of the required ten mats when it was quitting time. The crew chief told me I could continue the next day where I had left off.

To my chagrin, when I arrive early the next day I discovered that the night shift personnel had taken my hull down the production line, and the boat by now had floors, carpet, sink, and other amenities already installed, obviating the ability to bond the final fiberglass mats to strengthen the hull's seam. I protested to my crew chief, who nonchalantly replied not to worry myself about such things. "After all," he said, "the naval architects who designed the boat allowed considerable tolerance that should handle situations such as this." I made that my last day on the job at that company, and since then I've often wondered how that yacht fared in the middle of the Gulf of Mexico.

So too, the juxtaposition of Fisher's null with Neyman and E. Pearson's alternative leads to trembling, each part of the statistical hypothesis seemingly working against each other to go their separate ways. But this was not the end of the development of the frequentist theory. It surpassed E. Pearson (1962), who admitted "through the lack of close contact with my partner during the last 20 years, it would be a little difficult to say where precisely the Neyman and Pearson theory stands today" (p. 53). The same sentiment was also expressed by those who followed the age of the pioneers, such as Savage (1962) who echoed, "What I, and many other statisticians, call the Neyman-Pearson view may, for all I know, never have been held by Professor Neyman or by Professor Pearson" (p. 62). Wilks (1948) concluded that by now the "modern statistical method is a science in itself" (p. 1).

In truth, many of the foibles in hypothesis testing, since being admitted to the country club of mature disciplines, are traceable back to the statistician, not to the statistics. Fallacies, misconceptions, and myths abound. Which of the disciplines listed above are immune to this, and why is there an expectation that statistics should fare any better?

Yes, even under the best of circumstances there are those who have no use for hypothesis testing. Ernst Rutherford (cited in N T J Bailey 1967) said, "If your experiment needs statistics, you ought to have done a better experiment" (p. 23). But, Albert Einstein (cited in Shankland 1973) countered, "I thank you very much for sending me your careful study about the [Dayton] Miller experiments. Those experiments, conducted with so much care, merit, of course, *a very careful statistical investigation*," (p. 2283, italics added for emphasis).

Much of the criticism against hypothesis testing would presumably vanish if workers heeded the advice of Finney (1953), who advised "when you are experienced enough to make your own statistical analyses, be sure you choose the right technique and not merely any one that you can remember!" (p. 174). The sciences, physical and social, should be placated with McNemar's (1949) advice that "the student should be warned that he cannot expect miracles to be wrought by the use of statistical tools" (p. 3).

Proper selection of statistical tests based on their small samples properties, along with an understanding of their respective null and alternative hypotheses, research design, random sampling, nominal α, Type I and II errors, statistical power, and effect size would eliminate attacks against hypothesis testing from all save perhaps those who, as Bross (1969) characterized it, base their science on "a Bayesian *t*-test using an informationless prior" (p. 52). Has the world benefitted from frequentist hypothesis testing?

> The question is silly. No reputable quantitative physical, behavioral, or social scientist would overlook the breadth and depth of scholarly knowledge and its impact on society that has accrued from over a century of hypothesis testing. The definitive evidence: William Sealy Gosset created the *t* test to make better beer. (Sawilowsky 2003, p. 469)

About the Author

Shlomo S. Sawilowsky is Professor and Assistant Dean in the College of Education, and Wayne State University Distinguished Faculty Fellow. He is the author of *Statistics Through Monte Carlo Simulation With Fortran* (2003) and *Real Data Analysis* (2008), and over 100 peer-reviewed articles on applied data analysis. He is the founding editor of the *Journal of Modern Applied Statistical Methods* (http://tbf.coe.wayne.edu/jmasm). He has served as major professor on 52 doctoral dissertations, Co-advisor on 18 dissertations, 2*nd* advisor on 37 doctoral dissertations, Cognate advisor on 2 doctoral dissertations, and advisor on 23 Master's theses in applied data analysis. Approximately 1/2 of his graduates are female and 1/4 are African American. Professor Sawilowsky has won many teaching and research awards. He was the recipient of the 1998 Wayne State University Outstanding Graduate Mentor Award, and the College of Education's Excellence in Teaching Award. "Professor Sawilowsky's exceptional record as an academician is reflected in the excellence with which he mentors graduate students" (AMSTAT News, October 1998). Professor Sawilowsky was the 2008 President of the American Educational Research Association/SIG Educational Statisticians.

Full Bayesian Significant Test (FBST)

Carlos Alberto de Bragança Pereira
Professor, Head, Instituto de Matemática e Estatística
Universidade de São Paulo, São Paulo, Brazil

Introduction

Significance testing of precise (or sharp) hypotheses is an old and controversial problem: it has been central in statistical inference. Both frequentist and Bayesian schools of inference have presented solutions to this problem, not always prioritizing the consideration of fundamental issues such as the meaning of precise hypotheses or the inferential rationale for testing them. The Full Bayesian Significance Test, FBST, is an alternative solution to the problem, which attempts to ease some of the questions met by frequentist and standard Bayes tests based on Bayes factors. FBST was introduced by Pereira and Stern (1999) and reviewed by Pereira et al. (2008).

The discussion here is restricted to univariate parameter and (sufficient statistic) sample spaces;

$$\Theta \subset \mathcal{R} \text{ and } X \subset \mathcal{R}$$

A sharp hypothesis H is then a statement of the form $H : \theta = \theta_0$ where $\theta_0 \in \Theta$. The posterior probability (density) for θ is obtained after the observation of $x \in X$. While a frequentist looks for the set, C, of sample points at least as inconsistent with θ_0 as x is, a Bayesian could look for the tangential set T of parameter points that are more consistent with x than θ_0 is. This understanding can be interpreted as a partial duality between sampling and Bayesian theories. The evidence in favor of H is for frequentists the usual p-value, while for Bayesian it should be $ev = 1 - \underline{ev}$:

$$pv = Pr\{x \in C|\theta_0\} \text{ and } ev = 1 - \underline{ev} = 1 - Pr\{\theta \in T|x\}.$$

The larger pv and ev, the stronger the evidence favoring H.

In the general case, the posterior distribution is sufficient for ev to be calculated, without any complication due to dimensionality of neither the parameter nor of the sample space. This feature ceases the need for nuisance parameters elimination, a problem that disturbs some statisticians (Basu 1977). If one feels that the goal of measuring consistency between data and a null hypothesis should not involve prior opinion about the parameter, the normalized likelihood, if available, may replace the posterior distribution. The computation of ev needs no asymptotic methods, although numerical optimization and integration may be needed.

The fact that the frequentist and Bayesian measures of evidence, pv and ev, are probability values – therefore defined in a zero to one scale – does not easily help to answer the question "How small is *significant*?". For ►p-values, the NP lemma settles the question by means of subjective arbitration of critical values. For Bayesian assessment of significance through evaluation of ev, decision theory again clears the picture. Madruga et al. (2001) show that there exist loss functions the minimization of which render a test of significance based on ev into a formal Bayes test.

The FBST has successfully solved several relevant problems of statistical inference: see Pereira et al. (2008) for a list of publications.

FBST Definition

Significance FBST was created under the assumption that a significance test of a sharp hypothesis had to be performed. At this point, a formal definition of a sharp hypothesis is presented.

Consider general statistical spaces, where $\Theta \subset \mathcal{R}^m$ is the parameter space and $X \subset \mathcal{R}^k$ is the sample space.

Definition 1 A *sharp* hypothesis H states that θ belongs to a sub-manifold Θ_H of smaller dimension than Θ.

The subset Θ_H has null Lebesgue measure whenever H is sharp. A probability density on the parameter space is an ordering system, notwithstanding having every point probability zero. In the FBST construction, all sets of same nature are treated accordingly in the same way. As a consequence, the sets that define sharp hypotheses keep having nil probabilities. As opposed to changing the nature of H by assigning positive probability to it, the tangential set T of points, having posterior density values higher than any θ in Θ_H, is considered. H is rejected if the posterior probability of T is *large*. The formalization of these ideas is presented below.

Let us consider a standard parametric statistical model; i.e., for an integer m, the parameter is $\theta \in \Theta \subset \mathcal{R}^m$, $g(\bullet)$ a probability prior density over Θ, x is the observation (a scalar or a vector), and $L_x(\bullet)$ is the likelihood generated by data x. Posterior to the observation of x, the sole relevant entity for the evaluation of the Bayesian evidence ev is the posterior probability density for θ given x, denoted by

$$g_x(\theta) = g(\theta|x) \propto g(\theta)L_x(\theta).$$

Of course, one is restricted to the case where the posterior probability distribution over Θ is absolutely continuous; i.e., $g_x(\theta)$ is a density over Θ. For simplicity, H is used for Θ_H in the sequel.

Definition 2 (evidence) Consider a sharp hypothesis $H : \theta \in \Theta_H$ and

$$g^* = \sup_H g_x(\theta) \text{ and } T = \{\theta \in \Theta : g_x(\theta) > g^*\}.$$

The *Bayesian evidence value against* H is defined as the posterior probability of the tangential set, i.e.,

$$\underline{ev} = Pr\{\theta \in T|x\} = \int_T g_x(\theta)d\theta.$$

One must note that the evidence value supporting H, $ev = 1 - \underline{ev}$, is not an evidence against A, the alternative hypothesis (which is not sharp anyway). Equivalently, $\underline{ev}$ is not evidence in favor of A, although it is against H.

Definition 3 (test) The *FBST* (Full Bayesian Significance Test) is the procedure that rejects H whenever $ev = 1 - \underline{ev}$ is small.

The following example illustrates the use of the FBST and two standard tests, McNemar and Jeffreys' Bayes Factor. Irony et al. (2000) discuss this inference problem introduced by McNemar (1955).

Example 1 McNemar vs. FBST Two professors, Ed and Joe, from the Department of Dentistry evaluated the skills of 224 students in dental fillings preparation. Each student was evaluated by both professors. The evaluation result could be approval (A) or disapproval (F). The Department wants to check whether the professors are equally exigent. Table 1 presents the data.

This is a four-fold classification with probabilities p_{11}, p_{12}, p_{21}, and p_{22}. Using standard notation, the hypothesis to be tested is $H : p_{1\cdot} = p_{\cdot 1}$ which is equivalent to $H : p_{12} = p_{21}$ (against $A : p_{12} \neq p_{21}$). In order to have the likelihood function readily available, we will consider a uniform prior, i.e., a *Dirichlet* density with parameter $(1, 1, 1, 1)$.

The McNemar exact significance for this data set is $pv = .064$. Recall that this test is based in a partial likelihood function, a binomial with $p = p_{12}(p_{12} + p_{21})^{-1}$ and $n = 66$. With the normal approximation, the pv become .049 with the partial likelihood used by McNemar, the FBST evidence is $ev = .045$. The value of the Bayes Factor under the same uniform prior is $BF = .953$. If one assigns probability 1/2 to the sharp hypothesis H, its posterior probability attains $\pi = .488$. Hence, the posterior probability π barely differs from 1/2, the probability previously assigned to H, while pv and ev seem to be more conclusive against H. While, in the three dimension full model, $ev = 0.265$ may seem to be a not low value and the test cannot be performed without a criterion. In other

Full Bayesian Significant Test (FBST). Table 1 Results of the evaluation of 224 students

	Joe

F	25	96	121
Total	87	137	224

words, a decision is not made until *ev* is compared to a "critical value." The derivation of such a criterion – resulting from the identification of the FBST as a genuine Bayes procedure – is the subject of Madruga et al. (2001).

The strong disagreement among the values of *ev*, *pv*, and *BF* seldom occurs in situations where Θ is a subset of the real line. The speculation is that this is related to the elimination of nuisance parameters: By conditioning in McNemar case and by marginalization in the Bayes Factor case. In higher dimension, elimination of nuisance parameters seems to be problematic, as pointed by Basu (1977).

FBST Theory

From a theoretical perspective, on the other hand, it may be propounded that if the computation of *ev* is to have any inferential meaning, then it ought to proceed to a declaration of significance (or not). To this – in a sense – simultaneously NPW and Fisherian viewpoint can be opposed the identification of ev as an estimator of the indicator function $\phi = I(\theta \in \Theta_H)$. In fact, Madruga et al. (2001) show that there are loss functions the minimization of which makes *ev* a Bayes estimator of ϕ (see Hwang et al. 1992).

Madruga et al. (2001) prove that the FBST procedure is the posterior minimization of an expected loss λ defined as follows:

$$\lambda(\text{Rejection of } H, \theta) = a\{1 - I[\theta \in T]\} \text{ and}$$

$$\lambda(\text{Acceptance of } H, \theta) = b + dI[\theta \in T].$$

Here, a, b and d are positive real numbers. The operational FBST procedure is given by the criterion according to which H is to be rejected if, and only if, the evidence *ev* is smaller than $c = (b+d)/(a+d)$. One should notice that the evidence *ev* is the Bayesian formal test statistic and that positive probability for H is never required. A complete discussion of the above approach can be found in Pereira et al. (2008).

Final Remarks

The following list states several desirable properties attended by *ev*:

1. *ev* is a probability value derived from the posterior distribution on the full parameter space.
2. Both *ev* and FBST possesses versions which are invariant for alternative parameterizations.
3. The need of approximations in the computation of *ev* is restricted to numerical maximization and integration.
4. FBST does not violate the Likelihood Principle.
5. FBST neither requires nuisance parameters elimination nor the assignment of positive prior probabilities to sets of zero Lebesgue measure.
6. FBST is a formal Bayes test and therefore has critical values obtained from considered loss functions.
7. *ev* is a possibilistic support for sharp hypotheses, complying with the Onus Probandi juridical principle (In Dubio Pro Reo rule), Stern (2003).
8. Derived from the full posterior distribution, *ev* is a homogeneous computation calculus with the same two steps: constrained optimization and integration with the posterior density.
9. Computing time was not a great burden whenever FBST was used. The sophisticated numerical algorithms used could be considered a more serious obstacle to the popularization of the FBST.

ev was developed to be the Bayesian *pv* alternative, while maintaining the most desirable (known or perceived) properties in practical use. The list presented above seems to respond successfully to the challenge: the FBST is conceptually simple and elegant, theoretically coherent, and easily implemented for any statistical model, as long as the necessary computational procedures for numerical optimization and integration are available.

About the Author

Dr Carlos Pereira is a Professor and Head, Department of Statistics, University of São Paulo, Brazil. He is Past President of the Brazilian Statistical Society (1998–1990). He was the Director of the Institute of Mathematic and Statistics, São Paulo, Brazil (1994–1998). He was also Director of the Bioinformatic Scientific Center, University of São Paulo (2006–2009). He is an Elected member of the International Statistical Institute. He has authored and co-authored more than 150 papers and 4 books, including *Bayesian Analysis* (in Portuguese) in 1982 – the first Bayesian book published in Latin America. Professor Pereira has received the Ralph Bradley award from Florida State University in 1980. He was a research engineer at IEOR in Berkeley at the University of California (1986–1988). He was Associate editor of *Entropy*, *Environmetrics*, and *Brazilian J of Probability and Statistics*. Currently, he is the Statistical editor of the *Brazilian J of Psychiatry*. He was a member of both the Environmetrics Society and Board of Directors of *Entropy*.

Functional Data Analysis

Hans-Georg Müller
Professor of Statistics
University of California-Davis, Davis, CA, USA

Functional data analysis (FDA) refers to the statistical analysis of data samples consisting of random functions or surfaces, where each function is viewed as one sample element. Typically, the random functions contained in the sample are considered to be independent and smooth. FDA methodology is essentially nonparametric, utilizes smoothing methods, and allows for flexible modeling. The underlying random processes generating the data are sometimes assumed to be (non-stationary) ▶Gaussian processes.

Functional data are ubiquitous and may involve samples of density functions (Kneip and Utikal 2001) or hazard functions (Chiou and Müller 2009). Application areas include growth curves, econometrics, evolutionary biology, genetics and general kinds of longitudinal data. FDA methodology features functional principal component analysis (Rice and Silverman 1991), warping and curve registration (Gervini and Gasser 2004) and functional regression (Ramsay and Dalzell 1991). Theoretical foundations and asymptotic analysis of FDA are closely tied to perturbation theory of linear operators in Hilbert space (Bosq 2000). Finite sample implementations often require to address ill-posed problems with suitable regularization. A broad overview of applied aspects of FDA can be found in the textbook Ramsay and Silverman (2005).

The basic statistical methodologies of ANOVA, regression, correlation, classification and clustering that are available for scalar and vector data have spurred analogous developments for functional data. An additional aspect is that the time axis itself may be subject to random distortions and adequate functional models sometimes need to reflect such time-warping. Another issue is that often the random trajectories are not directly observed. Instead, for each sample function one has available measurements on a time grid that may range from very dense to extremely sparse. Sparse and randomly distributed measurement times are frequently encountered in longitudinal studies. Additional contamination of the measurements of the trajectory levels by errors is also common. These situations require careful modeling of the relationship between the recorded observations and the assumed underlying functional trajectories (Rice and Wu 2001; James and Sugar 2003; Yao et al. 2005). Initial analysis of functional data includes exploratory plotting of the observed functions in a "spaghetti plot" to obtain an initial idea of functional shapes, check for ▶outliers and identify "landmarks." Preprocessing may include outlier removal and curve alignment (registration) to adjust for time-warping.

Basic objects in FDA are the mean function μ and the covariance function G. For square integrable random functions $X(t)$,

$$\mu(t) = E(Y(t)),\ G(s,t) = \mathrm{cov}\{X(s), X(t)\},\quad s,t \in \mathcal{T}, \tag{1}$$

with auto-covariance operator $(Af)(t) = \int_{\mathcal{T}} f(s)G(s,t)\,ds$. This linear operator of Hilbert-Schmidt type has orthonormal eigenfunctions ϕ_k, $k = 1, 2, \ldots$, with associated ordered eigenvalues $\lambda_1 \geq \lambda_2 \geq \ldots$, such that $A\,\phi_k = \lambda_k\,\phi_k$. The foundation for functional principal component analysis is the Karhunen-Loève representation of random functions $X(t) = \mu(t) + \sum_{k=1}^{\infty} A_k\,\phi_k(t)$, where $A_k = \int_{\mathcal{T}}(Y(t) - \mu(t))\phi_k(t)\,dt$ are uncorrelated centered random variables with $var(A_k) = \lambda_k$.

Estimators employing smoothing methods (local least squares or splines) have been developed for various sampling schemes (sparse, dense, with errors) to obtain a data-based version of this representation, where one regularizes by truncating at a finite number K of included components. The idea is to borrow strength from the entire sample of functions rather than estimating each function separately. The functional data are then represented by the subject-specific vectors of score estimates $\hat{A}_k$, $k = 1, \ldots, K$, which can be used to represent individual trajectories and

for subsequent statistical analysis. Useful representations are alternatively obtained with pre-specified fixed basis functions, notably B-splines and wavelets.

Functional regression models may include one or several functions among the predictors, responses, or both. For pairs (X, Y) with centered random predictor functions X and scalar responses Y, the linear model is

$$E(Y|X) = \int_{\mathcal{T}} X(s)\beta(s)\, ds.$$

The regression parameter function β is usually represented in a suitable basis, for example the eigenbasis, with coefficient estimates determined by ►least squares or similar criteria. A variant, which is also applicable for classification purposes, is the generalized functional linear model $E(Y|X) = g\{\mu + \int_{\mathcal{T}} X(s)\beta(s)\, ds\}$ with link function g. The link function (and an additional variance function if applicable) is adapted to the (often discrete) distribution of Y; the components of the model can be estimated by quasi-likelihood.

The class of useful functional regression models is large. A flexible extension of the functional linear model is the functional additive model. Writing centered predictors as $X = \sum_{k=1}^{\infty} A_k \phi_k$, it is given by

$$E(Y|X) = \sum_{k=1}^{\infty} f_k(A_k)\phi_k$$

for smooth functions f_k with $E(f_k(A_k)) = 0$. Of practical relevance are models with varying domains, with more than one predictor function, and functional (autoregressive) time series models. In addition to the functional trajectories themselves, their derivatives are of interest to study the dynamics of the underlying processes.

Functional Derivatives in Statistics: Asymptotics and Robustness

Luisa Turrin Fernholz
Professor Emerita of Statistics
Temple University, Philadelphia, PA, USA

Introduction

Given a sample $X_1, \ldots, X_n$ of i.i.d. random variables with common distribution function (df) F and empirical df F_n, a statistic $S(X_1, \ldots, X_n)$ is called a *statistical functional* if it can be written in terms of a functional T, independent of n, such that $S(X_1, \ldots, X_n) = T(F_n)$ for all $n \geq 1$. The domain of T contains at least the population df F and the empirical df F_n for all $n \geq 1$. In this setting the statistic $T(F_n)$ estimates the parameter $T(F)$.

The sample mean is a statistical functional since $\overline{X} = 1/n \sum_1^n X_i = \int x dF_n(x) = T_1(F_n)$ which estimates the parameter $T_1(F) = \int x dF(x)$. The statistical functional corresponding to the sample median is $T_2(F_n) = F_n^{-1}(1/2) = \text{med}\{X_1, \ldots, X_n\}$ estimating the population median $T_2(F) = F^{-1}(1/2)$. Most statistics of interest are statistical functionals. They can be defined explicitly, such as T_1 and T_2, or implicitly, such as maximum likelihood type estimators or M-estimators which are solutions of equations in θ of the form $\int \psi(x, \theta)\, dF_n(x) = 0$.

Statistical functionals were introduced by von Mises (1947), who proposed the use of a functional derivative

called the Volterra derivative along with the corresponding Taylor expansion to obtain the asymptotic distribution of a statistic. However, the technical details were obscure with intractable notation and complicated regularity conditions. Consequently, the results appeared difficult to implement, and the von Mises theory was neglected until the late 1960s and 1970s with the surge of ▶robust statistics associated mainly with the work of Huber (1964, 1977) and Hampel (1968, 1974). For these new statistics, the statistical functional setting was found to be optimal for the study of robustness properties and the von Mises approach seemed to provide a natural environment for deriving the asymptotic distribution of the proposed robust estimates. During these robustness years the functional analysis concepts of differentiability and continuity were used to investigate the robustness aspects of the new statistics in addition to the asymptotics. In particular, the introduction of the influence function made a connection between robustness and classical asymptotics.

The Influence Function

Given a statistical functional T and a df F, the *influence function* of T at F is the real valued function $IF_{T,F}$ defined by

$$IF_{T,F}(x) = \lim_{t\to 0^+} \frac{T((1-t)F + t\Delta_x) - T(F)}{t},$$

where Δ_x is the d.f. of the point mass one at x. This function is normalized by setting $IF(x) = IF_{T,F}(x) - E_F(IF_{T,F}(X))$ so that $E_F(IF(X)) = 0$.

The influence function has played an important role in robust statistics. It was introduced by Hampel (1974), who observed that for large n, $IF_{T,F}(x)$ measures the effect on $T(F_n)$ of a single additional observation with value x. A bounded influence function indicates robustness of the statistic. For example, for the sample mean $T_1(F_n)$ as defined above, the influence function is $IF(x) = x - T_1(F)$. For the sample median $T_2(F_n)$, if $f = F'$, we have

$$IF(x) = \left[-1/(2f(T_2(F))\right] I_{\{x<(T_2(F)\}}(x) + \left[1/(2f(T_2(F))\right] I_{\{x\geq T_2(F)\}}(x).$$

Hence, the sample median with bounded influence function is more robust than the sample mean whose influence function is not bounded. A complete treatment of the robustness measures derived from the influence function can be found in Hampel et al. (1986).

In the framework of statistical functionals, the influence function can be viewed as a weak form of a functional derivative. Stronger derivatives were defined to analyze the asymptotic behavior of a statistic, but in all these derivatives the influence function is the crucial ingredient. It also provides a link between robustness and asymptotics as will be shown below.

Functional Derivatives

Consider a statistical functional T with domain an open set which lies in a normed vector space and contains a df F. A continuous linear functional T'_F is the *derivative* of T at F when

$$\lim_{t\to 0} \frac{T(F+tH) - T(F) - T'_F(tH)}{t} = 0, \qquad (1)$$

for H in subsets of the domain of T.

If (1) holds pointwise for each H, then T'_F is the *Gâteaux derivative*.

If (1) holds uniformly for all H in compact subsets of the domain of T, then T'_F is the *Hadamard derivative*.

If (1) holds uniformly for all H in bounded subsets of the domain of T, then T'_F is the *Fréchet derivative*.

Clearly Fréchet differentiability implies Hadamard differentiability, which implies Gâteaux differentiability. In all cases, the influence function is the central ingredient for any derivative since $T'_F(H) = \int IF_{T,F}(x)\, dH(x)$. Now, consider the Taylor expansion of T at F:

$$T(F+tF) - T(F) = T'_F(tH) + Rem$$

with

$$Rem = Rem(T, H, t) = o(t).$$

This remainder tends to zero either pointwise or uniformly according to whether F is Gâteaux, Hadamard, or Fréchet differentiable. For Hadamard derivatives see Reeds (1976) or Fernholz (1983) and for Fréchet derivatives see Huber (1981) or Serfling (1981).

When $t = 1/\sqrt{n}$ and $H = \sqrt{n}\,(F_n - F)$, the linear term of the Taylor expansion of T is

$$\int IF_{T,F}(x)\, d(F_n - F)(x) = \frac{1}{n}\sum_1^n IF(X_i),$$

where IF has been normalized, and the von Mises expansion of T at F is

$$T(F_n) = T(F) + \frac{1}{n}\sum_1^n IF(X_i) + Rem$$

or

$$\sqrt{n}(T(F_n) - T(F)) = \frac{1}{\sqrt{n}}\sum_1^n IF(X_i) + \sqrt{n}\, Rem.$$

When T is Hadamard or Fréchet differentiable, $\sqrt{n}\, Rem \to 0$ in probability, so that under certain regularity conditions for F we have the ▶asymptotic normality,

$$\sqrt{n}(T(F_n) - T(F)) \xrightarrow{\mathcal{D}} \mathrm{N}(0, \sigma^2).$$

In this case the influence function gives the asymptotic variance $\sigma^2 = E_F[IF(X)]^2$.

Remarks

The derivative used by von Mises for these calculations was similar to the Gâteaux derivative, so several strong regularity conditions had to be imposed on T to obtain its asymptotic normality. With the Hadamard or Fréchet derivatives these extra conditions are not needed.

It is important to note that the influence function plays a key role in these von Mises calculations. Note also that the influence function provides a link between robustness and asymptotics, and for this reason the von Mises approach via the influence function has become a useful method for obtaining asymptotic normality results.

The use of the Hadamard and Fréchet derivatives translates the problem of asymptotics into a problem of functional differentiability. Since Hadamard and Fréchet derivatives enjoy the chain rule property, we can show that a statistic $T(F_n)$ is asymptotically normal if the functional T is a composition of Hadamard or Fréchet differentiable functional components, where each component has a simple form. For references see Reeds (1976) or Fernholz (1983).

Higher Order Derivatives

The influence function is also called the *first kernel* since higher order derivatives can be defined for a real valued function T. If we set $\varphi_1(x) = IF(x)$ for the first kernel, the *second kernel* is

$$\varphi_2(x, y) = \frac{\partial^2}{\partial s\, \partial t} T\big(F(1 - s - t) + t\Delta_x + s\Delta_y\big)|_{t=0,s=0},$$

and in general, the *kernel of order* k is

$$\varphi_k(x_1, x_2, \ldots, x_k) = \frac{\partial^k}{\partial t_1\, \partial t_2 \ldots \partial t_k} T\left(F\left(1 - \sum_1^k t_i\right) + t_1\Delta_{x_1} + \ldots + t_k\Delta_{x_k}\right)\Big|_{(0,\ldots,0)}.$$

These kernels constitute the main ingredients for general Fréchet, Hadamard or Gâteaux higher order derivatives of T at F and for the corresponding higher order Taylor expansions. Hence, for $k \geq 2$ the k-th order von Mises expansion of $T(F_n)$ at F is:

$$T(F_n) - T(F) = \frac{1}{n}\sum_i \varphi_1(X_i) + \frac{1}{2n^2}\sum_{i,j}\varphi_2(X_i, X_j) + \cdots + \frac{1}{k!n^k}\sum_{i_1,\ldots,i_k}\varphi_k(X_{i_1}, \ldots, X_{i_k}) + Rem_k,$$

where, under certain differentiability conditions for T, the remainder of order k satisfies $Rem_k = o_P(n^{-k/2})$.

Higher order von Mises expansions were used to study the asymptotic distribution of a statistic when it is not normal (see von Mises 1947; Filippova 1972; Reeds 1976). These expansions are also useful to study the bias of a statistic since $E_F(T(F_n)) = T(F) + E_F(Rem_1)$, where

$$Rem_1 = \frac{1}{2n^2}\sum_{i,j}\varphi_2(X_i, X_j) + \cdots + \frac{1}{k!n^k}\sum_{i_1,\ldots,i_k}\varphi_k(X_{i_1}, \ldots, X_{i_k}) + Rem_k.$$

Results in this direction can be found in Sen (1988) and Fernholz (2001).

Multivariate Functionals

The formal von Mises calculations outlined above can be carried out for functionals of p variables after generalizing some basic rules of elementary calculus for the case of functional derivatives. Thus, if $T : \mathbb{R}^p \to \mathbb{R}$ and we have p samples of sizes $n_1, n_2, \ldots, n_p$ from the populations $F_1, \ldots, F_p$ respectively, we can consider the corresponding empirical df's $F_{n_1}, \ldots, F_{n_p}$. Then, the multivariate statistical functional $T(F_{n_1}, \ldots, F_{n_p})$ has p first order partial derivatives given by the corresponding multivariate influence function $\varphi_1 = (\varphi_{11}, \varphi_{12}, \ldots, \varphi_{1p})$, where for $1 \leq i \leq p$ the components are

$$\varphi_{1i}(x) = \frac{\partial T(F_1, \ldots, F_{i-1}, (1-\varepsilon)F_i + \varepsilon\Delta_x, F_{i+1}, \ldots, F_p)}{\partial \varepsilon}\Big|_{\varepsilon=0}.$$

Higher order partial derivatives can be found with the corresponding higher order von Mises expansions. For details, examples, and applications see Filippova (1972), Reeds (1976), and Fernholz (2001).

Statistical Functionals and the Bootstrap

Statistical functionals played a key role in the development of the bootstrap (see ▶Bootstrap Methods) introduced by Efron (1979). The "plug in" principle of Efron is essentially the study of a statistic in the setting of statistical functionals. After the bootstrap was introduced, the functional derivatives provided the answer for one of the basic asymptotic questions regarding the consistency of the bootstrap estimators $T(F_n^*)$. Does the bootstrap work when the von Mises method works? That is, does

$$\sqrt{n}(T(F_n) - T(F)) \xrightarrow{\mathcal{D}} N(0, \sigma^2) \text{ imply}$$
$$\sqrt{n}\left(T\left(F_n^*\right) - T(F_n)\right) \xrightarrow{\mathcal{D}} \mathrm{N}(0, \sigma^2) \ ?$$

The affirmative answer was given by R. Gill (1989) where he used von Mises expansions with Hadamard derivatives to show the asymptotic consistency of the bootstrap.

Smoothed Versions of Statistical Functionals

Using the convolution of F_n with a smooth df kernel sequence K_n we can obtain the smoothed version $\widetilde{F}_n(x) = \frac{1}{n}\sum_{i=1}^{n} K_n(x - X_i)$ of F_n. For a given statistical functional $T(F_n)$ estimating $T(F)$, we can consider the corresponding smoothed functional $T(\widetilde{F}_n)$ which, for continuous populations, may give a better estimate for $T(F)$. Some robustness aspects of $T(\widetilde{F}_n)$ can be analyzed through the influence function of T, and under reasonable regularity conditions for K_n, the ▶asymptotic normality of the smoothed version $T(\widetilde{F}_n)$ can be obtained when T is Hadamard differentiable. See Fernholz (1991, 1993).

About the Author

Luisa Turrin Fernholz is Professor Emerita of Statistics at Temple University, Philadelphia, PA (USA). She is currently the director of the Minerva Research Foundation and a member of the Advisory Council Committee for the Department of Mathematics at Princeton University as well as a member of the School of Mathematics Council for the Institute for Advanced Study, at Princeton, NJ (USA). She has previously held faculty positions at Princeton University, University of Pennsylvania, and the University of Buenos Aires. She is an elected member of the International Statistical Institute and a member of the ASA, the IMS, and the Bernoulli Society. She authored the research monograph *Von Mises Calculus for Statistical Functionals* (Springer Verlag, Lecture Notes in Statistics, Vol. 19, 1983). She co-edited several statistics volumes on Data Analysis and Robustness, and has published articles on probability theory as well as asymptotic expansions, robustness, functional derivatives, bias and variance reduction, and bootstrap applications, among other topics.

Fuzzy Logic in Statistical Data Analysis

Efendi N. Nasibov

Faculty of Science and Arts
Dokuz Eylul University, Imzir, Turkey

Probability and Statistics with Fuzziness

Fuzzy logic and fuzzy sets theory first discussed in 1965 by Zadeh (Zadeh 1965). In classical sets theory, classifications are precise and the subject either belongs to a set or not. On the contrary, in fuzzy sets theory, the subject located in the border both belongs and does not belong to a set simultaneously. As a mathematical representation, in classical

set theory, if the object is the member of a set, it takes the membership value of 1; otherwise it takes the membership value of 0. However, in fuzzy logic, objects could have membership degrees between 0 and 1. In fuzzy logic, for example, a 30-year-old person could be the member of both the "young people" set with a membership degree of 0.6 and the "not young people" set with a membership degree of 0.4.

The relation between "fuzzy sets theory" and "statistics and probability theory" is and important research areas. In probability theory, realization of events is based on the classical 0–1 logic, i.e., an event occurs or does not occur. When the boundaries of classes that reflect the events are precise, such logic is valid. For example, when a dice has been rolled, the event of "coming up 1 or 2" is a precise event and it has a precise probability. But the event of "coming up a little number" is an imprecise event since its boundaries can not be stated; consequently, its probability can not be designated. In such situations, using probability theory together with fuzzy logic and fuzzy sets theory provides more admissible results.

Another important utilization of fuzzy logic and fuzzy sets theory is in statistical data analysis. With improvement of fuzzy sets theory, many studies have been made to combine statistical analysis methods and fuzzy sets theory. An analysis in which fuzzy logic is used is more robust than the classical logic. Furthermore, more reliable results can be obtained by a fuzzy approach (Rubin 1998).

There are many instances where fuzzy logic is used in statistical data analysis, including clustering, classification, regression, ►principal component analysis (PCA), independent component analysis (ICA), ►multidimensional scaling, ►time series, hypothesis tests, and confidence intervals (Coppi et al. 2006; Pop 2004; Taheri 2003; Mares 2007).

Fuzzy Clustering and Classification

Bellman et al. (1966) and Ruspini (1969) are the pioneers who used fuzzy sets theory in cluster analysis. Afterwards, many approaches were proposed on the use of fuzzy logic in cluster analysis. The most widely used approaches are based on fuzzy partitioning.

Fuzzy partitioning: The fuzzy partitioning of the data set $X = x_1, x_2, \ldots, x_n$ into fuzzy clusters $C_1, C_2, \ldots, C_c (1 < c < n)$ is denoted by the matrix $U_f = (u_{ij}) = (\mu_{C_i}(x_j))$, which satisfies the conditions given below:

$$0 \le u_{ij} \le 1, \quad \forall i \in \{1, 2, \ldots, c\}, \quad \forall j \in \{1, 2, \ldots, n\}, \tag{1}$$

$$0 < \sum_{j=1}^{n} u_{ij} < n, \quad \forall i \in \{1, 2, \ldots, c\} \tag{2}$$

where u_{ij} is the membership degree of the element x_j to the cluster C_i. In most cases, the following normalization condition as well as (1) and (2) is required for fuzzy partitioning:

$$\sum_{i=1}^{c} u_{ij} = 1, \quad \forall j \in \{1, 2, \ldots, n\}. \tag{3}$$

The first solution algorithms for the clustering approach based on fuzzy partitioning were proposed by Dunn (1973) and improved by Bezdek (1973).

In the most widely used fuzzy c-means (FCM) algorithm, the optimal fuzzy partitioning is obtained by minimizing the following function:

$$J_f(U_f, v_1, \ldots, v_c) = \sum_{i=1}^{c} \sum_{j=1}^{n} u_{ij}^m d(v_i, x_j)^2 \tag{4}$$

where c is the predetermined number of clusters, $d(v_i, x_j)$ is the distance between the cluster center v_i and the object x_j, and $m (m > 1)$ is the fuzziness index. The solution of (1)–(4) is found through the iterative computation of membership degrees and cluster centers:

$$u_{ij} = \frac{d(v_i, x_j)^{-2/(m-1)}}{\sum_{t=1}^{c} d(v_t, x_j)^{-2/(m-1)}}, \; i = 1, \ldots, c; \; j = 1, \ldots, n \tag{5}$$

$$v_i = \frac{\sum_{j=1}^{n} u_{ij}^m x_j}{\sum_{j=1}^{n} u_{ij}^m}, \; i = 1, \ldots, c \tag{6}$$

The FCM algorithm is successful in finding spherical-shaped cluster structures. The Gustafson-Kessel algorithm based on FCM can find ellipsoidal cluster structures by using a covariance matrix. Fuzzy maximum likelihood estimation (FMLE) and the expectation maximization (EM) algorithms are also widely used fuzzy clustering algorithms (Doring et al. 2006).

Another approach for using fuzzy logic in cluster analysis is based on fuzzy neighborhood relations (FDBSCAN, FJP, FN-DBSCAN). In such an approach, the data are handled as fuzzy points and the classes are formed as crisp level sets based on the fuzziness level. Different clustering structures are obtained in different fuzziness levels. This approach could also be conceived as hierarchical clustering. The main point is to find the optimal hierarchy level and the optimal cluster structure convenient to this hierarchy level. In the fuzzy joint points based algorithms such as FJP, NRFJP, MFJP, such a problem has been solved by using an integrated cluster validity mechanism (Nasibov and Ulutagay 2007). The superiority of such algorithms over the FCM-based algorithms is not only the possibility

for finding arbitrarily shaped rather than only spherical-shaped clusters, but also not needing to determine the number of clusters in advance. On the other hand, using a fuzzy neighborhood relation among data can increase the robustness of clustering algorithm (Nasibov and Ulutagay 2009).

Classification is referred to as a supervised classification while clustering is referred to as an unsupervised classification. In a fuzzy supervised classification, the fuzzy partition X of elements is given in advance. One must specify the class of a datum x^* which is handled afterward. To do this, many approaches are used, including fuzzy inference system (FIS), fuzzy linear discriminant analysis, fuzzy k-nearest neighbors, and fuzzy-Bayesian classifier.

Fuzzy Regression

Fuzzy regression analysis is done by applying fuzzy logic techniques to classical regression models. There is no need for the assumptions of classical regression to hold for fuzzy regression. Moreover, fuzzy regression does not require normally distributed data, stability tests, or large samples. Classical regression analysis is able to respond to the needs of numerical science working with precise information. But in the social sciences, in which the personal perceptions are important, it is not easy to estimate the assumed appropriate and consistent estimators, because the concerned data are composed of imprecise, i.e., fuzzy data. In such situations, fuzzy logic can provide approximate ideas to reach adequate conclusions. There are various fuzzy regression models based on either fuzziness of the values of independent/dependent variables or fuzziness of the regression function (Näther 2006).

Usually, the fuzzy regression equation is as follows:

$$\tilde{y}_i = \tilde{b}_0 \oplus \tilde{b}_1 \odot \tilde{x}_{i1} \oplus \ldots \oplus \tilde{b}_p \odot \tilde{x}_{ip},\ i = 1, \ldots, n \qquad (7)$$

where $\oplus$ and $\odot$ are addition and multiplication processes on fuzzy numbers, $(\tilde{b}_0, \tilde{b}_1, \ldots, \tilde{b}_p)$ are fuzzy regression coefficients, $\tilde{y}_i$ is fuzzy response, and $(\tilde{x}_{i1}, \tilde{x}_{i2}, \ldots, \tilde{x}_{ip})$ are fuzzy explanatory variables.

The first study of fuzzy logic in regression analysis was made by Tanaka as fuzzy linear regression model (Tanaka et al. 1979, 1980, 1982). In Tanaka's approach, regression line is formed as a fuzzy linear function of data. Linear programming has been used to determine the parameters of this fuzzy function.

Another approach to fuzzy logic in regression analysis minimizes the sum of squares error between the observed and the predicted data which take fuzzy values. In determining the distance between fuzzy data, various fuzzy distances can be used and various models can be constructed (Diamond 1988; D'Urso 2003; Kim and Bishu 1998; Nasibov 2007).

As a third approach, Fuzzy c-Regression Models (FcRM), which arose from the technique of fuzzy clustering application on regression, can be specified. This approach, also called the switching regression, was proposed by Hathaway and Bezdek (Hathaway and Bezdek 1993). In this approach, all data are partitioned into distinct clusters since it is easier to express the structure with partial lines instead of a single regression function. The process works as in the FCM algorithm. The only difference is that, not only the membership degrees, but also the parameters of regression lines of the clusters are updated instead of cluster centers. The optimal value of the parameters has been found using the weighted least squares approach. For synthesis of the results, Fuzzy Inference Systems (FIS) such as Mamdani, Takagi-Sugeno-Kang (TSK), etc., can be used (Jang et al. 1997).

Fuzzy Principal Component Analysis

►Principal component analysis (PCA) is a preferred analysis method to reduce the dimension of the feature space and to extract information. PCA determines the linear combinations that describe maximum variability among the original data measurements. However, it is influenced by ►outliers, loss of data, and poor linear combinations. To resolve this problem, PCA models are created using fuzzy logic and the results are handled more efficiently than classical principal component analysis (Sarbu and Pop 2005). As with fuzzy regression, whole data sets are divided into fuzzy subsets in order to create better PCA models. Thus, the influence of outliers, which have minimum membership degree to clusters, is reduced.

The fuzzy covariance matrix for cluster A_i is constructed as follows:

$$C_{kl}^{(i)} = \frac{\sum_{j=1}^{n} [A_i(x^j)]^2 (x_{jk} - \bar{x}_k)(x_{jl} - \bar{x}_l)}{\sum_{j=1}^{n} [A_i(x^j)]^2}, \qquad (8)$$

where $A_i(x^j)$ indicates the membership degree of an object x^j to the cluster A_i and is inversely proportional with the distance between the object and the independent component.

One of the first studies about the fuzzy PCA was performed by Yabuuch and Watada in the construction of the principal component model using fuzzy logic for the elements in the fuzzy groups (Yabuuch and Watada 1997). The fuzzy PCA allows us to analyze the features of vague data samples. Hence, the fuzzy PCA gives more reliable results. Afterwards, the local fuzzy PCA method is used to reduce the dimension of feature vectors effectively. In this method, data space is partitioned into clusters using fuzzy clustering and then PCA is applied by constructing a fuzzy covariance

matrix (Lee 2004). In the study performed by Hsieh and Yang, fuzzy clustering is applied to find the hidden information in a DNA sequence by combining PCA and fuzzy adaptive resonance theory (fuzzy-ART) (Hsieh et al. 2008).

Fuzzy Independent Component Analysis

The recently developed and widely used independent component analysis (ICA) method is used to find linear form of non-Gaussian and statistically independent variables, and to extract information from databases (Hyvarinen et al. 2001). ICA is closely related to the blind source separation (BSS) method. The measurements $\mathbf{x} = (x_1, x_2, \ldots, x_n)$ of m unknown source signals ($\mathbf{s} = (s_1, s_2, \ldots, s_m)$) composed by unknown linear mixtures ($\mathbf{A}$) are performed:

$$\mathbf{x} = \mathbf{A}\mathbf{s}. \tag{9}$$

For the computational ease, $m = n$ is assumed. Hence, the matrix $\mathbf{A}$ is estimated by using the advantage of being an independent and non-Gaussian of source data and, using the matrix $\mathbf{W}$ (inverse of $\mathbf{A}$), source signals can be calculated from the equation below:

$$\mathbf{s} = \mathbf{W}\mathbf{x}. \tag{10}$$

The most widely used ICA algorithm is the Fast-ICA algorithm in terms of ease of use and speed. Honda et al. (2000) improved the Fast-ICA algorithm as the fuzzy Fast-ICA algorithm. In the fuzzy Fast-ICA algorithm, the Fuzzy c-Varieties (FCV) clustering method, which separates data into linear clusters using linear variability, is applied and then the local independent components in the fuzzy clusters are estimated by Fast-ICA algorithm.

Honda and Ichihashi (2008) have also proposed the fuzzy local ICA model as the improved version of the local ICA model. In the fuzzy local ICA model, fuzzy clustering, PCA, and multiple regression analysis are used simultaneously.

Gait biometrics have great advantages in comparison with the widely used biometrics such as face, fingerprint, and iris. In order to recognize gait, Lu et al. have developed a simple method based on human silhouette using genetic fuzzy vector machine (GFVM) and independent component analysis (Lu and Zhang 2007).

Fuzzy Time Series

The term "fuzzy time series" was first coined by Song and Chissom (Song and Chissom 1993ab, 1994).

Let $Y(t) \in R^1 (t = \ldots, 0, 1, 2, \ldots)$ be the universe of discourse on which fuzzy sets $f_i(t)(i = 1, 2, \ldots)$ are defined. Let $F(t)$ be a collection on $f_i(t)(i = 1, 2, \ldots)$. Then, $F(t)$ is called a fuzzy time series on $Y(t)(t = \ldots, 0, 1, 2, \ldots)$. In other words, fuzzy time series $F(t)$ is a chronological sequence of imprecise or fuzzy data ordered by time. Fuzzy time series are regarded as realizations of fuzzy random processes. In the fuzzy time series, fuzzy data as well as time-dependent dynamic relation can be considered as fuzzy:

$$F(t) = F(t-1) \circ \tilde{R}(t-1, t) \tag{11}$$

n^{th}-order fuzzy time series forecasting model, can be represented as follows:

$$F(t-1), F(t-2), \ldots, F(t-n) \rightarrow F(t) \tag{12}$$

For modeling of fuzzy time series, fuzzy ARMA, ARIMA processes, or fuzzy artificial neural networks are applied (Tseng et al. 2001; Zhang et al. 1998). Fuzzy time series can be analyzed and forecast by specifying an underlying fuzzy random process with the aid of generally applicable numerical methods.

Statistical Hypothesis Tests and Confidence Intervals

The main purpose of the traditional hypothesis test is to separate $\theta \in \Theta$ parameter space into two regions such as ω and $\Theta \backslash \omega$. The null and alternative hypotheses are as follows:

$$\begin{cases} H_0 : \theta \in \omega & (\textit{null hypothesis}) \\ H_1 : \theta \in \Theta \backslash \omega, & (\textit{alternative hypothesis}) \end{cases} \tag{13}$$

If the boundaries of ω and $\Theta \backslash \omega$ regions are assumed to be fuzzy, the fuzzy hypothesis test can be constructed as follows (Coppi et al. 2006):

$$\begin{cases} H_0 : \mu_\omega(\theta), & (\textit{null hypothesis}) \\ H_1 : \mu_{\Theta \backslash \omega(\theta)}, & (\textit{alternative hypothesis}) \end{cases} \tag{14}$$

Data handled in daily life are usually imprecise, i.e., fuzzy. For instance, water level of the river may not be fully measured due to fluctuations. In such a case, the well-known crisp hypothesis tests will not give reliable results.

Different approaches related to statistical hypothesis tests have been developed using fuzzy sets theory. First, Casals et al. (1986ab) and Casals and Gil (1989) have developed the ►Neyman-Pearson Lemma and Bayes method for statistical hypothesis tests with fuzzy data. There are two approaches to analyze statistical hypothesis tests: (1) observations are ordinary (crisp) and hypotheses are fuzzy (Arnold 1998), (2) both observations and hypotheses are fuzzy (Wu 2005). There may be some problems in applying classical statistical hypothesis to fuzzy observations. For instance, θ might be "approximately one" or θ might be "very large" and so on, where θ is any tested parameter. Bayes method might be useful for such types of hypothesis tests (Taheri and Behboodian 2001). However, if the fuzzy data are observed, the most appropriate method will be to apply fuzzy set theory to establish the statistical model.

In some approaches to using fuzzy logic in hypothesis tests, the estimators as fuzzy numbers are obtained using confidence intervals. If the estimator is a fuzzy number, the test statistic in hypothesis testing will also be a fuzzy number. Thus, the critical value at the hypothesis test is a fuzzy number. The result of this approach might be more realistic than a crisp hypothesis test (Buckley 2005). These results may be evaluated with probability theory (Hryniewicz 2006).

Fuzzy sets theory through the fuzzy random variables is applied to statistical confidence intervals for unknown fuzzy parameters. When the sample size is sufficiently large, an approximate fuzzy confidence interval could be constructed through a central limit theorem (Wu 2009). In case of fuzzy data, an interval estimation problem is formulated and the relation between fuzzy numbers and random intervals is found in (Coral et al. 1988; Gil 1992).

Fuzzy Set Theory and Probability Theory: What is the Relationship?

Lotfi A. Zadeh
Professor Emeritus
University of California-Berkeley, Berkeley, CA, USA

Relationship between probability theory and fuzzy set theory is associated with a long history of discussion and debate. My first paper on fuzzy sets was published in 1965 (Zadeh 1965). In a paper published in 1966, Loginov suggested that the membership function of a fuzzy set may be interpreted as a conditional probability (Loginov 1966). Subsequently, related links to probability theory were suggested and analyzed by many others (Coletti and Scozzafava 2004; Freeling 1981; Hisdal 1986a, b; Nurmi 1977; Ross et al. 2002; Singpurwalla and Booker 2004; Stallings 1977; Thomas 1995; Viertl 1987; Yager 1984). Among such links are links to set-valued random variables (Goodmanm and Nguyen 1985; Orlov 1980; Wang and Sanchez 1982) and to the Dempster–Shafer theory (Dempster 1967; Shafer 1976). A more detailed discussion of these links may be found in my l995 paper "Probability theory and fuzzy logic are complementary rather than competitive," (Zadeh 1995).

In reality, probability theory and fuzzy set theory are distinct theories with different agendas. Scientific theories originate in perceptions. Primitive perceptions such as perceptions of distance, direction, weight, loudness, color, etc. crystallize in early childhood. Among basic perceptions which crystallize at later stages of development are those of likelihood, count, class, similarity and possibility. Fundamentally, probability theory may be viewed as a formalization of perceptions of likelihood and count; fuzzy set theory may be viewed as a formalization of perceptions of class and similarity; and possibility theory may be viewed as a formalization of perception of possibility. It should be noted that perceptions of likelihood and possibility are distinct. Fuzzy set theory and possibility theory are closely related (Zadeh 1978). A key to a better understanding of the nature of the relationship between probability theory and fuzzy set theory is the observation that probability theory is rooted in perceptions of likelihood and count while fuzzy set theory is rooted in perceptions of class and similarity.

In debates over the nature of the relationship between probability theory and fuzzy set theory, there are four schools of thought. The prevailing view within the Bayesian community is that probability theory is sufficient for dealing with uncertainty and imprecision of any kind, implying that there is no need for fuzzy set theory. An eloquent spokesman for this school of thought is an eminent Bayesian, Professor Dennis Lindley. Here is an excerpt of what he had to say on this subject.

> *The only satisfactory description of uncertainty is probability. By this I mean that every uncertainty statement must be in the form of a probability; that several uncertainties must be combined using the rules of probability; and that the calculus of probabilities is adequate to handle all situations involving*

uncertainty… probability is the only sensible description of uncertainty and is adequate for all problems involving uncertainty. All other methods are inadequate… anything that can be done with fuzzy logic, belief functions, upper and lower probabilities, or any other alternative to probability can better be done with probability (Lindley 1987).

The second school of thought is that probability theory and fuzzy set theory are distinct theories which are complementary rather than competitive. This is the view that is articulated in my l995 Technometrics paper (Zadeh 1995). The third school of thought is that standard probability theory, call it PT, is in need of generalization through addition to PT of concepts and techniques drawn from fuzzy set theory and, more generally, from fuzzy logic, with the understanding that fuzzy set theory is a branch of fuzzy logic. Basically, fuzzy logic, FL, is a precise system of reasoning, computation and deduction in which the objects of discourse are fuzzy sets, that is, classes in which membership is a matter of degree. Thus, in fuzzy logic everything is, or is allowed to be, a matter of degree.

It is important to observe that any bivalent-logic-based theory, T, may be generalized through addition of concepts and techniques drawn from fuzzy logic. Such generalization is referred to as FL-generalization. The view that standard probability theory, PT, can be enriched through FL-generalization is articulated in my 2002 paper "Toward a perception-based theory of probabilistic reasoning" (Zadeh 2002), 2005 paper "Toward a generalized theory of uncertainty (GTU) – an outline" (Zadeh 2005) and 2006 paper "Generalized theory of uncertainty (GTU) – principal concepts and ideas" (Zadeh 2006). The result of FL-generalization, call it PTp, is a generalized theory of probability which has a key capability – the capability to deal with information which is described in a natural language and, more particularly, with perception-based probabilities and relations which are described in a natural language. What is not widely recognized is that many, perhaps most, real-world probabilities are perception-based. Examples: What is the probability that Obama will succeed in solving the financial crisis? What is the probability that there will be a significant increase in the price of oil in the near future? Such probabilities are perception-based and non-numerical. Standard probability theory provides no facilities for computation and reasoning with non-numerical, perception-based probabilities.

The fourth school of thought is that FL-generalization of probability theory should be accompanied by a shift in the foundations of probability theory from bivalent logic to fuzzy logic. This is a radical view which is put forth in my 2004 paper "Probability theory and fuzzy logic – a radical view" (Zadeh 2004).

Is probability theory sufficient for dealing with any kind of uncertainty and imprecision? Professor Lindley's answer is: Yes. In a paper published in 1986 entitled "Is probability theory sufficient for dealing with uncertainty in AI: A negative view," (Zadeh 1986) I argued that the answer is: No. In contradiction to Professor Lindley's assertion, here are some simple examples of problems which do not lend themselves to solution through the use of standard probability theory.

In these examples X is a real-valued variable.
X is larger than approximately a
X is smaller than approximately b

What is the probability that X is approximately c?

Usually X is larger than approximately a
Usually X is smaller than approximately b

What is the probability that X is approximately c?

Usually X is much larger than approximately a
Usually X is much smaller than approximately b

What is the probability that X is approximately c?
What is the expected value of X?

Usually it takes Robert about an hour to get home from work
Robert left work at about 5 pm

What is the probability that Robert is home at 6:l5 pm?

In these examples, question-relevant information is described in natural language. What these examples underscore is that, as was alluded to earlier, standard probability theory does not provide methods of deduction and computation with information described in natural language. Lack of this capability is a serious limitation of standard probability theory, PT. To add this capability to PT it is necessary to FL-generalize PT through addition to PT of concepts and techniques drawn from fuzzy logic.

What would be gained by going beyond FL-generalizat ion of PT, and shifting the foundations of PT from bivalent logic to fuzzy logic? There is a compelling reason for such a shift. At this juncture, most scientific theories, including probability theory, are based on bivalent logic. In bivalent-logic-based theories, the basic concepts are defined as bivalent concepts, with no shades of truth allowed. In reality, most basic concepts are fuzzy, that is, are a matter of degree. For example, in probability theory the concept of independence is defined as a bivalent concept, meaning that two events A and B are either independent or not independent,

with no degrees of independence allowed. But what is quite obvious is that the concept of independence is fuzzy rather than bivalent. The same applies to the concepts of event, stationarity and more generally, to most other basic concepts within probability theory. A shift in the foundations of probability theory would involve a redefinition of bivalent concepts as fuzzy concepts. Such redefinition would enhance the ability of probability theory to serve as a model of reality.

What is widely unrecognized at this juncture is that (a) the capability of probability theory to deal with real-world problems can be enhanced through FL-generalization. Even more widely unrecognized is that (b) the ability of probability theory to serve as a model of reality can be further enhanced through a shift in the foundations of probability theory from bivalent logic to fuzzy logic. But as we move further into the age of machine intelligence and automated decision-making the need for (a) and (b) will become increasingly apparent. I believe that eventually (a) and (b) will gain acceptance.

About the Author

Lotfi Zadeh was born in 1921 in Baku, Azerbaijan. After his PhD from Columbia University in 1949 in Electrical Engineering, he taught at Columbia for ten years till 1959 where he was a full professor. He joined the Electrical Engineering Department at the University of California, Berkeley in 1959 and served as its chairman from 1963 to 1968. Presently, he is a professor in the Graduate school serving as the Director of BISC (Berkeley Initiative in Soft Computing). He authored a seminal paper in fuzzy sets in 1965. This landmark paper initiated a new direction, which over the past three decades led to a vast literature, and a rapidly growing number of applications ranging from consumer products to subway trains and decision support systems. For this seminal contribution he received the Oldenburger medal from the American Society of Mechanical Engineers in 1993, the IEEE Medal of Honor in 1995, the Okawa prize in 1996, the B. Bolzano Medal from the Academy of Sciences of the Czech Republic, and the Benjamin Franklin Medal in Electrical Engineering. He is a member of the National Academy of Engineering and a Foreign Member of the Polish, Finnish, Korean, Bulgarian, Russian and Azerbaijan Academy of Sciences. He has single-authored over two hundred papers and serves on the editorial boards of over fifty journals. Dr. Zadeh is a recipient of twenty-six honorary doctorates.

Fuzzy Sets: An Introduction

Madan Lal Puri
Professor Emeritus
King Fahd University of Petroleum and Minerals,
Dhahran, Saudi Arabia
Indiana University, Bloomington, IN, USA

Some of the basic properties and implications of the concepts of fuzzy set theory are presented. The notion of a fuzzy set is seen to provide a convenient point of departure for the construction of a conceptual framework which parallels in many respects the framework used in the case of ordinary sets but is more general than the latter. The material presented is from the basic paper of Zadeh (1965) who introduced the notion of fuzzy sets. The reader is also referred to Rosenfeld (1982) for a brief survey of some of the concepts of fuzzy set theory and its application to pattern recognition (see ►Pattern Recognition, Aspects of and ►Statistical Pattern Recognition Principles).

Introduction

In everyday life we often deal with imprecisely defined properties or quantities–e.g., "a few books," "a long story," "a popular teacher," "a tall man," etc. More often than not, the classes of objects which we encounter in the real physical world do not have precisely defined criteria of membership. For example, consider the class of animals. This class clearly includes dogs, horses, birds, etc. as its members, and clearly excludes rocks, fluids, plants, etc. However, such objects as starfish, bacteria, etc. have an ambiguous status with respect to the class of animals. The same kind of ambiguity arises in the case of a number such as 10 in relation to the "class" of all numbers which are much greater than 1.

Clearly, the class of all real numbers which are much greater than 1, or "the class of tall men" do not constitute classes in the usual mathematical sense of these terms. Yet, the fact remains that such imprecisely defined "classes" play an important role in human thinking, particularly, in the domain of pattern recognition, communication of information, decision theory, control theory and medical diagnosis, among others.

The purpose of this note is to provide in a preliminary way some of the basic properties and implications of a concept which is being used more and more in dealing with the type of "classes"mentioned above. The concept in question is that of a "fuzzy set" with a continuum of grades of membership, the concept introduced by Zadeh (1965) in order to allow imprecisely defined notions to be properly formulated and manipulated.

Over the past 20–25 years there has been a tremendous growth of literature on fuzzy sets amounting by now to over 2,000 papers and several textbooks; there is even a journal devoted to this subject.

This note is intended to provide a brief survey of some of the basic concepts of fuzzy sets and related topics.

We begin with some basic definitions.

Definitions

Let $\mathcal{X}$ be a space of points (objects), with a generic element of $\mathcal{X}$ denoted by x. Thus, $\mathcal{X} = \{x\}$.

A fuzzy set (class) A in $\mathcal{X}$ is characterized by a *membership (characteristic) function* $f_A(x)$ which associates with each point x in $\mathcal{X}$ a real number in the interval $[0,1]$, with the value of $f_A(x)$ at x representing the "grade of membership" or "the degree of membership" of x in A. The key idea in fuzzy set theory is that an element has a "degree of membership" in a fuzzy set, and we usually assume that this degree is a real number between 0 and 1. The nearer the value of $f_A(x)$ to unity, the higher the degree of membership of x in A. In the case of the "fuzzy set" of tall men, the elements are men, and their degrees of membership depend on their heights; e.g., a man who is 5 ft tall might have degree 0, a man who is $6\frac{1}{2}$ ft tall might have degree 1, and men of intermediate heights might have intermediate degrees. Analogous remarks apply to such fuzzy sets as the set of young women, the set of rich people, the set of first rate mathematicians, and so on. When A is a set in the ordinary sense of the term, its membership function can take

on only two values 0 and 1, with $f_A(x) = 1$ if $x \in A$ or 0 if $x \notin A$. Thus, in this case, $f_A(x)$ reduces to the familiar characteristic function or indicator function of a so-called crisp set A.

It may be noted that the notion of a fuzzy set is completely nonstatistical in nature, and the rules which are commonly used for manipulating fuzzy set memberships are not the same as the rules for manipulating probabilities.

The Algebra of Fuzzy Subsets

The rules for combining and manipulating fuzzy subsets of $\mathcal{X}$ (Blurrian algebra) should reduce to the rules of ordinary subset algebra when subsets are crisp. This motivates the fuzzy subset algebra introduced by Zadeh (1965), where $\leq$, sup ($\vee$) and inf ($\wedge$) play the roles of $\subseteq$, $\cup$, and $\cap$, respectively. We say that

1. A fuzzy set is empty iff (if and only if) its membership function is $\equiv 0$ on $\mathcal{X}$.
2. Two fuzzy sets A and B are *equal* (and we write $A = B$) iff $f_A(x) = f_B(x)\ \forall\ x \in \mathcal{X}$. (Instead of writing $f_A(x) = f_B(x)\ \forall\ x \in \mathcal{X}$, we shall write $f_A = f_B$).
3. The *complement* of a fuzzy set A is denoted by A' and is defined as $f'_A = 1 - f_A$.
4. $A \subset B$ iff $f_A \leq f_B$.
5. The *union* of two fuzzy sets A and B with respect to respective membership functions $f_A(x)$ and $f_B(x)$ is a fuzzy set C, (and we write $C = A \cup B$) whose membership function is related to those of A and B by

$$f_C(x) = \max[f_A(x), f_B(x)] \quad \forall\ x \in \mathcal{X} \text{ i.e., } f_C = f_A \vee f_B. \tag{I}$$

(Note that the union has the associative property, i.e., $A \cup (B \cup C) = (A \cup B) \cup C$. Also note that a more intuitive way of defining the union is the following: The union of A and B is the smallest fuzzy set containing both A and B. More precisely, if D is any fuzzy set which contains both A and B, then it also contains the union of A and B.)

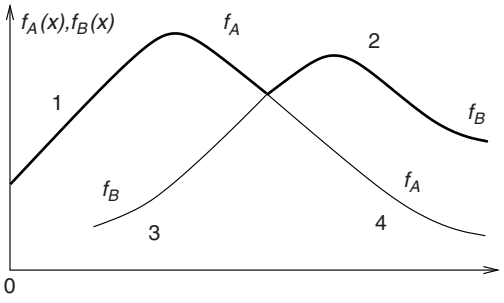
6. The *intersection* of two fuzzy sets A and B with respect to their respective membership functions $f_A(x)$ and $f_B(x)$ is a fuzzy set C (written as $C = A \cap B$) whose membership function f_C is related to those of A and B by $f_C(x) = \min[f_A(x), f_B(x)]\ \forall\ x \in \mathcal{X}$ i.e.,

$$f_C = f_A \wedge f_B.$$

As in the case of union, it is easy to show that the intersection of A and B is the *largest* fuzzy set which is contained in both A and B.

7. A and B are *disjoint* if $A \cap B = C$ is empty, i.e., $f_C(x) \equiv 0\ \forall\ x \in \mathcal{X}$.

Note that $\cap$, like union, has the associative property. Also note that the notion of "belonging" which plays a fundamental role in the case of ordinary sets, does not have the same role in the case of fuzzy sets. Thus, it is not meaningful to speak of a point x "belonging" to a fuzzy set A except in the trivial sense of $f_A(x)$ being positive. Less trivially, one can introduce two levels α and β ($0 < \alpha < 1$, $\beta < \alpha$, $0 < \beta < 1$) and agree to say that (1) $x \in A$ if $f_A(x) \geq \alpha$, (2) $x \notin A$ if $f_A(x) \leq \beta$; and (3) x has an intermediate status relative to A, if $\beta < f_A(x) < \alpha$. This leads to a three valued logic with three truth values: T ($f_A(x) \geq \alpha$), F ($f_A(x) \leq \beta$), and U ($\beta < f_A(x) < \alpha$). Note that the empty and universal (fuzzy) subsets are just the constant functions 0 and 1; they are in fact non-fuzzy!



(Curve segments 1 and 2 comprise the membership function of the union (heavy lines). Curve segments 3 and 4 comprise the membership function of the intersection).

It is clear that these definitions are the extensions of the definitions of $\subseteq$, $\cup$ and $\cap$ for ordinary sets. It is also trivial to verify that they have properties analogous to those of $\subseteq$, $\cup$ and $\cap$, e.g., $A \cup B$ is the $\cap$ of all fuzzy sets $C \supset A \subset C$ and $B \subset C$; and $A \cap B$ is the union of all fuzzy sets $C \supset C \subset A$ and $C \subset B$. Evidently $\subseteq$ is a partial order relation, and $\cup$ and $\cap$ are commutative, associative and distributive over each other. It is also easy to extend many of the basic identities which hold for ordinary sets to fuzzy sets. As examples, we have the De Morgan's Laws:

$$(A \cup B)' = A' \cap B' \tag{1}$$

$$(A \cap B)' = A' \cup B'. \tag{2}$$

To prove (1), for example, note that the left hand side

$$= 1 - \max[f_A, f_B]$$

$$= \min[1 - f_A, 1 - f_B] = \min[f_{A'}, f_{B'}]$$

$$= \text{Right hand side.}$$

This can easily be verified by testing it for two possible cases: $f_A(x) > f_B(x)$ and $f_A(x) < f_B(x)$. Essentially fuzzy sets in $\mathcal{X}$ constitute a distributive lattice with a 0 and 1 (Birkoff, 1948).

8. The *algebraic product* of A and B is denoted by AB, and is defined in terms of membership functions of A and B by the relation $f_{AB} = f_A \cdot f_B$. Clearly $AB \subset A \cap B$.
9. The *algebraic sum* of A and B is denoted by $A + B$ and is defined as

$$f_{A+B} = f_A + f_B$$

provided $f_A + f_B \leq 1$.

Thus, unlike the algebraic product, the algebraic sum is meaningful only if $f_A(x) + f_B(x) \leq 1 \; \forall \; x \in X$.

10. The *absolute difference* of A and B is denoted by $|A - B|$ and is defined as $f_{|A-B|} = |f_A - f_B|$. Note that in the case of ordinary sets, $|A - B|$ reduces to the relative complement of $A \cap B$ in $A \cup B$. ($|A - B|$ is the symmetric difference $A \triangle B = (A - B) \cup (B - A)$).
11. The dual of algebraic product is the sum $A \oplus B = (A'B')' = A + B - AB$. (Note that for ordinary sets $\cap$ and the algebraic product are equivalent operations, as are $\cup$ and $\oplus$.)

Convex Combination

By a convex combination of two vectors f and g is usually meant a linear combination of f and g of the form $\lambda f + (1 - \lambda)g$ where $0 \leq \lambda \leq 1$. The mode of combining f and g can be generalized to fuzzy sets in the following manner:

Let A, B and C be arbitrary fuzzy sets. *The convex combination* A, B and C is denoted by $(A, B; C)$ and is defined by the relation

$$(A, B; C) = CA + C'B$$

where C' is the complement of C. In terms of membership functions, this means

$$f_{(A,B;C)}(x) = f_C(x)f_A(x) + [1 - f_C(x)]f_B(x), \quad x \in \mathcal{X}.$$

A basic property of the convex combination of A, B and C is expressed as

$$A \cap B \subset (A, B; C) \subset A \cup B \quad \forall \; C.$$

This is an immediate consequence of

$$\min[f_A(x), f_B(x)] \leq \lambda f_A(x) + (1 - \lambda)f_B(x) \leq \max[f_A(x), f_B(x)], \quad x \in \mathcal{X}$$

which holds for all λ in $[0, 1]$. It is interesting to observe that given any fuzzy set C satisfying $A \cap B \subset C \subset A \cup B$, one can always find a fuzzy set $D \ni C = (A, B; D)$. The membership function of this set D is given by

$$f_D(x) = \frac{f_C(x) - f_B(x)}{f_A(x) - f_B(x)}, \quad x \in \mathcal{X}.$$

Functions

What about functions? Let f be a function from $\mathcal{X}$ into T, and let A be a fuzzy subset of $\mathcal{X}$ with membership function μ_A. Then, the image of A under f is defined in terms of its membership function μ_A by

$$[f(\mu_A)](y) \equiv \begin{cases} \sup\limits_{f(x)=y} \mu_A(x) \; \forall \; y \in T & \text{i.e., } \sup\limits_{x \in \inf f^{-1}(y)} \mu_A(x) \; \forall \; y \in T \\ 0 & \text{if } f^{-1}(y) = \emptyset. \end{cases}$$

Similarly if B is a fuzzy subset of T, then the preimage or inverse image of B under f is defined in terms of its membership function μ_B by

$$[f^{-1}(\mu_B)](x) \equiv \mu_B(f(x)) \quad \forall \; x \in \mathcal{X} \text{ i.e., } f^{-1}(\mu_B) \equiv \mu_B \circ f.$$

Explanation

Let $f : X \to T$. Let B be a fuzzy set in T with membership $\mu_B(y)$. The inverse mapping f^{-1} induces a fuzzy set A in $\mathcal{X}$ whose membership function is defined by

$$\mu_A(x) = \mu_B(y), \quad y \in T$$

for all x in $\mathcal{X}$ which are mapped by f into y.

Consider now the converse problem. Let A be a fuzzy set in $\mathcal{X}$, and as before, let $f : \mathcal{X} \to T$. Question: What is the membership function for the fuzzy set B in T which is induced by this mapping? If f is not $1 : 1$, then an ambiguity arises when two or more distinct points in $\mathcal{X}$, say x_1 and x_2, with different grades of membership in A, are mapped into the same point y in T. In this case, the question is: What grade of membership in B should be assigned to y? To resolve this ambiguity, we agree to assign the larger of the grades of membership to y. More generally, the membership function for B will be defined by

$$\mu_B(y) = \max_{x \in f^{-1}(y)} \mu_A(x), \quad y \in T$$

where $f^{-1}(y) = \{x; x \in X; f(X) = y\}$. Evidently these definitions generalize the standard definitions of the image and the preimage of a subset, and one can verify that these definitions are compatible with fuzzy subset algebra in the usual ways, e.g., one can show that f and f^{-1} have the following properties:

(a) $f^{-1}\left(\bigvee\limits_{i \in I} \mu_{A_i}\right) = \bigvee\limits_{i \in I} f^{-1}(\mu_{A_i})$

(b) $f^{-1}\left(\bigwedge\limits_{i \in I} \mu_{A_i}\right) = \bigwedge\limits_{i \in I} f^{-1}(\mu_{A_i})$

also

(c) $f\left(\underset{i\in I}{\vee}\mu_{A_i}\right) = \underset{i\in I}{\vee} f(\mu_{A_i})$

(d) $f\left(\underset{i\in I}{\wedge}\mu_{A_i}\right) \le \underset{i\in I}{\wedge} f(\mu_{A_i})$

(e) $\overline{f(\mu_A)} \le f(\overline{\mu}_A); \overline{f^{-1}(\mu_B)} = f^{-1}(\overline{\mu}_B).$

$\overline{\quad}$ means complement.

(f) $f(f^{-1}(\mu_B)) \le \mu_B; f^{-1}(f(\mu_A)) \ge \mu_A.$

Proof (a): $f^{-1}\left(\underset{i\in I}{\vee}\mu_A\right) = \left(\underset{i\in I}{\vee}\mu_{A_i}\right)\circ f = \underset{i\in I}{\vee}(\mu_{A_i}\circ f) = \underset{i\in I}{\vee} f^{-1}(\mu_{A_i})$ and so on.

(c)
$$f\left[\underset{i}{\vee}\mu_{A_i}\right](y) = \begin{cases} \underset{f(x)=y}{\sup}\left[\underset{i}{\vee}\mu_{A_i}\right](x) \\ 0 \qquad \text{if } x = f^{-1}(y) = \emptyset \end{cases}$$
$$= \begin{cases} \underset{i}{\vee}\ \underset{x\in f^{-1}(y)}{\sup}\ [\mu_{A_i}(x)] = \underset{i}{\vee} f(\mu_{A_i}) \\ 0 \end{cases}$$

Fuzzy Relations

The concept of a *relation* has a natural extension to fuzzy sets and plays an important role in the theory of such sets and their applications, just as it does in the case of ordinary sets. Ordinarily, a relation is defined as a set of ordered pairs, e.g., the set of all ordered pairs of real numbers x and y such that $x \ge y$. In the context of fuzzy sets, a *fuzzy relation* in $\mathcal{X}$ is a fuzzy set in the product space $\mathcal{X}\times\mathcal{X}$, e.g., the relation denoted by $x \gg y$; $x, y \in \mathbb{R}$ may be regarded as a fuzzy set A in $\mathbb{R}^2$, with the membership function of A, $f_A(x,y)$ having the following (subjective) representative values: $f_A(10,5) = 0; f_A(100,10) = 0.7, f_A(100,1) = 1$, etc.

More generally, one can define an *n–ary fuzzy relation* in $\mathcal{X}$ as a fuzzy set A in the product space $\mathcal{X}\times\mathcal{X}\times\ldots\times\mathcal{X}$. For such relations, the membership function is of the form $f_A(x_1,\ldots,x_n)$ where $x_i \in \mathcal{X}$, $i = 1,\ldots,n$.

In the case of binary fuzzy relations, the composition of two fuzzy relations A and B is denoted by $B\circ A$, and is defined as a fuzzy relation in $\mathcal{X}$ whose membership function is related to those of A and B by

$$f_{B\circ A}(x,y) = \sup_v \min[f_A(x,v), f_B(v,y)]$$
$$= \underset{v}{\vee}[f_A(x,v)\wedge f_B(v,y)]$$

$\forall\ x, y$ and v in $\mathcal{X}$. (Note also that this generalizes the usual definition.) Note that the operation of composition has the associative property: $A\circ(B\circ C) = (A\circ B)\circ C$.

Convexity

A fuzzy set A is *convex* iff the sets Γ_α defined by

$$\Gamma_\alpha = \{x; f_A(x) \ge \alpha\} \tag{3}$$

are convex for all α in the interval $(0,1]$.

An alternative and more direct definition of convexity is the following: A fuzzy set A is *convex* iff

$$f_A[\lambda x_1 + (1-\lambda)x_2] \ge \min[f_A(x_1), f_A(x_2)] \tag{4}$$

for all x_1 and x_2 in $\mathcal{X}$ and all λ in $[0,1]$.

Note that this definition does not imply that the function $f_A(x)$ must be a convex function of x.

It can be seen that the two definitions are equivalent (see Zadeh 1965).

A basic property of convex fuzzy sets is:

Theorem *If A and B are fuzzy convex, then $A\wedge B$ is also fuzzy convex.*

Boundedness

A fuzzy set A is bounded iff the sets $\Gamma_\alpha = \{x; f_A(x) \ge \alpha\}$ are bounded for all $\alpha > 0$; i.e., for all $\alpha > 0$, $\exists$ a finite $R(\alpha) \ni \|x\| \le R(\alpha)$ for all x in Γ_α.

If A is a bounded set, then for all $\varepsilon > 0$, $\exists$ a hyperplane $H \ni f_A(x) \le \varepsilon\ \forall\ x$ on the side of H which does not contain the origin. For example consider the set $\Gamma_\varepsilon = \{x; f_A(x) \ge \varepsilon\}$. By hypothesis this set is contained in a sphere S of radius $R(\varepsilon)$. Let H be any hyperplane supporting S. Then, all points on the side of H which does not contain the origin lie outside or on S, and hence for all such points $f_A(x) \le \varepsilon$.

Preliminary

As a preliminary, let A and B be two bounded fuzzy sets and let H be a hypersurface in $\mathbb{R}^{(n)}$ defined by the equation $h(x) = 0$ with all points for which $h(x) \ge 0$ being on one side of H and all points for which $h(x) \le 0$ being on the other side. Let K_H be a number dependent on $H \ni f_A(x) \le K_H$ on one side of H and $f_B(x) \le K_B$ on the other side. Let $M_H = \inf K_H$. The number $D_H = 1 - M$ is called the *degree of separation* of A and B by H.

In general one is concerned not with a given hypersurface H, but with a family of hypersurfaces $\{H_\lambda\}$, with λ

ranging over $\mathbb{R}^{(m)}$. The problem then is to find a member of this family which realizes the highest degree of separation.

A special case of this problem is one where the H_λ are hyperplanes in $\mathbb{R}^{(n)}$, with λ ranging over $\mathbb{R}^{(n)}$. In this case we define the *degree of separation* of A and B by

$$D = 1 - M \quad \text{where} \quad M = \inf_H M_H.$$

Separation of Convex Fuzzy Sets

The classical separation theorem for ordinary convex sets states, in essence, that if A and B are disjoint convex sets, then there exists a separating hyperplane H such that A is on one side of H and B is on the other side. This theorem can be extended to convex fuzzy sets, without requiring that A and B be disjoint, since the condition of disjointedness is much too restrictive in the case of fuzzy sets. It turns out that the answer is in the affirmative.

Theorem *Let A and B be bounded convex fuzzy sets in $\mathbb{R}^{(n)}$, with maximal grades M_A and M_B respectively i.e., $M_A = \sup_x f_A(x)$, $M_B = \sup_x M_B(x)$. Let M be the maximal grade for the intersection $A \cap B$ (i.e., $M = \sup_x \min[f_A(x), f_B(x)]$). Then $D = 1 - M$. (D is called the degree of separation of A and B by the hyperplane H).*

In other words, the theorem states that the highest degree of separation of two convex fuzzy sets that can be achieved with a hyperplane in $R^{(n)}$ is one minus the maximal grade in the intersection $A \cap B$. Zadeh has applied these types of results in the problems of optimization, pattern discrimination, etc.

Concluding Remarks

The concepts of fuzzy sets and fuzzy functions have been found useful in many applications, notably in pattern recognition, clustering, information retrieval and systems analysis, among other areas (cf. Negoita and Ralescu 1975). Motivated by some of these applications and related problems, Puri and Ralescu (1982, 1983) introduced the integration on fuzzy sets and differentials of fuzzy functions. This led to the study of fuzzy random variables, their expectations, concept of normality for fuzzy random variables and different limit theorems for fuzzy random variables (cf. Puri and Ralescu (1985, 1986, 1991), Klement, Puri and Ralescu (1984, 1986), and Proske and Puri (2002a, b and the references cited in these papers).

About the Author

Professor Puri was ranked the fourth most prolific statistician in the world for his writings in the top statistical journals in a 1997 report by the Natural Sciences and Engineering Research Council of Canada. Among statisticians in universities which do not have separate departments of statistics, Puri was ranked number one in the world by the same report. Puri has received a great many honors for his outstanding contributions to statistics and we mention only a few. Professor Puri twice received the Senior U.S. Scientist Award from Germany's Alexander von Humboldt Foundation, and he was honored by the German government in recognition of past achievements in research and teaching. Madan Puri has been named the recipient of the 2008 Gottfried E. Noether Senior Scholar Award (an annual, international prize honoring the outstanding statisticians across the globe), for "outstanding contributions to the methodology and/or theory and teaching of nonparametric statistics that have had substantial, sustained impact on the subject, its practical applications and its pedagogy." For many years Professor Puri has been highly cited researcher in mathematics according to ISI Web of knowledge ISI HighlyCited. com According to For many years Professor Puri has been highly cited researcher in mathematics according to ISI Web of Knowledge ISI HighlyCited.Com Professor Puri, his greatest honor came in 2003 when under the editorship of Professors Peter Hall, Marc Hallin, and George Roussas, the International Science Publishers published "Selected Collected Works of Madan L. Puri," a series of three volumes, each containing about 800 pages.

G

Gamma Distribution

Kimiko O. Bowman[1], L. R. Shenton[2]
[1]Oak Ridge National Laboratory, Oak Ridge, TN, USA
[2]Professor Emeritus of Statistics
University of Georgia, Athens, GA, USA

Introduction

For the gamma random variable X there is the probability function

$$Pr(X = x; s, a, \rho) = \frac{1}{a\Gamma(\rho)}\left(\frac{x-s}{a}\right)^{\rho-1}\exp\left(\frac{s-x}{a}\right) \quad (s < x < \infty; a, \rho > 0),$$

where a scale, ρ shape, and s location parameter. The gamma distribution is unimodal but may be inverse J-shaped. The moments are

$$\begin{aligned} &\textit{Mean}: \quad \mu_1' = a\rho + s, \quad \textit{variance}: \quad \mu_2 = a^2\rho, \\ &\textit{Skewness}: \quad \sqrt{\beta_1} = \mu_3/\mu_2^{3/2} = 2/\sqrt{\rho}, \\ &\textit{Kurtosis}: \quad \beta_2 = \mu_4/\mu_2^2 = 3 + 6/\rho. \end{aligned}$$

If $a = 1$, and $s = 0$, the distribution becomes the exponential distribution. If $s = 0$, $a = 2$, and $\rho = \nu/2$, the distribution becomes the familiar χ^2_ν distribution with ν degree of freedom.

$$P_{\chi^2_\nu}\chi = \frac{\chi^{\frac{\nu}{2}-1}e^{-\chi/2}}{2^{\nu/2}\Gamma(\nu/2)} \quad \chi \geq 0.$$

Also the gamma distribution is a Type III in the Pearson manifold of distributions.

The Fig. 1 shows distribution functions of $s = 0$, $a = 1$ and $\rho = 1, 2$ and 4.

Estimation

The maximum likelihood estimators $\hat{a}$ and $\hat{\rho}$ for the two parameter gamma distribution ($s = 0$) are the solution to the two equations

$$\begin{aligned} \ln(\hat{\rho}) - \psi(\hat{\rho}) &= \ln(A/G) \quad (\psi(x) = d\ln\Gamma(x)/dx) \\ \hat{\rho}\hat{a} &= A \end{aligned}$$

where $A = \sum X_j/n$, and $G = \sqrt[n]{X_1, X_2, \cdots, X_n}$. For the three parameter case, the equations to be solved are

$$\psi(\hat{\rho}) + \ln(\hat{s}) = n^{-1}\sum_{j=1}^{n}\ln(X_j - \hat{s}),$$

$$n^{-1}\sum_{j=1}^{N}(X_j - \hat{s}) = \hat{a}\hat{\rho},$$

$$n^{-1}\sum_{j=1}^{N}(X_j - \hat{s})^{-1} = (\hat{a}(\hat{\rho} - 1))^{-1}.$$

We must be aware that the moments of maximum likelihood estimators exist if $\rho > 1$ for the mean, $\rho > 2$ for the variance, $\rho > 3$ for skewness and $\rho > 4$ for kurtosis.

The moment estimators in the 2 parameter case are simple in form and are

$$a^*\rho^* = m_1, \quad a^{*2}p^* = m_2,$$

where m_1 is the sample mean, $m_1 = \sum_{j=1}^{n}(X_j)/n = \bar{X}$ and $m_2 = \sum_{j=1}^{n}(X_j - \bar{X})^2/n$ for a random sample $X_1, X_2, \cdots, X_n$. For the three parameter gamma distribution we use $2/\sqrt{\rho^*}$=sample skewness to determine ρ.

Properties of Estimators

Johnson et al. (1994) states "Estimation of parameters of gamma distribution has also received extensive attention in the literature in the last two decades. The contributions of Bowman and Shenton and of A.C. Cohen and his coworkers should be particularly mentioned. Bowman and Shenton (1988) monograph provides detailed analysis of maximum likelihood estimators for two-parameter gamma distribution with emphasis on the shape parameter and presents valuable information on distributions and moments of these estimators, including their joint distributions. Careful discussion of estimation problems associated with the three-parameter gamma density is also presented. ····· The authors also deal with the moments of the moments estimators. The list of references in the monograph covers the development of the authors' work on this area from 1968 onward."

Cohen and Whitten (1988) introduced mixed maximum likelihood approach, including the use of the smallest term of the sample; this approach avoids the difficulty that

12	500	20,000	272	1,239	0	0	0

S gives the number of solutions subscribing to the tolerance. F gives the number of failures. $\bar{S}$ gives the number of cases when no solution was found after 200 iterates.

the usual maximum likelihood method, which moments only exist if $\rho > 1$ for the mean, $\rho > 2$ for the variance. $\rho > 3$ for skewness and $\rho > 4$ for kurtosis. Balakrishanan and Cohen (1991) introduced estimators with an emphasis on modified estimators and censored samples.

For the details of methods to solve the equations see Bowman and Shenton (1988) and Johnson et al. (1994).

Negative Skewness in Gamma Sampling

With various values of ρ, samples of size 50 and 500 were taken and skewness $\sqrt{b_1}$ analyzed. In Table 1 the analysis is given showing the frequency of negative skewness.

We note: (a) No solutions were found when the sample skewness was negative. The failure rate in this case increases with large ρ and small n. (b) For small n, the failure rate (F) is high for both small and large ρ. (c) For large ρ, the abortive rate ($\bar{S}$) is high, and doubtless would become higher with more stringent tolerance.

A modified model has been given by Cheng and Traylor (1995) for which negative skewness is included in as a possibility. The new modified gamma distribution is

$$g(x;\mu,\sigma,\lambda) = \frac{1}{\sigma\lambda\Gamma(\lambda^2)}\left\{\lambda^{-2}\left[1+\frac{\lambda(\lambda-\mu)}{\sigma}\right]\right\}^{\lambda^{-2}-1} \exp\left\{-\frac{1}{\lambda^2}\left[1+\frac{\lambda(x-\mu)}{\sigma}\right]\right\}.$$
$$(\sigma > 0; \lambda \neq 0 \text{ and } 1+\lambda(x-\mu)/\sigma > 0)$$

In our notation

$$\rho = 1/\lambda^2, \quad a = \sigma\,|\,\lambda\,|, \quad s = \mu - \sigma\lambda^{-1}.$$

Moreover $\sqrt{\beta_1} = 2/\sqrt{\rho}$ = skewness.

Multiple Parameter Distributions and Mixtures

Everett and Hand (1981) study mixtures of Poisson distributions, and binomial distributions, giving, possible solutions. Bowman and Shenton refer to Poisson mixtures (2003, 2004, 2006). A global approach to the subject is due to Karlis and Xekalaki (2005) enlarging the concept of the Poissonian. The generalization of ideas could be applied to continuous univariate distributions.

Other works may be mentioned such as Bowman and Shenton (1998), distribution of ratio of gamma variate, Hirose (1995), three parameter gamma distribution, Revfeim (1991), inverse gamma.

Conclusion

The extensive paper of Karlis and Xekalaki (2005) opens up many new concepts for research. Simulation studies using computer facilities provide a powerful tool. In addition there is the remarkable power of symbolic codes such as Maple, Mathematica, etc.

Gaussian Processes

Herbert K. H. Lee
Professor
University of California-Santa Cruz, Santa Cruz, CA, USA

A Gaussian process (GP) specifies a distribution for values over a set (typically R^n) which could be an interval of time or a region of space, but could also be more arbitrary, such as the space of a set of explanatory variables. It is often used for modeling quantities that are spatially or temporally correlated, such as rainfall. In this way it differs from standard statistical models where the data are assumed to be independent given the model; here the data are assumed to be correlated and the correlation structure is part of the model as well. Applications are widespread, including time series, geostatistics (where it first appeared as kriging), and general approximation of functions. GPs have also become popular in machine learning, where they are used for regression and classification tasks.

A Gaussian process is a continuously-defined process such that its values at any finite collection of locations jointly have a multivariate Gaussian distribution (e.g., Cressie 1993). This model is highly flexible and can be used for nonparametric modeling. In practice, two common simplifying assumptions are often made: stationarity and isotropy. The idea of stationarity is that the distribution of the process does not depend on location, i.e., all points have the same mean and marginal variance, and the joint distribution of any finite collection of points is invariant to translation. Sometimes the marginal mean of the field is not constant, so the mean is modeled separately (such as with a linear model or a low-order polynomial) and then the de-trended field is treated as a stationary GP. A stationary field can also be isotropic, in that the covariance between any two points depends only on the distance between them (rather than also depending on the orientation).

Examples of Gaussian Processes include the Wiener process and the Ornstein-Uhlenbeck process (Cox and Miller 1965). A Wiener process is a mean-zero process such

that all increments of the process (the difference in values at two points) are independent and normally distributed with mean zero and variance proportional to the length of the increment. A generalization allows for a drift term μ. This process can be represented via a stochastic differential equation:

$$dW(t) = \mu dt + \sigma Z(t)\sqrt{dt},$$

where $W(t)$ is the value of the process at time $t \in R$, σ^2 is a variance term, and $Z(t)$ are independent standard normals. An Ornstein-Uhlenbeck process is related, but it is a mean-reverting process, so the distribution of its increments depends on the current value of the process:

$$dX(t) = -\beta X(t)dt + \sigma Z(t)\sqrt{dt} = -\beta X(t)dt + dW(t),$$

where $W(t)$ is a Wiener process and β controls the rate of mean reversion. An Ornstein-Uhlenbeck process is stationary, while a Wiener process is not.

If we observe a Gaussian process $X(s)$ at a set of locations $s_1, \ldots, s_n \in \mathcal{S}$, we can write its distribution in terms of its mean function $\mu(s)$ and its covariance function $C(s_i, s_j)$ as:

$$X \sim MVN(\boldsymbol{\mu}, \boldsymbol{\Sigma}),$$

where $X = (X(s_1), \ldots, X(s_n))$, $\boldsymbol{\mu} = (\mu(s_1), \ldots, \mu(s_n))$ and $\boldsymbol{\Sigma}$ is the variance-covariance matrix with elements $C(s_i, s_j)$. Under the typical assumptions of stationarity and isotropy, $\mu(s_i) = \mu$ for all i, and the elements of the covariance matrix simplify to:

$$C(s_i, s_j) = \theta_1 \rho(d/\theta_2),$$

where θ_1 is the marginal variance, d is the distance between s_i and s_j, $\rho(\cdot)$ is a correlation function, and θ_2 specifies the range of spatial dependence. The correlation function must be nonnegative definite. Common parameterizations of the correlation for spatial and functional applications include:

spherical correlogram	$\rho(d) = \left(1 - \frac{3}{2}d + \frac{1}{2}d^3\right) I_{\{0 \le d \le 1\}}(d)$
exponential correlogram	$\rho(d) = e^{-d}$
Gaussian correlogram	$\rho(d) = e^{-d^2}$
Matérn class	$\rho(d) = \left[(d/2)^{\nu} 2K_{\nu}(d)\right]/\Gamma(\nu)$

where $I_{\{0 \le d \le 1\}}(d)$ is the indicator function which is one when $0 \le d \le 1$ and zero otherwise, K_ν is a modified Bessel function of the second kind and ν is a smoothness parameter. The relationship between the smoothness of the realizations and the behavior of the correlation function near zero is given in (Stein 1999), along with further discussion of theoretical and practical properties of different choices of correlation functions. In the Bayesian paradigm, conjugate priors exist for the simpler GP models (Hjort and Omre 1994), and ▶Markov chain Monte Carlo can be used for the general case.

With the above formulation, the process interpolates the data. It is straightforward to include an additive random noise term in the model. An equivalent formulation arose in geostatistics, by thinking of including additional variability from a separate small-scale process, with the resulting term referred to as the nugget (Cressie 1993).

In practice, a convenient way of obtaining a Gaussian process is by convolving a white noise process with a smoothing kernel (Barry and Ver Hoef 1996; Higdon 2002). For locations $s \in \mathcal{S}$, let W be a Wiener process, and let $k(\cdot; \phi)$ be a kernel, possibly depending on a low dimensional parameter ϕ. Then we can obtain a Gaussian process by:

$$X(s) = \int_S k(u - s; \phi) dW(u). \quad (1)$$

The resulting covariance function depends only on the displacement vector $d_{s,s'} = s - s'$, for $s, s' \in S$, i.e.,

$$\begin{aligned} \mathrm{cov}(X(s), X(s')) &= \int_S k(u - s; \phi) k(u - s'; \phi) du \\ &= \int_S k(u - d_{s,s'}; \phi) k(u; \phi) du. \end{aligned}$$

Under suitable regularity conditions, there is a one to one relationship between the smoothing kernel k and the covariance function, based on the convolution theorem for Fourier transforms. A discrete approximation of Eq. 1 can be obtained by fixing a finite number of well-spaced background points, $s_1, \ldots, s_M$:

$$X(s) \approx \sum_{i=1}^{M} k(s_i - s; \phi) w(s_i),$$

where $w(s)$ is a white noise process.

The GP model can be extended to settings with a spatially-correlated multivariate response by employing methods such as cokriging (Wackernagel 1998). There are a variety of extensions for dealing with nonstationarity via approaches such as deformations (Sampson and Guttorp 1992), evolving convolutions (Higdon et al. 1999), or partitioning (Gramacy 2008).

About the Author

Professor Lee is a Fellow of the American Statistical Association and is currently Editor-in-Chief of the journal *Bayesian Analysis* and an Editor for *Chance*. He has previously been an Associate Editor for the *Journal of the*

American Statistical Association (2003–2009) and *Statistics and Computing* (2007–2009). He is the author of the book *Bayesian Nonparametrics via Neural Networks* (SIAM, 2004), and co-author of *Multiscale Modeling: A Bayesian Perspective* (with Marco A.R. Ferreira, Springer, 2007).

Gauss-Markov Theorem

Regents' Professor of Economics Emeritus
University of Minnesota, Minneapolis, MN, USA

The so-called Gauss-Markov theorem states that under certain conditions, ►least-squares estimators are "best linear unbiased estimators" ("BLUE"), "best" meaning having minimum variance in the class of unbiased linear estimators.

The linear regression model (see ►Linear Regression Models) $y_t = \sum_{j=1}^{k} x_{tj}\beta_j + \varepsilon_t$ $(t = 1, 2, \ldots, n)$ may be written as

$$y = X\beta + \varepsilon, \quad E\{\varepsilon\} = 0, \quad E\{\varepsilon\varepsilon'\} = \sigma^2 V \qquad (1)$$

(the prime denoting transposition), where y is an $n \times 1$ vector of observations on a variable of interest, X is an $n \times k$ matrix (generally assumed to have rank k) of n observations on $k < n$ explanatory variables x_{ij} $(i = 1, 2, \ldots, n;$ $j = 1, 2, \ldots, k)$, and ε is a vector of random errors; β is an unknown $k \times 1$ vector and $\sigma^2 > 0$ an unknown scalar; V (assumed known) is generally assumed to be positive-definite. (These rank assumptions will be relaxed below.) In the simplest case of independent observations, one takes $V = I$ (the identity matrix of order n). (Gauss [1823, §§16, 18, 35, 38] took V to be a diagonal matrix of weights, followed by Markov [1924, p. 325; 1912, p. 203]. Aitken [1935] generalized V to be a positive-definite matrix.) It is desired to obtain an estimator of β.

A (generalized) *least-squares* (GLS) estimate b of β is one that minimizes the (weighted) sum of squares $e'V^{-1}e = (y - Xb)'V^{-1}(y - Xb)$ of the residuals $e = y - Xb$. It is not hard to prove that this minimization is accomplished if and only if b is a solution of $X'V^{-1}Xb = X'V^{-1}y$ (the generalized "normal equations"). Such a solution always exists. (It is unique if and only if X has rank k.) This becomes an *ordinary least-squares* (OLS) estimate if $V = I$, and then the above become the ordinary normal equations.

A *Gauss-Markov (GM) estimator* of β in the model (1) is an affine estimator $\hat{\beta} = Ay + c$ which, among all affine estimators satisfying the condition of *unbiasedness*, namely

$$E\{\hat{\beta}\} = AX\beta + c = \beta \text{ for all } \beta, \quad \text{i.e., } AX = I \text{ and } c = 0, \quad (2)$$

has its variance $E\{A\varepsilon\varepsilon'A'\} = \sigma^2 AVA'$ minimized. Now, from the matrix Cauchy-Schwarz inequality (where $M \geq 0$ means that $x'Mx \geqq 0$ for all x) it follows that

$$AVA' \geq AX(X'V^{-1}X)^{-1}X'A', \quad \text{with equality} \iff$$
$$A = AX(X'V^{-1}X)^{-1}X'V^{-1}. \qquad (3)$$

Together with (3) this implies that the minimizing A is precisely $(X'V^{-1}X)^{-1}X'V^{-1}$, which provides the formula for the GM or GLS estimator $\hat{\beta} = (X'V^{-1}X)^{-1}X'V^{-1}y = b$.

In the model (1), an unbiased affine estimator of β exists if and only if $\text{rank}(X) = k$. To generalize the above results to the case $\text{rank}(X) < k$, one may employ either a set of imposed linear restrictions on β (see Pringle and Rayner 1971, pp. 90–98), or else a concept due to Bose (1944) of a (linearly) *estimable functional* $\psi = (\psi_1, \psi_2, \ldots, \psi_k)$, defined by the condition that there exists a vector $a = (a_1, a_2, \ldots, a_n)$ such that $E\{ay\} = \psi\beta$ identically in β. Clearly this implies $\psi = aX$, i.e., that the set of linearly

estimable functionals coincides with the row space of X. This leads to the following result: *An affine estimator $\hat{\beta} = Ay + c$ furnishes an unbiased estimator of any estimable function $\psi\beta$ in the regression model (1) if and only if X satisfies the two restrictions $XAX = X$ and $Xc = 0$.* This generalizes condition (3). Likewise, the second condition of (3) generalizes to $XAV = (XAV)'$.

It may be noted that in the special case $V = I$ the latter two conditions are conditions (1) and (3) of Penrose (cf. Pringle and Rayner 1971, pp. 1–2) defining a unique "generalized inverse" $A = X^{\dagger}$ of X, the other two being $AXA = A$ and $AX = (AX)'$. A matrix A satisfying just $XAX = X$ is sometimes called a weak generalized inverse or "g-inverse" of X, denoted $A = X^{-}$. Rao (1971) proposed the development of a "unified theory of linear estimation" generalizing the Gauss-Markov theory to take care of deficient rank of either X or V, or both. Goldman and Zelen (1964, Theorem 4) had already proposed the use of $(X'V^{\dagger}X)^{\dagger}X'V^{\dagger}y$, and Mitra and Rao (1968, p. 286) had proved that a sufficient condition for the formula $(X'V^{-}X)^{-}X'V^{-}y$ to be valid is that the column space of X be contained in that of V, i.e., $\mathcal{C}(X) \subseteq \mathcal{C}(V)$. Independently, the same formula for the GM estimator was introduced by Zyskind and Martin (1969, Theorem 1). (As explained by Zyskind [1967, p. 1092], Zyskind and Martin [1969, pp. 1190–1191], and Pringle and Rayner [1971, pp. 93–98], singular variance matrices arise naturally in the ▶analysis of variance; they also arise in econometrics, where Basmann's (1957) "generalized classical linear (GCL) estimator" has the form $(Z'VZ)^{-1}Z'Vy$ where Z is $n \times v$ of rank v and $V = V^{-}$ is an idempotent matrix of rank r, requiring $r \geqq v$ for "identifiability"). Rao and Mitra (1971, p. 299) later obtained a complete characterization

$$\hat{\beta} = [X'(V + cXX')^{-}X]^{-}X'(V + cXX')^{-}y,\ c > 0, \text{ or } c = 0 \text{ provided } \mathcal{C}(X) \subseteq \mathcal{C}(V). \tag{4}$$

The result (4) thus provides the desired generalization of the GM theorem to the case of singular V. Important additional results were supplied by Mitra (1973) and Rao (1979).

It was pointed out by Rao (1972, p. 370; 1973, pp. 276–277) that the condition $\psi = aX$ is no longer necessary for estimability if V is singular, since there will be linear functions of y "which are zero with probability 1 that can be added to any estimator without altering its value but violating [the above] condition." Assuming V to be of rank $r \leqq n$ he obtained the needed general condition that there exist an $n \times (n-r)$ matrix N such that $N'y = 0$ (with probability 1) and a $1 \times (n-r)$ vector ρ, such that $\psi = (a - \rho N')X$.

Anderson (1948) showed that if both X and V are of full rank, and $P = [P_1, P_2]$ is an $n \times n$ orthogonal matrix diagonalizing V to $P'VP = \Lambda$, where P_1 is $n \times k$, and if $X = P_1K$ for some K, then $(X'V^{-1}X)^{-1}X'V^{-1}y = (X'X)^{-1}X'y$. This is the basic result underlying the ▶Durbin-Watson test. [Intuitively, the condition $X = P_1K$ states that in time-series analysis, the columns of X (for suitable choice of V, and of P_1 including a constant column) are low-frequency sinusoidal functions of time.] Magness and McGuire (1962) independently showed that the condition $X = P_1K$ is both necessary and sufficient for the GM estimator to be OLS. These results were generalized by Zyskind (1967) to the case in which $\text{rank}(X) \leqq k$ and $\text{rank}(V) \leqq n$. Zyskind also proved the necessity and sufficiency of the simpler condition that there exist a matrix W such that $VX = XW$, i.e., that $\mathcal{C}(VX) \subseteq \mathcal{C}(X)$ (see also Kruskal 1968). When X and V have full rank, the condition implies that $\mathcal{C}(VX) = \mathcal{C}(X)$. For important generalizations see Watson (1967, 1972) and Mitra and Moore (1973).

An interesting special case of Zyskind's result was established independently by McElroy (1967). If X has a column of ones (for the constant term), then the set of positive-definite Vs satisfying Zyskind's condition $VX = XW$ for some W is given by $V = \lambda[v_{ij}]$, where $v_{ii} = 1$ and $v_{ij} = \rho$ for $i \neq j$ and $-1/(n-1) < \rho < 1$.

Historical Notes

The terminology "Gauss-Markov theorem" appears to derive from Lehmann (1951). The theorem had previously been referred to by Neyman (1934, pp. 593–597) and David and Neyman (1938) as the "Markoff theorem on least squares," based on Chap. VII of Markov (1924). R. A. Fisher pointed out (Neyman 1934, p. 616) that "this was in essence the system of Gauss." Later, Neyman (1938, p. 130), who referred to Gauss (1887), said that the principle "was developed by Gauss, but not in a very clear way. It was developed and put into practical form by …Markoff …." Considerably later, Plackett (1949, p. 459) concluded that "it is implicit that [Gauss] is seeking unbiased estimates." Seal (1967, pp. 5–6) went further and stated this categorically, but without specific reference to Gauss. However, Sprott (1978, pp. 193–194) has claimed that the concept of unbiasedness of a linear estimator is not to be found in Gauss; rather, that Gauss (1823, §19) based himself on a concept of "error consistency," namely that $\lim_{\varepsilon \to 0} \hat{\beta} = \beta$. In his words (but in the present notation) Gauss said: (1855, p. 28): "if $k < n$, each unknown $\beta_1, \beta_2, \ldots$ can be expressed as a function of $y_1, y_2, \ldots$ in an infinity of ways, and these values will in general be different; they would coincide if, contrary to our hypothesis, the observations were perfectly exact." In the case of the affine estimator $\hat{\beta} = Ay + c = A(X\beta + \varepsilon) + c$,

if this equation is to hold "exactly" (without error, i.e., for $\varepsilon = 0$) this leads directly to the two conditions on the right in (3). Clearly these conditions are equivalent to those for unbiasedness on the left, as also shown by Sprott (p. 198). It is perhaps only in this sense that the latter condition can be said to be "implicit" in Gauss.

Gauss (1823, §20) went on to show (in the case of unit weights $V = I$), as Plackett (1949, p. 459) points out, that the diagonal elements of AA' (the variances of the $\hat{\beta}_i$ divided by σ^2) are minimized when $X'XA = X'$; this result is of course a special case of the matrix Cauchy-Schwarz inequality (3). Gauss (1823, §§37–38) chose $s^2 = \sum_{i=1}^{n} e_i^2/(n-k)$ as an estimator of σ^2 (for $V = I$), showing that he was well aware of the concept of unbiasedness, yet chose not to use it for the estimation of β.

Already in 1809 Gauss had considered maximum-likelihood estimation of β for the special case in which X is a column of ones, hence the least-squares estimator of β (now a scalar) is the sample mean. He concluded (Gauss 1809, §177; 1857, pp. 257–259; 1855, §3, pp. 117–179; 1887, pp. 100–102) that in order for this estimator to maximize the likelihood, the density function of ε_t would have to be of the form $f(\varepsilon_t) = \left(h/\sqrt{\pi}\right) e^{-h^2\varepsilon_t^2}$, where h is the "precision" (today denoted $1/\sigma\sqrt{2}$), i.e., would have to be normal ("Gaussian"); see also Stigler (1986, p. 141), Stewart (Gauss 1995, pp. 215, 220). However, he later expressed a strong preference for his 1823 distribution-free criterion. See Gauss (1995, p. 183), Eisenhart (1978, p. 382), Sheynin (1979, p. 46), Stigler (1986, pp. 140–143), Stewart (Gauss 1995, pp. 214–217), and an 1839 letter of Gauss to Bessel quoted by Markov (1951, p. 247) (Edgeworth's translation of which is reproduced in Plackett 1972, p. 247), describing his earlier ground as a "metaphysic."

We may also discuss Gauss's role in the development of the method of least squares itself. The first published treatment of this method was that of Legendre (1805, Appendix). In his letters, Gauss claimed to have developed and used the method of least squares before Legendre. The validity of this claim, questioned by Stigler (1986, pp. 145–146), has received support from Stewart (Gauss 1995, pp. 210–211) and Sheynin (1999). Plackett (1972, pp. 241–242) reports that Gauss had completed his *Theory of Motion*– his first work on least squares – in 1806, but "had difficulty in finding a publisher" unless he translated it into Latin. Stewart (Gauss 1995, p. 211n) explains that "owing to the conquest of the German states by Napoleon, Gauss's publisher required him to translate his manuscript, which was started in 1805 and finished in 1806, from the original into Latin" (see also Eisenhart 1978, p. 380). Thus Gauss's contribution of the method of least squares itself did not appear until 1809.

Markov opened his Chapter VII on least squares (1924, p. 323n; 1912, p. 201n) by stating that his view concerning the various attempts to justify the method had been set forth in an earlier work (Markov 1899; 1951, p. 246; Sheynin 2004; see also Sheynin 2006). There he had based his approach to estimation – "without assuming any definite law of probability for the errors" – on three propositions: 1. "we consider only such approximate equalities which …do not contain any constant error" – which may be interpreted as following Gauss's error-consistency principle; 2. "to each approximate equality we assign a certain weight" which is "inversely proportional to the expectations of the squares of the errors," i.e., their variance; and 3. "we determine such an equality whose weight is maximal." Then: "To my mind, only this justification of the method of least squares is rational; it was indicated by Gauss. I consider it rational mainly because it does not obscure the conjectural nature of the method. Keeping to this substantiation, we do not ascribe the ability of providing the most probable, or the most plausible results to the method of least squares and only consider it as a general procedure furnishing approximate values of the unknowns along with a hypothetical estimation of the results obtained." This diffident acceptance of the method contrasts with the enthusiastic advocacy of it by his follower Neyman.

Markov's contribution must of course be judged by what he actually did, not on what he set out to do. First he defines what he means by a "constant error" (1924, p. 324; 1912, p. 202). If a scalar parameter a is unknown, if x is a "possible outcome" of an observation on it, and if "approximate values" x_t of it are observed, with probabilities q_t, then the $a - x_t$ are called the errors of observation, and the *constant error* is defined as $E(a-x) = \sum_{t=1}^{n} q_i(a-x_i) = a - \sum_{t=1}^{n} q_t x_t$ $[= a - E(x)]$. Thus, "absence of constant error" (a frequent phrase of Markov's) is actually equivalent to unbiasedness. (Neyman [1938, p. 131] stated: "Markoff was not a statistician, he was a mathematician. What I shall say will be exactly equivalent to what he says but it will have a form more familiar to statisticians." Thus, Markov's [and Gauss's] error-consistency was translated by Neyman into unbiasedness.) Markov then introduces "actual observations" $a', a'', \ldots$ of a, generated by random variables $u', u'', \ldots$, and further introduces the symbol $\doteq$ (similar to the contemporary $\approx$, and not to be confused with the inequality sign $\neq$) such that $a \doteq a'$ means that the symbol on the right represents an observation which approximates the unknown quantity represented by the symbol on the left. It is evident from Markov's analysis that if u' is a random variable generating the observation a', then $a \doteq u'$ implies that $E(u') = a$ (cf. Markov 1924, p. 328; 1912, pp. 205–206).

Markov proceeds (1924, §§43–44, pp. 323–344; 1912, §37–38, pp. 201–218) to take up (in our notation) the special case of a single unknown parameter β, hence $k = 1$ in (1). From his subsequent analysis it becomes apparent that he implicitly assumes that $x_t = 1$ for $t = 1, 2. \ldots, n$, hence his model is that of a weighted sample mean, i.e., $y_t = \beta + \varepsilon_t$ where V in (1) is a diagonal matrix with diagonal elements v_{tt}. His "approximate equality" for the estimator $\hat{\beta}$ (a concept he does not use) is given by $\beta \approx \sum_{t=1}^{n} a_t y_t$; in his notation,

$$a \mp \lambda' a' + \lambda'' a'' + \ldots + \lambda^{(n)} a^{(n)} \tag{5}$$

(Markov 1924, p. 328; 1912, p. 205), where his λ's correspond to our a's and his a's to our y's, but his a to our β. At this point Markov specifically invokes unbiasedness when he states (1924, p. 328; 1912, p. 206) that since (5) must be "free of constant error" – which implies that the random variables $u', u'', \ldots$ corresponding to the observations $a', a'', \ldots$ all have expectation a, which he writes as $a \mp a', a \mp a'', \ldots$ (Markov 1924, p. 327; 1812, p. 205) – "the mathematical expectation of [the expression on the right in (5)] is equal to $(\lambda' + \lambda'' + \ldots + \lambda^{(n)})a$ for arbitrary choice of [the λ's]," hence (1924, p. 328; 1912, p. 206) the sum of the λ's must be equal to 1. In the notation of (3), the condition $AX = I$ now becomes $aX = 1$, or $\sum_{t=1}^{n} a_t = 1$. This covers proposition 1 above.

Now we consider propositions 2 and 3. Referring to the line below (3) above, it is desired to minimize the variance $E\{a\varepsilon\varepsilon' a'\} = \sigma^2 aVa' = \sigma^2 \sum_{t=1}^{n} a_t^2 v_{tt}$. Markov (1924, p. 330; 1912, p. 207) denotes this by $k \sum_{t=1}^{n} \lambda^{(t)} \lambda^{(t)} / p^{(t)} = k/P$, where $k = \sigma^2$ and $P = 1/\sum_{t=1}^{n} a_t^2 v_{tt}$ is the "weight" to be maximized, subject to the unbiasedness condition $\sum_{t=1}^{n} a_t = 1$ (1924, p. 331; 1912, p. 208). He shows there that this maximum is attained when $a_i/a_j = v_{ii}/v_{jj}$. Thus, the desired estimator is $\hat{\beta} = \sum_{t=1}^{n} (y_t/v_{tt}) \big/ \sum_{t=1}^{n} (1/v_{tt})$ (formula (21)) [his notation replacing "$\hat{\beta} =$" by "$\beta \mp$"], and the weight reduces to $P = \sum_{t=1}^{n} 1/v_{tt}$ (formula (22)).

Markov also treats the general case (1924, §§46–47; 1912, §§39–40). The unbiasedness conditions $E\left(\sum_{t=1}^{n} a_{it} y_t\right) = \beta_i$ are displayed explicitly (1924, p. 376; 1912, p. 220), from which he derives the above result (2) in his formula $(*)$ (1924, pp. 376–377; 1912, p. 221). To treat minimum variance, he departs from Gauss's method and employs k Lagrangean multipliers μ_j, using the transformation $X^* = V^{-1/2} X$ to handle the variances of the y_ts (1924, p. 380; 1912, p. 223 (formula [A]), so as to reach his result $(* * *)$.

As we have seen above, while Gauss formulated the least-squares problem in terms of diagonal V (and he presumably used weighted least squares in his astronomical calculations) his theorems were limited to the case $V = I$ of independent observations. Plackett (1949, p. 460) famously stated that "Markoff, who refers to Gauss's work, may perhaps have clarified assumptions implicit there but proved nothing new" – an opinion that has been accepted as authoritative. However, it is clear that Markov extended Gauss's theorems to diagonal V (dependent observations). And while not abandoning Gauss's error consistency, he introduced unbiasedness explicitly when needed to obtain condition (3). And Neyman played a major role in formulating best unbiasedness as a principle of estimation.

About the Author

Professor Chipman, "*the eminence grise of Econometrics*," was born on June 28, 1926, in Montreal, Canada. He was Associate Editor of *Econometrica*; (1956–1969), Co-editor of *Journal of International Economics* (1971–1976) and Editor (1977–1987); and Associate Editor of *Canadian Journal of Statistics* (1980–1983). Among his many awards and professional honors, Professor Chipman was elected a Fellow, American Statistical Association (1974), American Academy of Arts and Sciences (1979), Member, National Academy of Sciences (1993) and Chair of Section 54 (Economic Sciences), (1997–2000), Member, International Statistical Institute (1994), and Distinguished Fellow, American Economic Association (1999). He has received three honorary doctorates. Professor Chipman received the Humboldt Research Award for Senior U.S. Scientists in 1992–1995 and 2003. He has supervised 32 Ph.D. students. The importance of his work and achievements, was also recognized in 1999, in the volume: *Trade, Theory and Econometrics: Essays in Honor of John S. Chipman* (Eds. J.R. Melvin, J.C. Moore, and R. Riezman, Routledge), with contributions of many distinguished economists, including Paul A. Samuelson ((May 15, 1915 – December 13, 2009) the first American to win the Nobel Prize in Economics). His recent publications include following books: *The Theory of International Trade* (Edward Elgar Pub, two volumes, 2008–2009) and *Introduction To Advanced Econometric Theory* (Routledge 2011).

General Linear Models

Yuehua Wu
Professor
York University, Toronto, ON, Canada

Let y be a random variable such that $E(y) = \mu$, or $y = \mu + \epsilon$, where ϵ is a random error with $E(\epsilon) = 0$. Suppose that $\mu = x_1\beta_1 + \cdots + x_p\beta_p$, where $x_1, \ldots, x_p$ are p variables and $\beta_1, \ldots, \beta_p$ are p unknown parameters. The model

$$y = x_1\beta_1 + \cdots + x_p\beta_p + \epsilon, \tag{1}$$

is the well-known multiple linear regression model (see ►Linear Regression Models). Here y is called dependent (or response) variable, $x_1, \ldots, x_p$ are called independent (or explanatory) variables or regressors, and $\beta_1, \ldots, \beta_p$ are called regression coefficients. Letting

$$(y_1, x_{11}, \ldots, x_{1p}), \ldots, (y_n, x_{n1}, \ldots, x_{np})$$

be a sequence of the observations of Y and $x_1, \ldots, x_p$, we have

$$y_i = x_{i1}\beta_1 + \cdots + x_{ip}\beta_p + \epsilon_i, \quad i = 1, \ldots, n, \tag{2}$$

where $\epsilon_1, \ldots, \epsilon_n$ are the corresponding random errors. Denote $\boldsymbol{y}_n = (y_1, \ldots, y_n)^T$, $X_n = (\boldsymbol{x}_1, \ldots, \boldsymbol{x}_p)$ with $\boldsymbol{x}_j = (x_{1j}, \ldots, x_{nj})^T$ for $j = 1, \ldots, p$, $\boldsymbol{\beta} = (\beta_1, \ldots, \beta_p)^T$, and $\boldsymbol{\epsilon}_n = (\epsilon_1, \ldots, \epsilon_n)^T$, where $\boldsymbol{a}^T$ denotes the transpose of a vector $\boldsymbol{a}$. (2) can therefore be expressed as

$$\boldsymbol{y}_n = X_n\boldsymbol{\beta} + \boldsymbol{\epsilon}_n. \tag{3}$$

For convenience, X_n is assumed to be nonrandom with rank p through this article (see Rao (1973) for the case that the rank of X_n is less than p). It is noted that if $x_1, \ldots, x_p$ in (1) are random variables, it is usually assumed that $E(y|x_1, \ldots, x_p) = x_1\beta_1 + \cdots + x_p\beta_p$, which replaces the $E(y)$ given above.

A well known method for estimating $\boldsymbol{\beta}$ in (3) is *Least Squares*. Its theoretical foundation was laid by Gauss (1809) and Markov (1900) among others. Assuming that $\epsilon_1, \ldots, \epsilon_n$ are uncorrelated with zero means and constant variance σ^2, the least squares estimator $\hat{\boldsymbol{\beta}}_n$ of $\boldsymbol{\beta}$ can be obtained by minimizing $(\boldsymbol{y}_n - X_n\boldsymbol{b})^T(\boldsymbol{y}_n - X_n\boldsymbol{b})$ among all possible $\boldsymbol{b} \in R^p$. It can be shown that $\hat{\boldsymbol{\beta}}_n = \left(X_n^T X_n\right)^{-1} X_n^T \boldsymbol{y}_n$. It is easy to verify that $E(\hat{\boldsymbol{\beta}}_n) = \boldsymbol{\beta}$ so that $\hat{\boldsymbol{\beta}}_n$ is an unbiased estimator of $\boldsymbol{\beta}$. Define the residual as $\boldsymbol{r}_n = \boldsymbol{y}_n - \hat{\boldsymbol{y}}_n$ with $\hat{\boldsymbol{y}}_n = X_n\hat{\boldsymbol{\beta}}_n$, the fitted (or predicted) vector. Since $E\left(\boldsymbol{r}_n^T\boldsymbol{r}_n\right) = (n-p)\sigma^2$, an unbiased estimator of σ^2 is given by $\hat{\sigma}_n^2 = \boldsymbol{r}_n^T\boldsymbol{r}_n/(n-p)$. As shown in Rao (1973) or Seber and Lee (2003), $\boldsymbol{c}^T\hat{\boldsymbol{\beta}}_n$ is the best linear unbiased estimate of $\boldsymbol{c}^T\boldsymbol{\beta}$ for any constant vector $\boldsymbol{c}$. If in addition $\epsilon_1, \ldots, \epsilon_n$ are independent with common third and fourth moments, $\hat{\sigma}_n^2$ can be shown to be the unique nonnegative quadratic unbiased estimator of σ^2 with minimum variance (Seber and Lee (2003)). If we further assume that $\epsilon_1, \ldots, \epsilon_n$ are independently and identically $N(0, \sigma^2)$ distributed, it can be shown that $\hat{\boldsymbol{\beta}}_n$ is actually the maximum likelihood estimator of $\boldsymbol{\beta}$. It can also be proved that $\hat{\boldsymbol{\beta}}_n$ is distributed as $N\left(\boldsymbol{\beta}, \sigma^2\left(X_n^T X_n\right)^{-1}\right)$, $(n-p)\hat{\sigma}_n^2$ is distributed as $\sigma^2\chi^2_{n-p}$, and, in additions, $\hat{\boldsymbol{\beta}}_n$ is independent of $\hat{\sigma}_n^2$. However the maximum likelihood estimator of σ^2 is $(n-p)\hat{\sigma}^2/n$ instead of $\hat{\sigma}^2$, which is biased for estimating σ^2 but is asymptotically equal to $\hat{\sigma}^2$ as $n \to \infty$ for a fixed p. It is noted that if $X_n^T X_n$ is nearly singular, a ridge estimator may be used to estimate $\boldsymbol{\beta}$. Although ridge estimators are biased but a properly chosen one will have a smaller mean squared error than the least squares estimator in such a case.

We now consider how to test the hypothesis $H_0 : \Gamma\boldsymbol{\beta} = \boldsymbol{c}$ with a known $q \times p$ matrix Γ of rank q and a known $q \times 1$ vector $\boldsymbol{c}$ for the model (3). Assume that $\epsilon_1, \ldots, \epsilon_n$ are independently and identically $N(0, \sigma^2)$ distributed. To test H_0, an F-test can be employed with the test statistic

$$F = \left((\Gamma\hat{\boldsymbol{\beta}}_n - \boldsymbol{c})^T\left[\Gamma\left(X_n^T X_n\right)^{-1}\Gamma^T\right]^{-1}(\Gamma\hat{\boldsymbol{\beta}}_n - \boldsymbol{c})/q\right)/\hat{\sigma}_n^2,$$

which is actually equivalent to the likelihood ratio test statistic (see, e.g., Seber and Lee (2003) and Rao et al. (2008)). It can be shown that $F \sim F_{q,n-p}$ under H_0, where $F_{q,n-p}$ denotes the central F distribution with degrees of freedom q and $n-p$, respectively. For a level of significance α, H_0 is rejected if $F > F_{q,n-p;1-\alpha}$. Here $F_{q,n-p;1-\alpha}$ denotes

the $(1-\alpha)$-quantile of $F_{q,n-p}$. For discussion on more general testing of hypotheses, see Seber and Lee (2003) and Rao et al. (2008) among others, which also explore how to construct confidence regions for parameters. In addition, a number of practical examples can be found in Draper and Smith (1998).

So far it has been assumed that the random errors have constant variance σ^2. We now assume that $E(\boldsymbol{\epsilon}_n) = 0$, $cov(\boldsymbol{\epsilon}_n) = \sigma^2 V$ and V is a known $n \times n$ positive definite matrix. To estimate $\boldsymbol{\beta}$ in (3), the generalized least squares method is used instead and the resulting estimator is $\tilde{\boldsymbol{\beta}}_n = \left(X_n^T V^{-1} X_n\right)^{-1} X_n^T V^{-1} \boldsymbol{y}_n$, which is the same as the least squares estimator of $\boldsymbol{\beta}$ for the model $\tilde{\boldsymbol{y}}_n = \tilde{X}_n \boldsymbol{\beta} + \tilde{\boldsymbol{\epsilon}}_n$ with $\tilde{\boldsymbol{y}}_n = V^{-1/2} \boldsymbol{y}_n$, $\tilde{X}_n = V^{-1/2} X_n$ and $\tilde{\boldsymbol{\epsilon}}_n = V^{-1/2} \boldsymbol{\epsilon}_n$. In this case, it can be shown that an unbiased estimator of σ^2 is given by $\tilde{\sigma}_n^2 = (\boldsymbol{y}_n - X_n \tilde{\boldsymbol{\beta}}_n)^T V^{-1} (\boldsymbol{y}_n - X_n \tilde{\boldsymbol{\beta}}_n)/(n-p)$. If we further assume that $\boldsymbol{\epsilon}_n \sim N(0, \sigma^2 V)$, it can be verified that $\tilde{\boldsymbol{\beta}}_n$ and $(n-p)\tilde{\sigma}_n^2/n$ are the maximum likelihood estimators of $\boldsymbol{\beta}$ and σ^2, respectively. The hypothesis testing and interval estimation of parameters can be carried out similar to those previous described.

The model (3) can be generalized to

$$Y_n G_n = X_n B H_n + Z_n \Theta Q_n + E_n, \tag{4}$$

where Y_n is an $n \times m$ random matrix, G_n is an $m \times k$ matrix, X_n, H_n, Z_n and Q_n are respectively $n \times p$, $q \times k$, $n \times u$ and $v \times k$ matrices, B is a $p \times q$ matrix of unknown parameters, Θ is a $u \times v$ random matrix, and E_n is an $n \times k$ matrix of random errors with zero means. This model is linear in parameters and is fairly general. The following models are its special cases: multiple ▶linear regression models, linear random effects models, ▶linear mixed models, analysis of variance (ANOVA) models (see ▶Analysis of Variance), multivariate analysis of variance (MANOVA) models (see ▶Multivariate Analysis of Variance (MANOVA)), ▶analysis of covariance (ANCOVA) models, multivariate analysis of covariance (MANCOVA) models, response surface regression models and growth curve models. Thus this model is named as a general linear model. It is noted that the model (4) may be extended to allow for change points to occur. Such an example can be found in Seber and Lee (2003) among others.

For simplicity, we limit our attention to the case that G_n^{-1} exists. Then (4) can be written as

$$\begin{aligned} Y_n &= X_n B H_n G_n^{-1} + Z_n \Theta Q_n G_n^{-1} + E_n G_n^{-1} \\ &= X_n B \widetilde{H}_n + Z_n \Theta \widetilde{Q}_n + \widetilde{E}_n \end{aligned}$$

with $\widetilde{H}_n = H_n G_n^{-1}$, $\widetilde{Q}_n = Q_n G_n^{-1}$, and $\widetilde{E}_n = E_n G_n^{-1}$. $Y_n = X_n B \widetilde{H}_n + Z_n \Theta \widetilde{Q}_n + \widetilde{E}_n$ is also a commonly used expression for a general linear model. Denote the Kronecker product of matrices A_1 and A_2 by $A_1 \otimes A_2$ and define a $\tau\varsigma$-dimensional vector $vec(A_3)$ of a $\tau \times \varsigma$ matrix A_3 by stacking its column vectors. Then the general linear model (4) can be rewritten as

$$\begin{aligned} \left(I_n \otimes G_n^T\right) vec\left(Y_n^T\right) = &\left(X_n \otimes H_n^T\right) vec\left(B^T\right) \\ &+ \left(Z_n \otimes Q_n^T\right) vec\left(\Theta^T\right) \\ &+ vec\left(E_n^T\right), \end{aligned} \tag{5}$$

or

$$\begin{aligned} \left(G_n^T \otimes I_n\right) vec\left(Y_n\right) = &\left(H_n^T \otimes X_n\right) vec\left(B\right) \\ &+ \left(Q_n^T \otimes Z_n\right) vec\left(\Theta\right) \\ &+ vec\left(E_n\right). \end{aligned} \tag{6}$$

Denote $E_n = (\boldsymbol{e}_1, \ldots, \boldsymbol{e}_n)^T$. If $\boldsymbol{e}_1, \ldots, \boldsymbol{e}_n$ are independently and identically distributed with zero mean vector and covariance matrix Σ, it can be shown that $vec\left(E_n^T\right)$ has zero mean vector and covariance matrix $I_n \otimes \Sigma$, and hence $vec\left(E_n\right)$ has zero mean vector and covariance matrix $\Sigma \otimes I_n$, where I_n is an $n \times n$ identity matrix.

Least squares method (see ▶Least Squares) may be used to estimate the parameters in (4) directly in terms of (5) or (6). For example, if $Y_n = X_n B H_n + E_n$ and $n \geq m + p$, the least squares method can be used to estimate B. Note that the estimation may not be unique if the rank of H_n is not q. A least squares estimator of B is given by $\widehat{vecB}_n = \left[\left(H_n \Sigma^{-1} H_n^T\right)^+ \otimes \left(X_n^T X_n\right)^{-1}\right]\left(H_n \Sigma^{-1} \otimes X_n^T\right) vec\left(Y_n\right)$, where A^+ denotes the Moore-Penrose inverse of a matrix A. If in addition $q = k = m$ and $H_n = I_m$, it follows that $\widehat{vecB}_n = \left[I_n \otimes \left(X_n^T X_n\right)^{-1} X_n^T\right] vec\left(Y_n\right)$, i.e., $\hat{B}_n = \left(X_n^T X_n\right)^{-1} X_n^T Y_n$. The residual is defined as $\Upsilon_n = Y_n - X_n \hat{B}_n$. If $vec\left(E_n\right)$ has zero mean vector and covariance matrix $\Sigma \otimes I_n$, it can be shown that $\hat{B}_n$ and $\hat{\Sigma}_n = \Upsilon_n^T \Upsilon_n/(n-p)$ are unbiased estimators of B and Σ, respectively. Now assume that $\boldsymbol{e}_1, \ldots, \boldsymbol{e}_n$ are independently and identically $N(0, \Sigma)$ distributed. Then it can be proved that $\hat{B}_n$ is the maximum likelihood estimator of B with the distribution $N\left(B, \left(X_n^T X_n\right)^{-1} \otimes \Sigma\right)$, $(n-p)\hat{\Sigma}_n$ is $W_m(n-p, \Sigma)$ distributed, and, moreover, $\hat{B}_n$ is independent of $\hat{\Sigma}_n$, where $W_k(\ell, \Psi)$ denotes the Wishart distribution with ℓ degrees of freedom and $k \times k$ covariance matrix Ψ. Related references include Rao (1973), Mardia et al. (1979), Muirhead (1982) and Fang and Zhang (1990).

The last two references also considered the case that the random errors are elliptically distributed.

When the random errors are not normally distributed but the error distributions are known up to some distribution parameters, maximum likelihood methods may be employed for estimating unknown parameters. If one suspects that there may be some departures from the underlying assumptions on error distributions or there may be some ►outliers in the data, one may consider to use weighted least squares method, M-estimation method, or other robust estimation methods to estimate the parameters (see Seber and Lee (2003) and Rao et al. (2008) among others).

In addition to those mentioned above, some commonly used general linear model techniques and tools include:

- Shrinkage estimation, heterogeneous linear estimation, Stein-rule estimation, multiway classification.
- Bonferroni simultaneous confidence intervals, Turkey's simultaneous comparisons, Scheffé multiple comparisons.
- Multivariate analysis of variance table, union-intersection approach, t-test, F-test, likelihood ratio test, Wilks's lambda statistic, Hotelling's T^2 test, Pillai's trace, Hotelling-Lawley trace, Roy's greatest root, sphericity test, invariant test, profile analysis, goodness-of-fit test.
- Classical prediction, optimal heterogeneous prediction, optimal homogeneous prediction, prediction regions, Stein-rule predictor, partial least squares, principal components regression, Kalman filter.
- Multiple correlation coefficient, partial correlation coefficient, Q-Q plot, high-leverage point, studentized residual, Cook's distance, variance ratio, analysis of residuals, partial regression plots, variable selection procedures including forward selection, backward elimination, stepwise regression, cross-validation, Mallows' C_p, information theoretic criteria, LASSO, SCAD.
- Imputation, Yate's procedure, Bartlett's ANCOVA.
- Canonical form, data centering and scaling, Cholesky decomposition method, orthogonal-triangular decomposition, recursive algorithm.
- Generalized variance, total least squares, orthogonal design matrix, hierarchical design, Bayesian method.

The problems associated with the general linear models include estimability of B and/or Θ, testability of hypotheses on B and/or Θ, estimation of B and/or Θ under some linear constraints, hypothesis testing of hypotheses on B and/or Θ under some linear constraints, construction of confidence regions, simultaneous testing, multiple comparisons, homogeneity of covariance matrices, collinearity, estimation of covariance, asymptotics, variable selection, high-dimensionality problem (e.g., $n << p$ in (2)), underfitting, overfitting, optimal design, censored data, missing observations, outliers, model assumptions, transformation, outside sample predictions, and efficiency.

Standard software pacakages including SAS, R, S-PLUS, SPSS and MATLAB may be used to solve statistical inference problems for general linear models.

About the Author

Yuehua (Amy) Wu received her doctorate in Statistics from University of Pittsburgh in 1989 (her advisor was Professor C.R. Rao). She is Professor of Mathematics and Statistics at York University and recently was Director of the Statistics section in the department of Mathematics and Statistics.

Generalized Extreme Value Family of Probability Distributions

Chris P. Tsokos
Distinguished University Professor
University of South Florida, Tampa, FL, USA

In real life phenomenon we experience largest observations (maximum extreme) or smallest observation (minimum extreme), such as "How tall should one design an embankment so that the sea reaches this level only once in 100 years?"; "What is the lowest value the Dow Jones Industrial Average can reach in the next three years?"; "How high a drug concentration in the bloodstream can go before causing toxicity?", among others.

To characterize and understand the behavior of these extremes, we usually use probabilistic extreme value theory. Such theory deals with the stochastic behavior of the minimum and maximum of independent identically distributed random variables. Here, we shall give a brief introduction of the generalized extreme value family of probability distribution that fits the subject observations. This family of probability distribution function (pdf) consists of three famous classical pdfs, namely the Gumbel, the Frechet, and the Weibull.

Extreme value theory has been successfully applied to address problems in floods, wind gusts, hurricanes, reliability, earthquakes, stock market crashes, survival analysis, rain fall, health sciences, drug evaluation, financial systems, among others. Some brief useful references on the theory are Abdelhafez and Thomas (1990), Achcar (1991), Ahsanullah (1990), Campell and Tsokos (1973a), Cheng et al. (1998), Cohen (1986), Daniels (1942), Davidovich (1992), De Haan (1970), Engelhardt and Bain (1973), Engelund and Rackwitz (1992), Frechet (1927), Galambos (1981), Galambos (1987), Gumbel (1935), Gumbel (1958), Gumbel (1962a, b, c), Gumbel and Goldstein (1964), Hassanein (1972), Hosking (1985), Jenkinson (1969), Mann et al. (1973), von Mises (1923), von Mises (1936), Pickands (1986), Pickands (1981), and Weibull (1939a), and applications Ahmad et al. Extreme Value Theory (EVT) is the study of probabilistic extremes and focuses primarily on the asymptotic behavior as the sample size approaches infinity. Let $X_1, X_2, \ldots, X_n$ be a sequence of independent random variables having a common cumulative probability distribution F. The model focuses on the statistical behavior of

$$M_n = \max\{X_1, X_2, \ldots, X_n\},$$

where X_i usually represent values of a process measured on a regular time scale. For example, hourly measurements of stock prices or plasma drug concentration over a certain period; so that M_n represents the maximum of the process over n time units of observation. If n is the number of observations in a day, then M_n corresponds to the daily maximum.

The probability distribution of M_n can be derived exactly for all values of n, that is,

$$\begin{aligned}\Pr\{M_n \le z\} &= \Pr\{X_1 \le z, \ldots, X_n \le z\} \\ &= \Pr\{X_1 \le z\} \ldots \Pr\{X_n \le z\} = F^n(z) \quad (1)\end{aligned}$$

The difficulty that arises in practice is the fact that the cumulative probability distribution F is unknown. One possibility is to use standard statistical techniques to estimate F from observed data, and then substitute this estimate into (1). But very small discrepancies in the estimate of F can lead to substantial discrepancies for F^n. This leads to an approach based on asymptotic argument which requires determining what possible limit probability distributions are possible for M_n as $n \to \infty$. The question then is "what are the possible limit distributions in the extreme case?"

We study the limiting probability distributions of $\frac{M_n - b_n}{a_n}$ where a_n and b_n are sequences of normalizing coefficients such that $F^n\left(\frac{M_n - b_n}{a_n}\right)$ leads to a non-degenerate probability distribution as $n \to \infty$. Specifically, we seek $\{a_n > 0\}$ and $\{b_n\}$ such that $\Pr\left\{\frac{M_n - b_n}{a_n} \le z\right\} \to G(z)$ where $G(z)$ does not depend on n.

Extremal Types Theorem: If there exist sequences of constants $\{a_n > 0\}$ and $\{b_n\}$ such that, as $n \to \infty$, $\Pr\left\{\frac{M_n - b_n}{a_n} \le z\right\} \to G(z)$ where G is a non-generate probability distribution function, then G belongs to one of the following families:

$$G(z) = \exp\left\{-\exp\left[-\left(\frac{z-b}{a}\right)\right]\right\}, -\infty < z < +\infty \quad (2)$$

$$G(z) = \begin{cases} 0, z < b \\ \exp\left\{-\left(\frac{z-b}{a}\right)^{-\partial}\right\}, \quad z \ge b \end{cases} \quad (3)$$

$$G(z) = \begin{cases} \exp\left\{-\left[-\left(\frac{z-b}{a}\right)^{\partial}\right]\right\}, \quad z \le b \\ 1, z > b \end{cases} \quad (4)$$

For parameters $a(\text{scale}) > 0, b(\text{location})$ and, in (3) and (4), $\partial(\text{shape}) > 0$.

Combining the three classes of probability distributions results in what we refer to as the Generalized Extreme Value (GEV) family of probability distribution. The GEV cumulative probability distribution can be written as

$$G(z) = \exp\left\{-\left[1 + \xi\left(\frac{z-\mu}{\sigma}\right)\right]^{-1/\xi}\right\},$$
$$1 + \xi\left(\frac{z-\mu}{\sigma}\right) > 0, -\infty < \xi < +\infty, \sigma > 0 \quad (5)$$

The equation above is the generalized extreme value family of distributions. This was obtained independently by von Mises (1923, 1936), and Jenkinson (1969) and Hosking (1985). Equation 5 can also be written as

$$G(z) = \begin{cases} \exp\left\{-\left[1 + \xi\left(\frac{z-\mu}{\sigma}\right)\right]^{-1/\xi}\right\}, & -\infty < z \le \mu - \frac{\sigma}{\xi}, \xi < 0; \\ & \mu - \frac{\sigma}{\xi} \le z < +\infty, \xi > 0; \\ \exp\left\{-\exp\left\{-\frac{z-\mu}{\sigma}\right\}\right\}, & -\infty < z < +\infty, \xi = 0. \end{cases} \quad (6)$$

From the GEV Eq. 6, if we take limit $\xi \to 0$, we obtain the Emil Gumbel (1891–1966), cumulative probability distribution (CPD), which is the same as exponential CPD (2). Gumbel developed the subject cdf for studying the extreme observations of climate and hydrology (Gumbel 1935, 1941). The Gumbel pdf is also known as the double exponential and log-Weibull pdf.

For the largest extremes (maximum) the Gumbel pdf is given by

$$f(z) = \frac{1}{\sigma}\exp\left[-\left(\frac{z-\mu}{\sigma}\right) - \exp\left(-\frac{z-\mu}{\sigma}\right)\right], -\infty < z < +\infty \quad (7)$$

where the scale parameter $\sigma > 0$, location parameter μ. For the smallest extremes (minimum) the Gumbel pdf is of the form,

$$f(z) = \frac{1}{\sigma}\exp\left[\left(\frac{z-\mu}{\sigma}\right) - \exp\left(-\frac{z-\mu}{\sigma}\right)\right],$$
$$-\infty < z < +\infty, \sigma > 0 \quad (8)$$

Cumulative Distribution Function

The corresponding Gumbel cdfs for maximum and minimum are given by

$$F(z) = \exp\left\{-\exp\left(\tfrac{z-\mu}{\sigma}\right)\right\}, -\infty < z < +\infty, \sigma > 0,$$

and

$$F(z) = 1 - \exp\left\{-\exp\left(\tfrac{z-\mu}{\sigma}\right)\right\}, -\infty < z < +\infty, \sigma > 0, \quad (9)$$

respectively.

To apply the subject pdfs using real data, we need to solve numerically the following equation to obtain maximum likelihood estimation of the true parameter μ and σ, that is

$$\hat{\mu} = -\hat{\sigma}\log\left[\frac{1}{n}\sum_{i=1}^{n}\exp\left(\frac{-z_i}{\hat{\sigma}}\right)\right]$$
$$\hat{\sigma} - \frac{1}{n}\sum_{i=1}^{n} z_i + \frac{\sum_{i=1}^{n} z_i \exp\left(-\frac{z_i}{\hat{\sigma}}\right)}{\sum_{i=1}^{n}\exp\left(-\frac{z_i}{\hat{\sigma}}\right)} = 0. \quad (10)$$

Furthermore, we can use these estimates $\hat{\mu}$ and $\hat{\sigma}$ to obtain a 95% confidence interval for μ and σ, that is

$$\left(\hat{\mu} - 1.96\sqrt{\frac{1.10867\hat{\sigma}^2}{n}}, \hat{\mu} + 1.96\sqrt{\frac{1.10867\hat{\sigma}^2}{n}}\right) \quad (11)$$

and

$$\left(\hat{\sigma} - 1.96\sqrt{\frac{0.60793\hat{\sigma}^2}{n}}, \hat{\sigma} + 1.96\sqrt{\frac{0.60793\hat{\sigma}^2}{n}}\right). \quad (12)$$

The CPD defined in Eq. 6 which can also be obtained for GEV CPD where $\xi > 0$, was initially discovered by Maurice Frechet (1878–1973). It is especially applicable to

heavy-tailed pdf. The Frechet pdf has wide ranging applications in engineering, environmental modeling, finance and other areas. Recent applications include prediction of solar proton peak fluxes and modeling interfacial damage in microelectronic packages and material properties of constituent particles in an aluminum alloy.

The three parameter Frechet pdf is given by

$$f(z) = \frac{\xi}{\sigma}\left(\frac{\sigma}{z-\mu}\right)^{\xi+1} \exp\left\{-\left(\frac{\sigma}{z-\mu}\right)^{\xi}\right\}, \quad \mu > 0, \xi > 0, \sigma > 0. \tag{13}$$

The corresponding cdf of (13) is given by

$$F(z) = \exp\left\{-\left(\frac{\sigma}{z-\mu}\right)^{\xi}\right\}, \ \mu, \xi, \sigma > 0, \tag{14}$$

where μ, ξ and σ are the location, shape and scale parameter, respectively.

To apply the above pdf to real data, we need to obtain the maximum likelihood estimate of the parameters μ, σ and ξ by numerically solving the following system of likelihood equations

$$\frac{n}{\hat{\xi}} + \frac{n\sum_{i=1}^{n}(t_i-\hat{\mu})^{-\hat{\xi}}\log(t_i-\hat{\mu})}{\sum_{i=1}^{n}(t_i-\hat{\mu})^{-\hat{\xi}}} = \sum_{i=1}^{n}\log(t_i-\hat{\mu}) \tag{15}$$

$$\frac{n\hat{\xi}\sum_{i=1}^{n}(t_i-\hat{\mu})^{-(\hat{\xi}+1)}}{\sum_{i=1}^{n}(t_i-\hat{\mu})^{-\hat{\xi}}} = (\hat{\xi}+1)\sum_{i=1}^{n}\frac{1}{t_i-\hat{\mu}} \tag{16}$$

and

$$\hat{\sigma} = \left\{\frac{1}{n}\sum_{i=1}^{n}(t_i-\hat{\mu})^{-\hat{\xi}}\right\}^{-1/\hat{\xi}}. \tag{17}$$

The CDF defined in the family of probability distributions was developed by Waloddi Weibull (1887–1979) and carried his name. It can also be obtained from the GEV for $\xi < 0$. Weibull did significant pioneering work on reliability, providing a statistical treatment of fatigue, strength, and lifetime in engineering design (Ahmad et al. 1988; Weibull 1939b). It is also applicable in environmental modeling, finance and other areas. Recent applications include evaluation the magnitude of future earthquakes in the Pacific, Argentina, Japan and in the Indian subcontinent.

The pdf of the three - parameter Weibull is given by

$$f(z) = \frac{\xi}{\sigma}\left(\frac{\sigma}{z-\mu}\right)^{\xi-1} \exp\left\{-\left(\frac{\sigma}{z-\mu}\right)^{\xi}\right\}, \ z, \mu, \xi, \sigma > 0. \tag{18}$$

Its CDF is given by

$$F(z) = 1 - \exp\left\{-\left(\frac{\sigma}{z-\mu}\right)\right\}, \ z, \mu, \xi, \sigma > 0. \tag{19}$$

Similarly, to apply the subject pdf we need to obtain a maximum likelihood estimate of the three parameters, μ, σ and ξ that are inherent in the Weibull pdf. We can obtain such estimates by solving numerical the following system of likelihood equations,

$$\frac{n}{\hat{\xi}} + \sum_{i=1}^{n}\log(t_i-\hat{\mu}) = \frac{n\sum_{i=1}^{n}(t_i-\hat{\mu})^{\hat{\xi}}\log(t_i-\hat{\mu})}{\sum_{i=1}^{n}(t_i-\hat{\mu})^{-\hat{\xi}}} \tag{20}$$

$$\frac{n\hat{\xi}\sum_{i=1}^{n}(t_i-\hat{\mu})^{-(\hat{\xi}-1)}}{\sum_{i=1}^{n}(t_i-\hat{\mu})^{-\hat{\xi}}} = (\hat{\xi}-1)\sum_{i=1}^{n}\frac{1}{t_i-\hat{\mu}} \tag{21}$$

and

$$\hat{\sigma} = \left\{\frac{1}{n}\sum_{i=1}^{n}(t_i-\hat{\mu})^{-\hat{\xi}}\right\}^{1/\hat{\xi}}. \tag{22}$$

Generalized Hyperbolic Distributions

Matthias Fischer
University of Erlangen-Nürnberg, Erlangen, Germany

The (univariate) generalized hyperbolic distribution (GHD) family was intensively discussed originally by Barndorff-Nielsen (1977, 1978) and arose as specific normal mean-variance mixture: Assuming that X follows a normal distribution with random mean $\mu + U\beta$ ($\mu, \beta \in \mathbb{R}$) and random variance U, where U in turn is assumed to follow a generalized inverse Gaussian (GIG) distribution (see, e.g., Jørgensen 1982) with parameters $\lambda \in \mathbb{R}$, $\chi \equiv \delta^2$, $\psi \equiv \alpha^2 - \beta^2$ for $\alpha, \delta > 0, |\beta| < \alpha$, the corresponding GH density on $\mathbb{R}$ derives as

$$f(x;\mu,\delta,\alpha,\beta,\lambda) = \left[\left(\sqrt{\alpha^2-\beta^2}\right)^{\lambda}\left(\sqrt{\delta^2+(x-\mu)^2}\right)^{\lambda-\frac{1}{2}} \mathbf{K}_{\lambda-\frac{1}{2}}\left(\alpha\sqrt{\delta^2+(x-\mu)^2}\right)\right] \Big/ \left[\sqrt{2\pi}\alpha^{\lambda-\frac{1}{2}}\delta^{\lambda}\mathbf{K}_{\lambda}\left(\delta\sqrt{\alpha^2-\beta^2}\right)e^{-\beta(x-\mu)}\right],$$

where $\mathbf{K}_{\lambda}(x) = \frac{1}{2}\int_0^{\infty} t^{\lambda-1}e^{-\frac{1}{2}x(t+t^{-1})}dt$ denotes the *modified Bessel function* of the third kind (see Abramowitz and Stegun 1965). The GHD is symmetric around the location parameter μ if the skewness parameter β is zero. The parameter δ describes the scale, whereas α and λ govern both peakedness and tail behavior, respectively. Note that the GHD has heavier tails than the normal distribution. The tail behavior is like that of an exponential function times a power of $|x|$ (see, e.g., Barndorff-Nielsen 1978). An included subfamily where one tail has polynomial and the other exponential tail behavior is discussed by Aas and Haff (2006). Despite its heavier tails, the moment-generating function of a GH variable X still exists and is given by

$$\mathcal{M}(u) \equiv \mathbb{E}(e^{uX}) = \exp(u\mu)\cdot\left(\frac{\alpha^2-\beta^2}{\alpha^2-((\beta+u)^2)}\right)^{\frac{\lambda}{2}}\cdot \frac{\mathbf{K}_{\lambda}\left(\delta\sqrt{\alpha^2-(\beta+u)^2}\right)}{\mathbf{K}_{\lambda}\left(\delta\sqrt{\alpha^2-\beta^2}\right)}, \quad |\beta+u|<\alpha.$$

Hence, mean, variance and higher moments can be derived in a straightforward manner (see, Barndorff-Nielsen and Blæsild 1981 and Blæsild 1990). Above that, the GHD is both infinitely divisible (see Barndorff-Nielsen and Halgreen 1977) and self-decomposable (see Halgreen 1979). Random numbers from a GH population can be generated using an efficient algorithm of Atkinson (1979). Maximum likelihood estimation of the unknown parameters based on i.i.d samples from a GHD might be challenging to some extent because of the flatness of the likelihood function in λ (see Prause 1999). Barndorff-Nielsen (1995), for instance, provides an example of two different GH families (with different λ's) whose density are practically identical over the range covering 99.99% of their mass.

This is one of the reasons why two specific subclasses gain special attraction within the GH-family.

Firstly, the hyperbolic (HYP) distribution family ($\lambda = 1$) whose name derives from the fact that for such a distribution the graph of the log-density is a hyperbola. Hyperbolic distributions were originally motivated as a distributional model for particle sizes of a sand sample from aeolian sand deposits (see Bagnold and Barndorff-Nielsen 1980) but were also successfully applied in turbulence (see Barndorff-Nielsen et al. 1989) and finance (see Eberlein and Keller 1995, Bibby and Sørensen 1997 or Küchler et al. 1999). Goodness-of fit tests for the hyperbolic distributions were proposed by Puig and Stephens (2001).

Secondly, the normal inverse Gaussian family (NIG) ($\lambda = -1/2$) which shows similar fit and flexibility but, in contrast to the hyperbolic distribution, has the feature of being closed under convolution. This can be used, for instance, to price different kind of options (see, e.g., Albrecher and Predota 2004). Barndorff-Nielsen (1995) and Rydberg (1997) discuss ►Lévy processes based on NIG distributions as a model for stock returns. Bayesian estimation of NIG distributions can be found in Karlis and Lillestöl (2004). Occasionally, the so-called hyperboloid distributions ($\lambda = 0$) are focussed (see, e.g., Blæsild 1990). Beyond that, both normal distribution ($\delta \to \infty, \delta/\alpha \to \sigma^2$) and Student-$t$ distribution ($\lambda = -\nu/2, \alpha = \beta \to 0, \delta = \sqrt{\nu}$) are included as limiting cases within the GHD family. As in the one-dimensional case, the multivariate generalized hyperbolic distribution results as a specific normal mean-variance mixture distribution and appeared first in Barndoff-Nielsen (1977, 1978) with intensive discussion in Blæsild (1981). Making use of the mixture representation, Protassov (2004) and Hu (2005) discuss the EM-based estimation maximum likelihood parameter estimation. Applications to finance are provided by Prause (1999) and Hu (2005), for example.

Generalized Linear Models

Joseph M. Hilbe
Emeritus Professor
University of Hawaii, Honolulu, HI, USA
Adjunct Professor of Statistics
Arizona State University, Tempe, AZ, USA
Solar System Ambassador
California Institute of Technology, Pasadena, CA, USA

History

Generalized Linear Models (GLM) is a covering algorithm allowing for the estimation of a number of otherwise distinct statistical regression models within a single framework. First developed by John Nelder and R.W.M. Wedderburn in 1972, the algorithm and overall GLM methodology has proved to be of substantial value to statisticians in terms of the scope of models under its domain as well as the number of accompanying model statistics facilitating an analysis of fit. In the early days of statistical computing - from 1972 to 1990 - the GLM estimation algorithm also provided a substantial savings of computing memory compared to what was required using standard maximum likelihood techniques. Prior to Nelder and Wedderburn's efforts, GLM models were typically estimated using a Newton-Raphson type full maximum likelihood method, with the exception of the Gaussian model. Commonly known as normal or linear regression, the Gaussian model is usually estimated using a least squares algorithm. GLM, as we shall observe, is a generalization of ordinary least squares regression, employing a weighted least squares algorithm that iteratively solves for parameter estimates and standard errors.

In 1974, Nelder coordinated a project to develop a specialized statistical application called GLIM, an acronym for Generalized Linear Interactive Modeling. Sponsored by the Royal Statistical Society and Rothamsted Experimental Station, GLIM provided the means for statisticians to easily estimate GLM models, as well as other more complicated models which could be constructed using the GLM framework. GLIM soon became one of the most used statistical applications worldwide, and was the first major statistical application to fully exploit the PC environment in 1981. However, it was discontinued in 1994. Presently, nearly all leading general purpose statistical packages offer GLM modeling capabilities; e.g., SAS, R, Stata, S-Plus, Genstat, and SPSS.

Theory

Generalized linear models software, as we shall see, allows the user to estimate a variety of models from within a single framework, as well as providing the capability of changing models with minimal effort. GLM software also comes with a host of standard residual and fit statistics, which greatly assist researchers with assessing the comparative worth of models.

Key features of a generalized linear model include (1) having a response, or dependent variable, selected from the single parameter exponential family of probability distributions, (2) having a link function that linearizes the relationship between the fitted value and explanatory predictors, and (3) having the ability to be estimated using an Iteratively Re-weighted Least Squares (IRLS) algorithm.

The exponential family probability function upon which GLMs are based can be expressed as

$$f(y_i;\theta_i,\phi) = \exp\{(y_i\theta_i - b(\theta_i))/\alpha_i(\phi) - c(y_i;\phi)\} \quad (1)$$

where the distribution is a function of the unknown data, y, which may be conditioned by explanatory predictors, for given parameters θ and ϕ. For generalized linear models, the probability distribution is re-parameterized such that the distribution is a function of unknown parameters based on known data. In this form the distribution is termed a likelihood function, the goal of which is to determine the parameters making the data most likely. Statistician's log-transform the likelihood function in order to convert it to an additive rather than the multiplicative scale. Doing so greatly facilitates estimation based on the function. The log-likelihood function is central to all maximum likelihood estimation algorithms. It is also the basis of the deviance function, which was traditionally employed in GLM algorithms as both the basis of convergence and as a goodness-of-fit statistic. The log-likelihood is defined as

$$L(\theta_i;y_i,\phi) = \sum_{i=1}^{n}\{(y_i\theta_i - b(\theta_i))/\alpha_i(\phi) - c(y_i;\phi)\} \quad (2)$$

where θ is the link function, $b(\theta)$ the cumulant, $\alpha_i(\phi)$ the scale, and $c(y;\phi)$ the normalization term, guaranteeing that the distribution sums to one. The first derivative of the cumulant with respect to θ, $b'(\theta)$, is the mean of the

function, μ; the second derivative, $b''(\theta)$, is the variance, $V(\mu)$. The deviance function is given as

$$2\sum_{i=1}^{n}\{L(y_i;y_i) - L(y_i,\mu_i)\} \tag{3}$$

Table 1 presents the standard probability distribution functions (PDF) belonging to the GLM family.

Each of the distributions in Table 1 are members of the exponential family. It should be noted, however, that the three continuous GLM distributions are usually parameterized with two rather than one parameter: Gaussian, gamma, and inverse Gaussian. Within the GLM framework though, the scale parameter is not estimated, although it is possible to point-estimate the scale value from the dispersion statistic, which is typically displayed in GLM model output. Binomial and count models have the scale value set at 1.0. As a consequence, $\alpha(\phi)$ and ϕ are many times excluded when presenting the GLM-based exponential log-likelihood.

Table 2 provides the formulae for the deviance and log-likelihoods of each GLM family. Also provided is the variance for each family function. The first line of each GLM distribution or family shows the deviance, with the next two providing the log-likelihood functions parameterized in terms of μ and $x'\beta$ respectively. The $x'\beta$ parameterization is used when models are estimated using a full maximum likelihood algorithm.

Generalized Linear Models. Table 1 GLM families: canonical

Family	Characteristics
Continuous distributions	
Gaussian	Standard normal or linear regression
Gamma	Positive-only continuous
Inverse gaussian	Positive-only continuous
Count	
Poisson	Equidispersed count
Negative binomial (NB-C)	Count, with the ancillary parameter a constant
Binary - Bernoulli	Binomial distribution with $m = 1$.
Logistic	Binary (1/0) response
Binomial	Proportional (y/m) :
Logistic (grouped)	y = number of 1's m = cases having same covariate pattern

Note that the link and cumulant functions for each of the above GLM log-likelihood functions can easily be abstracted from the equations, which are formatted in terms of the exponential family form as defined in Eq. 1. For example, the link and cumulant of the Bernoulli distribution, upon which ▶logistic regression is based, are respectively $\ln(\mu/(1-\mu))$ and $-\ln(1-\mu)$. With the link function defined in this manner, the linear predictor for the canonical Bernoulli model (logit) is expressed as:

$$\theta_i = x_i'\beta = \ln(\mu_i/(1-\mu_i)) = \beta_0 + \beta_1 x_1 + \beta_2 x_2 + \cdots + \beta_n x_n. \tag{4}$$

In GLM terminology, $x'\beta$ is also referred to as η, and the link as $g(\mu)$. For links directly derived from the GLM family PDF, the following terms are identical:

$$\theta = x_i'\beta = \eta = g(\mu). \tag{5}$$

The link function may be inverted such that μ is defined in terms of η. The resulting function is called the inverse link function, or $g^{-1}(\eta)$. For the above logit link, $\eta = \ln(\mu/(1-\mu))$. μ is therefore defined, for each observation in the logistic model, as

$$\mu_i = 1/(1+\exp(-\eta_i)) = (\exp(\eta_i))/(1+\exp(\eta_i)) \tag{6}$$

or

$$\mu_i = 1/\left(1+\exp\left(-x_i'\beta\right)\right) = \left(\exp\left(x_i'\beta\right)\right)/\left(1+\exp\left(x_i'\beta\right)\right) \tag{7}$$

Another key feature of generalized linear models is the ability to use the GLM algorithm to estimate non-canonical models; i.e., models in which the link function is not directly derived from the underlying pdf, i.e., $x'\beta$ or η is not defined in terms of the value of θ given in the above listing of log-likelihood functions. Theoretically any type of link function can be associated with a GLM log-likelihood, although many might not be appropriate for the given data. A power link is sometimes used for non-binomial models the power, p, in μ^p, is allowed to vary. The statistician employs a value for the power that leads to a minimal value for the deviance. Powers typically range from 2 to −3, with μ^2 being the square link, μ^1 the log, μ^0 the identity, and μ^{-1} and μ^{-2} the inverse and inverse quadratic link functions, respectively. Intermediate links are also used, e.g., $\mu^{.5}$, the square root link. The normal linear model has an identity link, with the linear predictor being identical to the fitted value.

The probit and log-linked negative binomial (NB-2) models are two commonly used non-canonical linked regression models. The probit link is often used with the ▶binomial distribution for probit models. Although the probit link is not directly derived from the binomial PDF, the estimates of the GLM-based probit model are identical

Generalized Linear Models. Table 2 GLM variance, deviance, and log-likelihood functions

Family	Variance, deviance, log-likelihood ($\mu\|x\beta$)
Gaussian	$\sum(y-\mu)^2$
1	$\sum\{(y\mu-\mu^2/2)/\sigma^2-y^2/2\sigma^2-5\ln(2\pi\sigma^2)\}$
	$\sum\{[y(x\beta)-(x\beta)^2/2]/\sigma^2-y^2/2\sigma^2-5\ln(2\pi\sigma^2)\}$
Bernoulli	$2\sum\{y\ln(y/\mu)+(1-y)\ln((1-y)/(1-\mu))\}$
$\mu(1-\mu)$	$\sum\{y\ln(\mu/(1-\mu))+\ln(1-\mu)\}$
	$\sum\{y(x\beta)-\ln(1+\exp(x\beta))\}$
Binomial	$2\sum\{y\ln(y/\mu)+(m-y)\ln((m-y)/(m-\mu))\}$
$\mu(1-\mu/m)$	$\sum\{y\ln(\mu/m)+(m-y)\ln(1-\mu/m)+\ln\Gamma(m+1)-\ln\Gamma(y+1)+\ln\Gamma(m-y+1)\}$
	$\sum\{y\ln((\exp(x\beta))/(1+\exp(x\beta)))-(m-y)\ln(\exp(x\beta)+1)+\ln\Gamma(m+1)-\ln\Gamma(y+1)+\ln\Gamma(m-y+1)\}$
Poisson	$2\sum\{y\ln(y/\mu)-(y-\mu)\}$
μ	$\sum\{y\ln(\mu)-\mu-\ln\Gamma(y+1)\}$
	$\sum\{y(x\beta)-\exp(x\beta)-\ln\Gamma(y+1)\}$
NB2	$2\sum\{y\ln(y/\mu)-(y+1/\alpha)\ln((1+\alpha y)/(1+\alpha\mu))\}$
$\mu+\alpha\mu^2$	$\sum\{y\ln((\alpha\mu)/(1+\alpha\mu))-(1/\alpha)\ln(1+\alpha\mu)+\ln\Gamma(y+1/\alpha)-\ln\Gamma(y+1)-\ln\Gamma(1/\alpha)\}$
	$\sum\{y\ln((\alpha\exp(x\beta))/(1+\alpha\exp(x\beta)))-(\ln(1+\alpha\exp(x\beta)))/\alpha+\ln\Gamma(y+1/\alpha)-\ln\Gamma(y+1)-\ln\Gamma(1/\alpha)\}$
NBC	$2\sum\{y\ln(y/\mu)-(y+1/\alpha)\ln((1+\alpha y)/(1+\alpha\mu))\}$
$\mu+\alpha\mu^2$	$\sum\{y\ln(\alpha\mu/(1+\alpha\mu))-(1/\alpha)\ln(1+\alpha\mu)+\ln\Gamma(y+1/\alpha)-\ln\Gamma(y+1)-\ln\Gamma(1/\alpha)\}$
	$\sum\{y(x\beta)+(1/\alpha)\ln(1-\exp(x\beta))+\ln\Gamma(y+1/\alpha)-\ln\Gamma(y+1)-\ln\Gamma(1/\alpha)\}$
Gamma	$2\sum\{(y-\mu)/\mu-\ln(y/\mu)\}$
μ^2	$\sum\{((y/\mu)+\ln(\mu))/-\phi+\ln(y)(1-\phi)/\phi-\ln(\phi)/\phi-\ln\Gamma(1/\phi)\}$
	$\sum\{(y(x\beta)-\ln(x\beta))/-\phi+\ln(y)(1-\phi)/\phi-\ln(\phi)/\phi-\ln\Gamma(1/\phi)\}$
Inv Gauss	$\sum\{(y-\mu)^2/(y\mu^2)\}$
μ^3	$\sum\{(y/(2\mu^2)-1/\mu)/-\sigma^2+1/(-2y\sigma^2)-5\ln(2\pi y^3\sigma^2)\}$
	$\sum\left\{y/(2x\beta)-\sqrt{x\beta}/-\sigma^2+1/(-2y\sigma^2)-5\ln(2\pi y^3\sigma^2)\right\}$

to those produced using full maximum likelihood methods. The canonical negative binomial (NB-C) is not the traditional negative binomial used to model overdispersed Poisson data. Rather, the use of the log link with the negative binomial (LNB) family duplicates estimates produced by full maximum likelihood NB-2 commands. However, like all non-canonical models, the standard errors of the LNB are slightly different from those of a full maximum likelihood NB-2, unless the traditional GLM algorithm in Table 5 is amended to produce an observed information matrix that is characteristic of full maximum likelihood estimation. The information derived from the algorithm given in Table 5 uses an expected information matrix, upon which standard errors are based. Applications such as Stata's *glm* command, SAS's *Genmod* procedure, and R's *glm*() and *glm.nb*() functions allow the user to select which information is to be used for standard errors.

The negative binomial family was not added to commercial GLM software until 1993 (Stata), and is in fact a member of the GLM family only if its ancillary or heterogeneity, parameter is entered into the algorithm as a constant. Setting the ancillary parameter, α, to a value

that minimizes the Pearson dispersion statistic closely approximates the value of α estimated using a full maximum likelihood command. SAS, Stata, and R provide the capability for a user to estimate α using a maximum likelihood subroutine, placing the value determined into the GLM algorithm as a constant. The resulting estimates and standard errors are identical to a full NB-2 estimation. These applications also provide the capability of allowing the software to do this automatically.

Generalized Linear Models. Table 3 Foremost non-canonical models

Family-link	Function
Continuous distributions	
Lognormal	Positive continuous
Log-gamma	Exponential survival model
Log-inverse gaussian	Steep initial peak; long slow tail
Bernoulli/binomial:	
Probit	Normal
Complementary loglog	Asymmetric distribution: >0.5 elongated
Loglog	Asymmetric distribution: <0.5 elongated
Negative binomial	
Log (NB2)	Overdispersed Poisson

The ability to incorporate non-canonical links into GLM models greatly extends the scope of models which may be estimated using its algorithm. Commonly used non-canonical models are shown in Table 3.

The link, inverse link, and first derivative of the link for the canonical functions of the standard GLM families, as well as the most used non-canonical functions, are given in Table 4.

IRLS Algorithm

Generalized linear models have traditionally been modeled using an Iteratively Re-Weighted Least Squares (IRLS) algorithm. IRLS is a version of maximum likelihood called Fisher Scoring, and can take a variety of forms. A schematic version of the IRLS algorithm is given in Table 5.

Goodness-of-Fit

GLM models are traditionally evaluated as to their fit based on the deviance and Pearson Chi2, or χ^2, statistics. Lower values of these statistics indicate a better fitted model. Recently, statisticians have also employed the Akaike (AIC) and Bayesian (BIC) Information Criterion statistics as measures of fit. Lower values of the AIC and BIC statistics also indicate better fitted models. The Pearson Chi2, AIC, and BIC statistics are defined in Table 5, and are calculated after a model has been estimated.

The Pearson dispersion statistic is used with Poisson, negative binomial, and binomial models as an indicator of excessive correlation in the data. Likelihood based models,

being derived from a PDF, assume that observations are independent. When they are not, correlation is observed in the data. Values of the Pearson dispersion greater than 1.0 indicate more correlation in the data than is warranted by the assumptions of the underlying distribution. Some statisticians have used the deviance statistic on which to base the dispersion, but simulation studies have demonstrated that Pearson is the correct statistic. See ►Modeling count data in this volume for additional information.

From the outset, generalized linear models software has offered users a number of useful residuals which can be used to assess the internal structure of the modeled data. Pearson and deviance residuals are the two most recognized GLM residuals associated with GLM software. Both are observation-based statistics, providing the proportionate contribution of an observation to the overall Pearson Chi2 and deviance fit statistics. The two residuals are given, for each observation, as:

$$\text{Pearson} \qquad (y - \mu)/\sqrt{V(\mu)} \tag{8}$$

$$\text{deviance} \qquad \text{sgn}(y - \mu)\sqrt{\text{deviance}} \tag{9}$$

The Pearson Chi2 and deviance fit can also be calculated on the basis of their residuals by taking the square of each of the residuals respectively, and summing them over all observations in the model. However, they are seldom calculated in such a manner.

Both the Pearson and deviance residuals are usually employed in standardized form. The standardized versions of the Pearson and deviance residuals are given by dividing the respective statistic by $\sqrt{1-h}$ where h is the hat matrix diagonal. Standardized Pearson residuals are normalized to a standard deviation of 1.0 and are adjusted to account for the correlation between y and μ. The standardized deviance residuals are the most commonly used residuals for assessing the internal shape of the modeled data.

Another residual now finding widespread use is the Anscombe residual. First implemented into GLM software in 1993, it now enjoys use in many major software applications. The Anscombe residuals are defined specifically for each family, with the intent of normalizing the residuals as much as possible. The general formula for Anscombe residuals is given as

$$\int_y^\mu d\mu V^{-1/3}(\mu) \tag{10}$$

with $V^{-1/3}(\mu)$ as the inverse cube of the variance. The Anscombe residual for the binomial family is displayed as

$$\frac{A(y) - A(\mu)}{\mu(1-\mu)^{-1/6}\sqrt{\frac{1-h}{m}}} \tag{11}$$

with $A()$ equal to $2.05339 \cdot (\text{Incomplete Beta } (2/3, 2/3, z)$, z taking the value of μ or y. A standard use of this statistic is to graph it on either the fitted value, or the linear predictor. Values of the Anscombe residual are close to those of the standardized deviance residuals.

Application

Consider data from the 1912 Titanic disaster. Information was collected on the survival status, gender, age, and ticket class of the various passengers. With *age* (1 = adult; 0 = child) and *sex* (1 = male; 0-female), and *class* (1 = 1st; 2 = 2nd; 3 = 3rd) with 3rd class as the reference, a simple binary ►logistic regression can be run using a GLM command (Stata). The type of model to be estimated is declared using the *family*() and *link*() functions. *eform* indicates that the coefficients are to be exponentiated, resulting in odds ratios for the logistic model. Note the fact that 1st class passengers had a near 6 times greater odds of survival than did 3rd class passengers. The statistics displayed in the model output are fairly typical of that displayed in GLM software applications.

QL Estimation for Independent Data

For $i = 1, \ldots, K$, let Y_i denote the response variable for the ith individual, and $x_i = (x_{i1}, \ldots, x_{iv}, \ldots, x_{ip})'$ be the associated $p-$dimensional covariate vector. Also, let β be the $p-$dimensional vector of regression effects of x_i on y_i. Further suppose that the responses are collected from K independent individuals. It is understandable that if the probability distribution of Y_i is not known, then one can not use the well known likelihood approach to estimate the underlying regression parameter β. Next suppose that only two moments of the data, that is, the mean and the variance functions of the response variable Y_i for all $i = 1, \ldots, K$, are known, and for a known functional form $a(\cdot)$, these moments are given by

$$E[Y_i] = a'(\theta_i) \text{ and } \text{var}[Y_i] = a''(\theta_i), \tag{1}$$

where for a link function $h(\cdot)$, $\theta_i = h\left(x_i'\beta\right)$, and $a'(\theta_i)$ and $a''(\theta_i)$ are the first and second order derivatives of $a(\theta_i)$, respectively, with respect to θ_i. For the estimation of the regression parameter vector β under this independence set up, Wedderburn (1974) (see also McCullagh (1983)) proposed to solve the so-called quasi-likelihood (QL) estimating equation given by

$$\sum_{i=1}^{K}\left[\frac{\partial a'(\theta_i)}{\partial\beta}\frac{(y_i - a'(\theta_i))}{a''(\theta_i)}\right] = 0. \tag{2}$$

Let $\hat{\beta}_{QL}$ be the QL estimator of β obtained from (2). It is known that this estimator is consistent and highly efficient. In fact, for Poisson and binary data, for example, $\hat{\beta}_{QL}$ is equivalent to the maximum likelihood (ML) estimator and hence it turns out to be an optimal estimator.

Illustration for the Poisson Case

For the Poisson data, one uses

$$a(\theta_i) = \exp(\theta_i) \tag{3}$$

with identity link function $h(\cdot)$, that is, $\theta_i = x_i'\beta$. This gives the mean and the variance functions as

$$\text{var}(Y_i) = a''(\theta_i) = E(Y_i) = a'(\theta_i) = \mu_i \text{ (say)} = \exp\left(x_i'\beta\right),$$

yielding by (2), the QL estimating equation for β as

$$\sum_{i=1}^{K} x_i(y_i - \mu_i) = 0. \tag{4}$$

Note that as the Poisson density is given by $f(y_i|x_i) = \frac{1}{y_i!}\exp[y_i log(\mu_i) - \mu_i]$, with $\mu_i = \exp(\theta_i) = \exp\left(x_i'\beta\right)$, it follows that the log likelihood function of β has the form $\log L(\beta) = -\sum_{i=1}^{K} log(y_i!) + \sum_{i=1}^{K}[y_i\theta_i - a(\theta_i)]$, yielding the likelihood equation for β as

$$\frac{\partial \log L}{\partial\beta} = \sum_{i=1}^{K}[y_i - a'(\theta_i)]\frac{\partial\theta_i}{\partial\beta} = \sum_{i=1}^{K} x_i(y_i - \mu_i) = 0, \tag{5}$$

which is the same as the QL estimating Eq. 4. Thus, if the likelihood function were known, then the ML estimate of β would be the same as the QL estimate $\hat{\beta}_{QL}$.

Illustration for the Binary Case

For the binary data, one uses

$$a'(\theta_i) = \frac{\exp(\theta_i)}{1 + \exp(\theta_i)} = \mu_i \text{ and } a''(\theta_i) = \mu_i(1 - \mu_i), \tag{6}$$

with $\theta_i = x_i'\beta$. The QL estimating Eq. 2 for the binary data, however, provides the same formula (4) as in the Poisson case, except that now for the binary case $\mu_i = \frac{\exp(\theta_i)}{1+\exp(\theta_i)}$, whereas for the Poisson case $\mu_i = \exp(\theta_i)$.

As far as the ML estimation for the binary case is concerned, one first writes the binary density given by $f(y_i|x_i) = \mu_i^{y_i}(1 - \mu_i)^{1-y_i}$. Next by writing the log likelihood function as $\log L(\beta) = \sum_{i=1}^{K} y_i\mu_i + \sum_{i=1}^{K}(1-y_i)(1-\mu_i)$, one obtains the same likelihood estimating equation as in (5), except that here $\mu_i = \frac{\exp(x_i'\beta)}{1+\exp(x_i'\beta)}$, under the binary model. Since the QL estimating Eq. 4 is the same as the ML estimating Eq. 5, it then follows that the ML and QL estimates for β would also be the same for the binary data.

GQL Estimation: A Generalization of the QL Estimation to the Correlated Data

As opposed to the independence set up, we now consider y_i as a vector of T repeated binary or count responses, collected from the i–th individual, for all $i = 1, \ldots, K$. Let $y_i = (y_{i1}, \ldots, y_{it}, \ldots, y_{iT})'$, where y_{it} represents the response recorded at time t for the ith individual. Also, let $x_{it} = (x_{it1}, \ldots, x_{itv}, \ldots, x_{itp})'$ be the p–dimensional covariate vector corresponding to the scalar y_{it}, and β be the p–dimensional regression effects of x_{it} on y_{it} for all $i = 1, \ldots, K$, and all $t = 1, \ldots, T$. Suppose that μ_{it} and σ_{itt} be the mean and the variance of Y_{it}, that is $\mu_{it} = E[Y_{it}]$ and $\text{var}[Y_{it}] = \sigma_{itt}$. Note that both μ_{it} and σ_{itt} are functions of β. But, when the variance is a function of mean, it is sufficient to estimate β involved in the mean function only, by treating β involved in the variance function to be known. Further note that since the T repeated responses of an individual are likely to correlated, the estimate of β to be obtained by ignoring the correlations, that is, the solution of the independence assumption based QL estimating equation

$$\sum_{i=1}^{K}\sum_{t=1}^{T}\left[\frac{\partial \mu_{it}}{\partial \beta}\frac{(y_i - \mu_{it})}{\sigma_{itt}}\right] = 0, \tag{7}$$

for β, will be consistent but inefficient. As a remedy to this inefficient estimation problem, Sutradhar (2003) has proposed a generalization of the QL estimation approach, where β is now obtained by solving the GQL estimating equation given by

$$\sum_{i=1}^{K}\frac{\partial \mu_i'}{\partial \beta}\Sigma_i^{-1}(\rho)(y_i - \mu_i) = 0, \tag{8}$$

where $\mu_i = (\mu_{i1}, \ldots, \mu_{it}, \ldots, \mu_{iT})'$ is the mean vector of Y_i, and $\Sigma_i(\rho)$ is the covariance matrix of Y_i that can be expressed as $\Sigma_i(\rho) = A_i^{\frac{1}{2}} C_i(\rho) A_i^{\frac{1}{2}}$, with $A_i = \text{diag}[\sigma_{i11}, \ldots, \sigma_{itt}, \ldots, \sigma_{iTT}]$ and $C_i(\rho)$ as the correlation matrix of Y_i, ρ being a correlation index parameter.

Note that the use of the GQL estimating Eq. 8 requires the structure of the correlation matrix $C_i(\rho)$ to be known, which is, however, unknown in practice. To overcome this difficulty, Sutradhar (2003) has suggested a general stationary auto-correlation structure given by

$$C_i(\rho) = \begin{bmatrix} 1 & \rho_1 & \rho_2 & \cdots & \rho_{T-1} \\ \rho_1 & 1 & \rho_1 & \cdots & \rho_{T-2} \\ \vdots & \vdots & \vdots & & \vdots \\ \rho_{T-1} & \rho_{T-2} & \rho_{T-3} & \cdots & 1 \end{bmatrix}, \tag{9}$$

(see also Sutradhar and Das (1999, Sect. 3)), for all $i = 1, \ldots, K$, where for $\ell = 1, \ldots, T-1$, ρ_ℓ represents the lag ℓ auto-correlation. As far as the estimation of the lag correlations is concerned, they may be consistently estimated by using the well known method of moments. For $\ell = |u - t|$, $u \neq t$, $u, t = 1, \ldots, T$, the moment estimator for the autocorrelation of lag ℓ, ρ_ℓ, has the formula

$$\hat{\rho}_\ell = \frac{\sum_{i=1}^{K}\sum_{t=1}^{T-\ell}\tilde{y}_{it}\tilde{y}_{i,t+\ell}/K(T-\ell)}{\sum_{i=1}^{K}\sum_{t=1}^{T}\tilde{y}_{it}^2/KT}, \tag{10}$$

(Sutradhar and Kovacevic (2000, Eq. (2.18), Sutradhar (2003)), where $\tilde{y}_{it}$ is the standardized residual, defined as $\tilde{y}_{it} = (y_{it} - \mu_{it})/\{\sigma_{itt}\}^{\frac{1}{2}}$.

The GQL estimating Eq. 8 for β and the moment estimate of ρ_ℓ by (10) are solved iteratively until convergence. The final estimate of β obtained from this iterative process is referred to as the GQL estimate of β, and may be denoted by $\hat{\beta}_{GQL}$. This estimator $\hat{\beta}_{GQL}$ is consistent for β and also highly efficient, the ML estimator being fully efficient which is however impossible or extremely complex to obtain in the correlated data set up.

With regard to the generality of the stationary auto-correlation matrix $C_i(\rho)$ in (9), one may show that this matrix, in fact, represents the correlations of many stationary dynamic such as stationary auto-regressive order 1 (AR(1)), stationary moving average order 1 (MA(1)), and stationary equi-correlations (EQC) models. For example, consider the stationary AR(1) model given by

$$y_{it} = \rho * y_{i,t-1} + d_{it}, \tag{11}$$

(McKenzie (1988), Sutradhar (2003)) where it is assumed that for given $y_{i,t-1}$, $\rho * y_{i,t-1}$ denotes the so-called binomial thinning operation (McKenzie 1988). That is,

$$\rho * y_{i,t-1} = \sum_{j=1}^{y_{i,t-1}} b_j(\rho) = z_{i,t-1}, \text{say}, \tag{12}$$

with $\Pr[b_j(\rho) = 1] = \rho$ and $\Pr[b_j(\rho) = 0] = 1 - \rho$. Furthermore, it is assumed in (11) that y_{i1} follows the Poisson distribution with mean parameter $\mu_{i\cdot}$, that is, $y_{i1} \sim Poi(\mu_{i\cdot})$, where $\mu_{i\cdot} = \exp(x_{i\cdot}'\beta)$ with stationary covariate vector $x_{i\cdot}$ such that $x_{it} = x_{i\cdot}$ for all $t = 1, \ldots, T$. Further, in (11), $d_{it} \sim P(\mu_{i\cdot}(1-\rho))$ and is independent of $z_{i,t-1}$. This model in (11) yields the mean, variance and auto-correlations of the data as shown in Table 1. The Table 1 also contains the MA(1) and EQC models and their basic properties including the correlation structures.

It is clear from Table 1 that the correlation structures for all three processes can be represented by $C_i(\rho)$ in (9). By following Qaqish (2003), one may write similar but different dynamic models for the repeated binary data, with their

Generalized Quasi-Likelihood (GQL) Inferences. Table 1 A class of stationary correlation models for longitudinal count data and basic properties

Model	Dynamic relationship	Mean-variance & correlations
AR(1)	$y_{it} = \rho * y_{i,t-1} + d_{it}, t = 2, \ldots$ $y_{i1} \sim Poi(\mu_{i\cdot})$ $d_{it} \sim P(\mu_{i\cdot}(1-\rho)), t = 2, \ldots$	$E[Y_{it}] = \mu_{i\cdot}$ $\text{var}[Y_{it}] = \mu_{i\cdot}$ $\text{corr}[Y_{it}, Y_{i,t+\ell}] = \rho_\ell$ $= \rho^\ell$
MA(1)	$y_{it} = \rho * d_{i,t-1} + d_{it}, t = 2, \ldots$ $y_{i1} = d_{i1} \sim Poi(\mu_{i\cdot}/(1+\rho))$ $d_{it} \sim P(\mu_{i\cdot}/(1+\rho)), t = 2, \ldots$	$E[Y_{it}] = \mu_{i\cdot}$ $\text{var}[Y_{it}] = \mu_{i\cdot}$ $\text{corr}[Y_{it}, Y_{i,t+\ell}] = \rho_\ell$ $= \begin{cases} \frac{\rho}{1+\rho} & \text{for } \ell = 1 \\ 0 & \text{otherwise,} \end{cases}$
EQC	$y_{it} = \rho * y_{i1} + d_{it}, t = 2, \ldots$ $y_{i1} \sim Poi(\mu_{i\cdot})$ $d_{it} \sim P(\mu_{i\cdot}(1-\rho)), t = 2, \ldots$	$E[Y_{it}] = \mu_{i\cdot}$ $\text{var}[Y_{it}] = \mu_{i\cdot}$ $\text{corr}[Y_{it}, Y_{i,t+\ell}] = \rho_\ell$ $= \rho$

correlation structures represented by $C_i(\rho)$. Thus, if the count or binary data follow this type of auto-correlations model, one may then certainly estimate the regression vector consistently and efficiently by solving the general auto-correlations matrix based GQL estimating Eq. 8, where the lag correlations are estimated by (10) consistently.

About the Author

Brajendra Sutradhar is a University Research Professor at Memorial University in St. John's, Canada. He is an Elected member of the International Statistical Institute and a Fellow of the American Statistical Association. He has published about 110 papers in statistics journals in the area of multivariate analysis, time series analysis including forecasting, sampling, survival analysis for correlated failure times, robust inferences in generalized linear mixed models with outliers, and generalized linear longitudinal mixed models with biostatistical and econometric applications. He has served as an Associate editor for six years for *Canadian Journal of Statistics* and for four years for the *Journal of Environmental and Ecological Statistics*. He has served for 3 years as a member of the advisory committee on statistical methods in Statistics Canada. Professor Sutradhar was awarded 2007 distinguished service award of Statistics Society of Canada for his many years of services to the society including his special services for society's annual meetings.

Generalized Rayleigh Distribution

Mohammad Z. Raqab[1], Mohamed T. Madi[2]
[1]Professor of Statistics
University of Jordan, Amman, Jordan
[2]Professor
UAE University, Al Ain, United Arab Emirates

The Rayleigh distribution is one of the most popular distributions in analyzing skewed data. The Rayleigh distribution was originally proposed in the fields of acoustics and optics by Lord Rayleigh (or by his less glamorous name J.W. Strutt), way back in 1880, and it became widely known since then in oceanography, and in communication theory for describing instantaneous peak power of received radio

signals. It has received a considerable attention from engineers and physicists for modeling wave propagation, radiation, synthetic aperture radar images, and other related phenomena.

A Rayleigh random variable X has cumulative distribution function (cdf)

$$F(x;\lambda) = 1 - e^{-(\lambda x)^2},\ x \geq 0, \lambda > 0, \tag{1}$$

and probability density function (pdf)

$$f(x;\lambda) = 2\lambda^2 x\, e^{-(\lambda x)^2},\ x \geq 0, \lambda > 0, \tag{2}$$

where λ is an inverse scale parameter. From (1), we obtain immediately the kth raw moment of X to be

$$E(X^r) = \frac{\Gamma\left(\frac{r}{2}+1\right)}{\lambda^r}. \tag{3}$$

Using Eq. 3, we compute the mean, variance, skewness and coefficient of kurtosis, respectively, as:

$$\begin{aligned} &\mu = \sqrt{\frac{\pi}{4}}\ \lambda^{-1} \approx 0.8862\,\lambda^{-1},\ \ \sigma^2 = \left(1-\frac{\pi}{4}\right)\lambda^{-2} \\ &\quad \approx 0.2146\,\lambda^{-2} \\ &\alpha_3 = \frac{2\sqrt{\pi}(\pi-3)}{(4-\pi)^{3/2}} \approx 0.6311,\ \ \alpha_4 = \frac{32-3\pi^2}{(4-\pi)^2} \approx 3.2451. \end{aligned} \tag{4}$$

Since the cdf of the Rayleigh distribution is in closed form, it has been used very effectively for analyzing censored lifetime data. It has a linearly increasing hazard rate given by $h_X(x) = 2\lambda^2 x$. Due to the monotone property of the hazard rate, the Rayleigh distribution has been used as a model for the lifetimes of components that age rapidly with time.

The likelihood function based on a complete sample $X_1, X_2, \ldots, X_n$ of size n from the Rayleigh distribution is

$$L(x_1,\ldots,x_n;\lambda) \propto \lambda^{2n}\left(\prod_{i=1}^{n} x_i\right) e^{-\sum_{i=1}^{n}(\lambda x_i)^2}. \tag{5}$$

Therefore, to obtain the maximum likelihood estimate (MLE) of λ, we can maximize (5) directly with respect to λ and get the MLE of λ as

$$\hat{\lambda} = \left\{\frac{n}{\sum_{i=1}^{n} x_i^2}\right\}^{1/2}.$$

By setting $E(X) = \overline{X}$, we get the method of moment estimator of λ (see (4)) as $\lambda^* = 0.8862/\overline{X}$. From the fact that $2\lambda^2 X_i^2 \sim \chi^2_2$ (▶chi-square distribution with two degrees of freedom), it follows that $2n\lambda^2/\hat{\lambda}^2$ has χ^2_{2n} distribution. This implies that a $100(1-\alpha)\%$ confidence interval for λ is derived to be

$$\left(\sqrt{\frac{\chi^2_{2n}(\alpha/2)\hat{\lambda}^2}{2n}},\ \sqrt{\frac{\chi^2_{2n}(1-\alpha/2)\hat{\lambda}^2}{2n}}\right),$$

where $\chi^2_{2n}(\alpha)$ represents 100αth percentile of the χ^2_{2n} distribution.

Burr (1942) introduced twelve different forms of cumulative distribution functions for modeling data. Among those twelve distribution functions, Burr-Type X and Burr-Type XII received the maximum attention. Recently, Surles and Padgett (2001) considered the two parameter Burr Type X distribution by introducing a shape parameter and correctly named it as the generalized Rayleigh (GR) distribution. If the random variable X has a two parameter GR distribution, then it has the cumulative distribution function (cdf);

$$F(x;\alpha,\lambda) = \left(1-e^{-(\lambda x)^2}\right)^{\alpha};\quad x>0, \alpha>0, \lambda>0,$$

and probability density function (pdf)

$$\begin{aligned} f(x;\alpha,\lambda) = 2\alpha\lambda^2 x e^{-(\lambda x)^2}\left(1-e^{-(\lambda x)^2}\right)^{\alpha-1}; \\ x>0, \alpha>0, \lambda>0, \end{aligned} \tag{6}$$

where α and λ are shape and inverse scale parameters, respectively. We denote the GR distribution with shape parameter α and inverse scale parameter λ as GR(α,λ). Several aspects of the one-parameter ($\lambda = 1$) Burr-Type X distribution were studied by Ahmad et al. (1997), Raqab (1998) and Surles and Padgett (2001). When $\alpha = 1$, the GR distribution reduces to the one-parameter Rayleigh distribution with cdf and pdf given in (1) and (2).

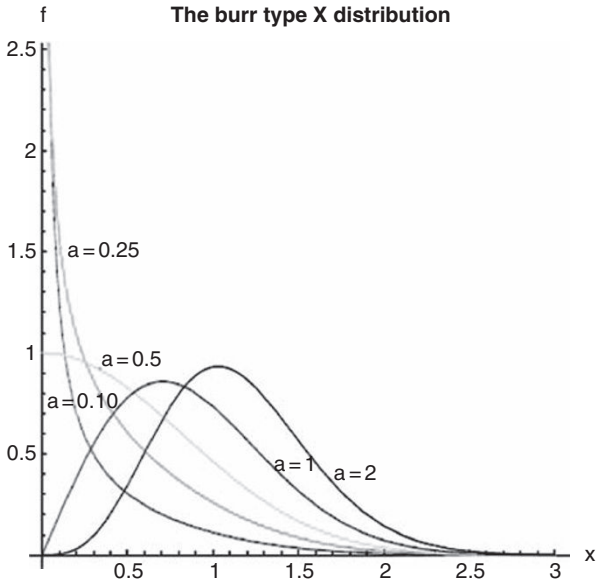
If $\alpha \leq \frac{1}{2}$, the density function in (6) is a decreasing function and for $\alpha > \frac{1}{2}$, it is a right skewed unimodal function. The mode of the density function is equal to $\frac{x_0}{\lambda}$, where x_0 is the solution of the non-linear equation

$$1 - 2x^2 - e^{-x^2}(1-2\alpha x^2) = 0.$$

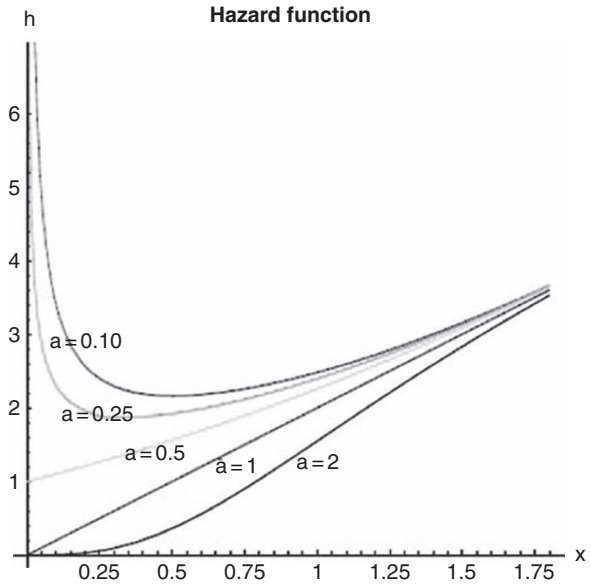
Clearly the mode is a decreasing function of λ as expected and it is an increasing function of α. Different forms of the density functions are presented in Fig. 1. It is clear from Fig. 1 that the GR density functions resemble the gamma and Weibull density functions. The median of a GR random variable occurs at $\left[-\frac{1}{\lambda}\ln\left(1-\left(\frac{1}{2}\right)^{\frac{1}{\alpha}}\right)\right]^{\frac{1}{2}}$ and is also a decreasing function of λ but an increasing function of α.

The hazard function of X is given by

$$h(x;\alpha,\lambda) = \frac{2\alpha\lambda^2 x e^{-(\lambda x)^2}\left(1-e^{-(\lambda x)^2}\right)^{\alpha-1}}{1-\left(1-e^{-(\lambda x)^2}\right)^{\alpha}}.$$



Generalized Rayleigh Distribution. Fig. 1 The density functions of the GR distribution for different shape parameters



Generalized Rayleigh Distribution. Fig. 2 The hazard functions of the GR distribution for different shape parameters

If $\alpha = 1$, the hazard function becomes $2\lambda^2 x$, a linear function of x. From Mudholkar et al. (1995), it follows that if $\alpha \leq \frac{1}{2}$, the hazard function of $GR(\alpha, \lambda)$ is bathtub type and for $\alpha > \frac{1}{2}$, it is increasing.

The hazard functions for different values of α are plotted in Fig. 2. For $\alpha \leq \frac{1}{2}$, it decreases from ∞ to a positive constant and then it increases to ∞. For $\alpha > \frac{1}{2}$, it is an increasing function and it increases from 0 to ∞. It is known that for shape parameter greater than 1, the hazard functions of gamma and Weibull are all increasing functions. The hazard function of ▶gamma distribution increases from 0 to 1. While for ▶Weibull distribution it increases from 0 to ∞. For $\alpha > \frac{1}{2}$, the hazard function of the GR distribution behaves like the hazard function of the Weibull distribution, whose shape parameter is greater than 1. In this respect the GR distribution behaves more like a Weibull distribution than gamma distribution. Therefore, if the data are coming from an environment where the failure rate is gradually increasing without any bound, the GR distribution can also be used instead of a Weibull distribution. As indicated in Fig. 1, the GR density functions are always right skewed and they can be used quite effectively to analyze skewed data sets.

In the context of estimating the model parameters, let $x_1, x_2, \ldots, x_n$ be a random sample of size n from $GR(\alpha, \lambda)$, then the log-likelihood function $L(\alpha, \lambda)$ can be written as:

$$L(\alpha, \lambda) \propto n\, ln\alpha + 2n\, ln\lambda + \sum_{i=1}^{n} ln\, x_i - \lambda^2 \sum_{i=1}^{n} x_i^2 + (\alpha - 1) \sum_{i=1}^{n} ln(1 - e^{-(\lambda x_i)^2}). \quad (7)$$

The normal equations become:

$$\frac{\partial L}{\partial \alpha} = \frac{n}{\alpha} + \sum_{i=1}^{n} ln(1 - e^{-(\lambda x_i)^2}) = 0, \quad (8)$$

$$\frac{\partial L}{\partial \lambda} = \frac{n}{\lambda} - \lambda \sum_{i=1}^{n} x_i^2 + \lambda(\alpha - 1) \sum_{i=1}^{n} \frac{x_i^2\, e^{-(\lambda x_i)^2}}{ln(1 - e^{-(\lambda x_i)^2})} = 0. \quad (9)$$

From (8), we obtain the MLE of α as a function of λ, say $\hat{\alpha}(\lambda)$, as

$$\tilde{\alpha}(\lambda) = \frac{n}{\sum_{i=1}^{n} -ln(1 - e^{-(\lambda x_i)^2})} = 0.$$

Substituting $\tilde{\alpha}(\lambda)$ in (7), we obtain the profile function $g(\lambda) = L(\tilde{\alpha}(\lambda), \lambda)$. By setting $\lambda^2 = \mu$, the MLE of λ, say $\tilde{\lambda}$ can be obtained as a fixed point solution of the following equation

$$h(\mu) = \mu, \quad (10)$$

where

$$h(\mu) = \left[\frac{\sum_{i=1}^{n} \frac{x_i^2 e^{-\mu x_i^2}}{1 - e^{-\mu x_i^2}}}{\sum_{i=1}^{n} ln(1 - e^{-\mu x_i^2})} + \frac{1}{n} \sum_{i=1}^{n} x_i^2 + \frac{1}{n} \sum_{i=1}^{n} \frac{x_i^2\, e^{-\mu x_i^2}}{1 - e^{-\mu x_i^2}} \right]^{-1}$$

If $\tilde{\mu}$ is a solution of (10), then $\tilde{\lambda} = \sqrt{\tilde{\mu}}$. Very simple iterative procedure can be used to solve (10).

To obtain the Bayesian estimates of the two parameters, we assume that α and λ are independent and that

$$\alpha \sim G(a_0, b_0) \quad \text{and} \quad \lambda \sim GEP(a_1, b_1), \tag{11}$$

where $G(a, b)$ denotes the gamma distribution with mean $\frac{a}{b}$, and $GEP(a_1, b_1)$ denotes the generalized exponential power distribution with density function

$$\pi(\lambda) \propto \lambda^{2a_1-1} e^{-b_1\lambda^2} I_{(\lambda>0)}$$

where a_0, b_0, a_1, b_1 are chosen to reflect prior knowledge about α and λ.

The likelihood function of α and λ for the given complete sample $\mathbf{X} = (X_1, X_2, \ldots, X_n)$ can be expressed as:

$$L(\alpha, \lambda|\mathbf{x}) \propto \alpha^n \lambda^{2n} \exp\{n \overline{\ln x} - n\lambda^2 \overline{x^2} - (\alpha - 1)D_n(\lambda)\}, \tag{12}$$

where $D_n(\lambda) = -\sum_{i=1}^n \ln(1 - e^{-(\lambda x_i)^2})$, $\overline{\ln x} = \frac{1}{n}\sum_{i=1}^n \ln x_i$ and $\overline{x^2} = \frac{1}{n}\sum_{i=1}^n x_i^2$. By combining (11) and (12), we obtain the joint posterior density of α and λ

$$\pi(\alpha, \lambda\,|\mathbf{x}) \propto h_\lambda(a_1 + n, b_1 + n\overline{x^2})\, g_\alpha(a_0 + n, D_n(\lambda) + b_0) \exp\{D_n(\lambda)\},$$

where g_α denotes the gamma density for α and h_λ denotes the generalized exponential power density for λ. The marginal posterior density of λ is given by

$$\pi(\lambda\,|\mathbf{x}) \propto h_\lambda(a_1 + n, b_1 + n\,\overline{x^2})\; W(\lambda), \tag{13}$$

where $W(\lambda) = (D_n(\lambda) + b_0)^{-(a_0+n)} \exp\{D_n(\lambda)\}$. From (13) and using importance sampling, we can express the Bayes estimate of λ as

$$E(\lambda|x) = \frac{E^{(1)}[\lambda\; W(\lambda)]}{E^{(1)}[W(\lambda)]},$$

where $E^{(1)}$ denotes the expectation with respect to $GEP(a_1 + n, b_1 + n\;\overline{x^2})$.

Since the marginal posterior density of α given λ and $\mathbf{x}$ is $g_\alpha(a_0 + n, D_n(\lambda) + b_0)$, the marginal posterior of α is equal to $E_{\lambda|\mathbf{x}}[g_\alpha(a_0 + n,\, D_n(\lambda) + b_0)]$, it follows that

$$\pi(\alpha|x) = \frac{E^{(1)}[W(\lambda)\, g_\alpha(a_0 + n, D_n(\lambda) + b_0)]}{E^{(1)}[W(\lambda)]}.$$

Using the fact that $E(\alpha\,|\,\lambda, \mathbf{x}) = (a_0 + n)/(D_\lambda + b_0)$, we obtain the Bayes estimate of α as

$$E(\alpha|x) = \frac{E^{(1)}[W(\lambda)\,(a_0 + n)/(D_n(\lambda) + b_0)]}{E^{(1)}[W(\lambda)]}.$$

If X follows GR(α, λ), then

$$E(X^2) = \frac{1}{\lambda^2}\left(\psi(\alpha + 1) - \psi(1)\right),$$

and

$$E(X^4) - (E(X^2))^2 = \frac{1}{\lambda^4}\left(\psi'(1) - \psi'(\alpha + 1)\right).$$

Here $\psi(.)$ and $\psi'(.)$ denote the digamma and polygamma functions, respectively. Let us define U and V as follows:

$$U = \frac{1}{n}\sum_{i=1}^n x_i^2, \quad V = \frac{1}{n}\sum_{i=1}^n x_i^4 - U^2.$$

The method of moment's estimator (MME) of α can be obtained as the solution of the following non-linear equation:

$$\frac{V}{U^2} = \frac{\psi'(1) - \psi'(\alpha + 1)}{(\psi(\alpha + 1) - \psi(1))^2}.$$

We denote the estimate of α as $\hat{\alpha}_{MME}$. Once $\hat{\alpha}_{MME}$ is obtained, we obtain the MME of λ, say $\hat{\lambda}_{MME}$ as

$$\hat{\lambda}_{MME} = \sqrt{\frac{\psi(\hat{\alpha}_{MME} + 1) - \psi(1)}{U}}.$$

It is not possible to obtain exact variances of $\hat{\alpha}_{MME}$ and $\hat{\lambda}_{MME}$. The asymptotic variances of $\hat{\alpha}_{MME}$ and $\hat{\lambda}_{MME}$ can be obtained from the normality asymptotic property of these estimates.

For other methods of estimation, one may refer to Kundu and Raqab (2005).

Generalized Weibull Distributions

Chin Diew Lai
Professor in Statistics
Massey University, Palmerston North, New Zealand

Introduction

The ▶Weibull distribution has been found very useful in fitting reliability, survival and warranty data and thus it is one of the most important continuous distributions in applications. A drawback of the Weibull distribution as far as lifetime analysis is concerned, is the monotonic behavior of its hazard (failure) rate function. In real life applications, empirical hazard rate curves often exhibit non-monotonic shapes such as a bathtub, upside-down bathtub (unimodal) and others. Thus there is a genuine desire to search for some generalizations or modifications of the Weibull distribution that can provide more flexibility in lifetime modelling.

Let T be the lifetime random variable with $f(t)$, $F(t)$ being its probability density function (pdf) and cumulative distribution function (cdf), respectively.

The hazard rate (failure rate) function is defined as

$$h(t) = \frac{f(t)}{1-F(t)} = \frac{f(t)}{R(t)}, \tag{1}$$

where $R(t) = 1 - F(t)$ is the reliability or survival function of T. The cumulative hazard rate function is defined as

$$H(t) = \int_0^t h(x)dx. \tag{2}$$

It is easy to show that the reliability function can be expressed as

$$R(t) = e^{-H(t)}. \tag{3}$$

It is easy to see that the cumulative hazard rate function completely determines the lifetime distribution and it must satisfies the following three conditions in order to yield a proper lifetime distribution:

(I) $H(t)$ is nondecreasing for all $t \geq 0$
(II) $H(0) = 0$
(III) $\lim_{t\to\infty} H(t) = \infty$.

We will see that (3) provides a convenient and important tool to construct Weibull-type lifetime distributions. Lai and Xie (2006, Chapter 3) gives a comprehensive account on Weibull related distributions.

Standard Weibull Distribution

The standard Weibull distribution is given by

$$R(t) = \exp(-\lambda t^{\alpha}), \quad \lambda, \alpha > 0;\ t \geq 0. \tag{4}$$

It follows from (3) that $H(t) = \lambda t^{\alpha}$. By a simple differentiation, we obtain the hazard rate function $h(t) = \lambda\alpha t^{\alpha-1}$, which is increasing (decreasing) if $\alpha > 1$ ($\alpha < 1$). We now see that despite its many applications, the Weibull distribution lacks flexibility for many reliability applications. For other properties of the Weibull distribution, we refer our readers to Murthy et al. (2003) for details.

Generalizations

There are many ways to generalize a Weibull distribution. Indeed, we now have many such generalizations or extensions in the literature. There is no clear guideline upon which one may identify a distribution as a generalized Weibull distribution.

On the basis of how a lifetime distribution is generated, we now attempt to classify generalized Weibull distributions into seven classes although these classes are not necessarily mutually exclusive.

C1: Distributions arise from a transformation of the Weibull random variable X, such as (a) linear transformation, (b) power transformation, (c) non-linear transformation; (d) log transformation or (e) inverse transformation. For example, $Y = \log X$, then Y is a log Weibull (also known as the type 1 extreme value distribution). If $Y = X^{-1}$, then Y has an inverse Weibull distribution with $R(t) = 1 - \exp\{-\lambda t^{-\alpha}\}$, $t > 0$.

C2: Families of generalized Weibull distributions with two or more parameters that contains (4) as a special case. For example, the modified Weibull of Lai et al. (2003) with

$$R(t) = \exp\{-at^{\alpha}e^{\lambda t}\}, \lambda \geq 0,\ \alpha, a > 0,\ t \geq 0 \tag{5}$$

is such an example. For moments of the above distribution, see Nadarajah (2005).

C3: Families of distributions that converge to a standard Weibull or a generalized Weibull in C2 when one of their parameters tends to zero. For example, The generalized Weibull of Modhalkar et al. (1996) defined by survival function:

$$R(t) = 1 - \left[1 - \left(1 - \lambda\left(\frac{t}{\beta}\right)^{\alpha}\right)^{1/\lambda}\right], \alpha, \beta > 0;\ t \geq 0. \tag{6}$$

As $\lambda \to 0$, $R(t) \to \exp\left\{-\left(\frac{t}{\beta}\right)^{\alpha}\right\}$. Another example, the beta integrated distribution of Lai et al. (1998) with $R(t) = \exp\{-\alpha t^{\gamma}(1-dt)^{c}\}$. Set $c = \lambda/d$ and let $d \to 0$ we obtain the distribution given by (5).

C4: Power transformations of either the cumulative distribution function or the survival function of the Weibull or a generalized Weibull. For example, the exponentiated Weibull of Mudholkar and Srivastava (1993) and the generalized modified Weibull of Carrasco et al. (2008) are the two prime examples.

C5: The survival function of a generalized Weibull is a function of the survival function of the Weibull. For example, the distribution of Marshall and Olkin (1997) and the distribution of Hjorth (1980).

C6: Involving two or more Weibull distributions: (a) finite mixtures; (b) n-fold competing risk (equivalent to independent components being arranged in a series structure); (c) n-fold multiplicative models; and (d) n-fold sectional models. See Murthy et al. (2003) for further details. The class also includes mixtures of two different generalized Weibulls, for example, Bebbington et al. (2007b).

C7: The class of distributions that are expressed as in (3) with the cumulative hazard rate function having a simple form. Of course, this class contains many generalized Weibull distributions that appear in the literature.

Some Important Generalized Weibull Families

We now present several families that have relatively simple survival functions. In addition, they can give rise to non-monotonic hazard rate functions of various shapes such as bathtub, upside-down bathtub (unimodal), or a modified bathtub.

Generalized Modified Weibull Family

The distribution studied by Carrasco et al. (2008) has the survival function given by

$$R(t) = 1-(1-\exp\{-at^{\alpha}e^{\lambda t}\})^{\beta},\ \lambda \geq 0,\ \alpha, a > 0;\ \beta > 0;\ t \geq 0. \tag{7}$$

Clearly, it is a simple extension of the modified Weibull distribution of Lai et al. (2003) since (7) reduces to (5) when $\beta = 1$. In fact, it includes several other distributions such as type 1 extreme value, the exponentiated Weibull of Mudholkar and Srivastava (1993) as given in (11) below, and others. An important feature of this lifetime distribution is its flexibility in providing hazard rates of various shapes.

Generalized Weibull-Gompertz Distribution

Nadarajah (2005) proposed a generalization of Weibull with four parameters having survival function given as below:

$$R(t) = \exp\{-at^{b}(e^{ct^{d}} - 1)\},\ a, d > 0;\ b, c \geq 0;\ t \geq 0. \tag{8}$$

Since it includes the Gompertz (or Gompertz-Makem) as its special case when $b = 0$, we may refer it as the generalized Weibull-Gompertz distribution. Clearly, it contains several distributions listed in Table 1 of Pham and Lai (2007). Again, it can prescribe increasing, decreasing or bathtub shaped hazard rate functions.

Generalized Power Weibull Family

Nikulin and Haghighi (2006) proposed a three-parameter family lifetime distributions

$$R(t) = \exp\{1-(1+(t/\beta)^{\alpha})^{\theta}\}, t \geq 0; \alpha, \beta > 0; \theta > 0. \tag{9}$$

Its hazard rate function $h(t)$ can give rise to increasing, decreasing, bathtub or upside-down bathtub shapes.

Flexible Weibull Distribution

Bebbington et al. (2007a) obtained a generalization of the Weibull having a simple and yet flexible cumulative hazard rate function H:

$$R(t) = \exp\{-(e^{\alpha t-\beta/t})\}; \alpha, \beta > 0; t \geq 0. \tag{10}$$

It was shown that F has an increasing hazard rate if $\alpha\beta > 27/64$ and a modified bathtub (N or roller-coaster shape) hazard rate if $\alpha\beta \leq 27/64$. Note that there are few generalized Weibull distributions that have this shape.

Exponentiated Weibull Family

Mudholkar and Srivastava (1993) proposed a simple generalization of Weibull by raising the cdf of the Weibull to the power of θ giving

$$R(t) = 1-[1-\exp(-t/\beta)^{\alpha}]^{\theta},\ t \geq 0;\ \alpha, \beta > 0,\ \theta \geq 0. \tag{11}$$

The distribution is found to be very flexible for reliability modelling as it can model increasing (decreasing), bathtub (upside-down) shaped hazard rate distributions.

Geometric and Negative Binomial Distributions

Adrienne W. Kemp
Honorary Senior Lecturer
University of St. Andrews, St. Andrews, UK

Introduction

The values of the probability mass function (pmf) for the *geometric* distribution are in geometric progression:

$$\Pr[X = x] = pq^x, \quad 0 < p < 1,\ q = 1 - p, \quad x = 0, 1, 2, \ldots. \tag{1}$$

It is the waiting time distribution that was studied by Pascal (1679) and Montmort (1713) concerning the number of failures (tails) in a sequence of throws of a coin before obtaining the first success (head) (p is the probability of a head).

The distribution is important in Markov chain models (see ►Markov Chains), e.g., in meteorological models for precipitation amounts and for weather cycles, in the estimation of animal abundance, in the analysis of runs of one botanical species in transects through mixtures of plants, and in surveillance for congenital malformations. Here it is sometimes called the *Furry* distribution.

The sum of $k = 1, 2, 3, \ldots$ geometric random variables, for example the waiting time for k heads in a sequence of throws of a coin, gives a *negative binomial* random variable. This approach enabled Montmort (1713) to solve the Problem of Points which was of intense interest in gambling circles at the time. Meyer (1879) used it to find the probability of x male births in a sequence of births containing a fixed number k of female births, assuming that the probability q of a male birth is constant. The distribution is sometimes called the *Pascal* distribution or *binomial waiting-time* distribution when k is an integer and the distribution is shifted k units from the origin to support $k, k + 1, \ldots$.

The pmf of the negative binomial distribution is

$$\Pr[X = x] = \binom{k + x - 1}{k - 1} p^k q^x, \quad 0 < p < 1,\ q = 1 - p, \quad x = 0, 1, 2, \ldots. \tag{2}$$

Whereas binomial pmf's are given by the terms of the binomial expansion $(1 - \pi + \pi)^n$, negative binomial pmf's are given by the terms of the negative binomial expansion

$p^k(1-q)^{-k} = p^k\left[1+kq+\frac{k(k+1)}{2}q^2+\cdots\right]$. The integer restriction on k is not necessary, provided that $k>0$.

A popular alternative parameterization takes $P=q/p$, i.e., $p=1/(1+P)$, giving the pmf

$$\Pr[X=x]=\binom{k+x-1}{k-1}\left(\frac{1}{1+P}\right)^k\left(\frac{P}{1+P}\right)^x, \quad P>0,\ k>0,\quad x=0,1,2,\ldots. \tag{3}$$

The probability generating function (pgf) is

$$G(z)=\left(\frac{1-q}{1-qz}\right)^k=(1+P-Pz)^{-k} \tag{4}$$

and the mean and variance are

$$\mu=k(1-p)/p=kP, \qquad \mu_2=k(1-p)/p^2=kP(1+P)>\mu. \tag{5}$$

The distribution is overdispersed. Taking $k=1$ gives the corresponding formulae for the geometric distribution.

A parameterization used in the ecological literature is $a=P, m=kP$, giving the pgf $(1+a-az)^{-m/a}$, and $\mu=m$, $\mu_2=m(1+a)$. This is equivalent to Cameron and Trivedi's (1986) NB1 model with $\lambda=kP$, $P=P$ giving $\mu=\lambda$, $\mu_2=\lambda(1+P)$, i.e., the variance is a linear function of the mean. For Cameron and Trivedi's NB2 model, $\lambda=kP$, $k=k$, giving $\mu=\lambda$, $\mu_2=\lambda+\lambda^2/k$, i.e., the variance is a quadratic function of the mean. The NB1 and NB2 models are used by econometricians for negative binomial regression when ▶Poisson regression for large data sets with explanatory variables is inadequate because it cannot handle overdispersion.

Derivations

The negative binomial distribution is both a mixed Poisson and a generalized Poisson distribution. Consider with Greenwood and Yule (1920) a mixture of Poisson distributions whose parameter θ has a ▶gamma distribution with probability density function

$$f(\theta)=\{\beta^\alpha\Gamma(\alpha)\}^{-1}\theta^{\alpha-1}\exp(-\theta/\beta), \quad \theta>0,\alpha>0,\beta>0.$$

Then the outcome is a negative binomial distribution

$$\Pr[X=x]=\{\beta^\alpha\Gamma(\alpha)\}^{-1}\int_0^\infty \theta^{\alpha-1}e^{-\theta/\beta}(\theta^x e^{-\theta}/x!)\,d\theta = \binom{\alpha+x-1}{\alpha-1}\left(\frac{\beta}{\beta+1}\right)^x\left(\frac{1}{\beta+1}\right)^\alpha. \tag{6}$$

The Poisson parameter θ represents the expected number of accidents for an individual; this is assumed to vary between individuals according to a gamma distribution. This "contagion" model has been applied, for example, to car accidents, personal injuries, aircraft failures, medical visits during spells of illness.

In the generalized Poisson derivation of Lüders (1934) and Quenouille (1949) the negative binomial distribution arises from the sum Y of a Poisson (θ) number N of independent random variables $X_1, X_2, \ldots, X_N$, all having the same logarithmic distribution with parameter λ. The pgf of Y is then

$$G(s)=\exp\left[\theta\left\{\frac{\ln(1-\lambda z)}{\ln(1-\lambda)}-1\right\}\right]=\left(\frac{1-\lambda}{1-\lambda z}\right)^{-\theta/\ln(1-\lambda)}. \tag{7}$$

This is called an *Arfwedson* process, also a *Poisson sum* (*Poisson-stopped sum*) of logarithmic rv's. It incorporates heterogeneity and has been used extensively to analyse ecological data, e.g., larval counts, plant densities, migration data.

A limiting form of the Pólya-Eggenberger urn model also yields the negative binomial distribution.

In ▶queueing theory the geometric distribution is the equilibrium queue-length distribution for the M/M/1 queue. The negative binomial is the equilibrium queue-length distribution for the M/M/1 queue given Bhat's (2002) form of balking.

Certain important ▶stochastic processes give rise to the negative binomial distribution, e.g., Yule's (1925) simple birth process with nonzero initial population, Kendall's (1948) simple birth-death-and-immigration process with zero initial population, McKendrick's (1914) time-homogeneous birth-and-immigration process with zero initial population, Lundberg's (1940) nonhomogeneous process with zero initial population known as the *Pólya* process, and Kendall's (1948) nonhomogeneous birth-and-death process with zero death rate.

Because it arises in so many ways the negative binomial distribution is often used to analyse overdispersed data when no particular derivation is agreed upon, e.g., haemocytometer counts, consumer expenditure, product choice, lost sales, lending-library data, family sizes, DNA adduct counts. Given a good empirical fit to data, interpretation of the fit can be problematical.

Properties

The characteristic function (cf) is

$$G(e^{it})=\left(\frac{1-q}{1-qe^{it}}\right)^k=(1+P-Pe^{it})^{-k}. \tag{8}$$

The factorial ▶moment generating function is $(1-Pt)^{-k}$, giving

$$\mu'_{[r]} = \frac{(k+r-1)!}{(k-1)!}P^r, \quad r = 1, 2, \ldots, \tag{9}$$

and the factorial cumulant generating function is $-k\ln(1-Pt)$, giving $\kappa_{[r]} = k(r-1)!P^r$, $r = 1, 2, \ldots$. Replacement of n by $(-k)$ and π by $(-P)$ in the formulae for the moment properties of the binomial distribution gives the corresponding negative binomial formulae.

The uncorrected moment generating function is $p^k(1-qe^t)^{-k}$, the central moment generating function is $e^{-kqt/p}p^k(1-qe^t)^{-k}$, and the cumulant generating function is $k\ln p - k\ln(1-qe^t)$.

In particular

$$\begin{aligned}
\mu &= \kappa_1 = kP, \quad \mu_2 = \kappa_2 = kP(1+P) = \frac{kq}{p^2},\\
\mu_3 &= \kappa_3 = kP(1+P)(1+2P) = \frac{kq(1+q)}{p^3},\\
\mu_4 &= 3k^2P^2(1+P)^2 + kP(1+P)(1+6P+6P^2)\\
&= \frac{3k^2q^2}{p^4} + \frac{kq(p^2+6q)}{p^4},\\
\sqrt{\beta_1} &= \frac{1+2P}{\{kP(1+P)\}^{1/2}} = \frac{1+q}{\sqrt{kq}},\\
\beta_2 &= 3 + \frac{(1+6P+6P^2)}{kP(1+P)} = 3 + \frac{p^2+6q}{kq},
\end{aligned} \tag{10}$$

The index of dispersion is $p^{-1} = 1+P$; the coefficient of variation is $(kq)^{-1/2} = \{(1+P)/(kP)\}^{1/2}$.

From

$$\frac{\Pr[X=x+1]}{\Pr[X=x]} = \frac{(k+x)P}{(x+1)Q}, \quad Q = 1+P \tag{11}$$

it follows that $\Pr[X=x+1] < \Pr[X=x]$ if $x > kP-Q$, and $\Pr[X=x] \geq \Pr[X=x-1]$ if $x \leq kP-P$. Thus if $(k-1)P$ is not an integer, then there is a single mode at X where X is the integer part of $(k-1)P$; when $(k-1)P$ is an integer, then there are two equal modes at $X = (k-1)P$ and $X = kP-Q$. The mode is at $X = 0$ when $kP < Q$, i.e., $kq < 1$.

The generalized Poisson derivation implies that the distribution is infinitely divisible.

If $k<1$, then $p_x p_{x+2}/p_{x+1}^2 > 1$ (where $p_x = \Pr[X=x]$) and the probabilities are log-convex; if $k > 1$, then $p_x p_{x+2}/p_{x+1}^2 < 1$ and the probabilities are log-concave. These log-convexity/log-concavity properties imply that the distribution has a decreasing failure (hazard) rate for $k < 1$ and an increasing failure (hazard) rate for $k > 1$. For $k = 1$ the failure rate is constant. This no-memory (Markovian, non-aging) property characterizes the geometric distribution, making it a discrete analogue of the (continuous) exponential distribution. It is important in reliability theory; also it enables geometric random variables to be computer generated easily. For other characterizations of the geometric distribution and the comparatively few characterizations of the negative binomial distribution see Johnson et al. (2005).

If X_1 and X_2 are independent negative binomial random variables with the same series parameter q and power parameters k_1 and k_2, then $X_1 + X_2$ has a negative binomial distribution with pgf $(1+P-Pz)^{-k_1-k_2} = p^{k_1+k_2}(1-qz)^{-k_1-k_2}$. When $k \to \infty$ and $P \to 0$, with $kP = \theta$ constant, the negative binomial distribution tends to a Poisson distribution with parameter θ. It tends to normality when $kP \to \infty$.

Estimation

The parameter of the geometric distribution is easy to estimate; here the first moment equation is also the maximum likelihood equation and $\hat{P} = (1-\hat{p})/\hat{p} = \bar{x}$.

When both parameters of the negative binomial distribution are unknown there is a choice of estimation methods. For the *Method of Moments* the sample mean $\bar{x}$ and sample variance s^2 are equated to their population values, giving $\tilde{k}\tilde{P} = \bar{x}$ and $\tilde{k}\tilde{P}(1+\tilde{P}) = \sum(x-\bar{x})^2/(n-1) = s^2$, i.e., $\tilde{P} = s^2/\bar{x} - 1$ and $\tilde{k} = \bar{x}^2/(s^2-\bar{x})$.

In the *Method of Mean-and-Zero-Frequency* the observed and expected numbers of zero values are used as well as the first moment equation. Let f_0 be the proportion of zero values. Then the equations are $f_0 = (1+P^\dagger)^{-k^\dagger}$ and $k^\dagger P^\dagger = \bar{x}$, giving $P^\dagger/\ln(1+P^\dagger) = -\bar{x}/\ln f_0$; this can be solved for $P^\dagger$ by iteration.

The *Method of Maximum Likelihood* equations are

$$\hat{k}\hat{P} = \bar{x} \text{ and } \ln(1+\hat{P}) = \sum_{j=1}^{\infty}\left\{(\hat{k}+j-1)^{-1}\sum_{i=j}^{\infty}f_j\right\}; \tag{12}$$

their solution requires iteration but this may be slow if the initial estimates are poor. The importance of the negative binomial distribution has led to much research on its inference in the past 2 decades. This includes rapid estimation methods for the initial estimates, the properties of the maximum likelihood estimators, Bayesian estimation, computer studies of the relative efficiences of different estimation methods, and goodness-of-fit tests; see Johnson et al. (2005).

Geometric Mean

Stevan Stević
Professor, Faculty of Economics, Brčko
University of East Sarajevo, Republic of Srpska, Bosnia and Herzegovina

According to Sir Thomas Thomas Heath (1921, p. 85) in Pythagoras's time, there were three means, the arithmetic, the geometric, and the subcontrary, and the "name of the third ('subcontrary') was changed by Archytas and Hippasus to harmonic." In English, the term geometrical mean can be found as early as in 1695 in the E. Halley's paper (Halley 1695–1697, p. 62). The geometric mean is a measure of central tendency that is "primarily employed within the context of certain types of analysis on business and economics" (Sheskin 2004, p. 8), such as an average of ►index numbers, ratios, and percent changes over time. For example, Fisher "ideal index" is the geometric mean of the Laspeyres index and the Paasche index. Geometric mean is also being used in modern ►portfolio theory and investment analysis (see, for example, Elton et al. 2009, p. 231), and in calculation of compound annual growth rate.

The geometric mean of n positive numbers $x_1, x_2, ..., x_n$ is defined as positive nth root of their product:

$$\bar{x}_G = \sqrt[n]{x_1 \cdot x_2 \cdot \ldots \cdot x_n} = \left(\prod_{i=1}^{n} x_i \right)^{1/n} \tag{1}$$

For example, the geometric mean of two numbers, 4 and 9, is the square root of their product, i.e., $\bar{x}_G = \sqrt[2]{4 \cdot 9} = 6$. It is important to emphasize that the calculation of geometric mean is either insoluble or meaningless if a data set contains negative numbers.

The geometric mean given in (1) can be expressed in a logarithmic form as

$$\ln \bar{x}_G = \left(\frac{1}{n} \sum_{i=1}^{n} \ln x_i \right),$$

or

$$\bar{x}_G = \exp\left(\frac{1}{n} \sum_{i=1}^{n} \ln x_i \right).$$

Just like the arithmetic and harmonic means, the geometric mean is under influence of each observation in the data set. It has an advantage over the arithmetic mean in that it is less affected by very small or very large values in skewed data.

The arithmetic–geometric–harmonic means inequality states that for any positive real numbers $x_1, x_2, \ldots, x_n$

$$\bar{x} = \frac{x_1 + x_2 + \ldots + x_n}{n} \geq \bar{x}_G = \sqrt[n]{x_1 \cdot x_2 \cdot \ldots \cdot x_n} \geq \bar{x}_H = \frac{n}{\frac{1}{x_1} + \frac{1}{x_2} + \ldots + \frac{1}{x_n}} \quad (2)$$

In (2) equality holds if and only if all the elements of the data set are equal. Interested reader can find 74 different proofs of the above inequality in Bullen (1987).

Geostatistics and Kriging Predictors

Shigeru Mase
Professor
Tokyo Institute of Technology, Tokyo, Japan

What Is Geostatistics?

Spatial statistics deals with spatial data. Geostatistics can be considered as a branch of spatial statistics. Its main objective is to interpolate values of a random field continuously from its sparsely observed data.

In the 1950s, South African gold mining engineer D.G. Krige introduced several statistical methods to predict average gold mine grade. Inspired by his work, French mathematician G. Matheron initiated a regression-based spatial prediction method for random field data in 1960s. He coined the term *kriging* (or, more frequently, *Kriging*) for his method, rewarding Krige's pioneering work. Actually, the kriging is a central tool of geostatistics and has been used almost synonymously.

Started as a mining technology, geostatistics has become now an indispensable statistical tool for various application fields where main objects spread continuously over a space. Examples are environmental sciences, ecology, forestry, epidemiology, oceanology, agriculture, fishery research, meteorology, civil engineering, and so on.

Kriging Predictions

The probabilistic framework of geostatistics is a random field $Z(\mathbf{x})$, $\mathbf{x} \in D \subset \mathbf{R}^d$, the dimension d being two or three typically. The data is a collection of values $Z(\mathbf{x}_1), Z(\mathbf{x}_2), \ldots, Z(\mathbf{x}_n)$ where $\mathbf{x}_i \in D$ may be regularly spaced or not. In Krige's case, $\mathbf{x}_i$ are locations of boring cores and $Z(\mathbf{x}_i)$'s are corresponding gold grades. A kriging predictor $\widehat{Z}(\mathbf{x}_0)$ of the value $Z(\mathbf{x}_0)$ at arbitrary location $\mathbf{x}_0 \in D$ is a liner combination of observed data:

$$\widehat{Z}(\boldsymbol{x}_0) = w_1 Z(\boldsymbol{x}_1) + w_2 Z(\boldsymbol{x}_2) + \cdots + w_n Z(\boldsymbol{x}_n). \quad (1)$$

As a result, one can plot the contour of predicted surfaces $\widehat{Z}(\mathbf{x}_0)$, $\mathbf{x}_0 \in D$.

Actually, it is usual to assume the second-order stationarity of $Z(\mathbf{x})$, that is, (1) the mean $\mu = \mathbf{E}\{Z(\mathbf{x})\}$ is constant, and (2) the covariance function depends only on the location difference, i.e., $C(\mathbf{x} - \mathbf{y}) = Cov(Z(\mathbf{x}), Z(\mathbf{y}))$. Coefficients $\{w_i\}$ of (1) are determined so that the mean squared kriging prediction error $\sigma_E^2(\mathbf{x}_0) = \mathbf{E}|\widehat{Z}(\mathbf{x}_0) - Z(\mathbf{x}_0)|^2$

$$\sigma_E^2(\boldsymbol{x}_0) = C(\mathbf{0}) - 2\sum_{i=1}^{n} w_i C(\boldsymbol{x}_0 - \boldsymbol{x}_i) + \sum_{i,j=1}^{n} w_i w_j C(\boldsymbol{x}_i - \boldsymbol{x}_j) \quad (2)$$

should be minimized under the unbiasedness condition $\mathbf{E}\{\widehat{Z}(\mathbf{x}_0)\} = \mu$, that is,

$$\sum_{i=1}^{n} w_i = 1. \quad (3)$$

A fortiori, the kriging predictor recovers the original data at every $\mathbf{x}_0 = \mathbf{x}_i$, $i = 1, 2, \ldots, n$. By the way, from a historical reason, the word "estimator" instead of "predictor" is preferred in the literature.

In geostatistical literature, the notion of the *intrinsic* stationarity has been preferred to the second-order stationarity. A random field Z is said to be intrinsic stationary if (1) $\mathbf{E}\{Z(\mathbf{x}) - Z(\mathbf{y})\} = 0$ and (2) $\mathbf{E}|Z(\mathbf{x}) - Z(\mathbf{y})|^2$ depends only on the difference $\mathbf{x} - \mathbf{y}$. The function $\gamma(\mathbf{h}) = \mathbf{E}|Z(\mathbf{x} + \mathbf{h}) - Z(\mathbf{x})|^2/2$ is called the *(semi-)variogram* of Z. Note that it is not assumed the existence of $\mathbf{E}\{Z(\mathbf{x})\}$. If Z is second-order stationary, then it is intrinsic stationary and there is the relation

$$\gamma(\boldsymbol{h}) = C(\mathbf{0}) - C(\boldsymbol{h}).$$

$\gamma(\mathbf{x})$ is non-negative, even and $\gamma(0) = 0$. Variogram functions may be unbounded contrary to covariance functions. Its characteristic property is the *conditional non-positive definiteness*: for every $\{\mathbf{x}_i\}$ and $\{w_i\}$ with $\sum_i w_i = 0$

$$\sum_{i,j=1}^{n} w_i w_j \gamma(\boldsymbol{x}_i - \boldsymbol{x}_j) \le 0.$$

In terms of variogram functions, the kriging prediction error can be expressed as

$$\sigma_E^2(\boldsymbol{x}_0) = -\gamma(\mathbf{0}) + 2\sum_{i=1}^{n} w_i \gamma(\boldsymbol{x}_i - \boldsymbol{x}) - \sum_{i,j=1}^{n} w_i w_j \gamma(\boldsymbol{x}_i - \boldsymbol{x}_j) \quad (4)$$

if the unbiasedness condition (3) is satisfied. The use of variograms instead of covariances intends to eliminate possible linear trends.

The followings are three frequently used covariance function models. They are all isotropic models, that is, depend only on the modulus $h = |\mathbf{h}|$:

spherical model
$$C_{sph}(h) = \begin{cases} b\left(1 - \dfrac{3|h|}{2a} + \dfrac{|h|^3}{2a^3}\right) & (0 \le |h| \le a) \\ 0 & (a < |h|) \end{cases},$$

exponential model
$$C_{exp}(h) = b\exp(-|h|/a) \quad (a, b > 0),$$

Gaussian model
$$C_{gau}(h) = b\exp(-h^2/a) \quad (a, b > 0).$$

The parameter a is called the *range*, from which values of the function are exactly or nearly equal to zero. The parameter b is called the *sill*, the maximal value of the function. Sometimes covariance functions have jumps at 0 showing a *nugget effect*, a pure random noise.

Kriging Equations

There are three types of standard kriging predictors:

1. Simple kriging: The common mean μ is assumed to be known.
2. Ordinary kriging: The common mean μ is assumed to be unknown.
3. Universal kriging: The mean function (trend) $\mu(\mathbf{x})$ is assumed to be a linear combination of given basis functions (say, spatial polynomials).

For example, coefficients $\{w_i\}$ of the ordinary kriging predictor are calculated by solving the following ordinary kriging equation (if expressed in terms of variograms):

$$\begin{pmatrix} \gamma(\boldsymbol{x}_1 - \boldsymbol{x}_1) & \dots & \gamma(\boldsymbol{x}_1 - \boldsymbol{x}_n) & 1 \\ \vdots & \ddots & \vdots & \vdots \\ \gamma(\boldsymbol{x}_n - \boldsymbol{x}_1) & \dots & \gamma(\boldsymbol{x}_n - \boldsymbol{x}_n) & 1 \\ 1 & \dots & 1 & 0 \end{pmatrix} \begin{pmatrix} w_1 \\ \vdots \\ w_n \\ \lambda \end{pmatrix} = \begin{pmatrix} \gamma(\boldsymbol{x}_1 - \boldsymbol{x}_0) \\ \vdots \\ \gamma(\boldsymbol{x}_n - \boldsymbol{x}_0) \\ 1 \end{pmatrix} \quad (5)$$

where λ is the Lagrange multiplier for the constraint $\sum_i w_i = 1$. The prediction error $\sigma_E^2(\mathbf{x}_0)$ is expressed as:

$$\sigma_E^2(\boldsymbol{x}_0) = -\gamma(\mathbf{0}) + \lambda + \sum_{i=1}^{n} w_i \gamma(\boldsymbol{x}_i - \boldsymbol{x}_0). \quad (6)$$

Block Kriging

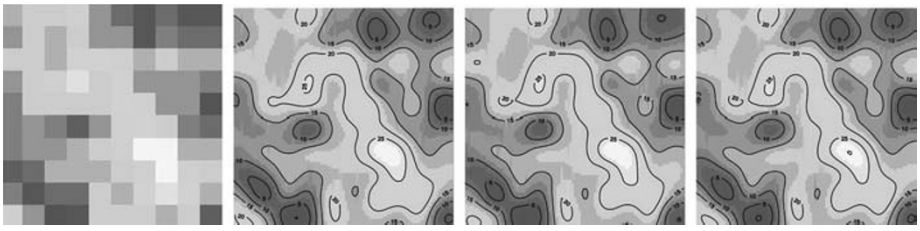
Sometimes, one wants to predict spatial averages

$$Z(D_0) = \frac{1}{|D_0|}\int_{D_0} Z(\boldsymbol{x})d\boldsymbol{x}$$

for a block D_0. The corresponding *block kriging* predictor $\widehat{Z}(D_0)$ is also an unbiased linear combination of point data $\{Z(\mathbf{x}_i)\}$. Note that, if Z has a constant mean μ, then $Z(D_0)$ has also the mean μ. Furthermore,

$$Cov(Z(D_0), Z(\boldsymbol{x})) = \frac{1}{|D_0|}\int_{D_0} Cov(Z(\boldsymbol{x}), Z(\boldsymbol{y}))d\boldsymbol{y}. \quad (7)$$

One can derive the simple or ordinary block kriging equation and its prediction error formula analogously as in (5) and (6).



Geostatistics and Kriging Predictors. Fig. 1 Mesh data of populations of Tokyo metropolitan area (1,000/km^2), block-to-point kriging result using the spherical model, the exponential model, and the Gaussian model from left to right

Actually, one can consider following four situations:

point-to-point kriging: $\widehat{Z}(\boldsymbol{x}_0) = \sum_{i=1}^n w_i Z(\boldsymbol{x}_i)$

point-to-block kriging: $\widehat{Z}(D_0) = \sum_{i=1}^n w_i Z(\boldsymbol{x}_i)$

block-to-point kriging: $\widehat{Z}(\boldsymbol{x}_0) = \sum_{i=1}^n w_i Z(D_i)$

block-to-block kriging: $\widehat{Z}(D_0) = \sum_{i=1}^n w_i Z(D_i)$

The standard procedure to derive kriging predictor coefficients is almost the same, at least formally, except for numerical difficulties. For example, the block-to-point or block-to-block kriging equations contain a lot of block data covariances such as

$$Cov(Z(D_i), Z(D_j)) = \frac{1}{|D_i||D_j|} \iint_{D_i \times D_j} Cov(Z(\boldsymbol{x}), Z(\boldsymbol{y}))d\boldsymbol{x}d\boldsymbol{y}.$$

as well as (7) which should be computed using numerical integrations (see ►Numerical Integration). Figure 1 shows a block-to-point prediction result (Mase et al. (2009)).

Covariance or Variogram Model Fittings

In order to apply the kriging method, one has to estimate the type and the parameters (usually the mean, the range, and the sill) of covariance or variogram models. This model fitting is the most difficult part of the kriging method. The standard method is the least squared fitting of an isotropic variogram model $\gamma_\theta(h)$ to the scatter plot (sample variogram) of $(|\mathbf{x}_i - \mathbf{x}_j|, |Z(\mathbf{x}_i) - Z(\mathbf{x}_j)|^2)$ called the *variogram cloud*. In practice, distances $|\mathbf{x}_i - \mathbf{x}_j|$ are classified into small consecutive intervals and corresponding values $|Z(\mathbf{x}_i) - Z(\mathbf{x}_j)|^2$ are averaged per intervals in order to increase robustness.

Another method is the maximum likelihood fitting of a covariance function model $C_\theta(\mathbf{h})$ assuming the Gaussianity of random field $Z(\mathbf{x})$. This procedure needs no data grouping and can be applied even to non-isotropic models. Let Z be a second-order stationary Gaussian random field with mean μ and covariance function $C_\theta(\mathbf{x})$. Then the data vector $\mathbf{Z} = (Z(\mathbf{x}_1), \cdots, Z(\mathbf{x}_n))^t$ is Gaussian with mean vector $\mu = (\mu, \cdots, \mu)^t$ and covariance matrix $\Sigma_\theta = (C_\theta(\mathbf{x}_i - \mathbf{x}_j))_{ij}$. Therefore, the log-likelihood of $\mathbf{Z}$ is

$$l(\mu, \theta) = -\frac{n}{2}\log(2\pi) - \frac{1}{2}\log|\Sigma_\theta| - \frac{1}{2}(\boldsymbol{Z} - \boldsymbol{\mu})^t \Sigma_\theta^{-1}(\boldsymbol{Z} - \boldsymbol{\mu}).$$

By maximizing $l(\mu, \theta)$, we can get the maximum likelihood estimators of μ and θ.

Multivariate Kriging Method

Sometimes there may be an auxiliary random field data $\{Z_2(\mathbf{y}_j)\}$ (or even more) in addition to the main data $\{Z_1(\mathbf{x}_i)\}$. Locations $\{\mathbf{x}_i\}$ may or may not be identical to $\{\mathbf{y}_j\}$. If we assume the second-order stationarity of the multivariate random field $(Z_1(\mathbf{x}), Z_2(\mathbf{x}))$, we can construct the *cokriging* predictor $\widehat{Z}_1(\mathbf{x}_0)$ as

$$\widehat{Z}_1(\boldsymbol{x}_0) = \sum_i w_i^{(1)} Z_1(\boldsymbol{x}_i) + \sum_j w_j^{(2)} Z_2(\boldsymbol{y}_j).$$

Two sets of coefficients $\{w_i^{(1)}\}$ and $\{w_j^{(2)}\}$ can be determined as before. If the number of auxiliary data is too large, one can lessen the resulting numerical complexity by restricting $\{Z_2(\mathbf{y}_j)\}$ to those closer to $\mathbf{x}_0$. In particular, the *collocated* kriging uses only $Z_2(\mathbf{x}_0)$ if it is available as data.

Glivenko-Cantelli Theorems

Olimjon Shukurovich Sharipov
Professor
Uzbek Academy of Sciences, Tashkent, Uzbekistan

The Glivenko-Cantelli Theorem

Let $X_1, \ldots, X_n, \ldots$ be a sequence of independent identically distributed (i.i.d.) random variables with a common distribution function $F(x)$. Introduce the empirical distribution function:

$$F_n(x) = \frac{1}{n}\sum_{i=1}^{n} I\{X_i < x\}$$

where $I\{\cdot\}$ is the indicator function. By the strong law of large numbers (SLLN) for any fixed point $x \in R$, we have

$$F_n(x) \to F(x) \text{ a.s., as } n \to \infty$$

The Glivenko-Cantelli theorem states that this convergence is uniform.

Theorem 1 *(Glivenko-Cantelli): As* $n \to \infty$

$$\sup_{x \in R} |F_n(x) - F(x)| \to 0 \text{ a.s.}$$

Theorem 1 was proved by V.I. Glivenko Birkhoff (1931) in the case of continuous $F(x)$ and by F.P. Cantelli Borovkov (1998) in the general case. In mathematical statistics, the Glivenko-Cantelli theorem can be interpreted as follows based on independent observations $x_1, \ldots, x_n$ of the random variable ξ one can approximate the distribution function $F(x)$ of ξ arbitrarily close by the empirical distribution function:

$$\overline{F}_n(x) = \frac{1}{n}\sum_{i=1}^{n} I\{x_i < x\}.$$

This is a very important fact. Because of this fact, the Glivenko-Cantelli theorem is commonly referred to as a central or fundamental result of mathematical statistics.

The proof of the theorem is based on the SLLN (see, for instance Bradley (2007), Cantelli (1933)). The following extension of Theorem 1 is valid.

Theorem 2 *Let* $X_1, \ldots, X_n, \ldots$ *be a stationary and ergodic sequence of random variables with a common distribution function* $F(x)$. *Then as* $n \to \infty$

$$\sup_{x \in R} |F_n(x) - F(x)| \to 0 \text{ a.s.}$$

The proof of Theorem 2 is almost the same as the proof of Theorem 1 except for a single difference: instead of using SLLN in the proof of Theorem 1 one should use Birkhoff's ergodic theorem Dudley (1984). Theorem 2 remains true for all stationary sequences of mixing random variables (see for mixing conditions Dudley et al. (1991)) since such sequences are ergodic.

We can reformulate the Gllivenko-Cantelli theorem using empirical measures. Denote by $P(A)$ a distribution of X_1. The empirical distribution is defined as:

$$P_n(A) = \frac{1}{n}\sum_{i=1}^{n} I\{X_i \in A\}. \quad (1)$$

By $\mathcal{A}$ we denote a class of all semi intervals [a,b) with finite or infinite endpoints. The following result takes place.

Theorem 3 *Let* $X_1, \ldots, X_n, \ldots$ *be a sequence of i.i.d. random variables with the common distribution* $P(A)$. *Then as* $n \to \infty$

$$\sup_{A \in \mathcal{A}} |P_n(A) - P(A)| \to 0 \text{ a.s.}$$

Theorems 1 and 3 are equivalent since they imply each other.

For some improvements of the Glivenko-Cantelli theorem, such as the law of the iterated logarithm see, for instance Bradley (2007).

Generalizations of Glivenko-Cantelli Theorem

The Glivenko-Cantelli theorem gave a start to investigations on convergence of empirical measures and processes in finite and infinite dimensional spaces.

Let $X_1, \ldots, X_n, \ldots$ be a sequence of i.i.d. random vectors with values in R^k and with a common distribution function $F(t)$. Define the empirical distribution function as:

$$F_n(t) = \frac{1}{n}\sum_{i=1}^{n} I\left\{X_i^{(1)} < t_1, \ldots, X_i^{(k)} < t_k\right\}$$

where $X_i = \left(X_i^1, \ldots, X_i^k\right)$ and $t = (t_1, \ldots, t_k)$.

The generalization of Theorem 1 is the following.

Theorem 4 *As* $n \to \infty$

$$\sup_{t \in R^k} |F_n(t) - F(t)| \to 0 \ a.s.$$

Now by $P(B)$ we denote a distribution corresponding to distribution function $F(t)$ and by $\mathcal{B}$ a class of all measurable convex sets in R^k. The empirical distribution $P_n(B)$ is defined as in (1).

Theorem 5 *Let* $X_1, \ldots, X_n, \ldots$ *be a sequence of i.i.d. random variables with values in* R^k *and with the common distribution* $P(B)$*, which is absolutely continuous with respect to the Lebesque measure in* R^k*. Then as* $n \to \infty$

$$\sup_{B \in \mathcal{B}} |P_n(B) - P(B)| \to 0 \ a.s.$$

Theorem 5 is a consequence of results by Ranga Rao Glivenko (1933) (see also Appendix I in Bradley (2007)).

In infinite dimensional spaces the situation is more complicated. Now, assume that $(\mathcal{X}, \mathcal{C})$ is a measurable space and let $X_1, \ldots, X_n, \ldots$ be a sequence of i.i.d. random variables with values in $\mathcal{X}$ with a common distribution $P \in \mathcal{P}$ (here $\mathcal{P}$ is a set of all distributions on $\mathcal{X}$) and again we denote by $P_n(B)$ the empirical distribution defined as in (1).

In separable metric spaces $\mathcal{X}$, Varadarajan Ranga Rao (1962) proved almost surely weak convergence of empirical distributions, i.e., as $n \to \infty$

$$P_n(B) \to P(B) \text{ for all Borel sets } B \in \chi \text{ such that } P(\partial B) = 0 \ a.s.$$

where ∂B is a boundary of B.

In general, in infinite dimensional spaces uniform convergence is not valid even over the class of all half-spaces (see Sazonov (1963)). Generalizations of the Glivenko-Cantelli theorem in linear spaces $\mathcal{X}$ are mostly devoted to studying the almost certain convergence properties of the following two values:

$$\Delta(V) = \sup_{B \in V} |P_n(B) - P(B)|$$

$$\Delta(\mathcal{F}) = \sup_{f \in \mathcal{F}} |P_n(f) - P(f)|$$

where V is a class of sets, $\mathcal{F}$ is a class of functions $f : \mathcal{X} \to R$ and $P(f) = \int f dP$ for any distribution P.

Generalizing the Glivenko-Cantelli theorem several notions such as Glivenko-Cantelli class, universal Glivenko-Cantelli class, and uniform Glivenko-Cantelli class of sets or functions were introduced.

The class of sets V is called a Glivenko-Cantelli class of sets, if as $n \to \infty$ the following holds:

$$\Delta(V) \to 0 \ a.s. \tag{2}$$

The class of sets V is called a universal Glivenko-Cantelli class of sets, if (2) holds for any $P \in \mathcal{P}$.

The class of sets V is called a uniform Glivenko-Cantelli class of sets, if as $n \to \infty$ the following holds:

$$\sup_{P \in \mathcal{P}} \Delta(V) \to 0 \ a.s.$$

The corresponding classes for the sets of functions can be defined similarly.

One of the problems in infinite dimensional spaces is a measurability problem in non-separable spaces. We will give two theorems and in one of them this problem will appear. Before giving results we need to introduce necessary notions and notation.

We denote by $N(\varepsilon, \mathcal{F}, \|\cdot\|)$ the covering number, which is defined as the minimal number of balls $\{g : \|g - f\| < \varepsilon\}$ of radius ε needed to cover $\mathcal{F}$. Given two functions l and u, the bracket $[l, u]$ is a set of all functions f such that $l \le f \le u$. An ε-bracket is a bracket $[l, u]$ with $\|l - u\| < \varepsilon$. The minimum number of ε-brackets needed to cover $\mathcal{F}$ we denote by $N_{[]}(\varepsilon, \mathcal{F}, \|\cdot\|)$. Note that $\log N(\varepsilon, \mathcal{F}, \|\cdot\|)$ and $\log N_{[]}(\varepsilon, \mathcal{F}, \|\cdot\|)$ are called an ▸entropy and an entropy with bracketing, respectively. An envelope function of $\mathcal{F}$ is any function $F(x)$ such that $|f(x)| \le F(x)$ for any x and $f \in \mathcal{F}$. As a norm $\|\cdot\|$ we use a $L_1(P)$-norm i.e.

$$||f||_{L_1(P)} = \int |f| dP.$$

A class $\mathcal{F}$ of measurable functions $f : \mathcal{X} \to R$ on probability *space*$(\mathcal{X}, \mathcal{C}, \mathcal{P})$ is called P-measurable if the function

$$(X_1, \ldots, X_n) \to \sup_{f \in \mathcal{F}} \left| \sum_{i=1}^{n} e_i f(X_i) \right|$$

is measurable on the completion of $(\mathcal{X}^n, \mathcal{C}^n, P^n)$ for every n and every vector $(e_1, \ldots, e_n) \in R^n$. By P^* we denote the outer probability.

Now we can formulate the following theorems (for the proofs see Varadarajan (1958)).

Theorem 6 *Let* $\mathcal{F}$ *be a class of measurable functions such that* $N_{[]}(\varepsilon, \mathcal{F}, L_1(P)) < \infty$ *for every* $\varepsilon > 0$*. Then* $\mathcal{F}$ *is the Glivenko-Cantelli class.*

Theorem 7 *Let* $\mathcal{F}$ *be a P-measurable class of measurable functions with envelope F such that* $P^*(F) < \infty$*. Let* $\mathcal{F}_M$ *be the class of functions* $fI\{F \le M\}$ *when f range over* $\mathcal{F}$*. If* $\log N(\varepsilon, \mathcal{F}_M, L_1(P_n)) = o_{P^*}(n)$ *for every* ε *and* $M > 0$*, then as* $n \to \infty$

$$\Delta(\mathcal{F}) \to 0 \ P^* - a.s.$$

i.e., $\mathcal{F}$ *is the Glivenko-Cantelli class.*

For other results in infinite dimensional spaces we refer to Shorack and Wellner 1986; Dudley 1984; Dudley et al. 1991; Vapnik and Červoninkis 1971; Vapnik and Červoninkis 1981; Talagrand 1987; TØpsoe 1970; van der Vaart and Wellner 1996 (see also references therein).

Graphical Analysis of Variance

G. E. P. Box
Professor Emeritus
University of Wisconsin, Madison, WI, USA

Walter Shewhart said:

"Original data should be presented in a way that would preserve the evidence in the original data," (1939, p. 88).

Frank Anscombe said:

"A computer should make both calculation and graphs. Both kinds of output contribute to understanding," (1973, p. 17).

And Yogi Berra said:

"You can see a lot by just looking."

A Simple Comparative Experiment

As an illustration of graphical analysis of variance, Table 1a shows coagulation times for samples of blood drawn from 24 animals randomly allocated to four different diets A, B, C, D. Table 1b shows an ►analysis of variance for the data.

While the standard analysis of variance shown in Table 1b yielding F values and p values is very useful, the additional graphical analysis in Table 1c can lead to a deeper understanding. This is because it puts the brain of the experimenter in direct contact with the data. In the graphical analysis of variance of Table 1c the coagulation data are represented by dots. The residual dots are calculated and plotted in the usual way. However the plots of the deviations of the treatment means from the grand mean are multiplied by a scale factor. If ν_R is the degrees of freedom for the residuals and ν_T is the degrees of freedom for the treatment means, then the scale factor is $\sqrt{\frac{\nu_R}{\nu_T}}$ in this example $\sqrt{\frac{20}{3}} = 2.6$. The scale factor is such that if there were no differences between treatment means, the expected value of *natural* variance for the treatments would be the same as that for the residuals. By the natural variance is meant the sum of squares of the dot deviations divided by the *number* of dots (not the degrees of freedom). This measure of the spread is

appropriate because it is equated to what the eye *actually sees* (The ratio of natural variances of the dot plots produces the usual F-value). The analysis asks the question, "Might the scaled treatment deviations just as well be part of the noise?" In this example the treatment dot deviations −7.8, 5.2, 10.4 and −7.8 are obtained by multiplying the treatment deviations −3, +2, +4, −3 by 2.6. The graphical analysis supports the finding that the differences in the treatments are unlikely due to chance. But it does more. The graphical analysis helps the analyst appreciate the nature of the differences and similarities produced by the treatments, something that the ANOVA table does not do well. It also directs attention to the individual residuals and any large deviations that might call for further study. For this example it makes clear that there is nothing suspicious about the distribution of the residuals. Also that the treatments A and D are almost certainly alike in their effects but C is markedly different. Experimenters sometimes believe that a high level of significance necessarily implies that treatment effects are accurately determined and separated. The graphical analysis discourages overreaction to high significance levels, and reveals "very nearly" significant differences.

A Latin Square

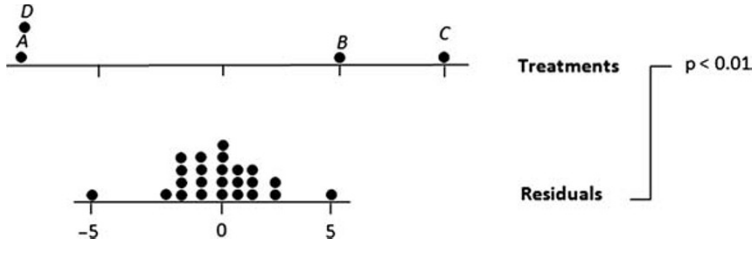
The following Latin square design was run to find out if the amount of carbon monoxide exuded by an automobile could be reduced by adding small amounts of additives A, B, C or D to the gasoline. The additives were tested with four different drivers and four different cars over a difficult fixed course. The design was used to help eliminate from the additive comparisons possible differences produced by drivers and cars. In this arrangement the additives were randomly allocated to the symbols A, B, C, D; the drivers to the symbols I, II, III, IV and the cars to the symbols 1, 2, 3, 4 as in Table 2a.

The standard analysis and the corresponding graphical analysis are shown in Table 2b, 2c. In this particular experiment, apparently there were differences between drivers but not between additives and cars.

A Split Plot Experiment

Two considerations important in choosing any statistical arrangement are convenience and efficiency. In industrial experimentation the split plot design is often convenient and is sometimes the only practical possibility. (The

Graphical Analysis of Variance. Table 1c Graphical Analysis of Variance



nomenclature is from agricultural experimentation where split plots were first used.) In particular this is so whenever there are certain factors that are difficult to change and others that are easy. Table 3a shows the data from an experiment designed to study the corrosion resistance of steel bars subjected to heat treatment with four different coatings C_1, C_2, C_3, C_4 arranged randomly within each of the six heats at furnace temperatures of 360, 370, 380, 380, 370, 360 °C. In this experiment changing the furnace temperature was difficult but re-arranging the positions of the coated bars in the furnace was easy. A fully randomized experiment would have required changing the temperature up to 24 times. This would have been very inconvenient and costly. Notice that there are two error sources - between heats (whole plots) and coatings (sub-plots).

The entries in the analysis of variance in Table 3b may be calculated as if there was no split plotting. Table 3c shows separately the analyzes for whole plots and sub-plots. They are conveniently arranged under two

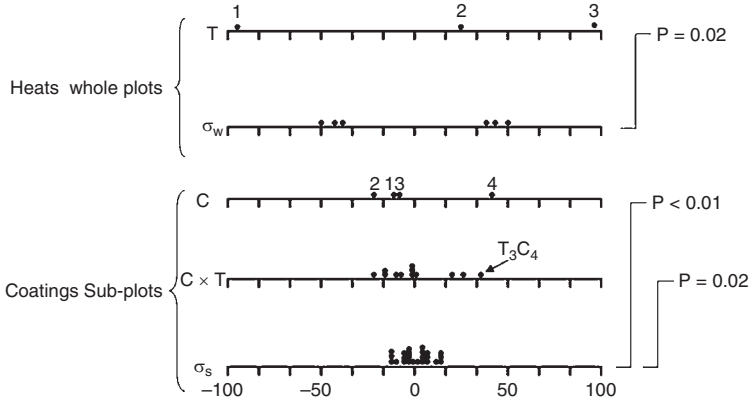
Graphical Analysis of Variance. Table 3c Graphical ANOVA, corrosion data



headings: Heats (whole plots) and Coatings (sub-plots). Notice the relatively small variances for coatings (sub-plots) as compared with that for heats (whole plots) and the detection of interaction between coatings and temperatures. This clearly shows the advantage of the split plot design since it was the comparison coatings that were of main interest.

About the Author

George Edward Pelham Box (born 18 October, 1919) was in Gravesend, Kent, England) was President of the American Statistical Association in 1978 and President of the Institute of Mathematical Statistics in 1979. He received his Ph.D. from the University College, London in 1953, under the supervision of Egon Pearson. He was employed as a statistician at Imperial Chemical Industries from 1948 to 1956, and from 1957 to 1959 he was Director of the Statistical Techniques Research Group at Princeton University. In 1960, he founded the Department of Statistics at the University of Wisconsin-Madison. In 1971 he was appointed Ronald Aylmer Fisher Professor of Statistics, and in 1980 he became Vilas Research Professor of Mathematics and Statistics, this being the highest honor that Wisconsin could bestow to a member of their faculty. He retired in 1992 and was given the title of Professor Emeritus by the University of Wisconsin. The importance of his fundamental contributions to many areas of statistics has been recognised by receiving many awards, among them the British Empire Medal in 1946, the Shewhart Medal from the American Society for Quality Control in 1968, the Wilks Memorial Award from the American Statistical Association in 1972, the R. A. Fisher Lectureship in 1974, the Guy Medal in Gold from the Royal Statistical Society in 1993 and the Deming medal in 1989, among others. He was elected a member of the American Academy of Arts and Sciences in 1974 and a Fellow of the Royal Society in 1985. Professor Box is very well-known for his work in Experimental Designs, Time Series, and Regression with his name on many important techniques including Box-Cox power transformation, Box-Jenkins time series models, Box-Muller transformation and Box-Behnken designs. He has also authored many well-known texts in time series and stochastic control, Bayesian statistics and experimental design and he invented the concept of evolutionary operation. He is a co-author (with Gwilym Jenkins) of the seminal book *Time Series Analysis: Forecasting and Control* (1970; Holden-Day). Professor Box holds four honorary doctorates.

"George Box, a legend in statistics, is one of the most respected living statisticians. His contributions to statistics are outstanding and he has made fundamental contributions in areas such as design and analysis of experiments, response surface methodology and time series analysis...Professor Box has created a school of industrial statisticians who span industry, academia and government; his followers are in every major corner of the world." (University of Waterloo, News Release, 80th Convocation, 2000, http://newsrelease.uwaterloo.ca/news.php?id=1408).

"All models are wrong, but some are useful. The quotation comes from George Box, one of the great statistical minds of the 20th century" (Ron Wasserstein "George Box: a model statistician", *Significance*, 7(3), 2010).

"George Box is truly one of the towering figures in the history of industrial experimentation" (Geoff Vining, "George's Contributions to Industrial Experimentation", *Quality and Productivity Research Conference*, Madison, 2008).

Graphical Markov Models

Nanny Wermuth
Professor of Statistics
Chalmers/University of Gothenburg, Gothenburg, Sweden

Graphical Markov models are multivariate statistical models which are currently under vigorous development and which combine two simple but most powerful notions, generating processes in single and joint response variables and conditional independences captured by graphs.

The development of graphical Markov models started in 1975–1980, extending early work in 1920–1930 by geneticist Sewall Wright. Wright used graphs, in which nodes represent variables and arrows capture dependence, to describe hypotheses about stepwise processes in single responses that could have generated his data.

He developed a method, called path analysis, to estimate linear dependences and to judge whether the hypotheses are well compatible with his data that he summarized in terms of simple and partial correlations. With this approach he was far ahead of his time, since corresponding formal statistical methods for estimation and tests of goodness of fit were developed much later and graphs that capture independences much later than tests of goodness of fit.

It remains a primary objective of graphical Markov models to uncover graphical representations that lead to an understanding of data generating processes. Such processes are no longer restricted to linear relations but contain linear dependences as special cases. A probabilistic data generating process is a recursive sequence of conditional distributions in which response variables may be vector variables that contain discrete or continuous components. Thereby, each conditional distribution specifies both the type of dependence of response Y_a, say, on its disjoint explanatory variable vector Y_b and the type of undirected associations of the components of Y_a.

Graphical Markov models generalize sequences in single responses and single explanatory variables that have been named ►Markov chains, after probabilist Andrey A. Markov. Markov recognized in 1900–1910 that seemingly complex joint probability distributions may be radically simplified by using the notion of conditional independence.

In a Markov chain of random variables $Y_1, \ldots, Y_i, \ldots, Y_d$, the joint distribution is built up by starting with the density of f_d of Y_d, by considering with $f_{d-1|d}$ conditional dependence of Y_{d-1} on Y_d, then taking conditional independence of Y_{d-2} from Y_d given Y_{d-1} into account by formulating $f_{d-2|d-1,d} = f_{d-2|d-1}$, by continuing such that, with $f_{i|i+1,\ldots d} = f_{i|i+1}$, response Y_i is conditionally independent of $Y_{i+2}, \ldots, Y_d$ given Y_{i+1} (written compactly in terms of nodes as $i \perp\!\!\!\perp \{i+2, \ldots, d\} | i+1$) and finally having with $f_{1|2,\ldots,d} = f_{1|2}$ just Y_2 as explanatory variable of response Y_1.

The directed graph that captures the independences in such a Markov chain is a single directed path of arrows, with an arrow starting at node d and pointing to node $d-1$ and ending with an arrow starting at node 2 and pointing

to node 1. Thus, for $d = 5$ and node set $N = \{1, 2, 3, 4, 5\}$, the graph of a Markov chain is

$$1 \longleftarrow 2 \longleftarrow 3 \longleftarrow 4 \longleftarrow 5.$$

The graph corresponds to the factorization of the joint density f_N given by

$$f_N = f_{1|2} f_{2|3} f_{3|4} f_{4|5} f_5.$$

The three defining local independence statements implied by the above factorization or by the corresponding path of dependences are $1 \perp\!\!\!\perp \{3, 4, 5\}|2$, $2 \perp\!\!\!\perp \{4, 5\}|3$ and $3 \perp\!\!\!\perp 5|4$. One also says that in the generating process, each response i remembers of its past just the nearest neighbor $i + 1$.

It remains an important secondary objective of graphical Markov models, that some type of graph is to capture the independence structure of interest for f_N, that is a set of all independence statements satisfied by f_V and that is implied by a given graph. In principle, all independence statements that arise from a given set of statements defining a graph, may be derived from basic laws of probability. Thus, the above Markov chain implies for instance

$$1 \perp\!\!\!\perp 4|3, \quad \{1, 2\} \perp\!\!\!\perp \{4, 5\}|3, \quad \text{or} \quad 2 \perp\!\!\!\perp 4|\{1, 3, 5\}.$$

For many variables, methods formulated for graphs alone considerably simplify the task of deciding whether an independence statement is implied or not. These are called separation criteria; see Geiger et al. (1990), Lauritzen et al. (1990) and Marchetti and Wermuth (2009) for criteria on directed acyclic graphs.

Directed acyclic graph are the most direct generalization of Markov chains. They have an ordered sequence of single nodes representing responses that may generate f_N, but each response may remember any subset or all of the variables in its past. Directed acyclic graphs are known as Bayesian networks when the node set consists of discrete random variables that correspond to features of observable units, but it may also include decisions or parameters.

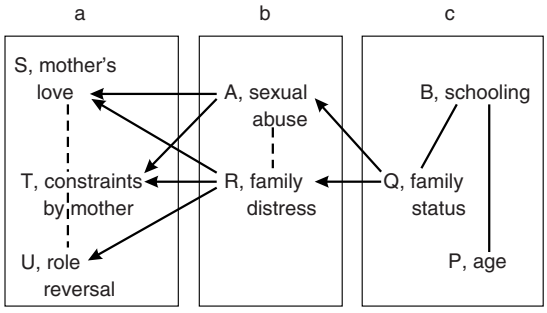
For ordered sequences of vector responses, the graphs are chains of joint responses and the associations and independences of the individual components of each response are represented by undirected edges being present or missing; see Cox and Wermuth (1993, 1996), Lauritzen (1996), Edwards (2000), Drton (2009), Marchetti and Lupparelli (2010), Wermuth and Cox (2004), Whittaker (1990).

The following small example of a well-fitting multivariate regression chain is for a set of data of Jochen Hardt, University of Mainz, on $n = 283$ adult, female patients who agreed to be interviewed at the offices of their general practitioners about different aspects of their childhood. Variables A, B are binary, the others are based on quantitative measurements. Each of Y_a and Y_c have three components and Y_b has two.

The graph is constructed after checking for nonlinear and interactive effects by using the results of a sequence of linear and logistic regressions (see ▶Logistic Regression). These show that the estimated dependencies, not displayed here, are in the direction hypothesized by the researchers. The background variable Y_c does not improve prediction of Y_a given the more specific information about childhood of Y_b.

The resulting factorization is $f_N = f_{a|b} f_{b|c} f_c$. The independences defining the regression chain graph are $S \perp\!\!\!\perp U|\{a, b\}$, $a \perp\!\!\!\perp c|b$, $b \perp\!\!\!\perp BP|Q$ and $Q \perp\!\!\!\perp P|B$, where relations within a are modeled using a covariance graph, those within b using a concentration graph.

For a complete linking of chain graphs and corresponding densities f_N, it is necessary to assure that independence statements satisfied by f_N combine in the same way as for the graphs. This requires special additional properties of the graphs, of the process by which the joint densities f_N are generated or directly of f_V; for discussions of special properties see Dawid (1979), Lauritzen (1996), Studený (2005), Kang and Tian (2009), San Martin et al. (2005), Wermuth (2010).



It is the outstanding feature of many graphical Markov models that consequences of a given model can be derived, for instance regarding implications after marginalizing over some variables, in set M, or after conditioning on others, in set C. In particular, graphs can be obtained for node set $N' = N/\{C, M\}$ which capture precisely the independence structure implied by a generating graph in node set N for $f_{N'|C}$ the density of Y'_N given Y_C, of the distribution of the variables in the reduced node set N'.

Such graphs are named independence-preserving, when they can be used to derive the independence structure that would have resulted from the generating graph by conditioning on a larger node set $\{C, c\}$ or by marginalizing over a larger node set $\{M, m\}$.

Three corresponding types of independence-preserving graphs are known which result from a given generating directed acyclic graph by using the same sets C, M:

graphs of the much larger class of MC-graphs of Koster (2002), maximal ancestral graphs (MAGs) of Richardson and Spirtes (2002) and summary graphs of Wermuth (2010); see Sadeghi (2009) for a proof of Markov equivalence that is for showing that the three corresponding but different types of graph capture the same independence structure.

More importantly, graphical criteria on the summary graph show when a generating conditional dependence of Y_i on Y_k, say, in f_N remains undistorted in $f_{N'|C}$ parametrised, as in a MAG model, in terms of conditional dependences within N' and when it be may be severely distorted; see also Wermuth and Cox (2008). Some of these distortions cannot be avoided for generating processes with randomized allocation of individuals to the levels of Y_k, but possibly by changing C or M. Thus, these results are relevant for controlled clinical trials, for meta analyzes and, more generally, for the planning stage of studies designed to replicate some of the given results of a larger study using a subset of the variables or a subpopulation.

More results on Markov equivalence, on estimation and goodness of fit tests, more direct applications as well as uses of the results concerning distortions and causal interpretations of graphical Markov models are expected in the near future; see also Drton et al. (2009), Cox (2007), Cox and Wermuth (2004). Comparative evaluations will be needed of alternative computational methods that are in use now for very large sets of data; see Balzarini (2007), Edwards et al. (2010), Dobra (2009), Meinshausen and Buhlmann (2006), Wainwright and Jordan (2008).

Handling with Missing Observations in Simple Random Sampling and Ranked Set Sampling

Carlos N. Bouza Herrera[1], Dante Covarrubias Melgar[2], Zoila Fernández[3]
[1]Professor
Universidad de La Habana, Habana, Cuba
[2]Universidad Autónoma de Guerrero, Mexico City, Mexico
[3]Professor
Universidad Católica del Norte, Antofagasta, Chile

Nonresponse in Simple Random Sampling

The existence of missing observations is a very important aspect to be considered in the applications of survey sampling; see Rueda and González (2004) for example. In human populations they may be motivated by a refusal of some interviewed persons to give the true value of Y. Hansen and Hurwitz (1946) proposed to select a subsample among the nonrespondents; see Cochran (1977). This feature depends heavily on the proposed subsampling rule. Alternative sampling rules to Hansen–Hurwitz's rule have been proposed; see for example Srinath (1971) and Bouza (1981). Theoretically, we deal with a particular case of double sampling (DS). It is described, when the sampling design is simple random sampling, as follows:

Step 1 Select a sample s from U and evaluate Y among the respondents (determine $\{y_i : i \in s_1 \subset U_1,\ |s_1| = n_1\}$).

Step 2 Determine $n_2' = \theta n_2$, $0 < \theta < 1$; $|s_2| = n_2$ with $s_2 = s \backslash s_1$.

Step 3 Select a subsample s_2' of size n_2' from s_2 and evaluate Y among the units in s_2' $\{y_i : i \in s_2' \subset s_2,\ s_2 \subset U_2\}$.

Step 4 Compute $\bar{y}_1 = \dfrac{\sum_{i=1}^{n_1} y_i}{n_1}$, $\bar{y}_1' = \dfrac{\sum_{i=1}^{n_2'} y_i}{n_2}$, and the estimate of μ $\bar{y} = \dfrac{n_1}{n}\bar{y}_1 + \dfrac{n_2}{n}\bar{y}_2' = w_1\bar{y}_1 + w_2\bar{y}_2'$.

This estimator is unbiased for the population mean. Using the techniques provided by double sampling (see Cochran 1977), the expected error of the estimator is given by $EV(\bar{y}) = \dfrac{\sigma^2}{n} + \dfrac{W_2(1-\theta)\sigma_2{}^2}{\theta}$. Commonly, Hansen–Hurwitz's rule is presented in textbooks (e.g., Cochran 1977), where $\theta = 1/K$ is the subsampling parameter and $EV(\bar{y}) = \dfrac{\sigma^2}{n} + \dfrac{W_2(K-1)\sigma_2{}^2}{n}$.

For other designs the DS procedure is used, and particular alternative estimators, when missing observations are present, must be derived. See, for example, a proposal for product-type estimators in Bouza (2008).

Nonresponse in Ranked Set Sampling

An alternative sampling design is ranked set sampling (RSS). It was first proposed by McIntyre (1952). Volume 12 of the *Handbook of Statistics* dedicated a section to RSS; see Patil et al. (1994). The basic procedure of RSS works as follows:

Step 1 Select m samples of size m using *SRS* with replacement independently.

Step 2 Each unit in the $s_{(t)}$, $t = 1, \ldots, m$, is ranked and the ▶order statistics (OS) $Y_{(1:t)}, \ldots, Y_{(m:m)}$ measured.

Step 3 Repeat the procedure r times and compute $\sum_{j=1}^{r}\sum_{i=1}^{m} Y_{(i:i)j}/rm = \mu_{(s)}$.

Each sampled unit may be ranked without measuring Y using some judgment or an auxiliary variable. See David and Levine (1972). Note that we measure the OS of order t $(t = 1, \ldots, m)$ in each tth sample in each cycle $(j = 1, \ldots, r)$ but the ranks do not intervene in the selection of the sample. As the procedure is repeated r times the sample size is $n = rm$ and the estimator of the mean is unbiased. The error of it is $V[\mu_{(s)}] = \sum_{t=1}^{n}\sigma_{(i)}^2/n^2 = V[\mu_{(s)}] - \sum_{t=1}^{n}\Delta_{(i)}^2/n^2$, where $\mu_{(i)} - \mu = \Delta_{(i)}$. Hence, it is smaller than the error of $\bar{y}$.

In the presence of missing observations and the use of DS for dealing with the nonresponses, a subsample strategy is to select a subsample s_{12}' of size $m(i,2)$ from each s_{i2}, $i = 1, \ldots, r$. The development of the corresponding theory of

Miodrag Lovric (ed.), *International Encyclopedia of Statistical Science*, DOI 10.1007/978-3-642-04898-2,

DS for RSS can be consulted in Al-Saleh and Al-Kadiri (1996). Bouza (2002a) proposed to use

$$\mu_{rss(nr)} = \sum_{k=1}^{r} M(i)/r,$$

where

$$M(i) = w(i,2)\left[\sum_{u=1}^{m(i,2)} Y'(i,u)/m(i,2)\right] + w(i,1)\left[\sum_{u=1}^{m} Y^*(i,u)/m(i,1)\right].$$

Defining $w(i,t) = m(i,t)/m$, $Y'(i,u)$ as the value of Y in the uth unit of s'_{12}, and $Y^*(i,u) = y_{u(u)}$ if the unit with rank u in the u-ranked set responds and zero otherwise. The use of DS showed that the estimator is unbiased and that the expected variance is $EV[\mu_{rss(nr)}] = V + G$, where $V = \frac{\sigma^2}{n} + \frac{W_2(1-\theta)\sigma_2^2}{n\theta}$ and $G = \Delta_1 - \Delta_2$, defining $\Delta_1 = \sum_{j=1}^{m}(\mu_{(j)} - \mu)^2/m$ and $\Delta_2 = \sum_{i=1}^{r} E\left[\sum_{j=1}^{m(i,2)} (\mu_{(j)} - \mu)^2\right]/n$. Hence, the use of RSS is more accurate than the use os srswr also when the nonrespondent sample is subsampled for solving the existence of missing observations in the sample.

Other results in this line are in progress; see for example Bouza (2008).

About the Author

Professor Carlos Narciso Bouza Herrera obtained his doctorate at the University of Belgrade in 1978 (former Yugoslavia, now Serbia). He teaches at the Faculty of Mathematics and Computer Science at the University of Havana. He is the (co)author of over 50 publications that have appeared in Cuba, Mexico, Brazil, Venezuela, Spain, France, Germany, and Pakistan.

Harmonic Mean

Jasmin Komić
Professor, Faculty of Economics
Banja Luka, University of Banja Luka, Republic of Srpska, Bosnia and Herzegovina

In the time of Pythagoras, there were only three means (Bakker 2003; Brown 1975; Huffman 2005), the arithmetic, the geometric, and third that was called subcontrary, but the "name of which was changed to harmonic by Archytas of Tarentum and Hippasus and their followers, because it manifestly embraced the ratios of what is harmonic and melodic" (Huffman 2005, p. 164). The harmonic mean is a measure of location used mainly in particular circumstances – when the data consists of a set of rates, such as prices ($/kilo), speeds (mph), or productivity (output/manhour). lt is defined as the reciprocal of the arithmetic mean of the reciprocals of the values.

The harmonic mean of n numbers $x_1, x_2, \ldots, x_n$ is calculated in the following way:

$$\bar{x}_H = \frac{n}{\frac{1}{x_1} + \frac{1}{x_2} + \ldots + \frac{1}{x_n}} = \frac{n}{\sum_{i=1}^{n} \frac{1}{x_i}}.$$

As a simple example, the harmonic mean of three numbers, 2, 5, and 10 is equal to

$$\bar{x}_H = \frac{3}{\frac{1}{2} + \frac{1}{5} + \frac{1}{10}} = \frac{3}{\frac{8}{10}} = 3.75.$$

The harmonic mean in this example is less then the arithmetic mean, 5.67. This can be generalized by saying that for any data set that shows variability and does not contain zero value, the harmonic mean will always be smaller than both the arithmetic mean and the geometric mean (for the precise inequality statement see the entry ►Geometric Mean).

Like the arithmetic and geometric means, harmonic mean is based on all observations. If any value of the data set equals zero, the harmonic mean cannot be calculated. Harmonic mean is sensitive to ►outliers when they have much smaller values than the rest of the data, and largely insensitive to outliers that have much larger values than the other data (the reciprocal of a large number is small, and the reciprocal of a small number is large, relatively).

The interested readers are urged to consult Ferger (1931), Francis (2004), Haans (2008), and Hand (1994) about the problems and confusion with the proper usage of the harmonic mean. Probably they will support the following claim given by Ya-Lun Chou (1989) "Because of the absolute necessity of using the harmonic mean in some cases and the confusion between the application of the arithmetic and harmonic averages, the harmonic mean deserves more attention than it receives in most elementary textbooks."

It is important to notice that extreme care must be taken when averages of rates are calculated. Since a rate is always expressed in terms of the ratio of two units (e.g., miles/gallon or price/kg), the criterion for choosing between arithmetic and harmonic means can be stated as follows (Ferger 1931; Francis 2004):

1. *Harmonic* mean is appropriate if the rates are being averaged over *constant numerator* units.
2. *Arithmetic* mean should be used if the rates are being averaged over *constant denominator* units.

Example 1 We want to compare average productivity (in items/day) of two production lines which are both producing the same items. Following abovementioned rule, the arithmetic mean should be used if the productivity for each line is measured over, say, 1 day (i.e., the same time, thus making the denominator units constant for both lines). However, if the productivity for each line is measured over, say, the production of a single item (i.e., the same quantity, thus making the numerator units constant for both lines), the harmonic mean is appropriate.

Suppose that three workers, A, B, and C, in a textile factory can make 6, 5, and 4 T-shirts per hour, respectively. Their productivity can be recorded in either one of the following ways.

Format 1

Worker A: 6 per hour
Worker B: 5 per hour
Worker C: 4 per hour

Format 2

Worker A: 10 min per T-shirt
Worker B: 12 min per T-shirt
Worker C: 15 min per T-shirt

In the first format, it is only appropriate to use the arithmetic mean to find the average productivity since time (denominator in the rate expression items/h) is held as a constant. The question here is: what is the average output per 1 h? Therefore, the average productivity equals 5 (15/3) T-shirts per hour. This means, that if 5 T-shirts are produced, on average, the output of all three workers will be 15 T-shirts in an hour.

However, in the second format, production (nominator in unit/h) is treated as constant and time as a variable. According to the postulated rule, only the harmonic mean will reflect the true average productivity. Now the question is: what is the average time required to complete one unit of product? Thus,

$$\bar{x}_H = \frac{3}{\frac{1}{10} + \frac{1}{12} + \frac{1}{15}} = 12 \text{ min per T-shirt.}$$

Using the suggested rule, it is easy to solve the efficiency paradox introduced by David Hand (1994, see also Haans [2008]), where two groups of engineers are in disagreement about the average fuel efficiency of a set of cars. One group, coming from England, measured efficiency on a miles per gallon scale, the other, coming from France, on a gallons per mile scale. When the arithmetic means are applied to both rates, English and French engineers come to the illogical, opposite conclusions. The paradox disappears if the average of the data in the gallons per mile scale is calculated by the harmonic mean. The reason is that the numerator of the efficiency rate (gallon/mile) has to be treated as a constant, since the question is how many miles can be passed with a single gallon.

Hazard Ratio Estimator

Per Kragh Andersen
Professor
University of Copenhagen, Copenhagen, Denmark

In survival analysis, statistical models are frequently specified via the hazard function $\alpha(t)$. A simple model for the relation between the hazard functions in two groups (e.g., a treatment group 1 and a control group 0) is the *proportional hazards model* where

$$\alpha_1(t) = \theta\alpha_0(t), \tag{1}$$

and θ is the treatment effect. For a parametrically specified baseline hazard, $\alpha_0(t)$, both the treatment effect and the parameters in the baseline hazard are usually estimated using maximum likelihood. In a semi-parametric model where the baseline hazard is left unspecified several estimators for θ are available: the maximum partial likelihood estimator, cf. Cox (1972), a class of rank estimators, and some ad hoc estimators.

Assume that the available data are $(X_{ij}, D_{ij}; i = 1,\ldots,n_j, j = 0,1)$ where the X_{ij} are the times of observation: a failure time if the corresponding indicator D_{ij} is 1, a right-censoring time if D_{ij} is 0. The Cox estimator, $\widehat{\theta}$, is then the solution to the equation

$$O_1 = E_1(\theta) \tag{2}$$

where, for $j = 0,1$, $O_j = \sum_i D_{ij}$ and

$$E_1(\theta) = \sum_{ij} \frac{Y_1(X_{ij})\theta}{Y_0(X_{ij}) + Y_1(X_{ij})\theta} D_{ij}.$$

Here, $Y_j(t) = \sum_i I(X_{ij} \geq t)$ is the number at risk at time $t-$ in group $j, j = 0,1$. Notice that (2) expresses that for $\theta = \widehat{\theta}$, the observed number, O_1, of failures in group 1 should be equal to a corresponding "expected" number, $E_1(\theta)$ under the proportional hazards assumption.

A class of explicit "rank" estimators, discussed by Andersen et al. (1993, Chap. V) is, for a given *weight process* $L(t)$, given by

$$\widehat{\theta}_L = \frac{\sum_{i=1}^{n_1} L(X_{i1}) \frac{D_{i1}}{Y_1(X_{i1})}}{\sum_{i=1}^{n_0} L(X_{i0}) \frac{D_{i0}}{Y_0(X_{i0})}}. \tag{3}$$

For $L(t) = I(t \leq t^*)$, $\widehat{\theta}_L$ is simply the ratio between the Nelson-Aalen estimators for the cumulative hazards in groups 1 and 0 evaluated at t^*. The Cox estimator, $\widehat{\theta}$ given by (2) is always less dispersed than any $\widehat{\theta}_L$ given by (3). Using an estimator $\widehat{\theta}_L$ and its estimated variance, the hypothesis $\theta = 1$ of no treatment effect may be tested. This gives all the standard linear non-parametric two-sample tests for ▶survival data and, in particular, the weight process given by

$$L(t) = \frac{Y_0(t)Y_1(t)}{Y_0(t) + Y_1(t)},$$

gives the logrank test.

Another explicit ad hoc estimator, discussed by Breslow (1975), is given by

$$\widetilde{\theta} = \frac{O_1/E_1(1)}{O_0/E_0(1)}$$

with

$$E_0(\theta) = \sum_{ij} \frac{Y_0(X_{ij})}{Y_0(X_{ij}) + Y_1(X_{ij})\theta} D_{ij}.$$

The estimator $\widetilde{\theta}$ is generally inconsistent when $\theta \neq 1$ but it has gained some popularity due to its simplicity and close connection to the logrank test which is also based on the observed, O_0 and O_1, and expected, $E_0(1)$ and $E_1(1)$, numbers of failures.

Hazard Regression Models

Per Kragh Andersen
Professor
University of Copenhagen, Copenhagen, Denmark

In many applications of survival analysis the interest focuses on how *covariates* may affect the outcome. In clinical trials, adjustment of treatment effects for effects of other explanatory variables may be crucial if the randomized groups are unbalanced with respect to important prognostic factors, and in epidemiological cohort studies reliable effects of exposure may be obtained only if some adjustment is made for confounding variables. In these situations, a *regression model* is useful.

Most regression models for ▶survival data are set up via the *hazard function*, e.g., Andersen et al. (1993, Chap. VII), and the most important such model is the Cox (1972) *proportional hazards regression model*.

Cox Regression Model

In its simplest form the Cox model states the hazard function for an individual, i, with covariates $\boldsymbol{Z}_i = (Z_{i1}, \ldots, Z_{ip})'$ to be

$$\alpha_i(t; \boldsymbol{Z}_i) = \alpha_0(t) \exp(\boldsymbol{\beta}' \boldsymbol{Z}_i) \tag{1}$$

where $\boldsymbol{\beta} = (\beta_1, \ldots, \beta_p)'$ is a vector of unknown regression coefficients and $\alpha_0(t)$, the *baseline hazard*, is the hazard function for individuals with all covariates equal to 0. Thus, the baseline hazard describes the common shape of the survival time distributions for all individuals while the *hazard ratio* function $\exp(\boldsymbol{\beta}' \boldsymbol{Z}_i)$ gives the level of each individual's hazard. The interpretation of the parameter, β_j for a dichotomous $Z_{ij} \in \{0, 1\}$ is that $\exp(\beta_j)$ is the hazard ratio for individuals with $Z_{ij} = 1$ compared to those with $Z_{ij} = 0$ all other covariates being the same for the two individuals. Similar interpretations hold for parameters corresponding to covariates taking more than two values. The model is semi-parametric in the sense that the hazard ratio part is modeled parametrically while the baseline hazard is left unspecified.

Assume that the available data are $(X_i, D_i, \boldsymbol{Z}_i; i = 1, \ldots, n)$ where the X_i are the times of observation: a failure time if the corresponding indicator D_i is 1, a right-censoring time if D_i is 0. The regression coefficients $\boldsymbol{\beta}$ are then estimated by maximizing the *Cox partial likelihood*

$$L(\boldsymbol{\beta}) = \prod_{i=1}^{n} \left[\frac{\exp(\boldsymbol{\beta}' \boldsymbol{Z}_i)}{\sum_{j \in R_i} \exp(\boldsymbol{\beta}' \boldsymbol{Z}_j)} \right]^{D_i} \tag{2}$$

where $R_i = \{j : X_j \geq X_i\}$, the *risk set* at time X_i, is the set of individuals still alive and uncensored at that time. Furthermore, the cumulative baseline hazard $A_0(t)$ is estimated by the *Breslow estimator*

$$\widehat{A}_0(t) = \sum_{X_i \leq t} D_i / \sum_{j \in R_i} \exp(\widehat{\boldsymbol{\beta}}' \boldsymbol{Z}_j). \tag{3}$$

In large samples, $\widehat{\boldsymbol{\beta}}$ is approximately normally distributed with the proper mean and with a covariance which is estimated by the information matrix based on (2), see e.g., Andersen et al. (1993, Chap. VII). This means that approximate confidence intervals for the hazard ratio parameters can be calculated and that the usual large sample test statistics based on (2) are available. Also, the asymptotic distribution of the Breslow estimator is normal; however, this estimate is most often used as a tool for estimating *survival probabilities* for individuals with given covariates, $\boldsymbol{Z}_0$. Such an estimate may be obtained by the product integral $\widehat{S}(t; \boldsymbol{Z}_0)$ of $\exp(\widehat{\boldsymbol{\beta}}' \boldsymbol{Z}_0) \widehat{A}_0(t)$. The joint asymptotic distribution of $\widehat{\boldsymbol{\beta}}$ and the Breslow estimator then yields an approximate normal distribution for $\widehat{S}(t; \boldsymbol{Z}_0)$ in large samples.

A number of useful extensions of this simple Cox model are available. Thus, in some cases the covariates are time-dependent, e.g., a covariate might indicate whether or not a given event had occurred by time t, or a time-dependent covariate might consist of repeated recordings of some measurement likely to affect the prognosis. In such cases the regression coefficients $\boldsymbol{\beta}$ are estimated replacing $\exp(\boldsymbol{\beta}' \boldsymbol{Z}_j)$ in (2) by $\exp[\boldsymbol{\beta}' \boldsymbol{Z}_j(X_i)]$. Also a simple extension of the Breslow estimator (3) applies in this case.

Another extension of (1) is the stratified Cox model where individuals are grouped into strata each of which has a separate baseline hazard. This model has important applications for checking the assumptions of (1). The model assumption of proportional hazards may also be tested in a number of ways, the simplest possibility being to add interaction terms of the form $Z_{ij} f(t)$ between Z_{ij} and time where $f(t)$ is some specified function. Also various forms of residuals as for normal linear models may be used for model checking in (1). In (1) it is finally assumed that a quantitative covariate affects the hazard log-linearly. This

assumption may also be checked in several ways and alternative models with other hazard ratio functions $r(\boldsymbol{\beta}'\boldsymbol{Z}_i)$ may be used.

Other Hazard Models

Though the Cox model is the regression model for survival data which is applied most frequently, other hazard regression models, e.g., *parametric* regression models also play important roles in practice. Examples include models with a multiplicative structure, i.e., models like (1) but with a parametric specification, $\alpha_0(t) = \alpha_0(t;\boldsymbol{\theta})$, of the baseline hazard. A multiplicative model with important epidemiological applications is the *Poisson regression* model (see ►Poisson Regression) with a piecewise constant baseline hazard. In large data sets with categorical covariates this model has the advantage that a sufficiency reduction to the number of failures and the amount of person-time at risk in each cell defined by the covariates and the division of time into intervals is possible. This is in contrast to the Cox regression model (1) where each individual data record is needed when fitting the model.

An alternative to the multiplicative structure is provided by *additive hazard models* and the main such example is Aalen's additive model

$$\alpha_i(t;\boldsymbol{Z}_i) = \beta_0(t) + \boldsymbol{\beta}(t)'\boldsymbol{Z}_i. \tag{4}$$

Here, both the baseline hazard, $\beta_0(t)$ and the regression functions $\beta_1(t),\ldots,\beta_p(t)$ are left completely unspecified and estimated non-parametrically much like the Nelson-Aalen estimator. Semi-parametric versions of (4) also exist, that is models where some or all regression functions $\beta_j(t), j = 1,\ldots,p$, are constant. Such models, as well as more general and flexible models containing both (1) and (4) as special cases are discussed by Martinussen and Scheike (2006).

About the Author

Dr. Per Kragh Andersen is Professor of biostatistics at Department of Public Health, Section of Biostatistics, University of Copenhagen, Denmark. He was elected as member of ISI in 1990. He is an author or co-author of more than 300 publications, including the books *Statistical Analysis of Survival Data in Medical Research* (in Danish, 1984, with M. Vaeth), *Statistical Models Based on Counting Processes* (with Ø. Borgan, R.D. Gill and N. Keiding, Springer, 1993), *Survival and Event History Analysis* (with N. Keiding, editors, Wiley, 2006), *Regression with Linear Predictors* (Springer 2010, with L. T. Skovgaard). He is Past President of Danish Society of Theoretical Statistics and has been on the editorial boards of *Scandinavian Journal of Statistics*, *Statistical Methods in Medical Research*, *Statistics in Medicine*, *Biometrics* and *Lifetime Data Analysis*.

Heavy-Tailed Distributions

Raoul LePage
Professor
Michigan State University, East Lansing, MI, USA

Throw a ball fast enough toward the horizon and it falls into orbit. Run fast enough to infinity on the positive real axis carrying a bucket leaking probability and you create a heavy-tailed probability distribution (HTD). Sample an HTD and you encounter not one but an infinite supply of instances in which an observation far exceeds all predecessors. Defining this phenomenon mathematically is a matter of deciding how fast to run. Run too fast and you wind up with tails levering their probability so very far out that you wait through extremely many ordinary samples before encountering the next "big one" and its a whopper! The following definition, popular although not pleasing everyone, is slow enough to provide a rich source of HTD but fast enough to capture most of the desired properties.

Definition of HTD

A probability distribution specified through its cumulative distribution function F on the real line is heavy right-tailed if and only if for every $t > 0$ the ratio $\frac{1-F(x)}{e^{-tx}}$ has an infinite limit as x tends to infinity. Such an F has right-tail probabilities $1-F(x)$ decaying to zero ever more slowly than any exponential distribution. A probability distribution is heavy left-tailed if $F(-x)$ is heavy right-tailed.

A probability distribution is heavy-tailed if it is heavy-tailed in at least one direction. An interesting class of HTD has Pareto-like tails.

$$1 - F(x) \sim x^{-p}, \text{ as } x \to \infty \tag{1}$$

for some $p > 0$. Pareto distributions are the case $F(x) = 1 - x^{-p}$ for all $x > 1$. By comparison, for a standard normal distributed random variable Z we have $P(Z > z) \sim \frac{e^{-z^2/2}}{z}$ as z tends to infinity, definitely not heavy-tailed.

HTD in Actual Use

Many processes appear to occasionally but indefinitely produce far larger (or smaller) values than everything seen before, the much wilder market swing, the unusually heavy burst of Internet activity. This may be attributed to specific causes, e.g., growth of large pools of risky investments, but such pools may themselves be cause for market swings to behave as samples from HTD. Now alert to the possibilities we are witness to a great many examples of empirical data looking for all the world like HTD. Most of these examples come from data-rich applications such as financial transactions, communications, spatial data, and the like. Resnick (1997) is a serious undertaking of this kind.

The link between heavy-tailed distributions and the phenomenon of out-sized samples is sufficiently colorful to have inspired some tendency to heavy-tailed this and that. HTD may refer to a probability distribution on any space whose "tail" probabilities (in some sense) are large, or to a random process whose distribution is HTD. The term heavy-tailed is sometimes applied also to particular random processes incorporating time or spatial dependencies but nonetheless exhibiting outsized observations.

This outsized samples phenomenon may be studied from a sequential view (a running account of data arrivals) or instead through distributional results saying that for a large sample the data will likely exhibit outsized values.

Remarks

With HTD we are puzzling over ideas outside the more regular world of normal distributions and their spawn. New thinking is continually required. We see remarkable progress in these matters. There are features of heavy-tailed behavior that might be highlighted, among them the role of conditioning. A good example to raise this point is found in the stationary symmetric a stable (SaS) process defined by the following stochastic integral integral with respect to a symmetric alpha stable ($S\alpha S$) Lévy motion Z on the interval $[-\pi/2, \pi/2]$ with $0 < \alpha < 2$

$$X(t) = \int e^{it\lambda} \mathrm{d}Z(\lambda), \quad t \in \mathbb{R}.$$

Through a *series construction* of this integral one may build the jumps of $\mathrm{d}Z$ out of the consecutive arrivals of a unit rate Poisson process on the half line. If jumps of $\mathrm{d}Z$ are each multiplied by a standard normal deviate, these being independent and identically distributed independently of Z, the distribution of the process X is unchanged except for scale. If we then condition on the jumps of the original $\mathrm{d}Z$ the result is that process X has conditionally a stationary normal distribution (with discrete spectral measure). Utilizing this fact and Bayesian-like calculations it is found for $d > 0$ that the conditional expectations $E(X(t) \mid X(t-d))$ and $E(X^2(t) \mid X(t-d), X(t-2d))$ are both finite almost surely (LePage 1987 includes 1980). Such is the dependency in this particular heavy-tail process that even one or two observations remove heavy-tails from consideration. This shows us that unconditional distributions may not play quite the accustomed role in heavy-tailed processes, for as observations are brought into the picture it is not always just a matter of using them to form estimates to be plugged into unconditional distributions of interest. Returning to $S\alpha S$ in any dimension one has a similar conditionally normal construction. Bayesian-like thinking can produce good estimators and predictors amenable to ►Markov Chain Monte Carlo without the need to solve for stable densities as some practitioners attempt in these problems.

The foregoing example is closely tied with what might be termed "granularity" of heavy tail random phenomena. I refer here to the central role played by individual extremes and in particular their capacity not only shift a trajectory but to radically alter the random experience. An example would be a surge of water great enough to precipitate the opening of a channel, eventually to alter an entire watercourse. Such can be achieved by models rooted in normal distributions and kin, but the necessarily volatile variances needed in that approach may sometimes only prove a distraction as set against direct description via the jumpy Poisson-like moves of heavy tail models. The two approaches do however appear to overlap considerably and we may expect a continuing supply of insights from their continuing interaction.

Worth mentioning also are heavy tail models of small scale events, for if you think about it the whole line (or space) can be compressed into arbitrarily small intervals (or patches) carrying heavy tail phenomena along with them.

We seek ways to model these rarities, how and why they tend to come, whether isolated or clustered, how foretold, their influence on various random behaviors and how we are informed by theory relative to a host of practical questions.

Resources

As mentioned above, HTD are increasingly being studied in connection with applications as diverse as dispersal of contaminants, river flow, large financial movements, bursts of insurance claims, internet traffic surges, and bottlenecks in queuing systems. These mostly arise in large systems ripe for study in the information rich environment of today. What is emerging focuses on probability models whose random constituents have tails sufficiently heavy as to produce effects like those alluded to above. The main objectives cannot be perfectly organized, but permit me to include only a few from the many excellent sources:

(a) Understanding the properties of existing statistical models when random components are heavy tailed, in particular propagation of heavy tail behaviors through systems (Adler, Feldman, Gallagher 1998).
(b) Developing models to match behaviors seen in the applied contexts above, in particular periods of benign behavior punctuated by great excursions (Resnick 1997).
(c) Extending and adapting statistical methods with which to effectively fit and guide statistical inference in heavy-tailed models (Calder and Davis 1998) (LePage, Podgorski, Ryznar 1997).
(d) Learning how a potential for future instabilities might be recognized in a system currently benign but revealing its character through other behaviors (various forms of the Hill estimator, see Resnick 1997).
(e) Developing theories of extreme behavior transcending the perspectives of specialized models Resnick (2007).
(f) Discovering new classes of probability distributions issuing from models or solving mathematical problems by linking their solution to heavy tailed variants of familiar processes such as diffusions (Baeumer, Meeschaert, Nane 2009).

Heteroscedastic Time Series

Biljana Č. Popović
Head of Department for Mathematical Statistics and Applications, Faculty of Sciences and Mathematics
University of Niš, Niš, Serbia

The trade-off between return and risk plays an important role in many financial models such as ►Portfolio theory and option pricing. So, economic theories in time series usually have implications on the conditional mean dynamics of underlying economic variables as well as on the volatility as the measure of risk.

Many models that are commonly used in empirical finance to describe returns and volatility are linear. There are, however, indications that ►nonlinear models may be more appropriate (as it can be seen, for instance, in Franses and van Dijk 2000). In order to model real data, a nonconstant error variance has to be incorporated.

A model that allows the possibility of nonconstant error variance is called a heteroscedastic model. A model of this kind was defined by Engle (1982). He estimated the means and variances of inflation in the UK. (Engle mentioned heteroscedastic time series previously in his paper Engle (1980).) His approach was as follows.

If the random variable Y_t that describes the state of (economic) space is dependent on the previous state of space, its conditional density function will be $f(y_t|y_{t-1})$. The forecast of today's value based on the past information is $E(Y_t|Y_{t-1})$ and the variance of one-period forecast is $Var(Y_t|Y_{t-1})$. This means that the forecast may be a random variable.

Consider the first-order autoregression

$$Y_t = \gamma Y_{t-1} + \varepsilon_t, \quad t \in D,$$

where D is the set of integers and (ε_t) is a white noise with $Var(\varepsilon_t) = \sigma_\varepsilon^2$ for any $t \in D$. The unconditional mean of Y_t is zero, while the conditional mean is γY_{t-1}. The unconditional variance of Y_t is $\frac{\sigma_\varepsilon^2}{1-\gamma^2}$ and the conditional variance is σ_ε^2, and the more general class of models seems desirable.

A preferable model is

$$Y_t = \varepsilon_t \sigma_t$$
$$\sigma_t^2 = \alpha_0 + \alpha_1 Y_{t-1}^2,$$

with $E(\varepsilon_t) = 0$, $Var(\varepsilon_t) = 1$, and ε_t is independent of past realizations of Y_{t-i}, $i = 1, 2, \ldots$. This is an example of an autoregressive conditional heteroscedastic (ARCH) model. Specially, it is the ARCH(1) process. The variance function can be expressed more generally as

$$\sigma_t^2 = h(Y_{t-1}, Y_{t-2}, \ldots, Y_{t-p}, \boldsymbol{\alpha}),$$

where p is the order of the ARCH process and $\boldsymbol{\alpha}$ is a vector of parameters.

If we set the information set available at time t to be $\mathcal{F}_{t-1}$, i.e., $\mathcal{F}_{t-1}$ denotes the σ-field generated by $\{Y_{t-1}, Y_{t-2}, \ldots\}$, it will be

$$Var(Y_t|\mathcal{F}_{t-1}) = E\left(Y_t^2|\mathcal{F}_{t-1}\right) = \sigma_t^2 = \\ = \alpha_0 + \alpha_1 Y_{t-1}^2 + \alpha_2 Y_{t-2}^2 + \cdots + \alpha_p Y_{t-p}^2.$$

If the normal distribution is specified, we will have the conditional density

$$Y_t|\mathcal{F}_{t-1} \sim \mathcal{N}\left(0, \sigma_t^2\right).$$

The ARCH model has a variety of characteristics that make it attractive for economic applications in particular. For instance, a large error through Y_{t-i}^2 gives rise to the variance, which tends to be followed by another large error. This phenomenon of volatility clustering is common in many financial time series.

When the conditional density is normal (with zero mean), the ARCH model has the following properties.

The pth-order linear ARCH process, with $\alpha_0 > 0$, $\alpha_1, \ldots, \alpha_p \geq 0$, is the second-order stationary (covariance stationary) if and only if the associated characteristic equation has all roots outside the unit circle. The stationary variance is given by $E\left(Y_t^2\right) = \alpha_0 / \left(1 - \sum_{j=1}^p \alpha_j\right)$.

Besides this often used condition, the next necessary and sufficient condition for the second-order stationarity of Y_t is valid.

The same pth-order linear ARCH process is the second-order stationary if and only if

$$\alpha_1 + \cdots + \alpha_p < 1.$$

Also, the last equation is a sufficient condition for strict stationarity and ergodicity of Y_t. (For more details, see, for instance, Li et al. 2002.)

It may be desirable to test whether the ARCH model is an appropriate one. In that case the Lagrange multiplier test can be applied. Generally, for time series data, the presence of heteroscedasticity would be tested at first.

A natural generalization of the ARCH process is to allow for the past conditional variance in the current conditional variance equation. This kind of generalization was done independently by Bollerslev (1986) and Taylor (1986). It is named the generalized autoregressive conditional heteroscedastic time series (GARCH). Volatility of the GARCH(p, q) is defined by

$$\sigma_t^2 = \alpha_0 + \alpha_1 Y_{t-1}^2 + \alpha_2 Y_{t-2}^2 + \cdots + \alpha_q Y_{t-q}^2 \\ + \beta_1 \sigma_{t-1}^2 + \cdots + \beta_p \sigma_{t-p}^2,$$

where

$$p \geq 0, \quad q > 0$$
$$\alpha_0 > 0, \quad \alpha_i \geq 0, \quad i = 1, \ldots, q,$$
$$\beta_j \geq 0, \quad j = 1, \ldots, p.$$

The necessary and sufficient condition for the second-order stationarity of the GARCH(p, q) is

$$\sum_{i=1}^q \alpha_i + \sum_{j=1}^p \beta_j < 1.$$

Clearly, when $p = 0$, the model reduces to the ARCH(q).

It is important to note that the regions of strict stationarity of these models are, in general, much larger than those of the second-order stationarity. The necessary and sufficient conditions for the strong stationarity of GARCH also can be displayed.

To estimate the unknown parameters of the GARCH (ARCH), one can use the Gaussian quasi-maximum likelihood and sometimes some other methods like the least square estimator. Note that some numeric procedure is necessary when quasi-maximum likelihood is applied. Statistical properties of the estimators will depend on the model itself.

If

$$\sum_{i=1}^q \alpha_i + \sum_{j=1}^p \beta_j = 1,$$

we deal with the so-called integrated GARCH(p, q) or the IGARCH(p, q) process.

To accommodate the asymmetric relation between many financial variables and their volatility and to relax the restriction on the coefficients in the model, EGARCH (exponential GARCH) was proposed. It was done by

Nelson (1991). The conditional variance of this model satisfies the equation

$$\ln\left(\sigma_t^2\right) = \gamma + \sum_{j=0}^{\infty} \mu_j g(a_{t-1-j}),$$

where γ is a constant, $\mu_0 = 1$, $a_t = \frac{Y_t}{\sigma_t}$, and the function g is chosen to allow for asymmetric changes depending on the sign of a_t. The coefficients μ_j are often assumed to relate to an autoregressive moving average specification of the attached GARCH.

Sometimes the conditional mean $E(Y_t|\mathcal{F}_{t-1})$ is allowed to be a constant, i.e.,

$$Y_t = \mu + \varepsilon_t$$

along with a GARCH(p, q) model for the conditional variance

$$Var\left(Y_t|\mathcal{F}_{t-1}\right) = E\left(\varepsilon_t^2|\mathcal{F}_{t-1}\right) = \sigma_t^2$$
$$= \omega + \sum_{i=1}^{q} \alpha_i \varepsilon_{t-i}^2 + \sum_{j=1}^{p} \beta_j \sigma_{t-1-j}^2,$$

where $\omega > 0$, $\alpha_i \geq 0$, $\beta_j \geq 0$. In this model, the tendency for large (small) residuals to be followed by other large (small) residuals but of unpredictable sign is fulfilled.

Many real time series data have the fatter (heavier) tails than are compatible with the normal distribution. One possible way to model these data with GARCH is to use t-distribution.

Bollerslev (1987) set the GARCH allowing for conditionally t-distributed errors.

The normally conditionally distributed errors of the ARCH, and even in the GARCH, make the model leptokurtic. t-distribution makes it fatter tailed. Some mixtures of normal distributions are also used. Fitting the distribution of the error in the GARCH is a widely discussed theme.

To determine the order of the model, one can use the autocorrelation and partial autocorrelation functions of the data, or, better stilt, sample autocorrelation and sample partial autocorrelation functions.

The requirement of heteroscedastic time series is evident not only in economy but also in some other disciplines, for instance, in chemistry (Tsay 1987) and so on.

Nowadays, plenty of heteroscedastic time series can be seen, e.g., one dimensional and multidimensional, which together are usually called GARCH-Zoo.

Heteroscedasticity

Introduction

One of the classical linear regression model assumptions (see ►Linear Regression Models) is that random errors u_i have a common variance σ^2. That does not mean that each error observation has the same size, but simply that each error observation has the same probability distribution with zero mean and constant variance, σ^2. When this assumption is violated, we are talking about heteroscedasticity. It can be defined as a systematic pattern in errors, which means that errors are drawn from different probability distributions with different variances, that is,

$$\text{var}(u_i) = \sigma_i^2 \quad i = 1, 2, \ldots, n. \tag{1}$$

The heteroscedasticity that results as a violation of the above-mentioned assumption of the classical linear regression model is known as a *pure* heteroscedasticity. It occurs when the regression model is correctly specified. Another reason for heteroscedasticity could be the model specification error, especially when a variable is omitted. That kind

of heteroscedasticity is known as *impure* heteroscedasticity. In that case, the corrective measure would be to find and include that variable in the model.

The existence of different variances of random errors or the problem of heteroscedasticity is most common for cross-section data that include data with different sizes. The bigger the difference between sizes of dependent variable observations, the higher the probability that the random errors will have different variances, and therefore will be heteroscedastic.

Heteroscedasticity can take many different forms. The most common one is when the error variance is related to an exogenous variable Z. That variable could be some of the explanatory variables in the model, but it can be also some variable outside the model. In the regression model:

$$Y_i = \beta_0 + \beta_1 X_{1i} + \beta_2 X_{2i} + u_i, \quad (2)$$

the variance of the stochastic term u_i can be expressed as:

$$\text{var}(u_i) = \sigma_i^2 Z_i^2. \quad (3)$$

The variable Z is called the proportionality factor, since the value of the error variance is changing proportionally to the squared Z_i. The higher the value of Z for some observation, the higher the variance of error is. Usually Z is a measure of the size of each observation. Note that the heteroscedasticity is not only a characteristic which is strictly valid for cross-section data. For time series data that express trend in the movement of a dependent variable, it is logical to expect that there would be also a trend in the movement of the random error. The heteroscedasticity can also arise if there are big changes in the movement of the dependent variable. One of the reasons for heteroscedasticity could be a dramatic change in the quality of data collection.

Figure 1 illustrates the problem of heteroscedasticity. The probability density function $f(Y_3|X_3)$ at point X_3 shows that there is a high probability that Y_3 will be close to $E(Y_3)$. As we move towards point X_2, the probability density function is more spread $f(Y_2|X_2)$ that is, we are less sure where Y_2 could be found.

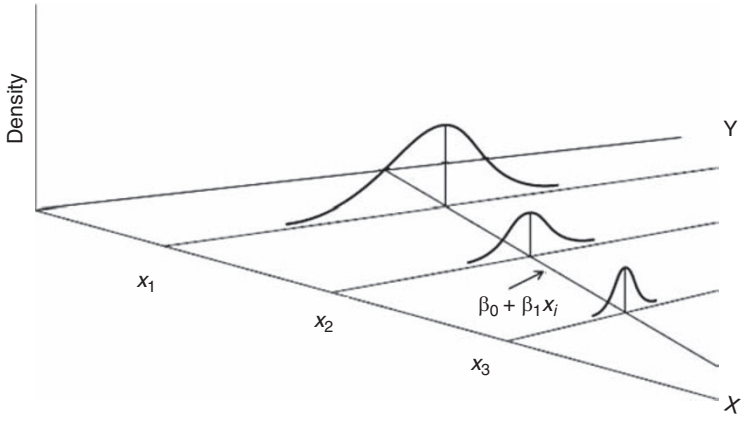
Consequences of Heteroscedasticity

- In the presence of pure heteroscedasticity, OLS estimators $\hat{\beta}$ remain unbiased, which means $E(\hat{\beta}) = \beta$. In other words, if we run regression many times using different data, then the average of all estimated $\hat{\beta}$ will give the real parameter value. However, in the case of impure heteroscedasticity, the consequences for the OLS estimators are more serious and OLS estimators are no longer unbiased.
- OLS estimators do not have the minimum variance anymore (they are not efficient).
- The standard errors of the OLS estimators computed in a usual way are incorrect and biased. This implies that confidence intervals and hypothesis tests that use these standard errors might be misleading.
- If the standard errors are biased, we cannot draw inferences based on *t* statistics or *F* statistics or *LM* statistics.

Detection of Heteroscedasticity

There are several tests that can be used to detect the presence of heteroscedasticity in the data. They can be divided into two groups:

1. Informal (graphical) test. This is a good starting point. The squared residuals are plotted against explanatory variables, or, in the case of the multiple regression model, against the dependent variable. If there is any



Heteroscedasticity. Fig. 1 Heteroscedastic errors

systematic pattern, it can be an indicator of possible heteroscedasticity.

2. Formal tests
   - *Park test*. It is designed for dealing with proportional heteroscedasticity. The Park test proceeds in the following way: the natural logarithm of the squared OLS residuals is regressed on the natural logarithm of the selected proportional factor (Z). With t-test we test the significance of the Z parameter and if it statistically significant, it is an evidence of heteroscedasticity.
   - *White test*. It is more general than the Park test. The test consists of regressing the squared residuals on all explanatory variables and their cross-products. This is an LM test, thus the test statistic is nR^2. The problem arises when the number of explanatory variables is large, thus leading to the problem of ►multicollinearity or even of loss of degrees of freedom, not to be able to estimate the model.
   - *Breusch–Pagan test*. It is very similar to White test, but it overcomes its shortcomings since the squared residuals are regressed on selected explanatory variables, those that cause the problem of heteroscedasticity.
   - *Goldfeld–Quandt test*. It orders the X observations in descending order and divides them into two subgroups, one with potential higher variance and the other one with potential smaller variance. Then the ratio of these two variances is calculated and compared to the critical value of F distribution.

The choice of the most appropriate test for heteroscedasticity is determined by how explicit we want to be about the form of heteroscedasticity.

Remedial Measures

As already stated, the problem with heteroscedasticity is that we cannot rely on the t-statistics, because the standard error estimators are biased. Various solutions are suggested for this problem:

1. The method of weighted least squares (WLS)
2. Obtaining heteroscedasticity-corrected standard errors
3. Redesigning the model

The WLS method can be used in the case when heteroscedasticity is caused by the proportionality factor, Z. It consists of the following steps:

1. Dividing each variable in the original regression model by the proportionality factor Z_i (this dividing will turn residuals into a white noise process u_i) and then, rerun the regression. The second regression model will not suffer from heteroscedasticity.

   For example, suppose we want to estimate the regression model (2) and the variance of the error term takes the form (3). Dividing the regression model by the proportionality factor Z_i, we obtain the following second regression model:

$$Y_i/Z_i = \beta_0/Z_i + \beta_1 X_{1i}/Z_i + \beta_2 X_{2i}/Z_i + u_i^* \qquad (4)$$

   The error term of the transformed regression model, u_i^*, has now a constant variance, and thus the regression model can be estimated by OLS.
2. The major problem, when using this method, consists of defining Z_i and choosing the functional form of Z_i, since different functional forms require different transformations. Wrong choice of the proportionality factor (or weight) can produce biased estimators of the standard errors. If Z_i is not any of the explanatory variables, then we must include a constant term in the above model, otherwise a constant is already included.

   We should be very cautious when interpreting the estimated coefficients of the model (4), since it can be noted that the coefficient β_1, which is a slope coefficient in model (2) now becomes an intercept in model (4). The opposite happens with coefficient β_0.

   Another problem related to WLS is the functional form of the relationship between proportionality factor and error variance. Until now, a direct proportionality of error variance to explanatory variable has been assumed. But, it is possible that error variance can be expressed as a linear relation of explanatory variables. Let's assume that this relation is:

$$\sigma_i^2 = \alpha_0 + \alpha_1 X_{1i}^2 + u_i^*. \qquad (5)$$

   Then, applying OLS we estimate the residuals from Eq. 5 as:

$$\hat{u}_i^{*2} = \alpha_0 + \alpha_1 X_{1i}^2. \qquad (6)$$

   Now, the weight is $\frac{1}{\sqrt{\hat{u}_i^{*2}}}$, and we divide all the variables in the original model with this weight. Finally, we test if the new error term is homoscedastic or not.

Obtaining heteroscedasticity-corrected standard errors is the most popular remedy, which improves the estimation of the standard errors using OLS coefficient estimates. It is very convenient when the form of heteroscedasticity is unknown.

The standard errors, as more accurate, are then used for recalculating the t-statistics using the same means taht remain unchanged. Typically, the corrected standard errors will be larger, thus leading to lower t-statistics. The

approach of corrected standard errors is the most suitable to large samples and is a part of some good statistical software packages. However, it does not work very well with small samples.

Acknowledgments

I would like to thank Professor John Chipman, Professor Badi Baltagi, and the editor for reading a draft of this article and providing me with comments and suggestions which resulted in many improvements.

Hierarchical Clustering

Fionn Murtagh
President of the British Classification Society
Director
Wilton Place, Dublin, Ireland
Professor
University of London, London, UK

Hierarchical clustering algorithms can be characterized as *greedy* (Horowitz and Sahni 1979). A sequence of irreversible algorithm steps is used to construct the desired data structure. Assume that a pair of clusters, including possibly singletons, is merged or agglomerated at each step of the algorithm. Then the following are equivalent views of the same output structure constructed on n objects: a set of $n - 1$ partitions, starting with the fine partition consisting of n classes and ending with the trivial partition consisting of just one class, the entire object set; a binary tree (one or two child nodes at each non-terminal node) commonly referred to as a dendrogram; a partially ordered set (poset) which is a subset of the power set of the n objects; and an ultrametric topology on the n objects. For background, the reader is referred to Benzécri et al. (1979), Lerman (1981), Murtagh and Heck (1987), Jain and Dubes (1988), Arabie et al. (1996), Mirkin (1996), Gordon (1999), Jain et al. (1999), and Xu and Wunsch (2005).

One could say with justice that Sibson (1973), Rohlf (1982) and Defays (1977) are part of the prehistory of clustering. Their $O(n^2)$ implementations of the single link method and of a (non-unique) complete link method have been widely cited.

In the early 1980s a range of significant improvements were made to the Lance-Williams, or related, dissimilarity update schema (de Rham 1980; Juan 1982), which had been in wide use since the mid-1960s. Murtagh (1983, 1985) presents a survey of these algorithmic improvements. The algorithms, which have the potential for *exactly* replicating results found in the classical but more computationally expensive way, are based on the construction of *nearest neighbor chains* and *reciprocal* or mutual NNs (NN-chains and RNNs).

A NN-chain consists of an arbitrary point (*a* in Fig. 1); followed by its NN (*b* in Fig. 1); followed by the NN from among the remaining points (*c*, *d*, and *e* in Fig. 1) of this second point; and so on until we necessarily have some pair of points which can be termed reciprocal or mutual NNs. (Such a pair of RNNs may be the first two points in the chain; and we have assumed that no two dissimilarities are equal.)

In constructing a NN-chain, irrespective of the starting point, we may agglomerate a pair of RNNs as soon as they are found. What guarantees that we can arrive at the same hierarchy as if we used traditional "stored dissimilarities" or "stored data" algorithms (Anderberg 1973)? Essentially this is the same condition as that under which no inversions or reversals are produced by the clustering method. This would be where s is agglomerated at a lower criterion value (i.e., dissimilarity) than was the case at the previous agglomeration between q and r. Our ambient space has thus contracted because of the agglomeration. This is due to the algorithm used – in particular the agglomeration criterion – and it is something we would normally wish to avoid.

Hierarchical Clustering. Fig. 1 Five points, showing NNs and RNNs

This is formulated as:

Inversion impossible if:

$d(i,j) < d(i,k)$ or $d(j,k) \implies d(i,j) < d(i \cup j,k)$

This is Bruynooghe's *reducibility property* (Bruynooghe 1977; see also Murtagh, 1985, 1992). Using the Lance-Williams dissimilarity update formula, it can be shown that the minimum variance method does not give rise to inversions; neither do the (single, complete, average) linkage methods; but the median and centroid methods cannot be guaranteed not to have inversions.

To return to Fig. 1, if we are dealing with a clustering criterion which precludes inversions, then c and d can justifiably be agglomerated, since no other point (for example, b or e) could have been agglomerated to either of these.

The processing required, following an agglomeration, is to update the NNs of points such as b in Fig. 1 (and on account of such points, this algorithm was dubbed *algorithme des célibataires,* the bachelors' algorithm, in de Rham 1980). The following is a summary of the algorithm:

NN-Chain Algorithm

Step 1 Select a point (i.e., an object in the input data set) arbitrarily.

Step 2 Grow the NN-chain from this point until a pair of RNNs are obtained.

Step 3 Agglomerate these points (replacing with a cluster point, or updating the dissimilarity matrix).

Step 4 From the point which preceded the RNNs (or from any other arbitrary point if the first two points chosen in Steps 1 and 2 constituted a pair of RNNs), return to Step 2 until only one point remains.

In Murtagh (1983, 1985) and Day and Edelsbrunner (1984), one finds discussions of $O(n^2)$ time and $O(n)$ space implementations of Ward's minimum variance (or error sum of squares) method and of the centroid and median methods. The latter two methods are termed the UPGMC and WPGMC criteria (respectively, unweighted and weighted pair-group method using centroids) by Sneath and Sokal (1973). Now, a problem with the cluster criteria used by these latter two methods is that the reducibility property is not satisfied by them. This means that the hierarchy constructed may not be unique as a result of inversions or reversals (non-monotonic variation) in the clustering criterion value determined in the sequence of agglomerations.

Murtagh (1984) describes $O(n^2)$ time and $O(n^2)$ space implementations for the single link method, the complete link method and for the weighted and unweighted group average methods (WPGMA and UPGMA). This approach is quite general vis à vis the dissimilarity used and can also be used for hierarchical clustering methods other than those mentioned.

Day and Edelsbrunner (1984) prove the exact $O(n^2)$ time complexity of the centroid and median methods using an argument related to the combinatorial problem of optimally packing hyperspheres into an m-dimensional volume. They also address the question of metrics: results are valid in a wide class of distances including those associated with the Minkowski metrics.

The construction and maintenance of the nearest neighbor chain as well as the carrying out of agglomerations whenever reciprocal nearest neighbors meet, both offer possibilities for parallelization, and implementation in a distributed fashion. Work in chemoinformatics and information retrieval can be found in Willett (1989), Gillet et al. (1998) and Griffiths et al. (1984). Ward's minimum variance criterion is favored.

For in depth discussion of data encoding and normalization as a preliminary stage of hierarchical clustering, see Murtagh (2005). Finally, as an entry point into the ultrametric view of clustering, and how hierarchical clustering can support constant time, or $O(1)$, proximity search in spaces of arbitrarily high ambient dimensionality, thereby setting aside Bellman's famous curse of dimensionality, see Murtagh (2004).

About the Author

Fionn Murtagh is a member of the Royal Irish Academy, and also Fellow of the International Association for Pattern Recognition, and a Fellow of the British Computer Society. He is President of the British Classification Society (2007 to date) and past President of the Classification Society of North America (2008–2009). He is a Fellow of the Royal Statistical Society and an elected member of the International Statistical Institute. He was Head of the Department of Computer Science, Royal Holloway, University of London (2004–2007). Apart from the University of London, he has held professorial chairs in computing in the past in Queen's University Belfast and the University of Ulster. His longest-serving appointment has been in the space sector, serving with the European Space Agency. He is currently directing Science Foundation Ireland's research funding programs in computing, engineering, telecommunications, mathematics, materials science, renewable energies and other fields. He takes particular pride in his doctoral genealogy, tracing back from his advisor, JP Benzécri, Henri Cartan (of Bourbaki) through Borel, Lebesgue, Poisson, Laplace, Lagrange, Euler, the Bernoullis, Leibniz, and Christiaan

Huygens (the last-mentioned playing a central role in the data analysis methodology of Benzécri.)

Hodges-Lehmann Estimators

Scott L. Hershberger
Global Director of Survey Design
Harris Intractive, New York, NY, USA

The *Hodges-Lehmann estimator* provides, in the one-sample case, an estimate of the center of a distribution, and in the two-sample case, an estimate of the difference in the centers of two distributions.

The one-sample estimator is defined as the *median* of the set of $n(n+1)/2$ *Walsh averages*. Each Walsh average is the arithmetic average of two observations. For example, consider the set of 5 observations $(1, 3, 8, 9, 15)$. Table 1 shows the computation of the $5(5+1/2) = 15$ Walsh averages.

The median of the Walsh averages is the one-sample Hodges-Lehmann estimator of the center of the distribution. In this example, the median of the 15 Walsh averages (the Hodges-Lehmann estimator) is 8. Note that in this case, the Hodges-Lehmann estimator is equal to the simple median of the original five observations, which is also 8. Of course, the Hodges-Lehmann estimator does not have to necessarily equal the sample median. While both the median and Hodges-Lehmann estimator are both preferable to the sample mean for nonsymmetric distributions, the Hodges-Lehmann estimator has larger asymptotic relative efficiency with respect to the mean than the median; i.e., 0.96 versus 0.64.

It possible to construct a $(1-\alpha)100\%$ *confidence interval* for the Hodges-Lehmann estimator. For an approximate $(1-\alpha)100\%$ confidence interval first find the value of $W_{\alpha/2}$ as the $100\alpha/2$ percentile of the distribution of the *Wilcoxon test statistic*. Then if $W_{\alpha/2} = K^*$, then the K^*th smallest to the K^*th largest of the Walsh averages

8	(8 – 2) = 6	(8 – 7) = 1	(8 – 10) = –2	(8 – 11) = –3	(8 – 12) = –4
9	(9 – 2) = 7	(9 – 7) = 2	(9 – 10) = –1	(9 – 11) = –2	(9 – 12) = –3
15	(15 – 2) = 13	(15 – 7) = 8	(15 – 10) = 5	(15 – 11) = 4	(15 – 12) = 3

determines the $(1-\alpha)$ 100% confidence interval. Values of $W_{\alpha/2}$ for finding approximate 90%, 95%, and 99% confidence intervals are found from readily available tables. For example, for the 15 Walsh averages given above, the 95% confidence interval for the Hodges-Lehmann estimator of 8 has a lower bound of 1 and upper bound of 15. For sample sizes of about 50 or more, K^* can be calculated approximately as

$$K^* = \frac{n(n+1)}{4} - \left(z_{1-\alpha/2} \times \sqrt{\frac{n(n+1)(2n+1)}{24}} \right),$$

rounded up to the next integer value, where $z_{1-\alpha/2}$ is the appropriate value from the standard normal distribution for the $(1-\alpha)$ 100% percentile.

The two-sample Hodges-Lehmann estimator is defined as the *median* of $n_1 \times n_2$ pairwise differences between samples X and Y, $y_j - x_k, j = 1, \ldots, n_1, k = 1, \ldots, n_2$. For example, consider the two samples, $x = (1, 3, 8, 9, 15)$ and $y = (2, 7, 10, 11, 12)$. Table 2 shows the computation of the 5×5 pairwise differences.

The median of the 25 pairwise differences is –2; thus the Hodges-Lehmann estimator of the center location difference between the two samples is –2. By comparison, the mean difference between the two samples is 36/5 – 42/5 = –1.2.

The confidence interval for the Hodges-Lehmann estimator of the center location difference is also based on the $n \times m$ pairwise differences. For an approximate $(1-\alpha)$ 100% confidence interval first calculate

$$K = W_{\alpha/2} - \frac{n_1(n_1+1)}{2},$$

where $W_{\alpha/2}$ is the $100\alpha/2$ percentile of the distribution of the *Mann-Whitney test statistic*. The Kth smallest to the Kth largest of the $n_1 \times n_2$ pairwise differences then determine the $(1-\alpha)$ 100% confidence interval. Values of $W_{\alpha/2}$ for finding approximate 90%, 95%, and 99% confidence intervals are found from readily available tables. For example, for the 25 pairwise differences given above, the 95% confidence interval for the Hodges-Lehmann estimator of –2 has a lower bound of –9 and upper bound of 7.

Horvitz–Thompson Estimator

Tapabrata Maiti
Professor
Michigan State University, East Lansing, MI, USA

Introduction and Definition

The Horvitz–Thompson (H–T) estimator is attributed to D.G. Horvitz and D.J. Thompson to estimate a finite population total when a sample is selected with unequal probabilities without replacement. Let $U = (1, \cdots, i, \cdots, N)$ denote a finite universe of N elements and s be a sample of size n. Let $\pi_i(>0)$ be the inclusion probability, the probability that the i-th unit is in the sample and $\pi_{ij}(>0)$ is the probability that both the units i and j are in the sample. If $p(s)$ is the probability of selecting a sample s, then $\pi_i = \sum_{s \ni i} p(s)$ and $\pi_{ij} = \sum_{s \ni i,j} p(s)$. The inclusion probabilities satisfies the following relations:

$$\sum_{i=1}^{N} \pi_i = n; \sum_{j \neq i}^{N} \pi_{ij} = (n-1)\pi_i; \sum_{i=1}^{N} \sum_{j>i} \pi_{ij} = \frac{1}{2} n(n-1)$$

Let y_i be the response attached to i-th unit $(i = 1, \cdots, N)$ and the target is to estimate the finite population total $T = \sum_{i=1}^{N} y_i$. The Horvitz–Thompson (1952) estimator of the population total is

$$t = \sum_{i \in s} \frac{y_i}{\pi_i}$$

The higher the selection probability π_i of unit i, the less weight $\left(\frac{1}{\pi_i}\right)$ the corresponding value y_i is given. The Hansen and Hurwitz (1943) estimator was constructed similarly for unequal probability sampling with replacement. The H–H estimator uses probability of selection of a unit instead the inclusion probabilities. If $p_1, \cdots, p_N$ are selection probabilities with $\sum_{i=1}^{N} p_i = 1$, and n independent draws are made to select a sample with replacement then the inclusion probability for i-th unit is

$$\pi_i = 1 - (1 - p_i)^n$$

For $n = 1, \pi_i = p_i$, but they are not same in general.

Properties of the H–T Estimator

The H–T estimator t is an unbiased estimator of the population total T, with variance

$$V_1(t) = \sum_{i=1}^{N} \frac{1-\pi_i}{\pi_i} y_i^2 + 2 \sum_{i=1}^{N} \sum_{j>i}^{N} \frac{\pi_{ij} - \pi_i \pi_j}{\pi_i \pi_j} y_i y_j$$

Following the relation $\sum_{j \neq i} (\pi_{ij} - \pi_i \pi_j) = -\pi_i(1-\pi_i)$ for a fixed sample size design, the variance can be expressed as

$$V_2(t) = \sum_{i=1}^{N} \sum_{j>i}^{N} (\pi_i \pi_j - \pi_{ij}) \left(\frac{y_i}{\pi_i} - \frac{y_j}{\pi_j} \right)^2$$

This form of variance is known as Yates–Grundy form (Sen 1953; Yates and Grundy 1953). The variance estimators are

$$\hat{V}_1(t) = \sum_{i=1}^{n} \frac{1-\pi_i}{\pi_i^2} y_i^2 + 2 \sum_{i=1}^{n} \sum_{j>i}^{n} \frac{\pi_{ij} - \pi_i \pi_j}{\pi_i \pi_j \pi_{ij}} y_i y_j$$

for the variance V_1 and

$$\hat{V}_2(t) = \sum_{i=1}^{n} \sum_{j>i}^{n} \frac{(\pi_i \pi_j - \pi_{ij})}{\pi_{ij}} \left(\frac{y_i}{\pi_i} - \frac{y_j}{\pi_j} \right)^2$$

for the variance V_2. Both of these variance estimators are unbiased.

Example Consider a ▶simple random sample without replacement of size n. The inclusion probabilities are $\pi_i = \frac{n}{N}$ and $\pi_{ij} = \frac{n(n-1)}{N(N-1)}$. The H–T estimator for the population total is $N\bar{y}$ where $\bar{y} = \frac{1}{n} \sum_s y_i$. The variance is $N^2 \frac{1-f}{n} S^2$ where $S^2 = \frac{1}{N-1} \sum_{i=1}^{N} \left(y_i - \frac{T}{N}\right)^2$ and $f = \frac{n}{N}$, known as the sampling fraction. The variance estimator is $N^2 \frac{1-f}{n} s^2$ where $s^2 = \frac{1}{n-1} \sum_s (y_i - \bar{y})^2$. Note that both the variance estimators take same form in this design.

Due to wide variation of $(\pi_i \pi_j - \pi_{ij})$, even sometimes being negative, both the variance estimators $\hat{V}_1$ and $\hat{V}_2$ can be negative for some sampling designs. Rao and Singh (1973) compared the coefficient of variation for these two variance estimators using Brewer's sample selection method (Brewer 1963) and found that the Yates–Grundy form of variance estimator is more stable than the other. Consequently, applying H–T estimator one should be carefully selecting a sampling design where the inclusion probabilities are chosen cautiously in relation to response variable; otherwise may end up with silly outcome as the famous "elephant" example of Basu (1971).

Hajek (1964) provided the necessary and sufficient condition for the ▶asymptotic normality of the H–T estimator under rejective sampling. Berger (1998) extended the asymptotic normality result for general sampling design and also provided the rate of convergence. Berger (1998) used the asymptotic framework as follows: Let $\{n_1, \cdots, n_k, \cdots\}$ and $\{N_1, \cdots, N_k, \cdots\}$ be sequences of sample size and population size respectively, where both n_k and N_k increase as $k \to \infty$.

Särnal et al. (1992) provided a very generalized treatment to the H–T estimator and called as π estimator. This general form of estimator also applies to unequal probability sampling design with replacement. The generalized concept has further been illustrated by Overton

and Stehman (1995). The H–T estimator has been adapted in model based inference by Kott (1988) and Särnal et al. (1992). Kott (1988) particularly derived the finite population correction for the H–T estimator under usual super population model. On the other hand, Särnal et al. (1992) adopted H–T estimator for predicting the population total under the super population model and then used the design perspective for statistical inference. The estimator is popularly known as GREG (generalized regression) predictor and the approach is known as model-assisted, as opposed to model-based approach. For a super population model ζ with p covariate $\boldsymbol{x} = (x_1, \cdots, x_p)^T$,

$$E_\zeta(y_i) = \boldsymbol{x}_i^T \boldsymbol{\beta}$$
$$V_\zeta(y_i) = \sigma_i^2$$

the GREG predictor for population total T is

$$t_{GREG} = \sum_s g_{is} \frac{y_i}{\pi_i}$$

where

$$g_{is} = 1 + \left(\sum_{i=1}^N \boldsymbol{x}_i - \sum_s \frac{\boldsymbol{x}_i}{\pi_i}\right)^T \left(\sum_s \frac{\boldsymbol{x}_i \boldsymbol{x}_i^T}{\pi_i \sigma_i^2}\right)^{-1} \frac{\boldsymbol{x}_i}{\sigma_i^2}$$

The approximate variance of GREG predictor is

$$V(t_{GREG}) \doteq -\sum_{i=1}^N \sum_{j=1}^N (\pi_i \pi_j - \pi_{ij}) \frac{E_i}{\pi_i} \frac{E_j}{\pi_j}$$

where $E_i = y_i - \boldsymbol{x}_i^T \boldsymbol{B}, \boldsymbol{B} = \left(\sum_{i=1}^N \frac{\boldsymbol{x}_i \boldsymbol{x}_i^T}{\sigma_i^2}\right)^{-1} \sum_{i=1}^N \frac{\boldsymbol{x}_i y_i}{\sigma_i^2}$.
An approximated variance estimator is

$$\hat{V}(t_{GREG}) \doteq -\sum_s \sum_s \frac{\pi_i \pi_j - \pi_{ij}}{\pi_{ij}} \frac{g_{is} e_i}{\pi_i} \frac{g_{js} e_j}{\pi_j}$$

where $e_i = y_i - \boldsymbol{x}_i^T \hat{\boldsymbol{B}}, \hat{\boldsymbol{B}} = \left(\sum_s \frac{\boldsymbol{x}_i \boldsymbol{x}_i^T}{\sigma_i^2 \pi_i}\right)^{-1} \sum_s \frac{\boldsymbol{x}_i y_i}{\sigma_i^2 \pi_i}$.

The formulae get simplified with variance structure $\sigma_i^2 = \boldsymbol{\lambda}^T \boldsymbol{x}_i$ for known $\boldsymbol{\lambda}$.

Hotelling's T^2 Statistic

Robert L. Mason [1], John C. Young [2]
[1]Southwest Research Institute, San Antonio, TX, USA
[2]Lake Charles, LA, USA

The univariate t statistic is well-known to most data analysts. If a random sample of n observations is taken from a normal distribution with mean μ and variance σ^2, the form

of the statistic is given by

$$t = \frac{\bar{x} - \mu}{s/\sqrt{n}}, \tag{1}$$

where $\bar{x}$ is the sample mean and s is the sample standard deviation. This statistic has a Student t-distribution with $(n-1)$ degrees of freedom. Squaring the statistic, we obtain

$$t^2 = n(\bar{x} - \mu)'(s^2)^{-1}(\bar{x} - \mu).$$

This value can be defined as the squared Euclidean distance between $\bar{x}$ and μ.

A multivariate analogue to the t statistic can easily be constructed. Suppose a random sample of n observation vectors, given by $\mathbf{x}_1, \mathbf{x}_2, \ldots, \mathbf{x}_n$, where $\mathbf{x}_i' = (x_{i1}, x_{i2}, \ldots, x_{ip})'$, is taken from a p-variate multivariate normal distribution (see ▶Multivariate Normal Distributions) with mean vector $\mathbf{u}$ and covariance matrix, Σ. Then the multivariate version of the t statistic in (1) is given by

$$T^2 = n(\bar{\mathbf{x}} - \boldsymbol{\mu})'\mathbf{S}^{-1}(\bar{\mathbf{x}} - \boldsymbol{\mu}), \tag{2}$$

where $\bar{\mathbf{x}} = \frac{1}{n}\sum_{i=1}^{n}\mathbf{x}_i$ is the sample mean and $\mathbf{S} = \sum_{i=1}^{n}(\mathbf{x}_i - \bar{\mathbf{x}})(\mathbf{x}_i - \bar{\mathbf{x}})'/(n-1)$ is the sample covariance matrix.

The statistic in (2) and its sampling distribution was first developed by Harold Hotelling (1931), and it is commonly referred to as Hotelling's T^2 statistic. It was first introduced for usage in testing the null hypothesis that the mean vector, $\boldsymbol{\mu}$, of a multivariate normal distribution is equal to a specific vector $\boldsymbol{\mu}_0$, i.e., $H_0 : \boldsymbol{\mu} = \boldsymbol{\mu}_0$, against the alternative hypothesis that it is not equal to this vector, i.e., $H_A : \boldsymbol{\mu} \neq \boldsymbol{\mu}_0$. Thus, it can be used as the statistic for a multivariate one-sample test of hypothesis.

The null distribution of the T^2 statistic in (2) is given by a central F distribution and the distribution under the alternative hypothesis is a non-central F distribution. For the above one-sample hypothesis the null distribution is given by

$$T^2 \sim \frac{(n-1)p}{n-p}F_{(p,n-p)}, \tag{3}$$

where $F_{(p,n-p)}$ is an F-distribution with p and $(n-p)$ degrees of freedom. Note that the limiting form of this F-distribution is a ▶chi-square distribution with p degrees of freedom. This is the form of the asymptotic distribution of the T^2 statistic.

The T^2 statistic has many interesting properties. First, it is invariant under all nonsingular linear transformations of the data given by

$$\mathbf{z} = \mathbf{A}\mathbf{x} + \mathbf{b},$$

where $\mathbf{x}$ is a sampled multivariate normal observation, $\mathbf{b}$ is a known vector of constants, and $\mathbf{A}$ is a non-singular matrix of known values. This invariance property means that the T^2 results are independent of scale and origin changes to the data so that the T^2 statistic based on $\mathbf{z}$ is identical to the T^2 statistic based on $\mathbf{x}$. From this one can conclude that testing the hypothesis $H_0 : \boldsymbol{\mu}_\mathbf{z} = \boldsymbol{\mu}_{\mathbf{z}_0}$ is equivalent to testing the hypothesis $H_0 : \boldsymbol{\mu}_\mathbf{x} = \boldsymbol{\mu}_{\mathbf{x}_0}$, where $\boldsymbol{\mu}_\mathbf{z}$ is the population mean of the $\mathbf{z}$ data and $\boldsymbol{\mu}_\mathbf{x}$ is the population mean of the $\mathbf{x}$ data. Second, the hypothesis test based on the T^2 statistic is the uniformly most powerful invariant test. This means that in the class of all invariant tests there is no test that has greater ability to detect a true null hypothesis than the T^2 statistic. Third, the T^2 statistic is equivalent to the likelihood ratio statistic for this hypothesis. Thus, the optimal and distributional properties of the likelihood ratio test hold for the T^2 statistic.

When two different multivariate normal populations, with means $\boldsymbol{\mu}_1$ and $\boldsymbol{\mu}_2$, have equal covariance matrices, the T^2 statistic can be used to test a two-sample null hypothesis of the form $H_0 : \boldsymbol{\mu}_1 = \boldsymbol{\mu}_2$. With independent samples of sizes n_1 and n_2, respectively, from each population, the T^2 statistic for the test procedure is based on the difference of the sample mean vectors, $(\bar{\mathbf{x}}_1 - \bar{\mathbf{x}}_2)$, and the pooled estimate of the common covariance matrix. The form of the statistic is given by

$$T^2 = \frac{n_1 n_2}{(n_1 + n_2)}(\bar{\mathbf{x}}_1 - \bar{\mathbf{x}}_2)'\mathbf{S}_p^{-1}(\bar{\mathbf{x}}_1 - \bar{\mathbf{x}}_2), \tag{4}$$

where n_1 and n_2 are the sizes of the two independent samples, $\bar{\mathbf{x}}_1$ and $\bar{\mathbf{x}}_2$ are the corresponding sample means and $\mathbf{S}_p = [(n_1 - 1)\mathbf{S}_1 + (n_2 - 1)\mathbf{S}_2]/(n_1 + n_2 - 2)$ is the pooled sample covariance matrix corresponding to the sample covariance matrices, $\mathbf{S}_1$ and $\mathbf{S}_2$. Similarly, the null distribution for this T^2 statistic is given by

$$T^2 \sim \frac{(n_1 + n_2 - p - 1)}{(n_1 + n_2 - 2)p}F_{(p,n_1+n_2-p-1)}. \tag{5}$$

The quadratic form of (4), given by

$$\mathbf{D}^2 = (\bar{\mathbf{x}}_1 - \bar{\mathbf{x}}_2)'\mathbf{S}_p^{-1}(\bar{\mathbf{x}}_1 - \bar{\mathbf{x}}_2), \tag{6}$$

is known as the squared sample Mahalanobis distance between the vectors $\bar{\mathbf{x}}_1$ and $\bar{\mathbf{x}}_2$. This statistic was developed by P.C. Mahalanobis (1930) at about the same time that Hotelling developed the T^2 statistic. Its square root is used as an estimate of the distance between the two means of the populations relative to the common covariance matrix.

The T^2 test statistic in (4) is also equivalent to the likelihood ratio test statistic for a two-population mean test. A form of the statistic was used by Fisher (1936) as a means for classifying a new observation $\mathbf{x}$ into one of two groups and is known as Fisher's linear discriminant function (e.g., see Johnson and Wichern 2008).

In addition to its use in multivariate analysis, the T^2 statistic also has been applied extensively in the area of multivariate statistical process control (MVSPC). This first

occurred in 1947 when Harold Hotelling used the statistic to solve problems concerning bombsights (Hotelling 1947). Since the advent of inexpensive computing power became available in the 1980's, the T^2 statistic has become one of the most popular charting statistics for use in monitoring the many variables of a multivariate process (see Mason and Young 2002).

In this short entry, we have discussed only a few of the numerous applications of Hotelling's T^2 statistic in multivariate analysis. Many more are available and information on them can be obtained in most applied multivariate statistics textbooks.

Hyperbolic Secant Distributions and Generalizations

Matthias Fischer
University of Erlangen-Nürnberg, Erlangen, Germany

The hyperbolic secant distribution (HSD) has its origin in Fisher (1921), Dodd (1925), Roa (1924) and Perks (1932). Some of its properties are developed by Talacko (1956, 1958, 1958). Given two independent standard normal variables Y_1 and Y_2, the variable $X \equiv \ln|Y_1/Y_2|$ is said to follow a *hyperbolic secant* distribution. Analogue to the ▶logistic distribution, probability density, cumulative distribution function and quantile function of X admit a closed form, namely

$$f(x) = \frac{2}{\pi(e^x + e^{-x})}, \quad F(x) = \frac{2\arctan(e^x)}{\pi} \text{ and}$$
$$F^{-1}(p) = \ln\left(\tan\left(\frac{\pi p}{2}\right)\right), \quad x \in \mathbb{R}.$$

Obviously, the density is symmetric around zero and has mode at zero with $f(0) = 1/\pi$. Since the moment-generating function of a HSD is given by $\mathcal{M}(t) = (\cos(\pi t/2))^{-1}$ for $|t| < \pi/2$, all moments exist. In particular, $\mathbb{E}(X^i) = 0$ for odd i, $Var(X) = \pi^2/4$ and $\mathbb{E}(X^4) = 5\pi^4/16$. Consequently, the kurtosis coefficient (i.e., the fourth standardized moment) of a HSD calculates as $m_4 = 5$, indicating that the HSD has heavier tails and higher peakedness than the normal distribution ($m_4 = 3$) and than the logistic distribution ($m_4 = 4.2$).

Basically, two major generalized hyperbolic distributions emerged.

The first one has its roots in the work of Baten (1934) who derived the probability density function of $X_1 + \ldots + X_n$ where each X_i follows a HSD for finite $n \in \mathbb{N}$ as well as for $n = \infty$. More generally, Harkness & Harkness (1968) discuss distribution families with characteristic function $\text{sech}(t)^\rho$, $\rho > 0$ which can be identified as ρ-th convolution of a hyperbolic secant variable. This symmetric distribution family is commonly termed as *generalized hyperbolic secant* (GHS) distribution with kurtosis parameter ρ. A corresponding skew GHS distribution is known in the statistical literature as NEF-GHS or Laha–Lukacs distribution (e.g., Morris 1982) or as Meixner distribution in the mathematical and financial literature (e.g., Meixner 1934 or Schoutens 2003).

The second generalization dates back to Perks (1932) who discussed probability densities of the form

$$f(x) = \frac{a_0 + a_1 e^{-x} + a_2 e^{-2x} + \ldots + a_m e^{-mx}}{b_0 + b_1 e^{-x} + b_2 e^{-2x} + \ldots + b_n e^{-nx}}$$

with parameters a_i, b_j such that f is a proper probability density. Setting $m = 1$, $a_0 = 0$, $a_1 = 1$ and $n = 2$, $b_0 = 1$, $b_1 = 0$, this equation reduces to the density of a HSD. More generally, Talacko (1956, 1958) focused on $m = 1$, $a_0 = 0$ and $n = 2$, $b_0 = b_2$. It took about 50 years until Talacko's generalized secant hyperbolic (GSH) distribution was re-examined by Vaughan (2002) and Klein and Fischer (2008) under a slightly different parameterization. Skew versions of the GSH distribution where introduced and successfully applied to financial return data in Fischer (2004, 2006) and Palmitesta and Provasi (2004).

Hypergeometric Distribution and Its Application in Statistics

Anwar H. Joarder
Professor
King Fahd University of Petroleum and Minerals,
Dhahran, Saudi Arabia

An important discrete distribution encountered in sampling situations is the hypergeometric distribution. Suppose that a finite population of N items contains two types of items in which K items are of one kind (say defective) and $N-K$ items are of a different kind (say non-defective). If n items are drawn at random in succession, without replacement, then X denoting the number of defective items selected follows a hypergeometric distribution. The probability of the event $D_1D_2\cdots D_xD'_{x+1}\cdots D'_n$ denoting x successive defectives items and $n-x$ successive non-defective items is given by

$$P\left(D_1D_2\cdots D_xD'_{x+1}\cdots D'_n\right)=\frac{C_{K-x}^{N-n}}{C_K^N},\quad \max\{0,n-(N-K)\}\le x\le \min\{n,K\},\qquad (1)$$

where C_x^n is the number of combinations of x items that can be chosen from a group of n items and is equal to $n!/[x!(n-x)!]$. The probability of any other particular sequence in the sample space is also the same as (1). Interested readers may refer to Joarder and Al-Sabah (2007).

Since there are C_x^n outcomes having x defective items and $(n-x)$ non-defective items out of at most 2^n elements in the sample space, the probability of x successes in n trials is given by

$$P(X=x)=\frac{C_x^nC_{K-x}^{N-n}}{C_K^N},\quad \max\{0,n-(N-K)\}\le x\le \min\{n,K\},\qquad (2)$$

(cf. Kendall and Stuart 1969, p. 133). The probability of x successes in n trials is commonly written as

$$P(X=x)=\frac{C_x^KC_{n-x}^{N-K}}{C_n^N},\quad \max\{0,n-(N-K)\}\le x\le \min\{n,K\}.\qquad (3)$$

Vandermonde's identity justifies the equivalence of the two forms in (2) and (3). The proof of (3) is available in most textbooks on statistics (e.g., Johnson 2007) and discrete mathematics (e.g., Barnett 1998). There are C_x^K ways of choosing x of the K items (say defective items) and C_{n-x}^{N-K} ways of choosing $(n-x)$ of the $(N-K)$ non-defective items, and hence there are $C_x^KC_{n-x}^{N-K}$ ways of choosing x defectives and $(n-x)$ non-defective items. Since there are C_n^N ways of choosing n of the N elements, assuming C_n^N sample points are equally likely, the probability of having x defective items in the sample is given by (3).

The name hypergeometric is derived from a series introduced by the Swiss mathematician and physicist, Leonard Euler, in 1769. The probabilities in (3) are the successive terms of

$$\frac{(N-n)!(N-K)!}{N!(N-K-n)!}\;{}_2F_1(-n,-K;N-K-n+1;1),\qquad (4)$$

where ${}_2F_1(a_1, a_2; b; x)$ is the generalized hypergeometric function (Johnson et al. 1993, p. 237).

Suppose that a random sample of $n = 3$ items is selected from a lot of $N = 5$ items in which there are $K = 3$ defective items (distinguishable or indistinguishable) and 2 non-defective items (distinguishable or indistinguishable). Let $D_i\,(i = 1, 2, 3)$ be the event that we have a defective item in the ith selection, and $N_i\,(i = 1, 2, 3)$ be the event that we have a non-defective item in the ith selection. Also let X be the number of defective items selected in the sample. The elements of the sample space are given by $D_1D_2D_3, D_1D_2N_3, D_1N_2D_3, D_1N_2N_3, N_1D_2D_3$, $N_1D_2N_3$, and $N_1N_2D_3$. By (1), the probabilities are given by 0.10, 0.2, 0.2, 0.10, 0.2, 0.10 and 0.10 respectively. Note that elements in the sample space are not equiprobable. The probability of having two defective items in the sample is given by $P(X = 2) = 0.2 + 0.2 + 0.2 = 0.6$. If n is large, it is not feasible to write out the sample space but one can use (2) directly.

Note that if the items in each of the two categories are distinguishable, or labeled to make them distinguishable, the sample space can be written out with all distinguishable items. Then the sample outcomes are equally likely or equiprobable resulting in a Simple Random Sampling. In the above example, let the defective items be labeled as D^1, D^2 and D^3 while the non-defective items be labeled as N^1 and N^2 to make the items in the population distinguishable. Then $C_n^N = 10$ elements in the sample space are given by $D^1D^2D^3$, $D^1D^2N^1$, $D^1D^2N^2$, $D^1D^3N^1$, $D^1D^3N^2$, $D^1N^1N^2$, $D^2D^3N^1$, $D^2D^3N^2$, $D^2N^1N^2$, and $D^3N^1N^2$ each with the probability 0.10, and hence $P(X = 2) = 0.6$. In case C_n^N is large, it is not feasible to write out the sample space but one can use (3) directly.

Suppose that n items are drawn at random, with replacement, and X denotes the number of defective items selected. The probability that any item is defective at any draw is $p = K/N$ (say). Then with arguments similar to above, the probability of having x defectives and $(n - x)$ non-defectives in any of the C_x^n sequence is given by $p^x q^{n-x}$ so that $P(X = x) = C_x^n p^x q^{n-x}$. Now if $N \to \infty$, and $p = K/N$, it is easy to prove that (2) has a limiting value of $C_x^n p^x q^{n-x}$. This shows the equivalence of binomial and hypergeometric distribution in the limit.

The mean and variance of hypergeometric distribution are given by np and $(1 - f)npq$ respectively, where $p = K/N$, $q = 1-p$, and f is the finite population correction factor defined by $(N-1)f = N - n$. The mode of the distribution is the greatest integer not exceeding $\frac{(n+1)(K+1)}{N+2}$.

The coefficient of skewness and that of kurtosis are given by

$$\frac{(N-2K)(N-2n)(N-1)^{1/2}}{[nK(N-K)(N-n)]^{1/2}(N-2)}, \tag{5}$$

and

$$\frac{N^2(N-1)}{n(N-2)(N-3)(N-n)}\left[\frac{N(N+1)-6n(N-n)}{K(N-K)} + \frac{3n(N-n)(N+6)}{N^2} - 6\right], \tag{6}$$

respectively (Evans et al. 2000, p. 111).

The maximum likelihood estimator of the number of defectives K in a lot is the greatest integer not exceeding $x(N + 1)/n$; if $x(N + 1)/n$ is an integer, then $[x(N+1)/n]-1$ also maximizes the likelihood function (Johnson et al. 1993, p. 263).

The distribution has got a number of important applications in the real world. In the industrial quality control, lots of size N containing a proportion of p defectives are sampled by using samples of fixed size n. The number of defectives X per sample follows a hypergeometric distribution. If $X \le c$ (the acceptance number), the lot is accepted; otherwise it is rejected. The design of suitable sampling plans requires the calculation of confidence intervals of Np, given N, n and c. Tables of these have been published by Chung and DeLury (1950) and Owen (1962). It is worth mentioning that in many cases binomial or Poisson approximations to the hypergeometric distribution suffice.

Another useful application is the estimation of the size of the animal populations from capture–recapture data. This kind of application dates back to Peterson (1896), quoted by Chapman (1952). Consider, for example, the estimation of the number N of animals in a population. A sample of size K is captured, tagged and then released into the population. After a while a new catch of n animals is made, the number of tagged animals (X) in the sample is noted. Assume that the two catches are random samples from the population of all animals. Indeed, if we assume that there were no births or deaths, then the proportion of tagged animals in the sample (X/n) is approximately the same as that in the population (K/N). That is, an estimate of N is $\hat{N} = nK/X$. It may be noted that this estimate maximizes the probability of observed value of X. Evidently, X has a hypergeometric distribution with probability mass function given by (2) or (3).

The hypergeometric distribution can be approximated by Poisson distribution with parameter λ if K, N and n all tend to infinity for K/N small and nK/N tending to λ. It

can also be approximated by normal distribution if n is large, but x/N is not too small. A concise description of many other types of hypergeometric distribution and their properties are available in Johnson et al. (1993).

About the Author

Dr. Anwar H Joarder has been working at the Department of Mathematics and Statistics, King Fahd University of Petroleum and Minerals (KFUPM), Dhahran, Saudi Arabia since 1997. He also worked at the University of Western Ontario, Jahangir Nagar University, University of Dhaka, North South University, Monash University and the University of Sydney. He is an Elected member of the Royal Statistical Society and the International Statistical Institute. He authored and co-authored around 60 research papers. He serves on the editorial board of five journals including *Model Assisted Sampling and Applications* and *International Journal of Mathematical Education in Science and Technology*.

Identifiability

Sander Greenland
Professor
University of California-Los Angeles, Los Angeles, CA, USA

Consider a vector $\boldsymbol{Y}$ of random variables having a distribution $F(\boldsymbol{y};\boldsymbol{\theta})$ that depends on an unknown parameter vector $\boldsymbol{\theta}$. $\boldsymbol{\theta}$ is *identifiable* by observation of $\boldsymbol{Y}$ if distinct values $\boldsymbol{\theta}_1$ and $\boldsymbol{\theta}_2$ for $\boldsymbol{\theta}$ yield distinct distributions for $\boldsymbol{Y}$, that is, if $\boldsymbol{\theta}_1 \neq \boldsymbol{\theta}_2$ implies $F(\boldsymbol{y};\boldsymbol{\theta}_1) \neq F(\boldsymbol{y};\boldsymbol{\theta}_2)$ for some $\boldsymbol{y}$ (Bickel and Doksum 1977). A function $g(\boldsymbol{\theta})$ is *identifiable* by observation of $\boldsymbol{Y}$ if $g(\boldsymbol{\theta}_1) \neq g(\boldsymbol{\theta}_2)$ implies $F(\boldsymbol{y};\boldsymbol{\theta}_1) \neq F(\boldsymbol{y};\boldsymbol{\theta}_2)$ for some $\boldsymbol{y}$. Note that $\boldsymbol{\theta}$ is identifiable if and only if all functions of $\boldsymbol{\theta}$ are identifiable.

There is some variation in the definition of identifiability, the preceding being the most general and central to topics such as ►*Bias analysis*. Variants typically employ the density $f(\boldsymbol{y};\boldsymbol{\theta})$ or the expectation $E(\boldsymbol{Y};\boldsymbol{\theta})$ in place of the distribution. The latter variants may explicitly involve a design matrix X of regressors; for example, $E(\boldsymbol{Y};X,\boldsymbol{\theta})$. The basic concept, however, is that $\boldsymbol{\theta}$ [or $g(\boldsymbol{\theta})$] is a function of the $\boldsymbol{Y}$ distribution, and hence observations from the distribution of $\boldsymbol{Y}$ can be used to discriminate among distinct values of $\boldsymbol{\theta}$ [or $g(\boldsymbol{\theta})$].

The term *estimable* is sometimes used as a synonym for identifiable, but is also used in more specific ways, especially in the context of linear models. For example, Scheffé (1959) defines a linear function $\boldsymbol{c}'\boldsymbol{\theta}$ of $\boldsymbol{\theta}$ to be estimable if there exists an unbiased estimator of $\boldsymbol{c}'\boldsymbol{\theta}$ that is a linear function of the observed realizations of $\boldsymbol{Y}$. This property has also been referred to as linear estimability. In epidemiology, estimability of $g(\boldsymbol{\theta})$ is sometimes used to mean that $g(\boldsymbol{\theta})$ can be consistently estimated from observable realizations of $\boldsymbol{Y}$. Several other definitions have been given, e.g., see Lehman (1983), McCullagh and Nelder (1989), and Seber and Wild (1989).

Imprecise Probability

Frank P. A. Coolen[1], Matthias C. M. Troffaes[1], Thomas Augustin[2]
[1]Durham University, Durham, UK
[2]Ludwig Maximilians University, Munich, Germany

Overview

Quantification of uncertainty is mostly done by the use of precise probabilities: for each event A, a single (classical, precise) probability $P(A)$ is used, typically satisfying Kolmogorov's axioms (Augustin and Cattaneo 2010). Whilst this has been very successful in many applications, it has long been recognized to have severe limitations. Classical probability requires a very high level of precision and consistency of information, and thus it is often too restrictive to cope carefully with the multi-dimensional nature of uncertainty. Perhaps the most straightforward restriction is that the quality of underlying knowledge cannot be adequately represented using a single probability measure. An increasingly popular and successful generalization is available through the use of *lower and upper probabilities*, denoted by $\underline{P}(A)$ and $\overline{P}(A)$ respectively, with $0 \leq \underline{P}(A) \leq \overline{P}(A) \leq 1$, or, more generally, by lower and upper expectations (previsions) (Smith 1961; Walley 1991; Williams 2007). The special case with $\underline{P}(A) = \overline{P}(A)$ for

Miodrag Lovric (ed.), *International Encyclopedia of Statistical Science*, DOI 10.1007/978-3-642-04898-2,

all events A provides precise probability, whilst $\underline{P}(A) = 0$ and $\overline{P}(A) = 1$ represents complete lack of knowledge about A, with a flexible continuum in between. Some approaches, summarized under the name *nonadditive probabilities* [18], directly use one of these set-functions, assuming the other one to be naturally defined such that $\underline{P}(A^c) = 1 - \overline{P}(A)$, with A^c the complement of A. Other related concepts understand the corresponding intervals $[\underline{P}(A), \overline{P}(A)]$ for all events as the basic entity (Weichselberger 2000, 2001). Informally, $\underline{P}(A)$ can be interpreted as reflecting the evidence certainly in favour of event A, and $1 - \overline{P}(A)$ as reflecting the evidence against A hence in favour of A^c.

The idea to use imprecise probability, and related concepts, is quite natural and has a long history (see Hampel 2009 for an extensive historical overview of nonadditive probabilities), and the first formal treatment dates back at least to the middle of the nineteenth century (Boole 1854). In the last twenty years the theory has gathered strong momentum, initiated by comprehensive foundations put forward by Walley (1991) (see Miranda (2008) for a recent survey), who coined the term *imprecise probability*, by Kuznetsov (1991), and by Weichselberger (2000, 2001), who uses the term *interval probability*. Walley's theory extends the traditional subjective probability theory via buying and selling prices for gambles, whereas Weichselberger's approach generalizes Kolmogorov's axioms without imposing an interpretation. Usually assumed consistency conditions relate imprecise probability assignments to non-empty closed convex sets of classical probability distributions. Therefore, as a welcome by-product, the theory also provides a formal framework for models used in frequentist robust statistics (Augustin and Hable 2010) and robust Bayesian approaches (Rios Insua and Ruggeri 2000). Included are also concepts based on so-called two-monotone (Huber and Strassen 1976) and totally monotone capacities, which have become very popular in artificial intelligence under the name (Dempster–Shafer) belief functions (Dempster 1967; Shafer 1976). Moreover, there is a strong connection (de Cooman and Hermans 2008) to Shafer and Vovk's notion of game-theoretic probability (Shafer and Vovk 2001).

The term "imprecise probability" – although an unfortunate misnomer as lower and upper probability enable more accurate quantification of uncertainty than precise probability – appears to have been established over the last two decades, and actually brings together a variety of different theories. In applications, clear advantages over the established theory of precise probability have been demonstrated (see sections "►Applications in Statistics and Decision Theory" and "►Further Applications"). This justifies the further development of imprecise probability, particularly toward building a complete methodological framework for applications in statistics, decision support, and related fields. Imprecise probability provides important new methods that promise greater flexibility for uncertainty quantification. Its advantages include the possibility to deal with conflicting evidence, to base inferences on weaker assumptions than needed for precise probabilistic methods, and to allow for simpler and more realistic elicitation of subjective information, as imprecise probability does not require experts to represent their judgements through a full probability distribution, which often does not reflect their beliefs appropriately.

The Society for Imprecise Probability: Theories and Applications (www.sipta.org) organizes conferences, workshops and summer schools, and provides useful introductory information sources and contacts through its web-page.

The increased attention to imprecise probability during the last two decades has led to many new methods for statistical inference and decision support, with applications in a wide variety of areas.

Applications in Statistics and Decision Theory

Following Walley (1991), many of the imprecise probability-based contributions to statistics follow a generalized Bayesian approach. Typically, a standard precise parametric sampling model with a set of prior distributions is used. In particular, the use of models from the exponential family is popular in conjunction with classes of conjugate priors. Walley's Imprecise Dirichlet Model (IDM) for inference in case of multinomial data (Walley 1996) has attracted particular attention (Bernard 2009). One successful application area for the IDM is classification (Zaffalon 2002), where the use of lower and upper probabilities makes the learning process more stable and enables in a quite natural way an item to be explicitly not classified into a unique category, indicating that no clear decision for a single category can be made on the basis of the information available. In these models, updating to take new information into account is effectively done by updating all elements of the set of prior distributions as in Bayesian statistics with precise prior distributions, leading to a set of posterior distributions which forms the basis for inferences. From the technical perspective this procedure is therefore closely related to robust Bayesian inference, but, by reporting the indeterminacy resulting from limited information, use and interpretation of the resulting imprecise posterior goes far beyond a simple sensitivity and robustness analysis.

Other approaches to statistical inference with imprecise probabilities have been developed, which tend to move further away from the precise probabilistic approaches. Examples of such approaches are Nonparametric Predictive Inference (Coolen 2010), generalizations of the frequentist approach, see e.g., Augustin (2002) for hypotheses testing and Hable (2010) for estimation, as well as several approaches based on logical probability (Kyburg 1974; Levi 1980; Weichselberger 2005).

Imprecise probabilities have also proven their use in decision support (Troffaes 2007), where, in tradition of Ellsberg's experiments (Ellsberg 1961), ambiguity (or non-stochastic uncertainty) plays a crucial role (Hsu et al. 2005). If only little information is available about a variable, then it is often more natural to refuse to determine a unique optimal decision, when gains and losses depend on that variable. Imprecise probability theory grasps this in a rigorous manner, resulting in a set of possibly optimal decisions, rather than providing only a single, arbitrarily chosen, optimal decision from this set. Imprecise probability theory is especially useful in critical decision problems where gains and losses heavily depend on variables which are not completely known, such as for instance in pollution control (Chevé and Congar 2000) and medical diagnosis (Zaffalon et al. 2003).

Further Applications

Recent collections of papers (Augustin et al. 2009; Coolen-Schrijner et al. 2009; de Cooman et al. 2007) give an impression of the huge variety of fields of potential application. In artificial intelligence, for example in pattern recognition (Loquin and Strauss 2010, see also ►Pattern Recognition, Aspects of and ►Statistical Pattern Recognition Principles) and information fusion (Benavoli and Antonucci 2010), uncertain expert knowledge can be represented more accurately by means of imprecise probability. Because imprecise probability methods can process information without having to add unjustified assumptions, they are of great importance in risk and safety evaluations, design engineering (Aughenbaugh and Paredis 2006) and reliability (Coolen and Utkin 2010). The ongoing intensive debate on bounded rationality makes reliable decision theory based on imprecise probability particularly attractive in microeconomics and in social choice theory. In finance, imprecise probability is gaining strong influence given its very close connection to risk measures (Artzner et al. 1999; Vicig 2008). Imprecise probability also yields deeper insight into asset pricing (Richmond et al. 2008). The study of ►Markov chains with imprecise transition probabilities (de Cooman et al. 2009) is also important for many areas of application.

Challenges

Imprecise probability and its applications in statistical inference and decision support offer a wide range of research challenges. On foundations, key aspects such as updating have not yet been fully explored, and different approaches have different conditioning rules. The relation between imprecision and information requires further study, and many of the most frequently used statistical methods (such as complex regression models) have not yet been fully generalized to deal with imprecise probability. In cases where generalizations are easily found, it may be unclear which of many possible approaches is most suitable. Of course, early developments of new theoretic frameworks tend to include illustrative applications to mostly text-book style problems. The next stage required toward widely applicable methods involves upscaling, where in particular computational aspects provide many challenges. Even methods such as simulation, mostly straightforward with precise probabilities, become non-trivial with imprecise probabilities.

For applications which require the use of subjective information, elicitation of expert judgements is less demanding when lower and upper probabilities are used, but while practical aspects of elicitation have been widely studied this has, thus far, only included very few studies involving imprecise probabilities.

In decision making, algorithms to find optimal solutions need to be improved and implemented for large-scale applications. As many problems have a sequential nature, ways of representing sequential solutions efficiently also need to be developed, the more so as classical techniques such as backward induction and dynamic programming often cannot be extended directly.

About the Authors

Overview

Reliability analysis is an important application area of statistics and probability theory in engineering, with several specific features which often complicate application of standard methods. Such features include data censoring, for example due to maintenance activities, lack of knowledge and information on dependence between random quantities, for example if failures occur due to competing risks, and required use of expert judgements, for example when new or upgraded versions of units are used. While mathematical approaches for dealing with such issues have been presented within the framework of statistics using precise probabilities, the use of imprecise probability (Coolen et al. 2010) provides exciting new ways for dealing with such challenges in reliability. One of the first approaches that generalized probability in reliability was fuzzy reliability theory (Cai 1996), but this suffers from vagueness about axioms and rules for combination of information, and lack of clear interpretation of the results. We restrict attention to generalized uncertainty quantification in reliability via lower and upper probabilities, also known as "imprecise probability" (Walley 1991) or "interval probability" (Weichselberger 2000, 2001). During the last two decades, imprecise probability (Coolen et al. 2010) has received increasing attention, and interesting applications have been reported. It is widely accepted that, by generalizing precise probability theory in a mathematically sound manner, with clear axioms and interpretations, this theory provides a better approach to generalized uncertainty quantification then its current alternatives.

In classical probability theory, a single probability $P(A) \in [0,1]$ is used to quantify uncertainty about event A. Imprecise probability theory (Walley 1991; Weichselberger 2000, 2001) generalizes this by using lower probability $\underline{P}(A)$ and upper probability $\overline{P}(A)$ such that $0 \leq \underline{P}(A) \leq \overline{P}(A) \leq 1$, where the difference between $\overline{P}(A)$ and $\underline{P}(A)$ represents lack of perfect information about the uncertainty involving event A, see Coolen et al. (2010) for a further introduction. For reliability, attractive features of this generalization include that one does not need to make strong assumptions in order to derive at precise probabilities for all situations. For example, one may have partial information about dependence of failure times for different components, or one may have to rely on expert judgement with an only limited elicitation possible due to time constraints. All kinds of partial information that might be available in practice can be formulated as constraints on underlying probabilities, which can be satisfied by sets of probabilities.

Applications

A recent extensive introduction to imprecise reliability, together with a discussion of many applications, has been presented by Utkin and Coolen (2007). As an example of an imprecise reliability application, Fetz and Tonon (2008) consider bounds for the probability of failure of a series system when no information is available about dependence between failure probabilities of different modes. They consider several models, including random sets and p-boxes, and they provide a detailed list of references to the literature on such topics. They also discuss some computational methods, which is an important aspect of application of imprecise reliability to medium or larger size practical problems.

One of the possible ways in which output from imprecise probability methods can be useful is in the study of sensitivity of model outputs with respect to variations in input parameters. An interesting recent study by Oberguggenberger et al. (2009) presents such an approach to a large-scale modeling problem to assess reliability in an aerospace engineering application, comparing the use of classical probabilities and a variety of imprecise probability methods.

Imprecise probabilistic approaches to statistics are of great value to reliability problems. Recent examples include the use of Walley's imprecise Dirichlet model (Walley 1996) for system reliability without detailed assumptions on dependence of components (Troffaes and Coolen 2009), and system reliability from the perspective of nonparametric predictive inference (Coolen 2010). Another recent development is combination of imprecise Bayesian methods for some parameters with a generalized maximum likelihood approach for other parameters in an inferential problem, where the former can be used to explicitly deal with incomplete expert judgements while the latter can be appropriate on aspects of the problem for which data are available but no strong expert opinions. This has been explored for software reliability growth models, using the maximum likelihood approach for the temporal growth aspect together with imprecise Bayesian methods

for the parameters modeling the stationary aspects of the model (Utkin et al. 2009).

Challenges

Imprecise reliability is a relatively new area of research, with methods presented that are inspired by practical problems but that are not yet suitable for applications of substantial size. The main challenges are in upscaling the methods to become useful for practical problems, together with aspects of implementation which include consideration of elicitation and model choice. The combination of substantial optimization problems and statistical modeling and updating may also lead to a level of complexity that requires attention to methods for computation, for example it is not clear how modern simulation-based methods, that are for example popular in ►Bayesian statistics, can best be used or adapted for imprecise approaches.

The models for imprecise reliability that have been presented so far are still pretty basic, and for example inclusion of covariates requires further research. Generally, imprecise approaches can be found that generalize the established methods in varying ways, so in addition to developing new methods one must find ways to decide on how useful they are, which requires careful consideration of fundamental aspects of uncertainty and information. Hybrid methods, which combine imprecise models where useful to model indeterminacy with precise models where possible due to sufficient data or information, provide exciting opportunities for research, with issues that must be addressed including interpretation of results, choice of models and methods, and computation.

About the Authors

For biography of Frank P.A. Coolen *see* the entry ►Nonparametric Predictive Inference.

Lev V. Utkin received his M.Sc. (1986) from the Institute of Electrical Engineering in Leningrad. He obtained his Ph.D. in information processing and control systems (1989) from the same institute. Currently, he is Vice-rector for Research work and professor in the Department of Computer Science, St. Petersburg Forest Technical Academy. His research papers are on fuzzy reliability theory, the theory of imprecise probabilities, imprecise probability models in the reliability theory, optimization and uncertainty representation.

Imputation

Roderick J. Little
Richard D. Remington Collegiate Professor of Biostatistics
University of Michigan, Ann Arbor, MI, USA

Missing data is a difficult problem that degrades the quality of empirical studies. There are no foolproof methods, so the best approach is to seek to avoid missing values by careful design and prevention strategies, such as avoiding excessive respondent burden and strong efforts to elicit responses. Despite our best attempts to limit levels of nonresponse, missing values inevitably occur. For example, individuals in a sample survey refuse to answer items that are sensitive or difficult to answer; in a longitudinal study, individuals drop out prior to the end to a study because of relocation, or study fatigue. Analysis methods for data

subject to missing values are thus needed. A limited objective is to provide valid point estimates of population quantities from the incomplete data. Since good statistical analyses usually also require an assessment of statistical uncertainty of estimates through confidence intervals or test of hypotheses, it is also important that such inferences reflect the loss of information arising from missing data, so that, for example nominal 95% confidence intervals cover the true population quantity at least approximately 95% of the time, in repeated sampling.

Imputation is a method for the analysis of data with missing values, where missing values are replaced by estimates and the filled-in data are analyzed by complete-data methods. Often a single value is imputed (single imputation). Multiple imputation imputes more than one set of imputations of the missing values, allowing the assessment of imputation uncertainty.

A common alternative to imputation in public use files is to include incomplete cases in a data set, with missing value codes to indicate which values are missing. A drawback of this procedure is that different users may get different answers for the same research question, because they use different methods for dealing with the missing values. Most statistical software discards cases that have missing values on any of the variables included in the analysis, leading to complete-case analysis or listwise deletion (Little and Rubin 2002, Chap. 3). The information contained in observed variables in the incomplete cases is thus lost, and the complete cases may not be representative of the original sample.

Imputation is a method that allows incomplete cases to be included in the analysis. In fact, the main reason for imputation is not to recover the information in the missing values, which is lost and usually not recoverable, but rather to allow the information in observed values in the incomplete cases to be retained. If there is little information to be recovered in the cases with missing values, as for example cases in regression for which the outcome variable is missing, then imputation is not very useful.

A common naive imputation approach imputes missing values by their simple unconditional sample means (i.e., marginal means). This can yield satisfactory point estimates of unconditional means and totals, but it yields inconsistent estimates of other parameters, for example variances or regression coefficients (Kalton and Kasprzyk 1982; Little and Rubin 2002, Sect. 4.2). Inferences (tests and confidence intervals) based on the filled-in data are seriously distorted by bias and overstated precision. Thus the method cannot be generally recommended.

An improvement over unconditional mean imputation is *conditional mean* imputation, in which each missing value is replaced by an estimate of its conditional mean given the values of observed values. For example, in the case of univariate nonresponse with $Y_1, \ldots, Y_{p-1}$ fully observed and Y_p sometimes missing, one approach is to classify cases into cells based on similar values of observed variables, and then to impute missing values of Y_p by the within-cell mean from the complete cases in that cell. A more general approach is regression imputation, in which the regression of Y_p on $Y_1, \ldots, Y_{p-1}$ is estimated from the complete cases, including interactions as needed, and the resulting prediction equation is used to impute the estimated conditional mean for each missing value of Y_p. For a general pattern of missing data, the missing values for each case can be imputed from the regression of the missing variables on the observed variables, computed using the set of complete cases. Iterative versions of this method lead (with some important adjustments) to maximum likelihood estimates under multivariate normality (Little and Rubin 2002, Sect. 8.2).

Although conditional mean imputation incorporates information from the observed variables and yields best predictions of the missing values in the sense of mean squared error, it leads to distorted estimates of quantities that are not linear in the data, such as percentiles, correlations and other measures of association, variances and other measures of variability. A solution to this problem is to use random draws rather than best predictions to preserve the distribution of variables in the filled-in data set. An example is *stochastic regression* imputation, in which each missing value is replaced by its regression prediction plus a random error with variance equal to the estimated residual variance. Other imputation methods impute values observed in the dataset. One such method is the *hot-deck,* as used by the Census Bureau for imputing income in the Current Population Survey (CPS) (Hanson 1978). Each nonrespondent is matched to a respondent based on variables that are observed for both; the missing items for the nonrespondent are then replaced by the respondent's values. For the CPS, matching is achieved by classifying respondents and nonrespondents into adjustment cells based on the observed variables. When no match can be found for a nonrespondent based on all of the variables, the CPS hot-deck searches for a match at a lower level of detail, by omitting some variables and collapsing the categories of others. A more general approach to hot-deck imputation is to define a distance function based on the variables that are observed for both nonrespondents and respondents. The missing values for each nonrespondent are then imputed from a respondent that is close to the nonrespondent in terms of the distance function. For a review of hot-deck methods see Andridge and Little (2010).

A serious defect with imputation is that it invents data. More specifically, a single imputed value cannot represent

all of the uncertainty about which value to impute, so analyses that treat imputed values just like observed values generally underestimate uncertainty, even if nonresponse is modeled correctly and random imputations are created.

Two approaches to this deficiency are (a) to apply a replication method of variance estimation, and recompute the imputations on each replicate sample (Fay 1996, Rao 1996, Efron 1994), and (b) multiple imputation (MI) (Rubin 1987, 1996). Instead of imputing a single set of draws for the missing values, a set of M (say $M = 10$) datasets are created, each containing different sets of draws of the missing values from their predictive distribution. We then apply the analysis to each of the M datasets and combine the results in a simple way. In particular, for scalar estimants, the *MI* estimate is the average of the estimates from the M datasets, and the variance of the estimate is the average of the variances from the five datasets plus $1 + 1/M$ times the sample variance of the estimates over the M datasets (The factor $1 + 1/M$ is a small-M correction). The last quantity here estimates the contribution to the variance from imputation uncertainty, missed by single imputation methods. Another benefit of multiple imputation is that the averaging over datasets results in more efficient point estimates than does single random imputation. Often *MI* is not much more difficult than doing a single imputation – the additional computing from repeating an analysis M times is not a major burden and methods for combining inferences are straightforward. Multiple imputation is available for the multivariate normal model in a variety of software packages (e.g., Proc *MI* in SAS), and more flexible sequential multiple imputation methods are available in IVEware (http://www.isr.umich.edu/src/smp/ive/) and MICE (http://www.multiple-imputation.com/).

Most approaches imputation to date have assumed that the missing data are MAR (Rubin 1976, Little and Rubin 2002, Sect. 6.2), which means that differences in the distribution of the missing variables for respondents and nonrespondents can be captured using observed variables. Non-MAR models are needed when missingness depends on the missing values. For example, suppose a subject in an income survey refused to report an income amount because the amount itself is high (or low). If missingness of the income amount is associated with the amount, after controlling for observed covariates (such as age, education or occupation) then the mechanism is not MAR, and methods for imputing income based on MAR models are subject to bias. A correct analysis must be based on the full likelihood from a model for the joint distribution of the data and indicators for the missing values. ►Sensitivity analysis is the preferred approach to assess the impact of non-MAR missing values (e.g., Little and Rubin 2002, Chap. 15).

About the Author

Roderick Little Chaired the Biostatistics Department at the University of Michigan from 2007–1993–2001 and 2007–2010. Dr. Little is also a professor in the University's Statistics Department and a research professor in the University's Institute for Social Research. He is an Elected ASA Fellow (1985) an Elected Member of International Statistical Institute (1989), and a Fellow of the American Academy of Arts and Sciences (2010). He has over 160 publications (including *Statistical Analysis with Missing Data*, with D.B. Rubin, John Wiley, 1987), notably on methods for the analysis of data with missing values and model-based survey inference, and the application of statistics to diverse scientific areas Professor Little was awarded the Samuel S. Wilks Medal, American Statistical Association (2005) for "significant and pioneering contributions to the development of statistical methodology." Currently, he is Vice-President of the American Statistical Association (2010–2012).

Incomplete Block Designs

Nam-Ky Nguyen[1], Kalina Trenevska Blagoeva[2]
[1]Vietnam National University, Hanoi, Vietnam
[2]Faculty of Economics
University "SS. Cyril and Methodius," Skopje, Macedonia

Introduction

Blocking is the division of experimental material into blocks or sets of homogeneous experimental units. Proper blocking can control the source of variability which is not of primary interest and thus can reduce the experimental error. If the number of treatments is the same as the block size, a randomized block design can be used. However, if the number of treatments exceeds the block size, an incomplete block design (IBD) should be considered.

An IBD of size (v, k, r) is an arrangement of v treatments set out in b blocks, each of size $k(< v)$ such that each treatment occurs in r blocks where $vr = bk$ and no treatment occurs more than once in any block. The following is an IBD of size $(v, k, r) = (4, 2, 3)$ (Note that all IBDs in this article are displayed with blocks as columns.):

0	2	0	1	1	0
1	3	3	2	3	2

An IBD is said to be r/s-resolvable if the blocks can be divided into s *replicate sets* (of blocks) and each set is an IBD of size $(v, k, r/s)$. A 1-resolvable IBD is a resolvable IBD (see the above example). The following is a 2-resolvable IBD of size $(v, k, r) = (6, 4, 4)$:

3	0	3	1	0	2
4	2	4	3	4	3
5	5	2	5	2	4
0	1	1	0	1	5

The books of John and Williams (1995) and Raghavarao and Padgett (2005) give a more complete treatment on the subject.

A Criterion for Comparing IBDs

Associated with each IBD is its (treatment) *concurrence* matrix $NN' = \{\lambda_{ij}\}$ where λ_{ij} $(i, j = 1, \ldots, v)$ is the number of blocks in which treatment i and j both appear. Obviously, $\lambda_{ii} = r$. When $\lambda_{ij} = \lambda$ for all $i \neq j$, the IBD is called a balanced IBD (BIBD). Below is an IBD of size $(v, k, r) = (6, 3, 2)$:

0	0	1	1
2	3	3	2
5	4	5	4

The concurrence matrix of this IBD is

$$\begin{pmatrix} 2 & 0 & 1 & 1 & 1 & 1 \\ 0 & 2 & 1 & 1 & 1 & 1 \\ 1 & 1 & 2 & 0 & 1 & 1 \\ 1 & 1 & 0 & 2 & 1 & 1 \\ 1 & 1 & 1 & 1 & 2 & 0 \\ 1 & 1 & 1 & 1 & 0 & 2 \end{pmatrix}.$$

As $\sum \lambda_{ij}$ is constant $(=vkr)$, $\sum \lambda_{ij}^2$ is minimized if λ_{ij}'s $(i \neq j)$ differ by at most 1. IBDs with this property were called regular graph designs (RGDs) by John and Mitchell (1977) who conjectured that D-, A- and E- optimal IBDs are also RGDs. Thus, RGDs include BIBDs, i.e., IBDs whose λ_{ij}'s $(i \neq j)$ do not differ and all near-BIBDs whose λ_{ij}'s $(i \neq j)$ differ by 1. RGD is an important class of IBDs not only because it has been conjectured that optimal IBDs are RGDs but also because most IBDs used by researchers in practice are actually RGDs. This fact has prompted Nguyen (1994) to search for RGDs as the first step in constructing optimal IBDs.

A common criterion for comparing IBDs of the same size is the *efficiency factor* defined as $E = (v-1)/\sum e_i^{-1}$ where e_i's are the $v-1$ nonzero eigenvalues of $r^{-1}C$ and $C = rI - k^{-1}NN'$ is the information matrix for the adjusted treatment effects. Here, we assume that the IBD is *connected*, i.e., $\text{rank}(C) = v-1$. An IBD which has the maximal value of E is said to be A-optimal (John and Williams 1995, Sect. 2.4). The upper bounds for the efficiency factor of an IBD have been discussed extensively in Sect. 2.6 of John and Williams (1995). These upper bounds are used to establish the stopping rule for any IBD algorithm.

IBDs with High Efficiency Factors

This section introduces BIBDs and some classes of computer-generated IBDs. These designs have become more popular among designers of experiments as with the advent of the computer, the flexibility and goodness of the design have succeeded ease of analysis as their criteria in design selection.

The parameters (v, b, k, r, λ) of a BIBD satisfy two relationships: (i) $bk = vr$ and (ii) $r(k-1) = \lambda(v-1)$. These two relationships, however, are necessary but not sufficient for

a BIBD to exist. For any combination of v and k ($k < v$), an *unreduced* BIBD can be constructed by taking all $b = \binom{v}{k}$ combinations of v treatments k at a time. The blocks of a BIBD for $v = b = 5$, $r = k = 4$ and $\lambda = 3$ are (0123), (0124), (0134), (0234) and (1234). Another well-known class of BIBDs which is resolvable and requires a smaller number of blocks and replications is *balanced lattice*. An $s \times s$ balanced lattice is a resolvable BIBD of size $v = s^2$, $b = s(s+1)$, $k = s$, $r = s+1$, and $\lambda = 1$ constructed from a complete set of $s \times s$ *mutually orthogonal Latin squares*. Chapters 4 and 9 of Raghavarao and Padgett (2005) describe the combinatorics of BIBDs and lattice designs in detail.

Cyclic IBDs are IBDs generated by the cyclic development of one or more suitably chosen initial blocks. Cyclic IBDs account for a large number of BIBDs in literature (see Table 4.4 of Raghavarao and Padgett 2005) . They also provide efficient alternatives to many partially BIBDs catalogued in Clatworthy (1973). Chap. 3 of John and Williams (1995) gives a summary of cyclic IBDs. When the number of replications r is equal to or is a multiple of the block size k, cyclic IBDs render automatic elimination of heterogeneity in two directions (see Sect. 5.7 of John and Williams 1995). The following is a cyclic BIBD for $v = 7$, $b = 14$, $k = 3$, $r = 6$ and $\lambda = 2$ generated by two initial blocks (1, 2, 6) and (1, 2, 4).

1	2	3	4	5	6	0	1	2	3	4	5	6	0
2	3	4	5	6	0	1	2	3	4	5	6	0	1
6	0	1	2	3	4	5	4	5	6	0	1	2	3

Patterson and Williams (1976a) introduced a new class of resolvable IBDs called α-design. α-designs are available for many (r, k, s) combinations where r is the number of replicates, k is the block size and s is the number of blocks per replicate (the number of treatments $v = ks$). An α-design was generated by an $r \times k$ array α with elements in set of residues mod s. Thus, the construction of an α-design (or a cyclic IBD) resorts to the construction of an array α (or one or more initial blocks). Chapter 4 of John and Williams (1995) gives a summary of resolvable IBDs including α-designs. α-designs and cyclic IBDs can be generated by the CycDesignN software (http://www.cycdesign.co.nz/) and the Gendex DOE toolkit (http://designcomputing.net/gendex/).

Cyclic solutions are not always optimal. Following is a non-cyclic solution for an IBD of size $(v, k, r) = (15, 6, 4)$. This optimal IBD with $E = 0.8861$ was constructed by the algorithm of Nguyen (1994).

7	5	4	6	5	8	8	10	13	14
9	13	6	10	13	2	5	0	12	7
5	7	8	12	14	6	3	9	3	1
12	4	0	4	9	13	2	2	8	12
3	0	9	14	11	7	14	11	1	0
6	10	1	11	1	11	4	3	10	2

Two Tools for IBD Construction

To construct certain IBDs with a large number of treatments effortlessly, we have to note a relationship between (1) an IBD and its *dual* and (2) a 2-replicate resolvable IBD and its *contraction*. An IBD is optimal if its dual (or contraction) is optimal (see Sects. 2.7 and 4.7 of John and Williams 1995). A *dual* of an IBD D of size (v, k, r) is an IBD D' of size $(v', k', r') = (b, r, k)$ obtained by swapping the treatments and blocks symbols in the original design. For example, the dual of the IBD of size $(v, k, r) = (4, 2, 3)$ displayed in section "▶Introduction" is the IBD of size $(v', k', r') = (6, 3, 2)$ displayed in section "▶A Criterion for Comparing IBDs".

Patterson and Williams (1976b) showed that a 2-replicate resolvable IBD D of size $(v, k, r) = (ks, k, 2)$ is uniquely determined by its contraction, a *symmetrical* IBD D^* of size $(v^*, k^*, r^*) = (s, k, k)$. The following 2-replicate resolvable IBD of size $(v, k, r) = (24, 4, 2)$ was obtained from a symmetrical IBD of size $(v^*, k^*, r^*) = (6, 4, 4)$ in section "▶Introduction":

0	4	8	12	16	20
1	5	9	13	17	21
2	6	10	14	18	22
3	7	11	15	19	23

3	7	5	0	1	2
4	11	10	8	9	6
15	12	18	13	17	14
16	19	20	21	22	23

Since the original designs in these two examples are optimal, their derived designs are also optimal. Additional examples on the use of these tools are given in Nguyen (1994) and Sects. 2.7 and 4.7 of John and Williams (1995).

Some Applications of IBDs

IBDs are related to several more complex combinatorial structures. As such they can be used to build these structures. The apparent application of IBDs is to use the blocks of an IBD as the column component of a row-column design (RCD). These designs are used for elimination of heterogeneity in two directions. Nguyen and Williams (1993) and Nguyen (1997) suggested a method for constructing optimal RCDs by permuting the treatments

within the blocks of an IBD used as the column component of the RCD. The following is an optimal RCD for 15 treatments, each replicated four times, set out in a 6 × 10 array obtained by permuting the treatments within the blocks of the IBD of size $(v, k, r) = (15, 6, 4)$ in section ►"IBDs with High Efficiency Factors":

12	7	4	11	9	8	5	10	1	2
3	5	0	12	11	6	4	2	13	1
7	4	9	6	1	13	2	3	10	14
6	10	1	14	5	7	8	11	3	0
9	13	8	4	14	11	3	0	12	7
5	0	6	10	13	2	14	9	8	12

This optimal RCD with $E = 0.856$ has been recommended for a taste test experiment involving 15 food products. The columns represent the tasters and the rows represent the order in which the products are introduced to the tasters.

Supersaturated designs are designs in which the number of factors $m > n - 1$ where n is the number of runs. Nguyen (1996) and Liu and Zhang (2000) described a method of constructing optimal 2-level supersaturated designs from cyclic BIBDs. The following optimal supersaturated design for 14 factors in eight runs was obtained from the cyclic BIBD in section "►IBDs with High Efficiency Factors". Each factor (column) of this design corresponds to a block of this BIBD. The treatments in each block of this BIBD are used to allocate the high level of a factor to a run:

1	1	1	1	1	1	1	1	1	1	1	1	1	1
−1	1	−1	−1	−1	1	1	−1	−1	−1	1	−1	1	1
1	−1	1	−1	−1	−1	1	1	−1	−1	−1	1	−1	1
1	1	−1	1	−1	−1	−1	1	1	−1	−1	−1	1	−1
−1	1	1	−1	1	−1	−1	−1	1	1	−1	−1	−1	1
−1	−1	1	1	−1	1	−1	1	−1	1	1	−1	−1	−1
−1	−1	−1	1	1	−1	1	−1	1	−1	1	1	−1	−1
1	−1	−1	−1	1	1	−1	−1	−1	1	−1	1	1	−1

IBDs have also been used to construct 3-level response surface designs (Box and Behnken 1960 and Nguyen and Borkowski 2008) and orthogonal and near-orthogonal arrays (Nguyen and Liu 2008). Other novel applications of IBDs can be found in Chapts. 5 and 8 of Raghavarao and Padgett (2005).

Incomplete Data in Clinical and Epidemiological Studies

Geert Molenberghs
Professor
Universiteit Hasselt and Katholieke Universiteit Leuven, Leuven, Belgium

In many longitudinal and multivariate settings, not all measurements planned are taken in actual practice. It is important to reflect on the nature and implications of such

incompleteness, or missingness, and properly accommodate it in the modeling process.

When referring to the missing-value process we will use terminology of Little and Rubin (2002, Chap. 6). A non-response process is said to be *missing completely at random* (MCAR) if the missingness is independent of both unobserved and observed data and *missing at random* (MAR) if, conditional on the observed data, the missingness is independent of the unobserved measurements. A process that is neither MCAR nor MAR is termed *non-random* (MNAR).

Given MAR, a valid analysis that ignores the missing value mechanism can be obtained, within a likelihood or Bayesian framework, provided the parameters describing the measurement process are functionally independent of the missingness model parameters, the so-called parameter distinctness condition. This situation is termed ignorable by Rubin (1976) and Little and Rubin (2002) and leads to considerable simplification in the analysis (Verbeke and Molenberghs 2000). There is a strong trend, nowadays, to prefer this kind of analyses, in the likelihood context also termed *direct-likelihood* analysis, over *ad hoc* methods such as *last observation carried forward* (LOCF), *complete case analysis* (CC), or simple forms of ►imputation (Molenberghs and Kenward 2007). Practically, it means conventional tools for longitudinal and multivariate data, such as the linear and generalized linear mixed-effects models (Verbeke and Molenberghs 2000; Molenberghs and Verbeke 2005) can be used in exactly the same way as with complete data. Software tools like the SAS procedures MIXED, NLMIXED, and GLIMMIX facilitate this paradigm shift.

In spite of direct likelihood's elegance, fundamental model assessment and model selection issues remain. Such issues, occurring under MAR and even more under MNAR, are the central theme of this paper.

Indeed, one can never fully rule out MNAR, in which case the missingness mechanism needs to be modeled alongside the mechanism generating the responses. In the light of this, one approach could be to estimate from the available data the parameters of a model representing a MNAR mechanism. It is typically difficult to justify the particular choice of missingness model, and the data do not necessarily contain information on the parameters of the particular model chosen (Molenberghs and Kenward 2007). For example, different MNAR models may fit the observed data equally well, but have quite different implications for the unobserved measurements, and hence for the conclusions to be drawn from the respective analyses. Without additional information one can only distinguish between such models using their fit to the observed data, and so goodness-of-fit tools typically do not provide a relevant means of choosing between such models. It follows that there is an important role for sensitivity analysis in assessing inferences from incomplete data (Verbeke and Molenberghs 2000; Molenberghs and Verbeke 2005; and Molenberghs and Kenward 2007).

Index Numbers

Dimitri Sanga
Acting Director
African Centre for Statistics, Addis Ababa, Ethiopia

Definition

An index number can be defined as a single indicator representing the change in the value of a variable relative to its value at some base date or state referred to as the base period. The index is often conventionally scaled so that its base value is 100. The variables considered represent a number of concepts including prices, quantity, volumes, value of a commodity, or other general economic variable such as national income, or gross output, cost of living, value of stock exchange etc. It constitutes a convenient way to standardize the measurement of numbers so that they are directly comparable.

Index numbers are used in several instances. The most commonly used include price indexes, quantity indexes, value indexes, or special-purpose indexes etc. Some of

the most widely known and used indexes include the Consumer Price Index (CPI), the Producer Price Index (PPI), the Human Development Index (HDI), etc. The CPI describes the change in prices of a basket of goods purchased by a representative consumer relative to a base period while the PPI is its equivalent but on the producer side. Stock market indexes, on the other hand report on the change in the prices of stocks on different markets. These include the Dow Jones Industrial Average, which is published daily, and that describes the overall change in common stock prices of 30 large companies during the day, while the Standard and Poor's 500 Stock Average is based on a 500 most important firms which stocks trade on the New York Stock Exchange divided by a factor that is adjusted for stock splits. There are equivalent of these indexes in other countries and cities such as the CAC 40 in Paris, the DAX in Frankfurt, the FTSE 100 in London, and the Nikkei 225 in Tokyo.

Since the development of indices has been dominated by price indices and that many of the developments do also apply to other types of indexes, the remaining of the text will concentrate and use examples of these kinds of indexes.

Types of Indexes

When the measurements over time and/or space are on a single variable, for example, the price of a certain commodity, the index is called a simple index number. Thus, the index of a variable for any year t is defined as:

$$I_t = \frac{X_t}{X_0} \times 100,$$

where I is the index number at period t, X_t and X_0 being the values of the variable at time t and base period respectively. For example, if a commodity costs twice as much in 2010 as it did in 2000, its index number would be 200 relative to 2000.

When the measurements over time and/or space are on the multiple aspects of a concept such as the level of economic development, general disparities, or for two or more items, the index is called composite index. The index related to the concept for any year t, in this case, is defined as:

$$I_t = f\left(\omega_i, \frac{X_t^i}{X_0^i}\right),$$

where I is the index number at period t, X_t and X_0 the values of the concept at time t and base period respectively, f a functional form (might be a product or sum), and ω_i the weight of component (aspect) i. The well-known Laspeyres price index is a special case of the above with the weights being values (prices time quantities) of different products (goods or services) in the basket during the base period as follows: $L_P = \omega_i \sum_{i=1}^{n} \frac{P_t^i}{P_0^i}$, with $\omega_i = \frac{P_0^i Q_0^i}{\sum_{i=1}^{n} P_0^i Q_0^i}$ and P the prices and Q quantities at respective periods. The Laspeyres price index is therefore a weighted average of the relative prices of different goods being part of a basket between periods 0 and t.

Elementary Indexes

Elementary indexes also called unweighted indexes are those that compare the prices in different periods without using weights. They are called elementary because they are computed for a single good (product, item, concept etc.). In fact, the computation of price indexes for a single good does not require the use of weights since only one type of good is being aggregated. Below are some well-known elementary price indices.

The Dutot Index

Developed by the French economist Charles de Ferrare Dutot in 1738, this index is a ratio of average prices as follows:

$$D_P = \frac{\frac{1}{n}\sum_{i=1}^{n} P_t^i}{\frac{1}{n}\sum_{i=1}^{n} P_0^i} = \frac{\sum_{i=1}^{n} P_t^i}{\sum_{i=1}^{n} P_0^i}.$$

The Carli Index

Developed by the Italian economist Rinaldo Carli in 1764, this index is an arithmetic average of price ratios as follows:

$$C_P = \frac{1}{n}\sum_{i=1}^{n} \frac{P_t^i}{P_0^i}.$$

The Jevons Index

Developed by the English economist Stanley Jevons in 1738, this index is a geometric average of prices as follows:

$$J_P = \prod_{i=1}^{n} \left(\frac{P_t^i}{P_0^i}\right)^{1/n}.$$

Because in some instances, prices or price ratios need to be aggregated to derive price indices, arithmetic or geometric means (see ▶Geometric Mean) are used. The debate over the correct method for computing price indexes namely on the use of arithmetic or geometric averages and whether to weight the index and by which quantities goes back as far as the 1800s. Three pioneers on price indexes development exchanged a lot on this. Laspeyres

argued for an arithmetic average weighted by quantities in the first period even if he did not use that himself in practice. Paasche was of the same opinion as Laspeyres on the use of arithmetic means but differed on the weights as he privileged the use of weights from the current period as opposed to Laspeyres who used those of the base period. Unlike the other two economists, Jevons was defending geometric averaging. The debates on these issues still exist nowadays and have been studied for centuries.

To illustrate the debate on arithmetic versus geometric means, let's consider the prices of two goods A and B from period 0 to t. If the price of good A doubles between 0 to t, the index will rise from 100 to 200. If in the meantime the price of good B decreases by half during the same period, the related index will decrease from 100 to 50. The average prices level of the two goods in t will be 125 resulting in an average price change of 25%. Using geometric means, the average price change (square root of the product of the indexes in t) will be 100, meaning no change in average prices. As can be observed from this example, the choice of the aggregation method will influence the index. The geometric means assure that expenditures shares are constant. The argument against arithmetic averages and in favor of geometric ones can be summarized in the fact that buyers substitute towards those goods whose relative price has fallen. The geometric means takes into account substitutions holding expenditures shares constants while the arithmetic means assumes that quantities remain constants.

Fixed-Weights Indexes

Fixed-weights indexes are those indexes that use weights derived for a given period in their calculation. In practice, the computation of price indexes entails only collecting prices in the current period (t) as the indices are explained as a function of the ratios of prices of the items between the current and the base periods. These ratios are then aggregated using either arithmetic or geometric means. Once this decided upon, there is still the issue of the weights to be used. These weights can be computed either for the base period or the current one. The Laspeyres index commonly used to compute the CPI in official statistics of countries across the world uses weights from the base period while the Paasche index uses weights from the current period. While both are fixed-weights indices, the Laspeyres is very attractive in practice because at t the weights in period 0 (the base) can be derived from the expenditures from household budget surveys as they have already been observed in the past. Below are some widely used fixed-weights indexes.

The Laspeyres Index

Developed by the German economist Ernst Louis Étienne Laspeyres in 1871, this index is a weighted arithmetic average of price ratios with weights derived from the base period as follows:

$$L_P = \frac{\sum_{i=1}^{n} P_t^i \, Q_0^i}{\sum_{i=1}^{n} P_0^i \, Q_0^i} = \omega_i \sum_{i=1}^{n} \frac{P_t^i}{P_0^i}, \text{ with } \omega_i = \frac{P_0^i \, Q_0^i}{\sum_{i=1}^{n} P_0^i \, Q_0^i}.$$

The Paasche Index

Developed by the German Statistician/economist Hermann Paasche in 1874, this index is a weighted arithmetic average of price ratios with weights derived from the current (t) period as follows:

$$P_P = \frac{\sum_{i=1}^{n} P_t^i \, Q_t^i}{\sum_{i=1}^{n} P_0^i \, Q_t^i}.$$

By virtue of the use of the base period weights, the Laspeyres index is known to overstate price changes. In fact, according to economic theory, consumers substitute goods that are becoming more expensive with less expensive ones while the index assumes that the basket of goods and services chosen in the base period remains fixed. This index ends up using an outdated fixed structure that does not take into accounts the substitution effect. The Paasche index understates price changes for the same reason. To deal with this problem, Fisher came up with a proposal that lies between the two previous ones.

Chained Indexes

To overcome the problem related to the use of outdated fixed weights structures, indexes are often chained using updated weights. In the case of the Laspeyres price index, its chained version will take the following form:

$$LC_P = \frac{\sum_{i=1}^{n} P_1^i \, Q_0^i}{\sum_{i=1}^{n} P_0^i \, Q_0^i} \cdot \frac{\sum_{i=1}^{n} P_2^i \, Q_1^i}{\sum_{i=1}^{n} P_1^i \, Q_1^i} \cdot \ldots \cdot \frac{\sum_{i=1}^{n} P_t^i \, Q_{t-1}^i}{\sum_{i=1}^{n} P_{t-1}^i \, Q_{t-1}^i} \cdot \ldots \cdot \frac{\sum_{i=1}^{n} P_s^i \, Q_{s-1}^i}{\sum_{i=1}^{n} P_{s-1}^i \, Q_{s-1}^i}$$

where s is the number of periods over which the chain index extends. This has been and remains the practice in the computation of official CPIs of many of the countries across the world.

The Fisher Index

Developed by the American economist Irving Fisher in 1920/1922, this index is a geometric mean of Laspeyres and

Paasche indexes as follows:

$$F_P = (L_P \cdot P_P)^{1/2}.$$

Non-Fixed-Weights Indexes

The non-fixed weights indexes include the following:

The Marshall-Edgeworth Index

Developed by Alfred Marshall (1887) and Edgeworth (1925), this index is a weighted relative of current prices with weights being arithmetic averages of current and base period quantities as follows:

$$ME_P = \frac{\sum_{i=1}^{n}\left[P_t^i \cdot \frac{1}{2} \cdot \left(Q_0^i + Q_t^i\right)\right]}{\sum_{i=1}^{n}\left[P_0^i \cdot \frac{1}{2} \cdot \left(Q_0^i + Q_t^i\right)\right]}.$$

This formulation has however a major drawback as it can be problematic when comparing the price levels of a small entity versus a large one as the quantities of the large entity might dominate those of the small.

Superlative Indexes

Superlative indexes provide close approximations of the true cost of living index. They produce similar results and constitute an exact approximation for a flexible functional form that can provide a second order approximation to other twice differentiable functions around the same point (Diewert 1976).

The Fisher index is a superlative index and is also called "Fisher Ideal Price Index." Another superlative index is the Tornqvist Index. Beside the fact that the Fisher index is superior theoretically to the Laspeyres and the Paasche, it has a number of desirable properties from the National Accounts perspective. In fact, it is reversible over time that is the index showing the change between period 0 and t is the reciprocal of the index showing the change between period t and 0. Moreover, it also has the property of reversibility of factors by which the product of the price and quantity indexes is equal to the change in current values. The other indexes do not have these properties.

The Tornqvist Index

Developed by Tornqvist in 1936, this index is a weighted geometric mean of price ratios with weights being average expenditures shares on each good as follows:

$$T_P = \prod_{i=1}^{n}\left(\frac{P_t^i}{P_0^i}\right)^{\frac{1}{2}\left[\frac{P_0^i \cdot Q_0^i}{\sum_{i=1}^{n} P_0^i \cdot Q_0^i} + \frac{P_t^i \cdot Q_t^i}{\sum_{i=1}^{n} P_t^i \cdot Q_t^i}\right]}.$$

Other Composite Indexes

A composite index is a comprehensive single number representing a vast array of measurements on the multiple aspects of a conceptual entity such as general price level, cost of living, level of economic development, general disparities, statistical development etc. Representatives of these kinds of indices are the HDI, the General Index of Development (GID), Physical Quality of Life Index (PQLI), Index of Social Progress (ISP) etc.

There are several advantages related to the development of composite indexes. The advantages of composite indices include: excellent communication tools for use with practically any constituency including the media, general public, and decision makers; the provision of single targets that facilitate the focus of attention; facilitation of the necessary negotiations about practical value and usefulness due to simplicity; provision of a means to simplify complex, multidimensional phenomena and measures; easy measure and visual representation of overall trends in several distinct indicators over time or across space; and provision of a means to compare diverse phenomena and assessing their relative importance, status or standing on the basis of some common scale of measurement across time and space. On the other hand, there are also some disadvantages. These include sending misleading policy messages if composite indices are poorly constructed or misinterpreted; possibility of inviting simplistic policy conclusions; misused to support desired policy, if the construction process is not transparent and lacks sound statistical or conceptual principles; selection of indicators and weights could be the target of political challenge; and leading to inappropriate policies of dimensions of performance that are difficult to measure.

The bottom line of the relevance of composite indicators is that they are needed as a starting point for initiating discussions and attracting public interest to the phenomenon at stake as they provide a very simple and useful way of presenting complex multidimensional phenomena into an easily understandable measure. Nevertheless, one as to be cautious in its development as the index is meant to be used for important decision-making and expression of views on the considered phenomenon. Therefore, constituencies affected by its use should ascertain their relevance.

Areas of Research

Several issues on index numbers theory and practice are still worth exploring for future research. These include the use of geometric versus arithmetic means, the use or not of weights and from which time, approximation of the cost

of living index, aggregation formulas, change in quality, introduction of new goods etc.

There is a wealth of literature on index construction and applications, desirable properties of index numbers and the relationship between index numbers and economic theory. For further details concerning the discussed matter, the reader may refer, *inter alia*, to the below references.

Industrial Statistics

Ursula Gather[1,2], Sonja Kuhnt[2], Thomas Mühlenstädt[2]
[1]Rector of TU Dortmund University, Dortmund, Germany
[2]Faculty of Statistics
TU Dortmund University, Dortmund, Germany

Industrial statistics deals with the assurance and improvement of quality in industrial (production-) processes and products.

Quality Assurance

One of the most important considerations regarding a production process is the assurance of a stable and steady quality of the process output, i.e., the process is *under control*. Otherwise, if the process shows erratic and undesired behavior, it is *out of control*. An underlying random variable Y measuring the quality of the process, is often assumed to have a distribution P_θ, with θ being a parameter(-vector), possibly mean and variance $\theta = (\mu, \sigma^2)$.

Acceptance Sampling

►Acceptance sampling aims at accepting or rejecting a lot of products by inspecting only a small proportion of the items (Kenett and Zacks 1998). Items are chosen according to an acceptance sampling scheme and rated as either conforming or nonconforming to given quality specifications. An important characterization of an acceptance sampling plan is given by the operating characteristic (OC) function, which yields the probability of accepting a lot with proportion p of defective items.

Control Charts

By observing series of samples $y_{m,1}, \ldots, y_{m,g}$, of size $g \in \mathbb{N}$, $m = 1, 2, 3, \ldots$, one wants to check if the process is under control. A control chart is a graphical tool which plots a summary statistic of the samples against the sample number (Montgomery 2009). To determine whether the process is out of control, control limits $((ucl, lcl))$ are calculated. If the control limits are exceeded the process is rated out of control and thus the reason for the deviation has to be investigated. The control limits are estimated from samples, for which it is known that the process was under control. The summary statistic used most frequently is the arithmetic mean: $\bar{y}_m := \frac{1}{g} \sum_{i=1}^{g} y_{m,i}$.

The performance of the control chart can also be described by the OC-function. Possible extensions of ►control charts are control charts with memory, multivariate control charts or control charts for the variance of the process.

Process Capability Indices

Process capability indices summarize the behavior of a process with a single number in order to have a simple decision rule to determine if the process performance can be accepted or not. Well known process capability indices are the C_p and the C_{pk} index:

$$C_p := \frac{ucl - lcl}{6\sigma}, \qquad C_{pk} := \min\left(\frac{\mu - lcl}{3\sigma}, \frac{ucl - \mu}{3\sigma}\right), \tag{1}$$

using the same notation as before. Here, the *ucl* and *lcl* are most frequently defined by the desired properties for the product. In practice, μ and σ are estimated by the arithmetic mean $\bar{y} = \frac{1}{n}\sum_{i=1}^{n} y_i$ and the empirical standard deviation $s = \sqrt{\frac{1}{n-1}\sum_{i=1}^{n}(y_i - \bar{y})^2}$, and then substituted into the formulae. For the C_p index, the mean μ of the process is not included in the formula. This reflects the assumption that the position of a process is (often) easy to adjust, while the variation of the process is difficult to control and hence should be the only value to be used for judging a process. The C_{pk} index also considers the location of the process. For both indices, higher values represent a better process. For the C_p index, this means that the variation of the process compared to the range of the control limits is small, while for the C_{pk} the location of the process has to be inside the control limits as well. There are many possible extensions of the concept of process capability indices for situations like one sided process specifications or skew distributions of Y, e.g., see Kotz and Lovelace (1998).

Quality Improvement

If a new process is under investigation, good configurations of the process are wanted. Here the random variable Y representing the process depends on some covariates $x \in \mathbb{R}^k$. A configuration of x which optimizes Y in some suitable way is searched for. This can be maximizing/minimizing Y, or searching for an x which results in the smallest deviation of Y from a nominal value T. In industrial statistics, methods for this kind of problem are often summarized under the topic of ►response surface methodology (RSM, Myers et al. 2009). Formally, this usually results in a regression model:

$$Y(x) = f(x) + \varepsilon, \tag{2}$$

where $f(x)$ is an unknown function $f : \mathbb{R}^k \to \mathbb{R}$ and ε a random variable representing process variation with expectation $E(\varepsilon) = 0$ and constant variance $var(\varepsilon) = \sigma^2$. Given some data $y_1 = y(x_1), \ldots, y_n = y(x_n)$ with $x_1, \ldots, x_n \in \mathbb{R}^k$ an estimate $\hat{f}$ is calculated and used for optimizing Y.

Design of Experiments (DoE)

A powerful tool for improving process quality is called design of experiments, which refers to statistically planning experiments. DoE leads to a design matrix $X = [x_1, \ldots, x_n]'$ for n runs of the experiments to be conducted, where each row of X specifies the settings of the covariates for one run. The choice of X depends on a number of issues, e.g. the purpose and scope of the experiment, the assumed statistical model and the desired degree of precision of the results and conclusions. Standard designs such as fractional factorial designs and response surface designs exist, primarily for use in situations where the estimation of a regression model is desired.

Robust Parameter Design/Taguchi Methods

Taguchi (e.g., see Myers et al. 2009) was one of the first to consider not only the mean f of the process under investigation but also the variance of Y. It is assumed that there are some control variables $x \in \mathbb{R}^k$ which are easy to adjust in mass production settings but also noise variables $z \in \mathbb{R}^d$, which are adjustable in a laboratory but not during mass production, e.g., fluctuations in raw materials. In order to reduce the influence of noise factors on the process, a configuration for the control variables x is investigated, which not only optimizes the mean of Y but also results in a small variation of Y. As these two aims are not always achievable at the same time, strategies for finding compromises have to be applied. Crucial for achieving this is the use of suitable experimental designs like crossed designs, which combine a design for the control variables and a design for the noise variables.

Further Topics

Six Sigma

►Six Sigma is a methodology for implementing process improvements in companies. Applying Six Sigma implies using a specific organizational form. One of the most important aspects of Six Sigma is its focus on projects. A project should consist of a "potential breakthrough" for product or service improvement, Montgomery and Woodall (2008). Each project is strictly organized by the DMAIC cycle: Define, Measure, Analyze, Improve and Control, which makes research projects more traceable.

Another key aspect of Six Sigma is its belt system, dividing the educational status of an employee into three classes: green belt (lowest level), black belt or master black belt (highest level).

The name Six Sigma is taken from reliability theory. Consider a process with nominal value T and symmetrical control limits lcl, ucl. A Gaussian random variable Y with mean $\mu = T$ and variance $\sigma = (ucl - lcl)/6$ has a probability of 99.73 percent of being within the control limits. This reflects the claim of Six Sigma to achieve processes which have only a very small probability of being outside the control limits.

Reliability Analysis

Reliability analysis deals with the analysis of how reliably a product is performing its task (Kenett and Zacks 1998). A product which functions for a long time without any defects is said to be reliable. A central concept is the reliability function $R(t)$: $R(t) :=$ *Probability that the product is working according to its specifications after t time units.* In order to estimate the reliability function, a sample of products is investigated and the failure times are noted. As this can be very time consuming, accelerated life testing is often used, where the product is set under higher stress than under normal conditions. Reliability analysis is not only applied to products but also, for example, to software.

Computer Experiments

In many industrial research situations, a real world process can be replaced by simulation models, which reproduce the real process in a software environment. As a result, huge cost reductions can be achieved. However, care has to be taken, as computer experiments are very different from conventional experiments. Most of the time, the computer experiment is deterministic and a single run is very time consuming. Thus the computer experiment should be planned carefully (Fang et al. 2006). Designs for computer experiments are summarized as space filling designs while models for a computer experiment should interpolate the observations as no random error is observed. Furthermore, validating the computer experiment as replacement for the real world experiment is crucial in order to assure that valid results for real world applications are derived from the computer experiment.

About the Authors

Professor Gather was appointed rector of TU Dortmund University on 1 September 2008. She is vice-chair of the Senate of the German Aerospace Center, council member of the International Statistical Institute, and spokesperson of the DFG-Review Board Mathematics. Professor Gather was Editor of Metrika (1996–2006).

Dr. Sonja Kuhnt has a temporary professorship of Mathematical Statistics and Industrial Applications in the Statistics Department at TU Dortmund University.

Inference Under Informative Probability Sampling

Michail Sverchkov
Bureau of Labor Statistics, Washington, DC, USA

One of the outstanding features of sample surveys is that the samples are often drawn with unequal probabilities, at least at one stage of the sampling process. The selection probabilities are generally known for the sampled units in the form of the sampling weights (inverse of the sampling probability and possibly adjusted for nonresponse or calibration). The sampling weights are in common use for randomization-based inference on finite population quantities of interest, by weighting the sample observations by the corresponding sampling weights. This is discussed and illustrated in every text book on sample surveys. In this paper we focus on model-based inference.

In what follows we distinguish between the model holding for the population outcomes, hereafter the *population model*, and the (conditional) *sample model* holding for the sample outcomes. When the selection probabilities are correlated with the outcome values even after conditioning on the model covariates, the sampling is *informative*

and the two models can be very different, in which case the sampling process cannot be ignored in the modeling process. To see this, denote the population model by $f_U(y|x)$, where y is the outcome variable and x is a set of covariates. Following Pfeffermann et al. (1998), the sample model is defined as

$$f_s(y_i|x_i) \stackrel{def}{=} f(y_i|x_i, i \in s) = \frac{\Pr(i \in s|y_i, x_i) f_U(y_i|x_i)}{\Pr(i \in s|x_i)} = \frac{E_U(\pi_i|y_i, x_i) f_U(y_i|x_i)}{E_U(\pi_i|x_i)}, \quad (1)$$

where $\pi_i = \Pr(i \in s)$ is the sample inclusion probability and $E_U(\cdot)$ defines the expectation under the population model. Note that $\Pr(i \in s|y_i, x_i)$ is generally not the same as π_i, which may depend on all the population values $\{y_i, x_i\}, i \in U$ and possibly also on the values z_i of design variables z, which are not included in the model but are used for the sample selection. By (1), if $\Pr(i \in s|y_i, x_i) \neq \Pr(i \in s|x_i)$, the population and the sample models are different and fitting the population model to the sample data ignoring the sampling process may bias the inference very severely. In the rest of this paper we review approaches that account for the sampling effects under informative probability sampling. See Pfeffermann and Sverchkov (2009) for a more comprehensive discussion with examples.

The first approach utilizes the fact that if for every x, $\Pr(i \in s|y_i, x_i) = \Pr(i \in s|x_i) \forall y_i$, the population and the sample models are the same. Therefore the sampling effects can be accounted for by including among the model covariates all the design variables and interactions that are related to the outcome values and affect the sample selection probabilities. See, e.g., Gelman (2007). However, this paradigm is not always practical because there may be too many variables to include in the model and some or all of them may not be known or accessible to the modeler. Notice also that by including these variables among the model covariates, the resulting model may no longer be of scientific interest, requiring integrating them out of the model at a later stage, which can be complicated and not always feasible.

Alternatively, one could include in the model the sampling weights as surrogates for the design variables as proposed by Rubin (1985). The use of his strategy may again distort the interpretation of the model requiring therefore integrating out the sampling weights at a second stage. This is a feasible procedure for estimating the sample model because the integration is then with respect to the conditional sample distribution of the sampled weights given the covariates, which can be assessed from the observed weights and the covariates. However, for estimating the population model the integration of the sampling weights must be with respect to the population model of the weights given the covariates. Notice also that the vector of sampling weights may not be an adequate summary of all the design variables used for the sample selection.

A third approach, and the one in common use, is to estimate the population model by weighting the sample observations in the model-based estimating equations by the sampling weights. When the estimating equations are defined by the score function, the use of this approach is known in the sampling literature as "pseudo likelihood" estimation. The use of this approach is limited, however, mostly to point estimation, and probabilistic inference such as the construction of confidence intervals or the application of hypothesis testing generally require large samples normality assumptions. The inference is based on the randomization distribution and as such, it does not permit conditioning on the selected sample, for example, conditioning on the observed covariates, or on the selected clusters in a multi-level model. In addition, the use of this approach does not lend itself to prediction problems other than the prediction of the finite population quantities from which the sample is taken, and the estimators often have large variances, depending on the dispersion of the weights. See Pfeffermann and Sverchkov (2009) for further discussion on the use of this approach with many references.

A fourth approach is based on the relationship between the population model and the sample model in (1). Following Pfeffermann and Sverchkov (1999),

$$f_U(y_i|x_i) = \frac{E_s(w_i|y_i, x_i) f_s(y_i|x_i)}{E_s(w_i|x_i)}, \quad (2)$$

where $w_i = 1/\pi_i$ and $E_s(\cdot)$ is the expectation under the sample model. Thus, one can identify and estimate the population model by fitting the sample model $f_s(y_i|x_i)$ to the sample data and estimating the expectation $E_s(w_i|y_i, x_i)$, again using the sample data. For example, suppose that the population model is governed by the vector parameter $\theta = (\theta_0, \theta_1, \ldots, \theta_k)'$ and let $\mathbf{d}_{Ui} = (d_{Ui,0}, d_{Ui,1}, \ldots, d_{Ui,k})' = \partial \log f_U(y_i|x_i; \theta)/\partial\theta$ be the i^{th} score function. Assuming that the conditional expectations $E_s(w_i|y_i, x_i)$ are known or have been estimated and that the expectations $E_s(w_i|x_i) = \int_y E_s(w_i|y, x_i) f_s(y|x_i; \theta) dy$ are differentiable with respect to θ, it follows from (2) that if the sample outcomes are independent (see Remark 1 below), the sample likelihood equations are,

$$W_s(\theta) = \sum_{i \in s} E_s\{[\partial \log f_s(y_i|x_i; \theta)/\partial\theta]|x_i\} = \sum_{i \in s} E_s\{[\mathbf{d}_{Ui} + \partial \log E_s(w_i|x_i)/\partial\theta]|x_i\} = 0. \quad (3)$$

Therefore, θ can be estimated by solving the equations in (3).

Remark 1. Pfeffermann et al. (1998) showed that under some general regularity conditions if the population measurements are independent, the sample measurements are "asymptotically independent" with respect to the sample model. The asymptotic framework requires that the population size increases but the sample size stays fixed. The result is shown to hold for many sampling schemes with unequal probabilities in common use.

Instead of basing the likelihood on the sample distribution, one could use instead the "full likelihood" based on the joint distribution of the sample outcomes and the sample membership indicators $I_i = 1(0)$ for $i \in s (i \notin s)$. Let $\mathrm{I} = (I_1, \ldots, I_N)'$ and denote $\mathrm{x} = \{x_i, i \in U\}$. Then,

$$f(\mathrm{I}, y_s|\mathrm{x}) = \prod_{i \in s} \Pr(i \in s|y_i, x_i) f_U(y_i|x_i) \prod_{j \notin s} [1 - \Pr(j \in s|x_j)], \tag{4}$$

where $\Pr(i \in s|x_i) = \int \Pr(i \in s|y_i, x_i) f_U(y_i|x_i) \mathrm{d}y_i$; see, e.g., Gelman et al. (2003), Pfeffermann and Sverchkov (2003) and Little (2004). The use of (4) has the theoretical advantage of employing the information on the sample selection probabilities for units outside the sample, but it requires knowledge of the covariates for every unit in the population, unlike the use of (3). Other estimation approaches are considered in Breckling et al. (1994) and Pfeffermann and Sverchkov (2003).

So far we considered model estimation but the sample distribution enables also to predict missing population values. For this we define the *sample-complement* model,

$$f_c(y_i|x_i) \stackrel{def}{=} f(y_i|x_i, i \notin s) = \frac{\Pr(i \notin s|y_i, x_i) f_U(y_i|x_i)}{\Pr(i \notin s|x_i)} = \ldots = \frac{E_s[(w_i - 1)|y_i, x_i] f_s(y_i|x_i)}{E_s[(w_i - 1)|x_i]}, \tag{5}$$

with the last equation obtained in Sverchkov and Pfeffermann (2004). The sample-complement model is again a function of the sample model $f_s(y_i|x_i)$ and the expectation $E_s(w_i|y_i, x_i)$, and thus can be estimated from the sample.

Remark 2. When predicting the outcome value for a specific nonsampled unit (say, a unit with a given set of covariates), or the mean of a given nonsampled area in a small area estimation problem, and the sampling process is informative, there seems to be no alternative but to base the prediction on the sample-complement model. Classical randomization based inference is suited for estimating parameters of the finite population from which the sample is drawn, but not for prediction problems. Sverchkov and Pfeffermann (2004) illustrate how many of the classical randomization-based estimators of finite population totals, such as the ►Horvitz-Thompson estimator, Hajek/Brewer estimator and the GREG, are obtained as special cases of the application of the sample-complement model. The authors develop also a method for estimating the MSE of the prediction errors. Small area estimation under informative sampling of areas and within the areas is considered in Pfeffermann and Sverchkov (2007).

Influential Observations

Deng-Yuan Huang
Professor
Fu-Jen Catholic University, Taipei, Taiwan

Fitting liner regression models usually uses the ▶least squares method. The fitted model may be largely influenced by a few observations. These observations are called influential observations. It is necessary to define a criterion to find out these observations. They may include important information.

The analysis of residuals may reveal various functional forms to be suitable for the regression model. Some appropriate criteria to measure the influence of the model were studied for detecting influential data.

We consider the following linear model:

$$\underline{Y} = X\underline{\beta} + \underline{e}, \tag{1}$$

where $E(\underline{e}) = \underline{0}$, $Var(\underline{e}) = \sigma^2 I_n$, and I_n denotes the identity matrix of order n, $\underline{Y}$ is an $n \times 1$ vector of responses, X is an $n \times p$ $(n > p)$ matrix of known constants of rank p, and $\underline{\beta}$ is a $p \times 1$ parameter vector.

Several authors have studied the influence on the fitted regression line when the data are deleted. Let $\hat{\underline{\beta}}$ be the usual least squares estimator of $\underline{\beta}$ based on the full data and let $\hat{\underline{\beta}}_A$ be an alternative least squares estimator based on a subset of the data. The empirical influence function for $\hat{\underline{\beta}}$, namely, IF_A, is defined to be

$$IF_A = \hat{\underline{\beta}} - \underline{\beta}. \tag{2}$$

For a given positive definite matrix M and a nonzero scale factor c, Cook and Weisberg (1980) defined the distance $D_A(M, c)$ between $\hat{\underline{\beta}}$ and $\hat{\underline{\beta}}_A$ as follows:

$$D_A(M, c) = (IF_A)'M(IF_A)/c. \tag{3}$$

They suggested that the matrix M can be chosen to reflect specific interests. They also pointed out that in some applications, measuring the influence of cases on the fitted values, $\hat{\underline{Y}} = X\hat{\underline{\beta}}$, may be more appropriate than measuring the influence on $\hat{\underline{\beta}}$. They mentioned an example to describe the fact that if prediction is the primary goal, it may be convenient to work with a reparameterized model where the regression coefficients are not of interest. They tried to treat their measurement of the influence on the fitted values $X\hat{\underline{\beta}}$ and used the empirical influence function for $\hat{\underline{Y}}$, denoted by $X(IF_A)$.

Welsch (1982) pointed out that in an earlier paper, Cook (1977) chose to measure influence by

$$D_i = \frac{(\hat{\underline{\beta}} - \hat{\underline{\beta}}_{(i)})'X'X(\hat{\underline{\beta}} - \hat{\underline{\beta}}_{(i)})}{s^2 p}, \tag{4}$$

where s^2 is the residual mean square for full data and $\hat{\underline{\beta}}_{(i)}$ is the least squares estimator of $\underline{\beta}$ based on the data set with the ith component in $\underline{Y}$ deleted.

Welsch (1982) gave an example to explain that when all of the observations but one lie on a line, (4) can give potentially confusing information since it may indicate that some observations on the line are more influential than the one observation not on the line. This is counterintuitive since the deletion of this one observation leads to a perfect fit. Therefore, finding a more reasonable measurement is very important. We shall consider the case of one-at-a-time data deletion, since, for the case of deletion of a subset, computations can be similarly carried out (Cook and Weisberg 1980; Gray and Ling 1984).

Gupta and Huang (1996) derived a suitable choice of M and c in (3) to measure the influence and bias are derived as follows:

$$D_{(i)} = \frac{(\hat{\underline{\beta}} - \hat{\underline{\beta}}_{(i)})'X'_{(i)}X_{(i)}(\hat{\underline{\beta}} - \hat{\underline{\beta}}_{(i)})}{s^2_{(i)}p}, \tag{5}$$

where $X_{(i)}$ denotes the data set with the ith component in X deleted, and $s^2_{(i)}$ is the residual mean square for the ith component in $\underline{Y}$ deleted.

Gupta and Huang's statistic $D_{(i)}$ in (5) measures the influence on residuals and on $X\hat{\underline{\beta}}$. It should be pointed out that the large influence on $X\hat{\underline{\beta}}$ should have much influence on $\hat{\underline{\beta}}$ though the converse may not hold.

Information Theory and Statistics

Evgueni Haroutunian
Professor, Head of the Laboratory of Information Theory and Applied Statistics
Institute for Informatics and Automation Problems of the Armenian National Academy of Sciences, Yerevan, Armenia

Information theory is a branch of mathematics based on probability theory and statistical theory. The founder of information theory, Claude Shannon, created the "mathematical theory of communication" and the successors of Shannon thoroughly developed firm mathematical constructions for descriptions of communication processes ensuring data reliable compression, transmission and protection (Blahut 1974, 1987; Cover and Thomas 2006; Rissanen 2007).

Modern information theory is characterized as a "unifying theory with profound intersection with probability, statistics, computer science, and other fields" Verdú (1998), it has main applications in communication engineering, neurobiology, psychology, linguistics, electrical engineering, data analysis, and statistical inference.

What might statisticians learn from information theory? Basic concepts like ►entropy, mutual information, and ►Kullback-Leibler divergence (also called informational divergence, or relative entropy, or discrimination information), along with many various generalizations of them, certainly play an important role in statistics. The definitions of these notions are given in publications cited below Blahut (1987), Cover (2006), Csiszár (2004), Liese (2006), Pardo (2006). The elements of large deviations theory (see ►Large Deviations and Applications), limit theorems, hypothesis testing, estimation of parameters, some modern principles of statistical inference such as the maximum entropy principle, model selection methodologies like AIC and the principle of minimum description length, are explained with usage of information theory methodology in Ahlswede (1987), Kullback (1959), Pardo (2006), and Rissanen (2007).

Statistical theory shares with information theory the common optimal methods of usage of considered random data. Interaction of information theory and statistics creates the opportunity for formulating and solving of many interesting specific theoretical and practical problems Ahlswede (1986), Barron (1997), Rényi (1968). Information theoretic proofs have been given to various limit theorems of probability theory Kendall (1963), Linnik (1959).

A specific scientific field established by a series of works of information theory experts is the hypotheses testing with finite statistics Hellman (1970).

One of new directions of statistical studies initiated by information theorists is development of statistical inference, in particular of hypothesis testing, for models of two or many similar stochastic objects Ahlswede (2005), Haroutunian et al. (2008).

Specific applications of the information theory models to design of statistical experiments are summarized by M. Malytov in the supplement to the Russian translation of Ahlswede (1987).

The early stages of information theory development involved the participation of such mathematicians as C. Shannon, N. Wiener, A. Kolmogorov, J. Wolfowitz, A. Rényi and their disciples. Leaders of the next generation were R. Gallager, A. Wyner, R. Dobrushin, M. Pinsker, J. Ziv, R. Ahlswede, T. Berger, R. Blahut, T. Cover, I. Csiszár, T. S. Han, and others. But in recent years much development of information theory in connection with statistics has taken place in general in work of specialists in electrical engineering. The most active last years have been S. Verdú , V. Poor, N. Merhav, S. Shamai (Shitz), R. Yeung, and many others.

Major information and theoretic journals and scientific meetings regularly incorporate publication of results of statistical investigations.

About the Author

From 1958 to 1970 and since 1987 Professor Evgueni A. Haroutunian has been with the Computing Center (in 1990 it was reorganized to the Institute for Informatics and Automation Problems) of the Armenian National Academy of Sciences. Since 1959, he has taught at the Yerevan State University and at the Armenian State Engineering University. During 1975–1978 and 1981–1984 he was a Visiting Professor at Algerian Universities. During 2002–2004 he was a participant of the research project

"General Theory of Information Transfer and Combinatorics" at the Center of Interdisciplinary Research (ZIF), Bielefeld University, Germany. His research interests lie in Shannon theory, hypotheses testing, and identification, as well as in application of information-theoretical and statistical methods. Professor Haroutunian is a member of the International Statistical Institute (ISI), Bernoulli Society for Mathematical Statistics and Probability and International Association for Statistical Computing (all since 1996), an Associate member of IEEE Information Theory Society (since 1994). In 2002, he was elected to the Russian Academy of Natural Sciences as a foreign member. He was a founder and the President of the Armenian Statistical Computing Society for a number of years. In October 2005 he co-organized a NATO Advanced Study Institute session on "Network Security and Intrusion Detection", Yerevan, Armenia. He is a (co-)author of more than 160 publications including Haroutunian et al. (2008).

Instrumental Variables

Michael P. Murray
Charles Franklin Phillips Professor of Economics
Bates College, Lewiston, ME, USA

Instrumental variables (IV) estimation can provide consistent estimates of a linear equation's parameters when ordinary ►least squares (OLS) is biased because an explanatory variable in the equation is correlated with the equation's disturbance. The necessary ingredient for consistent IV estimation is a "valid" instrument, which is a variable correlated with the offending explanatory variable but uncorrelated with the equation's disturbance term. IV estimation was first used to overcome biases in OLS by Phillip Wright (Wright 1928).

If the attractive large sample properties of the instrumental variable estimator are to be well approximated in finite samples, the correlation between the instrument and

the troublesome explanatory variable must be sufficiently high (Nelson and Startz 1990). Instruments lacking such correlation are called "weak." IV can consistently estimate an equation's parameters if there is for each troublesome explanatory variable at least one valid instrument that is not itself a variable in the model.

Suppose the equation of interest is

$$\mathbf{Y} = \mathbf{X}\beta + \varepsilon.$$

IV estimation is desirable when $E(\mathbf{X}'\varepsilon) \neq 0$. If $\mathbf{Z}$ is a matrix of instruments with the same dimensions, *kxn*, as $\mathbf{X}$ (explanatory variables uncorrelated with the disturbances, i.e., non-troublesome explanatory variables, can serve as their own instruments), then the IV estimator is

$$\tilde{\beta} = (\mathbf{Z}'\mathbf{X})^{-1}\mathbf{Z}'\mathbf{Y}. \quad (1)$$

When there are multiple candidate instruments for use as the instrument for a troublesome explanatory variable, any linear combination of the candidate instruments can, in principle, serve as the instrument in $\tilde{\beta}$.

Conventional practice is to form the variables in $\mathbf{Z}$ in a specific way: (i) regress each variable in X on all of the candidate instruments plus any non-troublesome explanatory variables using OLS; and (ii) set each explanatory variable's instrument equal to the explanatory variable's fitted values from (i). When the instruments are constructed in this fashion, so that $\mathbf{Z} = \hat{\mathbf{X}}$, the IV estimator can be expressed as

$$\tilde{\beta} = (\hat{\mathbf{X}}'\hat{\mathbf{X}})^{-1}\hat{\mathbf{X}}'\mathbf{Y}, \quad (2)$$

which is the OLS estimator of the equation with the actual values of the explanatory variables replaced by their fitted values. The estimator in (2) is called the *two-stage least squares* (2SLS) estimator; the first stage is the regression of each element of $\mathbf{X}$ on the m candidate instruments (Plus any non-troublesome explanatory variables, and the second stage is the OLS regression indicated by (2). When the number of candidate instruments, m, equals k (the number of explanatory variables in the equation of interest) the equation of interest is said to be *exactly identified*. The 2SLS estimator has only $m - k$ finite moments.

There are other IV estimators of the form (1) besides 2SLS. The limited information maximum likelihood (LIML) estimator simultaneously estimates the first stage equations for the troublesome variables and the equation of interest by maximum likelihood, assuming the disturbances are normally distributed. LIML is an IV estimator. Indeed, when the equation of interest is exactly identified, LIML is equivalent to 2SLS. The LIML estimator is also generally asymptotically equivalent to 2SLS, but LIML has no finite moments. Despite its lack of moments, when the number of observations is small and m is appreciably larger than k, LIML has been found to perform better than 2SLS (Davidson and MacKinnon 1993). Fuller (1977) proposed an IV estimator that performs better than 2SLS or LIML when instruments are weak (Hahn et al. 2004).

IV estimation is also applied to non-linear regression models as part of a generalized method of moments estimation. The lack of correlation between an instrument and a model's disturbances provides a moment restriction to be exploited in estimation: $E(\mathbf{Z}'\varepsilon) = 0$.

An equation's explanatory variables can be correlated with the disturbances because an explanatory variable is omitted, mis-measured, or endogenous, or because an explanatory variable is a lagged dependent variable. IV estimation can, in principle, overcome any of these problems. But IV estimation is not a panacea. At least one valid instrument must be at hand for each troublesome explanatory variable, and the cloud of uncertainty about instruments' validity that hovers over IV estimates is hardly ever entirely dispelled.

There are steps one can take to partially assess the claim that one's instruments are valid. When an equation is over-identified ($m > k$), one can formally test whether all of the instruments agree about what the parameter's actual value (this is called an over-identification test). But failing to reject this null hypothesis is consistent with all of the instruments being valid *and* with none of them being valid. Only if an instrument has been randomly assigned or if other data besides the sample in hand establish the validity of an instrument can one be secure about validity. Nonetheless, even in the case of exact identification, one can buttress confidence in the validity of an instrument by formally testing specific proposals about how an invalidating correlation between the disturbance and the instrument occurs or by appealing to either economic theory or intuition. One can also check to see whether the sign on the instrumental variable in the first stage regression of 2SLS accords with the intuitive or theoretical rationale for the instrument's validity. A significant negative coefficient in the first stage when one expects a positive sign undercuts one's faith in the instrument.

Weak instruments pose two problems: (1) the IV estimator can be almost as seriously biased as OLS in even very large samples; and (2) t- and F-tests based on the IV estimator can suffer serious size distortions. Weakness can be tested for formally using the first stage regression from 2SLS. In the case of a single troublesome explanatory variable, the classic F-statistic for the null hypothesis that variables appearing in $\mathbf{Z}$, but not in $\mathbf{X}$, have coefficients of zero in the first stage is a statistic for testing the null hypothesis that the instruments are weak, but its distribution is non-standard. Stock and Yogo (2005) offer suitable critical values. For examples, they offer critical values both for the

null hypothesis that the bias of 2SLS is greater than 10% of that of OLS and for the null hypothesis that the size distortion in a nominally 5% significance level is greater than 10%. When there are several troublesome variables, the appropriate test statistic is Cragg and Donald's multivariate extension of the F-test (Cragg and Donald 1993). Stock and Yogo provide critical values for the case of two troublesome variables.

When instruments are weak, estimation with Fuller's IV estimator is robust, even in moderate sized samples. When instruments are weak and the disturbances homoskedastic, a conditional likelihood ratio test proposed by Moreira (2003) provides optimal two-sided tests for hypotheses about linear combinations of an equation's coefficients. Moreira's critical regions can also be used to construct confidence intervals that are robust to weak instruments.

When the coefficient on an explanatory variable in a linear equation is itself a random variable, the interpretation of the IV estimator becomes more arcane. In such "heterogeneous response" cases, the IV estimator converges in probability to a weighted average of the realizations of the random coefficient *for a specific subset of the population*. In the most common of such applications, a binary instrumental variable is used to estimate the heterogeneous effect of a binary treatment variable. Imbens and Angrist (1994) named the estimand of IV estimation in this case the "local average treatment effect" (LATE). They show that the local average treatment effect is the mean effect on Y of the binary explanatory variable X ($X = 1$ indicates treatment) *for those people who would have* $X = 0$ *if* Z *were zero and would have* $X = 1$ *if* Z *were one*. IV estimation consistently estimates the LATE if the instrument: (1) is not itself an explanatory variable for Y, given X; (2) is, in essence, randomly assigned, and (3) does not both increase X for some people and decrease X for others. (The last is a constraint not required when the estimated coefficient is not random.) Sometimes the LATE is what one wants to know sometimes it is not – one might actually be interested in the mean effect of X on Y for a different subgroup of the population or for the whole population; special care must be taken when estimating heterogeneous responses by IV methods.

Insurance, Statistics in

Steve Drekic
Associate Professor
University of Waterloo, Waterloo, ON, Canada

In attempting to analyze insurance losses arising in connection with health coverages as well as property and casualty insurance situations involving homeowner and automobile coverages, it is imperative to understand that

a portfolio of insurance business is very complicated in terms of the nature of its past and future risk-based behavior. There are many deterministic and stochastic influences at play, and the precise prediction of the future claims experience necessitates that all such influences and their effects be identified. The role of probability and statistics is vitally important in this regard, not only in terms of providing the required statistical methodology to properly analyze any data collected by the business, but also in assessing whether a quantitative (i.e., theoretical) model is able to accurately predict the claims experience of a portfolio of insurance business.

First of all, in situations when the underlying data are very extensive and have been collected in the most appropriate form for its intended purpose, it is indeed possible to answer many of the questions which arise in general insurance using observed claim size distributions and/or observed claim counts. However, it is quite often the case that data are far from extensive and may not actually be in the most convenient form for analysis. In such circumstances, calculations are only possible if certain (mathematical) assumptions are made. In other words, a quantitative model is formulated involving the use of theoretical probability distributions. Moreover, even in situations where the data are extensive, the use of theoretical distributions may still be essential. Several reasons emphasizing the importance of their use include:

1. Knowledge of their convenient and established properties, which facilitate the analysis of many problems
2. The fact that the distribution is completely summarized by a relatively small number of parameters (which characterize its location, spread, and shape) and it is not necessary to work with a lengthy set of observed data
3. The fact that they enable one to make statistical inferences concerning the behavior of insurance portfolios
4. Their tractability in terms of mathematical manipulation, permitting the development of useful theoretical results.

The Central Limit Theorem justifies why normal distributions play such an important role in statistics. In particular, the well-known law of large numbers is employed in the literature on risk management and insurance to explain pooling of losses as an insurance mechanism. For most classes of general insurance, the claim size distribution is markedly skew with a long tail to the right. If an insurer were to experience a large number of claims with respect to a particular block of business, its total payout (i.e., aggregate claims) might, however, be expected to be approximately normal distributed, being the sum of a large number of individual claims. This assumption is certainly reasonable for many purposes. There may, however, be problems associated with the extreme tails of the distribution, and these tails are particularly important for reinsurance purposes. Serious consequences could result from an insurance business basing financial risk management decisions on a model which understates the probability and scope of large losses. As a result, other parametric models, such as the gamma, log-normal, and Pareto distributions, are often much better suited to capture the positively skewed nature of the claim size distribution, and would therefore be much safer to use for estimating reinsurance premiums with regard to very large claims.

The most common and certainly best known of the claim frequency models used in practice is the Poisson distribution (see ►Poisson Distribution and Its Application in Statistics). In particular, the compound Poisson model for aggregate claims is far and away the most tractable analytically of all the compound models, as it is useful in a wide variety of insurance applications. It is also consistent with various theoretical considerations including the notion of infinite divisibility, which has practical implications in relation to the subdivision of insurance portfolios and business growth. On the other hand, the Poisson model inherently assumes that the individual risks within a portfolio of business are homogeneous from the point of view of risk characteristics, and this unfortunately leads to an inadequate fit to insurance data in some coverages. Consequently, perhaps the most important application of the negative binomial distribution, as far as general insurance applications are concerned, is in connection with the distribution of claim frequencies when the risks are heterogeneous, providing a significantly improved fit to that of the Poisson distribution.

In reference to the probability models above, it is also critical to realize that the parameters of a distribution are seldom known a priori. As a result, they need to be estimated from claims data before the distribution can be applied to a particular problem. Oftentimes, several different functions of the observed data will suggest themselves as possible estimators, and one needs to decide which one to use. The following criteria provide a good basis for determination:

1. The estimator should be *unbiased*, so that its expectation is equal to the true value of the parameter,
2. The estimator should be *consistent*, so that for an estimate based on a large number of observations, there is

a remote probability that its value will differ seriously from the true value of the parameter,
3. The estimator should be *efficient*, so that its variance is minimal.

Statisticians have developed a variety of different procedures for obtaining point estimates of parameters, including the method of moments, ►least squares, and maximum likelihood. In simple situations, the various methods often produce identical results. When sample sizes are large, they all tend to provide more or less the same answers, even in more complicated cases. In other instances, however, markedly different results can emerge, and the three criteria above are frequently used by risk practitioners in deciding which estimator to use for a given insurance application.

In conclusion, thorough treatments of these topics can be found in several reference texts including Boland (2007), Bowers et al. (1997), Daykin et al. (1994), Dickson (2005), Hossack et al. (1999), Kaas et al. (2001), and Klugman et al. (2008).

Integrated Statistical Databases

Samir Pradhan
Senior Researcher
Economics Program at the Gulf Research Center, Dubai, United Arab Emirates

In the current age of "information revolution," statistical information is critical for the development of society and the competitiveness of an economic system. Over the last few decades, statistical information has become the cornerstone of public decision making processes across the globe. To address the contemporary multidimensional issues of sustaining economic and social development amidst overriding changes at the national, regional and global level, statistical information systems, both official and commercial, have adopted a unified approach to integrate varied statistical information sources and tool-sets to achieve a coherent framework for production, reference and dissemination activities. In other words, statistical authorities have developed a seamless network in which users have transparent access to statistical information from a variety of sources, which are popularly known as integrated statistical databases.

An integrated statistical database (ISD) refers to amalgamation of data from varied sources through statistical integration. Statistical integration implies a framework of applications, techniques and technologies (Willis Oluoch-Kosura 2009) for combining data from different sources in order to provide the user with a unified view of the data (Lenzerini 2002) or the process of combining data

from separate sources for making use of the information in estimating accurately the missing values in any of the single datasets or an approach for enhancing the information content of separate statistical collections by ensuring consistency (Colledge 1999). These databases could be augmented with summary measures of regional and neighborhood characteristics. Integrated data offer a potent and flexible platform for analyzing various dimensions of economic behavior and the consequence of public policies. This integrated platform provides reliable, robust tools, processes and procedures for transforming disparate, unrefined data into understandable, credible and easily accessible information for action (Polach and Rodgers 2002), which could be attributed to the stupendous success of the Information and Communication Technology (ICT) Revolution in manipulating data repositories for the purpose of bridging the information deficit.

Integrated statistical databases produce and disseminate information out of data through the process called "information life cycle" (Gregory E. Farmakis et al. 2009) which transforms elementary data collected from a multitude of different sources, into valid and valuable information, suitable for statistical analysis and delivers them to information consumers, with different and often ad hoc requirements. Being conceptually different from other databases and statistical warehouses, an integrated statistical database is "a set of measurable transformations from an abstract sample space into a Euclidean space with known norm. This set of variables is accompanied by its underline structure (variance-covariance matrix, hierarchies) and its metadata specifications. These specifications refer both to the data set as a whole and to the individual variables separately, describe and where possible quantify the individualities of the statistical data set like the sampling scheme, non-response, editing, etc." (Gregory E. Farmakis et al. 2009).

As an example, an integrated economic statistical database for a particular country or region could comprise statistical reconciliation of the systems of national accounts, balance of payments, government financial statistics and other monetary and financial statistics. Conventionally, for an integrated economic statistical database, statistical integration involves three-dimensional processes – horizontal, vertical and temporal (Carol A. Hert et al. 2004). For horizontal integration, the various primary statistics on production, trade, labor and consumption need to be reconciled before they enter macroeconomic accounts (national accounts and balance of payments). Vertical integration is about reconciling primary statistics and macroeconomic accounts as well as national and international economic statistics. Temporal integration refers to reconciliation of short-term and structural economic statistics produced at different points in time but referring to the same phase in the business cycle.

An integrated statistical database involves primarily three important issues, namely, conceptual issues, statistical production issues and institutional issues. Apart from numerical consistency, ISD should also provide a framework for coordination of data in order to facilitate conceptual consistency based upon certain universally accepted concepts, definitions, classifications, and accounting rules. These classifications are applied to appropriately defined statistical units for the coherence of statistics produced. Usually a comprehensive registration process is used as a platform for structuring different units and assigning respective classifications for those units. Finally, a proper institutional arrangement is envisaged to effectively coordinate the mechanisms of the whole system.

With the current surge in regional economic integration witnessed in the proliferation of regional economic blocs across the world economy, integrated statistical databases have become an important platform for dissemination of statistical information. Good quality statistics constitute the cornerstone of success of any unified economic and monetary policy framework at the regional level (Fasano and Iqbal 2002). This, therefore, makes the harmonizing of statistical standards at the national level and developing of new statistics at the regional level imperative. The experience of Eurostat and Afristat in Europe and sub-Saharan Africa, respectively provide examples of two such successful regional ventures.

The six member states of the Gulf Cooperation Council (GCC)–Bahrain, Kuwait, Oman, Qatar, Saudi Arabia, and United Arab Emirates (UAE)–have intensified regional economic integration through establishing a common market and are on the way to a complete monetary union by 2010 based on economic convergence. In order to synergize the economic and monetary policies of the member states for the fulfillment of the convergence criteria, members are putting in place various measures to develop comparable economic data for member countries and data for the region as a whole. Efforts to coordinate statistical activity to achieve cross-country comparability are being taken in the Gulf States, particularly in the form of biannual meetings of the heads of statistical agencies. This group is developing a common vision, and each country is making an effort to bring key economic indicators up to international standards, which should contribute to greater comparability (Al-Mansouri and Dziobek 2006). In this context, the purchasing power parity (PPP) data, generated by the International Comparison Program for the six GCC

countries, are being used as a valuable tool for monitoring of economic convergence. In addition, the GCC Secretariat publishes a statistical bulletin–a starting point for a regional program of data dissemination. In this regard, the member countries are striving for an integrated statistical database for the GCC called Gulfstat in the near future. In April 2005, the heads of national statistical offices of the six countries agreed to intensify the program of statistical coordination and to consider in particular the institutional structure of statistics serving the monetary union. In principle, the heads agreed to conduct a regionally coordinated household survey in 2006 and a population census in 2010. The survey and the census will provide source data for regional economic statistics.

Interaction

Sander Greenland
Professor
University of California-Los Angeles, Los Angeles, CA, USA

In ordinary English, the term "interaction" usually connotes some type of causal interaction among two or more factors in producing an effect (►Causation and Causal Inference). Formal versions of these ideas are discussed in the article ►Effect Modification and Biological Interaction. The present article concerns instead the common use of the term "interaction" in the statistics literature without explicit reference to causality.

In the context of regression modeling, the phrase "interaction term" or "interaction" is most often used as a synonym for a model term involving the product of two or more variables. Consider a ►logistic regression to predict a man's actual sexual preference A ($A = 1$ for men, 0

for women) from his self-reported preference R in an interview, with G indicating the interviewer's gender ($G = 1$ for male, 0 for female):

$$P(A = 1|R, G) = \text{expit}(\alpha + \beta R + \gamma G + \delta \cdot R \cdot G),$$

where $\text{expit}(x) = e^x/(1 + e^x)$ is the logistic function. Such a model can be useful for correction of misreporting. The term $\delta \cdot R \cdot G$ is often called an "interaction," although sometimes the product $R \cdot G$ is called the "interaction term" and the coefficient δ is called the "interaction" of R and G. Nonetheless, $\delta \cdot R \cdot G$ is more accurately called a "product term," for presumably neither self-report nor interviewer status have any causal effect on actual preference, and thus cannot interact causally or modify each other's effect (because there is no effect to modify).

If $\delta \neq 0$, the product term implies that the regression of A on R depends on G: For male interviewers the regression of A on R is

$$\begin{aligned} P(A = 1|R, G = 1) &= \text{expit}(\alpha + \beta R + \gamma \cdot 1 + \delta \cdot R \cdot 1) \\ &= \text{expit}(\alpha + \gamma + (\beta + \delta)R) \end{aligned}$$

whereas for female interviewers the regression of A on R is

$$\begin{aligned} P(A = 1|R, G = 0) &= \text{expit}(\alpha + \beta R + \gamma \cdot 0 + \delta \cdot R \cdot 0) \\ &= \text{expit}(\alpha + \beta R). \end{aligned}$$

Thus we can say that the gender of the interviewer affects or modifies the logistic regression of actual preference on self-report. Nonetheless, since neither interviewer gender nor self-report affect actual preference (biologically or otherwise), they have no biologic interaction.

When both the factors in the regression causally affect the outcome, it is common to take the presence of a product term in a model as implying biologic interaction, and conversely to take absence of a product term as implying no biologic interaction. Outside of linear models, neither inference is even remotely correct: The size and even direction of the product term can change with choice regression model (e.g., linear versus logistic), whereas biologic interaction is a natural phenomenon oblivious to the model chosen for analysis (Greenland et al. 2008; Rothman 1976). The chief connection is that absence of biologic interaction leads to an absence of a product term in a linear causal model (structural equation) for risks (Greenland and Poole 1988; VanderWeele and Robins 2007). On the other hand, by definition, the presence of a product term in a causal model corresponds to effect modification when the coefficients of the model are taken as measures of effect. See ►Effect Modification and Biological Interaction for further explanation.

Interactive and Dynamic Statistical Graphics

Jürgen Symanzik
Associate Professor
Utah State University, Logan, UT, USA

Interactive and dynamic statistical graphics allow data analysts from all statistical disciplines to quickly carry out multiple visual investigations with the goal of obtaining insights into relationships for all kinds of data – from simple to complex. Often, there are no previously established hypotheses for these data, or the data set may be too big and heterogeneous for simple summaries and statistical models.

Interactive graphics and dynamic graphics are two closely related, but different, terms. On one hand, interactive graphics allow a data analyst to interact with graphical displays, typically via a computer. Depending on keystrokes, movements of the mouse, or clicks on the mouse buttons, different follow-up graphics will be produced. On the other hand, dynamic graphics display a sequence of plots without any additional user interaction. This can be some continuous rotation of a point cloud or updating plots in real time, based on additional data obtained from simulations or via data streams. Often, these two methods are used side-by-side for the investigation of the same data set. Interactive and dynamic statistical graphics play an important role in the context of ►Exploratory Data Analysis (EDA) and visual data mining (VDM).

Main Concepts of Interactive and Dynamic Statistical Graphics

Interactive and dynamic statistical graphics commonly make use of multiple, but relatively simple, plots. Frequently used plots for quantitative variables include:

- *Scatterplots*, where different symbols are plotted at horizontal ($x-$) and vertical ($y-$) positions in a two-dimensional plot area to represent the values of two quantitative variables
- *Scatterplot Matrices* (for more than two quantitative variables), where multiple scatterplots are arranged in a systematic way in a matrix
- *Parallel Coordinate Plots,* where a d-dimensional observation is represented by a continuous line drawn through d parallel coordinate axes
- *Histograms*, where area is used to display frequencies or percentages for multiple classes or intervals
- *Spinograms* (that are similar to histograms) where height is kept constant but width differs to represent the frequency or percentage for each class

In case of additional categorical variables (such as gender, race, nationality, etc.) different colors or plotting symbols are used in the previously mentioned plots to distinguish among the different groups represented by these variables.

Categorical variables themselves can be displayed via:

- *Bar Charts*, where bar length is proportional to the observed frequencies or percentages
- *Spine Plots* (that are similar to bar charts), where bar length is kept constant and bar width differs
- *Mosaic Plots,* a complex hierarchical structure that allows to display several categorical variables and visually explore questions such as independence of these variables
- *Pie Charts,* where angular areas in a circle are used to display frequencies or percentages

For data with a geographic (spatial) context, *choropleth maps* are a common component of interactive displays.

The main idea behind interactive graphics is to *link* multiple graphical displays and *brush* (or highlight) subsets of observations in these linked displays. For example, for a given data set (age, income, gender, educational level, ethnicity, nationality, and geographic subregion), consider the following scenarios:

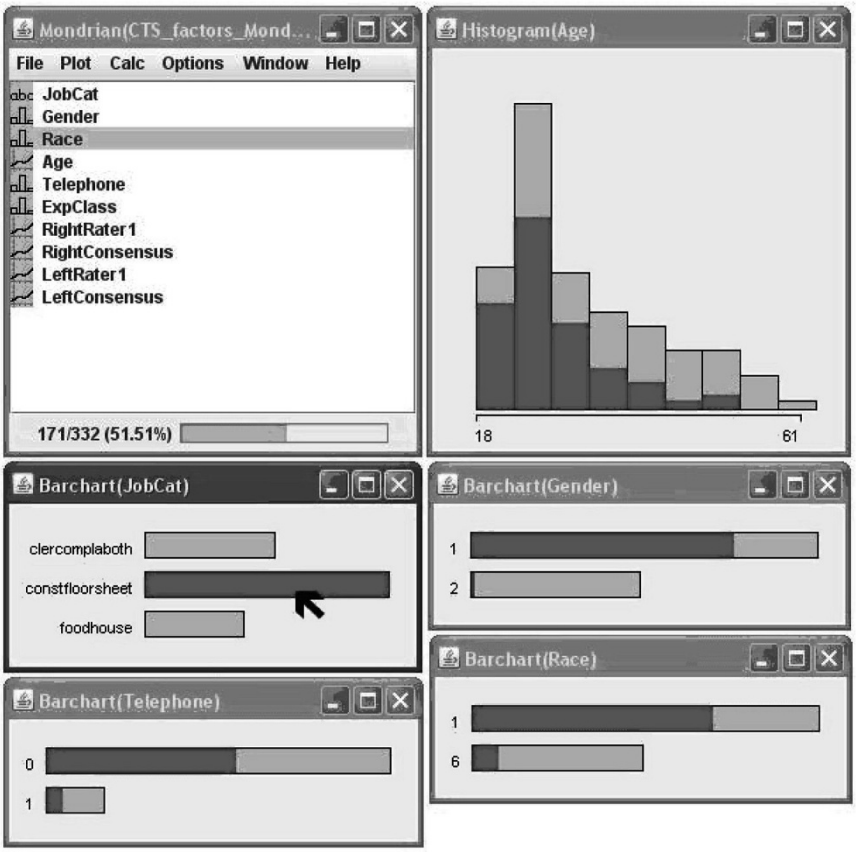
Scenario 1: In order to compare the income of individuals with a doctoral degree to those with no completed degree, then for a scatterplot showing age and income, one might want to brush different educational levels in a bar chart.

Scenario 2: In order to compare men's and women's income who are at a certain age and educational level, one might want to brush gender in another bar chart.

Scenario 3: In order to investigate the effect of ethnicity, nationality, or geographic subregion (in case a map is linked to the other displays) that may further affect the relationship between age and income, additional brushing can be performed in various linked plots.

Interactive and dynamic graphics often reveal the unexpected. For example, when distinguishing between female workers with young children and female workers without young children, a data analyst may observe that on average female workers with young children earn more money than female workers without young children as further discussed in the ►Econometrics entry of this encyclopedia.

In addition to linking and brushing, some other techniques frequently can be found in applications of interactive and dynamic statistical graphics. These techniques include *focusing* on a subset of the data (via *zooming* into a small plot area in case of overplotting of multiple nearby points or lines, or via *slicing* a high-dimensional data set into sections or slices), *rescaling* the data (e.g., by taking the log, standardizing the data, or mapping the data to a 0–1 scale), and *reformatting* the data (e.g., by swapping the axes in a scatterplot or changing the order of the axes in a parallel coordinate plot). *Rotations* are used to give the illusion of a third dimension, and even more, to find interesting views that do not align with the main coordinate axes and therefore cannot be seen in a scatterplot matrix. *Projections* often are used in sophisticated ways (such as the *grand tour*, a continuous sequence of projections) to display high-dimensional data on a 2-dimensional computer screen.



Interactive and Dynamic Statistical Graphics. Fig. 1 Data from a CTS study explored in *Mondrian*. The `Job Category` **constfloorsheet** has been brushed to further investigate the `Gender`, `Race`, and `Age` variables for this category

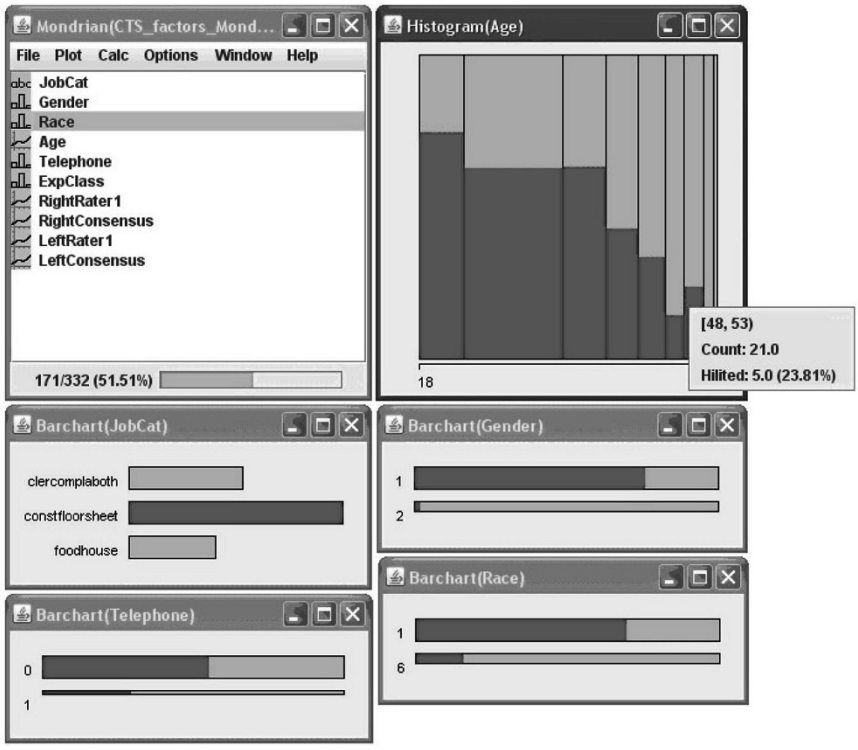
Software for Interactive and Dynamic Statistical Graphics

PRIM-9 (Picturing, Rotation, Isolation and Masking in up to nine dimensions), developed in the early 1970s, is the landmark example of software for interactive and dynamic statistical graphics. Many of the software packages developed over the following decades (and even developed these days) contain features that can be traced back to *PRIM*-9. There are three main families of software packages for interactive and dynamic statistical graphics that are freely available and widely used in the statistical research community:

- The *REGARD/MANET/Mondrian* family was initiated in the late 1980's. *Mondrian* can be freely downloaded from http://rosuda.org/mondrian/. The R package *iplots* is closely related to this family.
- The *HyperVision/ExplorN/CrystalVision* family also was initiated in the late 1980s. *CrystalVision* can be freely downloaded from http://www.galaxy.gmu.edu/pub/so%9Fware
- The *Data Viewer/XGobi/GGobi* family was already initiated in the mid 1980s. *GGobi* can be freely downloaded from http://ggobi.org. The R package *rggobi* is closely related to this family.

All of these software packages are based on the main concepts presented in the previous section. Linking and linked brushing are key components. To point out differences among these packages, *Mondrian* et al. have their strengths for categorical data and maps. *GGobi* et al. have their strengths for higher-dimensional quantitative data, in particular with respect to the *grand tour*. *CrystalVision* et al. have their main focus on parallel coordinate plots.

Web-based applications of interactive and dynamic statistical graphics that are based on *linked micromaps* (which are series of small maps linked to multiple statistical displays) can be found at the *National Cancer Institute* (NCI) State Cancer Profiles Web page at http://statecancerpro%9dles.cancer.gov/micromaps/ and at the *Utah State University* (USU) West Nile Virus Micromaps Web page at http://webcat.gis.usu.edu:.ý.ý/index.

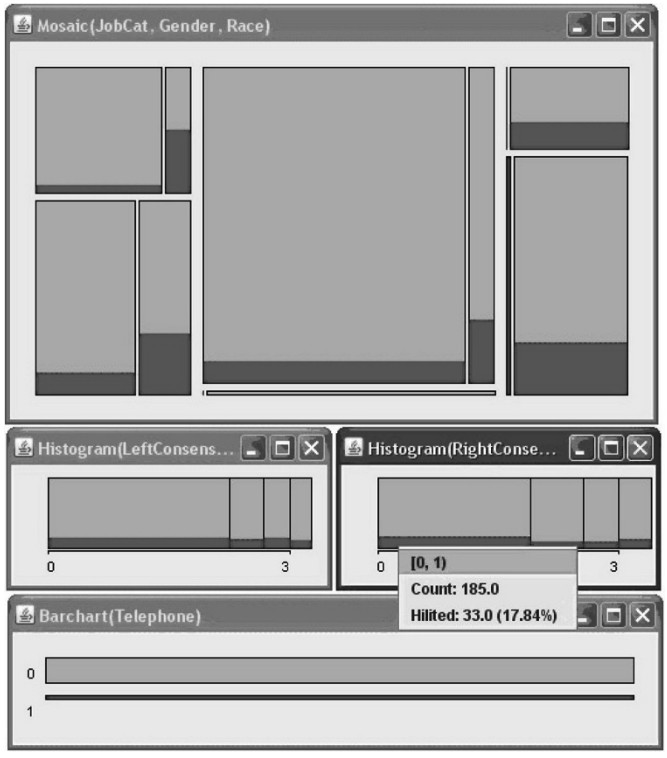


Interactive and Dynamic Statistical Graphics. Fig. 2 Histogram and bar charts interactively converted to spinogram and spine plots to better compare proportions

html. The *Gapminder Foundation* provides access to more than 200 factors of global development via its impressive interactive and dynamic Web-based software at http://www.gapminder.org/.

An Interactive Graphical Example

Some of the concepts from the previous sections will be demonstrated using a medical data set from a carpal tunnel syndrome (CTS) study. CTS is a common diagnosis of the upper extremity that may affect up to 5% of the US population - and up to 10% in some specific industries. Figure 1 shows some graphical displays for some of the variables of this study: Bar charts of `Job Category` (where *clercomplaboth* represents office and technical workers, including computer and laboratory workers; *constfloorsheet* represents construction workers, carpenters, floorlayers, and sheetmetal workers; and *foodhouse* represents service jobs, including housekeepers and food service workers), `Gender` (1 = male, 2 = female), `Race` (1 = Caucasians, 6 = others, including African Americans, Asians, and Native Americans), and `Telephone` (0 = self-administered, 1= telephone interview), and a histogram of `Age`. The main window in the upper left allows the user to interactively select additional variables, create plots, and perform statistical modeling. Currently, the `Job Category` *constfloorsheet* has been brushed in red (via a mouse click) and it turns out that most of the people in this `Job Category` are Caucasian male workers aged 18–53. Via mouse clicks and menus in these plots, the histogram is converted into a spinogram and three of the bar charts are converted into spine plots (Fig. 2). While moving the mouse over the various bars, a user can read for example that about 76% of all male workers but only about 2% of all female workers work in the *constfloorsheet* `Job Category` in this study. Similarly, about 75% of all 18–23 year olds, but only about 24% of all 48–53 year olds work in this `Job Category` - the percentage almost steadily decreasing by `Age`. About 15% of the data for this CTS study were collected via telephone interviews (`Telephone` = 1) while the remaining data were collected via self-administered questionnaires. In Fig. 3, `Telephone` = 1 has been brushed in red (via a mouse click) in the bottom plot. A mosaic plot is shown in the top plot. The first horizontal split separates `Job Category` (*cler-comp-lab-oth*, *constfloorsheet*, and *foodhouse* from left to right), the first vertical split separates `Gender` (male top and female bottom), and the second horizontal split separates `Race` (Caucasians left



Interactive and Dynamic Statistical Graphics. Fig. 3 Mosaic plot for `Job Category/Gender/Race` (*top*) and spinograms of CTS severity for *left* and *right* hands (*middle*), based on the fact whether the data were obtained via a telephone survey (brushed in *red* in the bottom spine plot) or via a self-administered questionnaire

and others right). It is apparent that the need to conduct a telephone interview highly depends on the combination of `Job Category/Gender/Race`. However, the main response variables of this study, the severity of CTS (ranging from 0 to 3) are not particularly affected by the data collection method as can be seen in the two spinograms in the middle plots. For each severity level of CTS, about 10–20% of the study participants submitted their data via telephone interviews.

The next stages of an interactive exploratory analysis could be to determine whether there is a relationship between the severity of CTS for the left hand and the right hand or how closely the diagnosis of a particular medical expert (`RightRater1` and `LeftRater1` in Fig. 1) matches the joint diagnosis of three experts (`RightConsensus` and `LeftConsensus` in Fig. 1). It should be noted that the plots created by most current software packages for interactive and dynamic graphics are crude plots with no titles, labels, or legends. It will take an additional step to transform selected graphics from an interactive exploratory session into graphics that can be used for presentations or publications.

Further Reading and Viewing

This encyclopedia entry is a brief summary of Symanzik (2004). Interested readers should refer to Symanzik (2004) for further details and for a detailed list of references that covers about 40 years of developments in the field of interactive and dynamic statistical graphics. Cook and Swayne (2007) and Theus and Urbanek (2009) are recently published textbooks that focus on interactive and dynamic graphics via *GGobi/rggobi* and *Mondrian/iplots*, respectively. Additional details on *iplots* can be found in Theus and Urbanek (2004). The *Gapminder* software is further discussed in Rosling and Johansson (2009). The Video Library of the *Sections on Statistical Computing and Statistical Graphics of the American Statistical Association* (ASA) contains 38 graphics videos covering the period from 1962 to 1996. Recently, these videos have been converted to digital format and can be watched for free at http://stat-graphics.org/movies/. The data underlying the figures of this article have been analyzed in more detail in Dale et al. (2008) and have been reused by permission. The original study was supported by Centers for Disease Control and Prevention, National Institute

for Occupational Safety and Health, Grant number R01OH008017-01.

About the Author

Dr. Jürgen Symanzik is an Associate Professor, Department of Mathematics and Statistics, Utah State University, Logan, Utah, USA. He is a Co-Editor of *Computational Statistics* (since 2005) and he previously was an Associate Editor of the same journal (1998–2005). He is currently (2010) the Chair-Elect of the Section of Statistical Graphics of the American Statistical Association (ASA) and he will take office as Chair of this section in 2011. He is also a Vice President of the International Association for Statistical Computing (IASC, 2009–2011). Dr. Symanzik has authored and co-authored a combined total of more than 60 journal papers, proceedings papers, and book chapters. He became an Elected Member of the International Statistical Institute (ISI) in 2007.

Internet Survey Methodology: Recent Trends and Developments

Silvia Biffignandi
Professor of Statistics, DMSIA, Faculty of Economics,
Director of the Center for Statistical Analyses and Surveys
Bergamo University, Bergamo, Italy

Data collected over the Internet (Internet surveys) includes e-mail surveys and Web surveys. In e-mail surveys the ►questionnaire is completed off-line. The respondent returns the questionnaire as an email attachment and responses are given in Word or Excel format, or via other software that may be available to the respondent. In Web surveys the questionnaire is presented to respondents as a set of Web pages, answers being submitted immediately by clicking a submit/next button. Thus, Web surveys are completed on-line. Many methodological problems are common to both e-mail and Web surveys. The key advantages of Internet surveys are said to include easy access to a large group of potential respondents, low cost (costs not specifically related to the number of interviews) and timeliness. However, despite such appealing characteristics, there are serious methodological problems and even the extent of the above-mentioned advantages has yet to be fully verified in terms of actual benefit.

The University of Ljubljana (Vasja Vehovar), Bergamo University (Silvia Biffignandi), Linkoeping University (Gosta Forsman), ZUMA (Wolfing Bandilla) have been working as partners in the WebSm (WebSurvey Methodology) European project. As part of the project they have set up a website which publishes literature, software references and relevant comments within a well-organized framework (website: www.websm.org; Lozar Manfreda and Vehovar 2006). Since 2005, the group created in the context of this project has been meeting in informal workshops, under the heading of Internet Survey Methodology (ISM). The most recent Internet Survey Methodology Workshop (ISM09), organized by S. Biffignandi, was held in Bergamo from September 17–19th, 2009, and brought together highly-qualified specialists involved in analyzing and dealing with Internet survey research results.

One of the major trends in Internet survey methodology is a growing importance of Web surveys across different application fields. Initially, the main field of application was in the area of social surveys, with just a handful of papers related to ►business statistics; nowadays social surveys and business statistics are equally represented, with increasingly greater attention paid to official statistics. New research on methodological issues is emerging, together with complex research strategies. The original focus was on response rates and questionnaire design and these topics have remained of key importance, although they are now studied via more sophisticated approaches (examples would be mixed mode, complex design, questionnaire usability). These days, in fact, a great deal of attention is devoted to problems arising from the use of mixed mode, estimation, panels, and the use of incentives.

The major research areas of prime importance are: (1) survey questionnaire design; (2) methodological aspects,

especially: (a) timeliness; (b) response rate improvement, (c) participant recruitment and statistical inference.

With regard to point (1) (web questionnaire design), since web surveys are self-administered, user-friendliness and limited questionnaire length are highly important. Visual elements, pictures, color and sound are all tools that can make the questionnaire more attractive, although further research is required in order to understand whether, and how, such tools improve survey participation and quality, and what the potential disadvantages and problems may be (for example, technical limitations and information overload). For a discussion on web questionnaire design see Couper (2008) and Dillman (2007).

The first methodological aspect quoted at point (2), timeliness, requires study to establish whether this is of effective benefit to surveys. Timeliness therefore should be analyzed with reference both to the whole survey period length and to participation behavior within the survey period, as well as to the reminders timetable and mode. Some studies have shown that response times to Internet or Web surveys are different to other modes (e.g., Biffignandi and Pratesi 2000, 2002). Other research has highlighted that while there is no gain in shorter survey periods using Internet surveys, reactions to first contact and reminders are more timely.

With regard to the second methodological aspect quoted at point (2), a crucial point in web surveys is that they mostly achieve low response rates. Some studies concentrate on keeping respondents focused on the relevant parts of the computer screen, and keeping distraction to a minimum (eye-tracking analysis is used for such purposes). An interesting strategy for improving response rates is to use mixed modes. However, new problems arise with the mixed approach, since mode effects are to be taken into account in analyzing survey results. Occurrence and treatment of mixed-mode effects need further investigation.

As to the third methodological aspect quoted at point (2) (participants recruitment and statistical inference), the problem is how to select a representative sample, or, if a sample is not representative, how to correct data so as to obtain statistically representative results.

Web surveys are substantially affected by coverage, because not every member of a target population may have access to the Internet. Moreover, it is often difficult to select a proper probability sample because a sampling frame is lacking and the subpopulation with Internet access may not represent the population of interest. In general, good frames should provide a list of sampling units from which a sample can be selected and sufficient information on the basis of which the sample units can be uniquely identified in the field. In general, well-defined sampling frames are not available for most Internet surveys. At present, attempts to widen the scope of Internet-based samples beyond the population of active Internet users are unusual, being a task that is difficult to achieve. Thus, in such surveys, the respondents are a selective sample of the population; moreover, they are obviously the most skilled computer users and may therefore be much quicker than others in understanding and answering Internet interview questions. Because they may respond differently, one needs to find a way to generalize from such a sample to a target population. Major problems arise in household surveys, since many households are not Internet users and therefore cannot be recruited via Internet. In addition, even those with Internet access are potentially not expert in using the Web. Therefore, despite being set up for the Internet (possibly in an "ad hoc" way), they probably show differing survey behavior.

Scientifically meaningful results can only be obtained if proper probability samples are selected and the selection probabilities are known and positive for every member of the population. Unfortunately, many web surveys rely on a process of self-selection of respondents. The survey is simply put on the web. Respondents are those people who happen to have Internet access, visit the website and decide to participate in the survey. If an invitation for participation to the survey is sent, this invitation cannot reach the whole target population. The survey researcher is not in control of the selection process. These surveys are called self-selection surveys. See, for instance, Bethlehem (2008).

Due to imperfect frames in Web surveys, traditional probabilistic samples are in many cases not easy to implement. In order to bypass the problem of frame coverage, a number of Internet-based panels are maintained. Internet-based panels (so-called access panels) are constructed by wide participation requests on well-visited sites and Internet portals. Thus, they are also based on self-selection. Many access panels consist of volunteers and it is impossible to evaluate how well these volunteers represent the general population; in any case, they represent a non-probability sample and no statistical inference applies. However, recent research attempts to tackle the task of how to apply probabilistic recruitment to panels and how to draw inferences from them. Put briefly, trends in Web survey frames are moving in two directions. One is towards the improvement of frames by enlarging and completing the list of web users; such an approach might find greatest success with business frames and closed populations. The second direction is in the treatment of panels by

using special recruitment approaches and/or methodologies for handling results in the light of adequate auxiliary variables.

At the time of registration, basic demographic variables are recorded. A large database of potential respondents is created in this way. For future surveys, samples are selected from this database. Only panel members can participate in these Web panel surveys. The target population is however unclear. One can only say that it consists of people who have an Internet connection, who have a non-zero probability of being confronted with the invitation, and who decide to participate in the panel. Research in the Netherlands has shown that panel members differ from the general population. Access panels have the advantage that values of basic demographic variables are available for all participants. So the distribution of these variables in the survey can be compared with their distribution in the population. Over- or under-representation of specific groups can be corrected via weighting adjustment techniques. However, there is no guarantee that this leads to unbiased estimates.

To allow for the unbiased estimation of the population distribution, a reference survey can be conducted that is based on a true probability sample from the entire target population. Such a reference survey can be small in terms of the number of questions asked. It can be limited to so-called "webographic" or "psychographic" questions. Preferably, the sample size of the reference survey should be large enough to allow for precise estimations. A small sample size results in large standard errors of estimates (Bethlehem 2008).

Since most access panels are based on self-selection, it is impossible to compute unbiased estimates of population characteristics. In order to apply statistical inference properly, probability sampling, in combination with a variety of data collection modes, can be applied for panel recruitment. For example, a sample is selected from the general population and respondents are recruited using, perhaps, CAPI or CATI. Respondents without access to the Internet are provided with Internet facilities. A probabilistic sampling design can be achieved using specific methods, such as random digit dialing (RDD). Some probability-based Internet panels have already been constructed in this way (for instance, Huggins and Krotki 2001).

Another approach to correcting a lack of representativity is to apply propensity scoring methodology. Propensity scores (based on the Rosenbaum and Rubin methodology) have been used to reweight web survey results (Schonlau et al. 2009; Biffignandi and Pratesi 2005, 2003 and ISI, Berlin, August 2003).

About the Author

Dr Silvia Biffignandi is Full professor of Business and Economic Statistics at the Bergamo University and Director of CASI (Center for Statistical Analyses and Surveys). She is past Head of the (DMSIA) Department of Mathematics, Statistics, Informatics and Application (academic period 2002/2003–2008/2009 and period 1990/1991–1995/1996). She has organized the Internet Survey Methodology 2009 workshop (ISM09) held in Bergamo (17–19 September 2009). She was co-editor of the *Review Statistical Methods and Application* (Springer, 2003–2009), and previously Associate Editor of the *International Journal of Forecasting*, (Wiley editor) and of the International Journal of Forecasting (Elsevier editor). She is a Fellow of the American Statistical Association, International Statistical Institute, Italian Statistical Association, International Association Social Surveys, and International Association Official Statistics. She has been a member of the scientific committee and organization of many international conferences. Professor Biffignandi is the author of the text Handbook of Web Surveys (with J.G. Bethlehem, Wiley, Hoboken, NJ. USA, forthcoming 2011).

Intervention Analysis in Time Series

Florance Matarise
Acting Department Chairperson
University of Zimbabwe, Harere, Zimbabwe

Intervention analysis is the application of modeling procedures for incorporating the effects of exogenous forces or interventions in time series analysis. These interventions, like policy changes, strikes, floods, and price changes, cause unusual changes in time series, resulting in unexpected, extraordinary observations known as ►outliers. Specifically, four types of outliers resulting from interventions, additive outliers (AO), innovational outliers (IO), temporary changes (TC), and level shifts (LS), have generated a lot of interest in literature. They pose nonstationarity challenges, which cannot be represented by the usual Box and Jenkins (1976) autoregressive integrated moving average (ARIMA) models alone.

The most popular modeling procedures are those where "intervention" detection and estimation is paramount. Box and Tiao (1975) pioneered this type of analysis in their quest to solve the Los Angeles pollution problem. Important extensions and contributions have been made by Chang et al. (1988), Chen and Liu (1993), and Chareka et al. (2006). Others, like Kirkendall (1992) and Abraham and Chuang (1993), propose the use of robust procedures where model estimation is insensitive to the effects of the interventions.

Intervention Model

An intervention model for a time series $\{Y_t\}$ according to Box and Tiao (1975) is of the dynamic form

$$Y_t = f(\kappa, X_t, t) + Z_t \tag{1}$$

where $Y_t = F(Y_t)$ *is some appropriate transformation of* Y_t *such as* $\log Y_t$ *or* $\sqrt{Y_t}$, $f(\kappa, X_t, t)$ *is a function incorporating the effects of exogenous variables* X_t, *in particular interventions,* κ *is a set of unknown parameters, and* Z_t *is the stochastic background or noise.*

The Noise model $Z_t = \pi(B) = \frac{\theta(B)}{\phi(B)\alpha(B)}$ is the usual Box and Jenkins (1976) ARIMA models, while the outliers or exogenous variables X_t themselves follow dynamic models like the following:

$$f(\delta, \omega, X_t, t) = \sum_{j=1}^{k} \frac{\omega(B)}{\delta(B)} X_t^{(i)}$$

where κ parameters are denoted by δ and ω. This intervention model can then be simplified to the general transfer function model given by

$$Y_t = Z_t + \frac{\omega(B)}{\delta(B)} X_t^{(i)} \tag{2}$$

where $Z_t = \pi(B)$ as above and

$$X_t^{(i)} = \begin{cases} 1, & t = i \\ 0, & otherwise \end{cases} \tag{3}$$

which is an indicator variable taking values 0 or 1 denoting nonoccurrence and occurrence of an intervention, respectively. For simplicity of derivation, a single exogenous variable at a time has been considered below for each of the four outlier models.

1. *The additive outlier (AO)* is usually referred to as a gross error affecting the tth observation as shown in Fig. 1. The AO model where $\delta = 0$ in the general form

$$Y_t = Z_t + \frac{\omega}{1 - \delta B} X_t^{(i)} \tag{4}$$

is represented by

$$Y_t = Z_t + \omega X_t^{(i)} \tag{5}$$

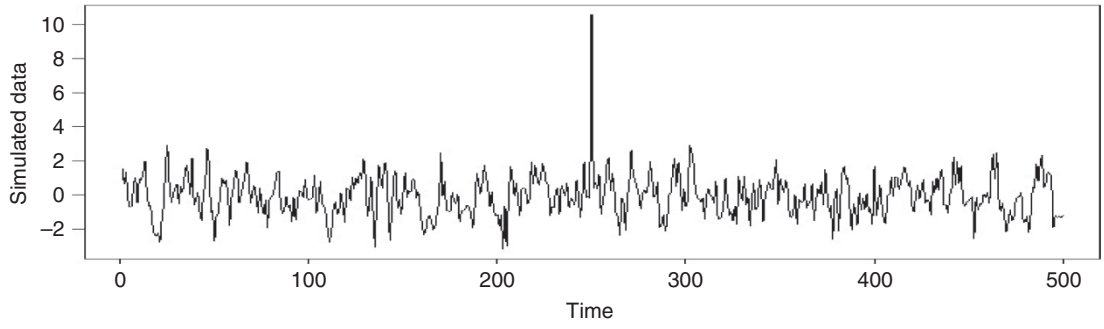
with the residual model given by $e_t = \omega\pi(B)X_t^{(i)} + a_t$.

2. *The level shift (LS)* shown in Fig. 2 is an abrupt but permanent shift by ω in the series caused by an intervention and takes on the maximum value of $\delta = 1$ in Eq. 4 so that the model becomes

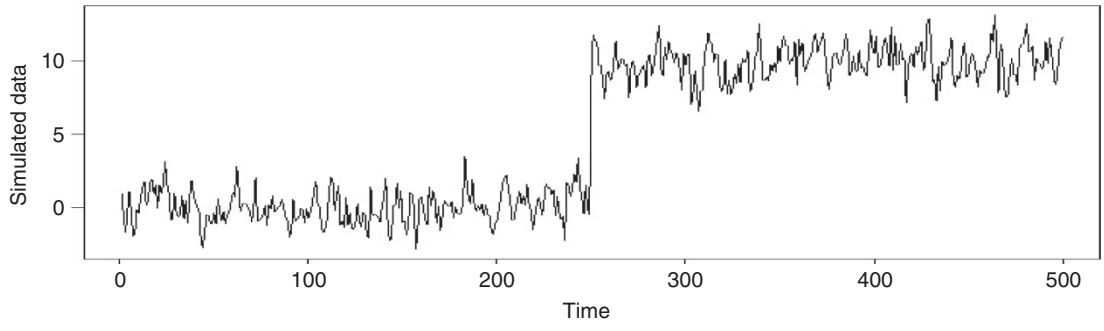
$$Y_t = Z_t + \frac{\omega}{1 - B} X_t^{(i)} \tag{6}$$

The resulting residual model is $e_t = \omega \frac{\pi(B)}{1-B} X_t^{(i)} + a_t$

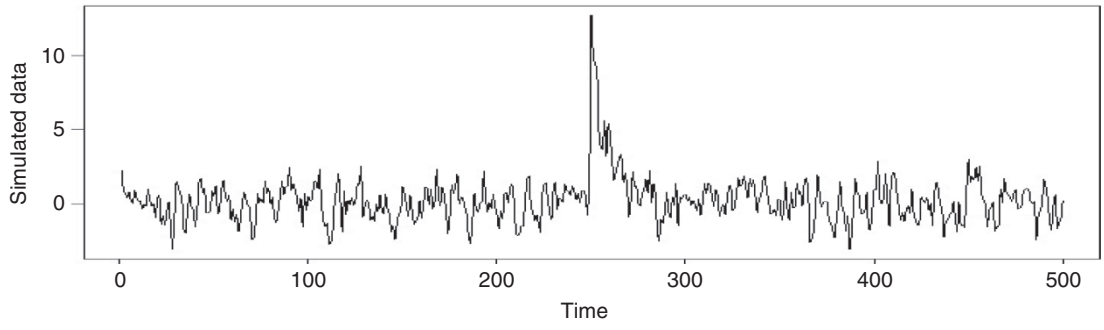
3. *The temporary change (TC)* shown in Fig. 3 is an intervention that occurs when $0 < \delta < 1$ and takes up the general form in Eq. 4. The resulting outlier has an effect ω at time t_1, which dies out gradually and has the residual model $e_t = \omega \frac{\pi(B)}{1-\delta B} X_t^{(i)} + a_t$ (see Chen and Liu 1993).
4. *The innovational outlier (IO)* shown in Fig. 4 is an extraordinary shock at time t influencing $Y_t, Y_{t+1} \ldots$



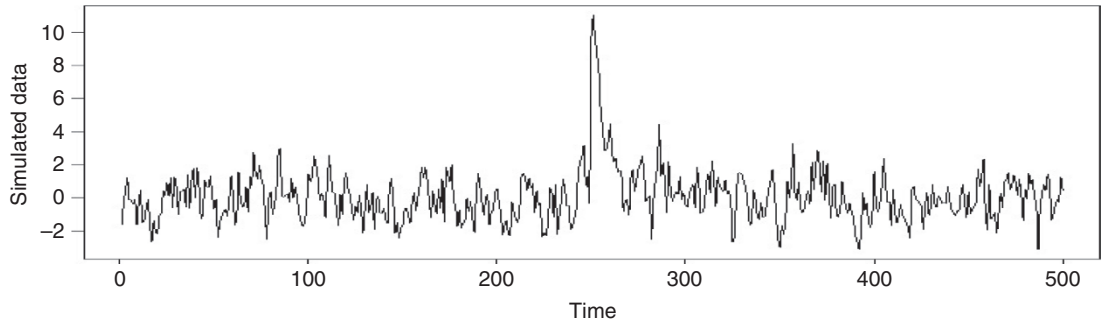
Intervention Analysis in Time Series. Fig. 1 Additive outlier effect



Intervention Analysis in Time Series. Fig. 2 Level shift



Intervention Analysis in Time Series. Fig. 3 Temporary change effect



Intervention Analysis in Time Series. Fig. 4 Innovational outlier effect

through the dynamic system resulting in the model

$$Y_t = \pi(B)\left(\omega X_t^{(i)} + a_t\right) \tag{7}$$

with residuals given by $e_t = \omega_0 X_t^{(i)} + a_t$. The underlying ARIMA model affects the overall innovational effect and can result in a gradual change, a permanent level shift or a seasonal level shift.

Stages in Intervention Analysis

There are four main stages in intervention analysis applicable to both long and short memory time series. These are intervention or outlier detection, model estimation, model diagnostics, and forecasting. However, the major challenge in intervention analysis is determining whether an intervention has actually occurred and what type it is, as described below.

Intervention/Outlier Detection

1. Plot the data to get a picture of the type of series and possible outliers in the data.
2. Assume that the underlying autoregressive moving average (ARMA) series $\{Y_t\}$ contains no outliers and use maximum likelihood estimation or ►least squares procedures to estimate its parameters.
3. State the hypothesis being tested, which is

$$H_0 : \omega_0 = 0 \quad \text{against} \quad H_1 : \omega_0 \neq 0$$

4. Compute the residuals, the impact ω and the test statistic like the popular Chang et al. (1988) likelihood ratio test statistic given by

$$T = \max\{|t_n(1)|, \ldots, |t_n(n)|\} = \max\left\{\frac{|\hat{\omega}_0(1)|}{s_n(1)}, \ldots, \frac{|\hat{\omega}_0(n)|}{s_n(n)}\right\} \tag{8}$$

where $s_n(i)$ is an estimate of the standard error of $\hat{\omega}_0(i)$; $\hat{\omega}_0(i)$ is the estimated intervention or impact at time $t = i$; the Chareka et al. (2006) statistic $C_n = \frac{T_{nn}^2 - d_n}{c_n}$, which by extreme value theory converges to the Gumbel distribution $\Lambda(x) = \exp(-e^{-x})$, $-\infty < x < \infty$; or the Abraham and Chuang (1989)s statistic $Q_{k(t)} \approx \sum_{i=t}^{t+k-1} e_i^2/(1-h_{ii})$, which asymptotically is χ^2.
5. Determine the critical values to use in the test. These can be Chang et al. (1988) critical values simulated in SPLUS, R, or others using distribution-free methods for each particular series and each outlier type at different levels of significance; Chareka et al. (2006) critical values of the Gumbel distribution 2.2504, 2.9702, and 4.6102 for $\alpha = 0.10, 0.05$, and 0.01, which can be used for all outliers as shown in recent research; while χ^2 critical values, which can be used for Abraham and Chuang (1989) test for the AO and the IO.
6. Determine whether observations are outliers and remove each outlier from the series by subtracting the value of the impact ω_i. Then apply the ARIMA modeling procedure to obtain the most adequate model and use it for forecasting future values of the series.

Robust Model Estimation

Model estimation and forecasting are the main goals of robust estimation procedures, which are insensitive to the effect of interventions. The E-M algorithm is one option proposed by Abraham and Chuang (1993). Each observation in $\mathbf{Y_t}$ is assumed to have two states, namely, the observable state and the outlier or unobservable state where $\mathbf{Y_t}$ is viewed as incomplete data and $\mathbf{X} = \left(\mathbf{Y}, \mathbf{X_t^{(i)}}\right)$ is complete data. The algorithm involves maximizing the incomplete data's likelihood function using the conditional expectation of the complete data in each iteration, resulting in parameter converging if the likelihood function meets the set conditions.

State space modeling using the Kalman filter as described in Kirkendall (1992) is another robust approach, which is based on the Markov property of ►Gaussian processes that allows the likelihood function and the ►Akaike Information Criteria to be calculated recursively for a given set of parameters. The Kalman filter model consists of the state equation $X_t = X_{t-1} + w_t$ and the measurement equation $Y_t = X_t + v_t$ with normally distributed w_t and v_t. The standard Kalman recursions are applied, and using criteria such as Bayes' rule, the observations are classified into steady state or outlier models and the various parameters are determined by minimizing the likelihood functions with respect to the parameters.

Intraclass Correlation Coefficient

William D. Johnson[1], Gary G. Koch[2]
[1]Professor of Biostatistics
Louisiana State University, Baton Rouge, LA, USA
[2]Professor of Biostatistics
University of North Carolina, Chapel Hill, NC, USA

A sampling plan that has two (or more) stages of selecting study units is called a two-stage (multistage) cluster sample. A sample of the primary sampling units (the *clusters*) is selected at the first stage and a sample of the component sampling units is selected from each cluster at the second stage and so on throughout any subsequent stages. In a broader context, if observations on a set of study units are arranged in classes, categories, groups or *clusters* and some of the cluster means vary significantly, the within cluster observations will tend to be more homogeneous than those from different clusters and in this sense they will tend to be correlated. The *intraclass correlation coefficient* ρ_I quantifies the propensity for observations on units within the same cluster to be more homogeneous than those in different clusters. Early writers referred to the groups of observations as classes, hence the terminology intraclass correlation coefficient, but the evolving widespread use of cluster samples (see ▶Cluster Sampling) in both survey sampling and designed experiments has made the term "cluster" more popular; nevertheless, "intraclass" is used by most authors in referring to within cluster correlation.

Consider a finite set of M observations y_{ij} on each of N clusters where $i = 1, 2, \ldots, N$ and $j = 1, 2, \ldots, M$; for ease of notation but without loss of generality the present discussion is restricted to the case of all clusters having an equal number of observations. Further note that the observations are in arbitrary order within the clusters. Let μ represent the finite set mean of all NM observations and $v = \sum_{i=1}^{N}\sum_{j=1}^{M}(y_{ij}-\mu)^2/(NM)$ denote the corresponding variance. Further, let $v_a = \sum_{i=1}^{N}(\bar{y}_{i\cdot}-\mu)^2/N$ represent the variance among the cluster means and $v_w = \sum_{i=1}^{N}\sum_{j=1}^{M}(y_{ij}-\bar{y}_{i\cdot})^2/(NM)$ represent the within cluster variance where $\bar{y}_{i\cdot} = \sum_{j=1}^{M} y_{ij}/M$. A computational formula for the intraclass correlation coefficient can be expressed as (Koch 1982)

$$\rho_I = \frac{\sum_{1=1}^{N}\sum_{j\neq j'}(y_{ij}-\mu)(y_{ij'}-\mu)}{NM(M-1)v} = \frac{v_a - v_w/(M-1)}{v}$$

where $-1/(M-1) \le \rho_I \le 1$ and the lower bound is attained when the cluster means $\bar{y}_{i\cdot}$ are all equal so that $v_a = 0$ and the upper bound is attained when the cluster means are not all equal but there is no within cluster variation so $v_w = 0$ and $v = v_a$. As $M \to \infty$, ρ_I simplifies to

$$0 \le \rho_I = 1 - v_w/v \le 1.$$

In this form, the intraclass correlation coefficient is seen to be the *additive complement* of the proportion of the total variance that is attributable to variability among observations within clusters, or simply, $\rho_I = v_a/v$, the proportion of the total variance that is attributable to the component of variance for *among cluster means*. As in Koch (1982), an estimator of interest for ρ_I is that for a two stage random sample of size n from a set of N clusters and a sample of size m from each of the selected clusters where both N and M are very large relative to n and m (e.g., $N = 1,000$, $n = 50$, $M = 40$, and $m = 2$); this estimator is

$$r_I = \left(s_a^2 - s_w^2\right)/\left[s_a^2 + (m-1)s_w^2\right]$$

where $s_a^2 = m\sum_{k=1}^{n}(\bar{y}_{k\cdot}-\bar{y}_{\cdot\cdot})^2/(n-1)$ and $s_w^2 = \sum_{k=1}^{n}\sum_{l=1}^{m}(y_{kl}-\bar{y}_{k\cdot})^2/[n(m-1)]$, respectively, are the among and within cluster mean squares; $\bar{y}_{k\cdot}$ is the sample mean for observations in the k^{th} cluster and $\bar{y}_{\cdot\cdot}$ is the overall sample mean. The observations can be represented by the two-stage nested "random effects" model $y_{kl} = \mu + c_k + e_{kl}$ where μ is the overall mean, M and N are both very large and $n/N \doteq m/M \doteq 0$; the cluster effects $\{c_k\}$ and the residual errors $\{e_{kl}\}$ are mutually uncorrelated random variables with $E(c_k) = 0$, $\text{var}(c_k) = v_a$, $E(e_{kl}) = 0$ and $\text{var}(e_{kl}) = v_w$. If the $\{c_k\}$ and $\{e_{kl}\}$ also have mutually independent normal distributions, then $Q_1 = (n-1)s_a^2/(mv_a + v_w)$ has the $\chi^2(n-1)$ distribution; $Q_2 = n(m-1)s_w^2/v_w$ has the $\chi^2[n(m-1)]$ distribution; and Q_1 and Q_2 are independent. A $100(1-\alpha)$ % confidence interval for ρ_I is (Scheffe 1959)

$$\frac{\left(s_a^2/s_w^2\right) - F_2}{\left(s_a^2/s_w^2\right) + (m-1)F_2} \le \rho_I \le \frac{\left(s_a^2/s_w^2\right) - F_1}{\left(s_a^2/s_w^2\right) + (m-1)F_1}$$

where $F_1 = F_{\alpha_1}[(n-1), n(m-1)]$ and $F_2 = F_{1-\alpha_2}[(n-1), n(m-1)]$ with $\alpha_1 + \alpha_2 = \alpha$. For the case with $m = M$ and N very large, there is a random sample of clusters but all observations are used within the clusters in the sample so no subsampling is conducted at the second stage. In this situation, the sample is called a *single-stage cluster sample* and formulation of confidence intervals is based on large sample approximations.

A well-known use of the intraclass correlation is to measure observer reliability (Fleiss 1999). Suppose each of a sample of m observers follows a standard protocol to independently and in random order measure the waist circumference (WC) of each of a sample of n subjects (clusters). The two stage nested random effects model mentioned above is appropriate for the resulting data and the s_a^2 and s_w^2 can be obtained as mean squares in an ▶analysis of variance (ANOVA) and used to calculate r_I as a quantitative assessment of *inter-observer correlation*. Now, suppose a single observer measures the waist circumference (WC) on each subject in a sample of n subjects on p occasions where the observer is unaware of values of previous measurements on a given subject. Calculation of r_I from the two-stage nested random effects ANOVA is again of interest but in this case to assess *intra-observer correlation*. The closer r_I is to zero the stronger the evidence the observer *can not reliably measure* WC and conversely the closer it is to one the stronger the evidence the observer *can reliably measure* WC. Analogously, if multiple observers are used with each observer making replicate measurements, then a three-stage nested random effects model can be used to estimate variance components required for calculating both inter- and intra-observer correlation coefficients.

Intraclass correlation has been used for many years to investigate hereditary properties of human characteristics (Fisher 1918, 1946). In twin studies, for example, the clusters are defined as twin pairs and there are $m = 2$ sibs per cluster; hence, the estimator of ρ_I simplifies to $r_I = \left(s_a^2 - s_w^2\right)/\left(s_a^2 + s_w^2\right)$. The closer r_I is to zero the stronger the evidence a characteristic of interest *is not heritable* and conversely the closer it is to one the stronger the evidence it *is heritable*. Monozygotic (MZ) twins develop from a single fertilized egg and therefore share virtually all their genetic similarities whereas dizygotic (DZ) twins develop from two fertilized eggs and share on average half their similarities just as non-twin siblings. A characteristic y_{ij} can be modeled as $y_{ij} = \mu + g_i + s_i + e_{ij}$ where μ is the overall mean, the $\{g_i\}$ and $\{s_i\}$ are random genetic effects and shared environment effects, respectively, and the $\{e_{ij}\}$ are residual errors including unshared environmental effects. Let G and S denote the estimator of the proportion of total variance for y that is attributable to genetics and shared environment, respectively; further, let $r_{MZ} = G + S$ and $r_{DZ} = 0.5G + S$ represent the calculated intraclass correlation coefficients for the monozygotic and dizygotic twins, respectively. Then, the genetic or heritability coefficient is $H^2 = 2(r_{MZ} - r_{DZ})$.

For a sample of clusters, the required sample size for the total number of subjects needs to be larger than for a corresponding ▶simple random sample to account for greater variability inherent in cluster based estimators. If n_S is the required number of subjects under simple random sampling, $[n_{CS} = (DEFF)\, n_S]$ will be the required total number of subjects under cluster sampling where $DEFF \geq 1$, called the *design effect* by authors such as Kish (1965) and Cochran (1977), is the ratio of an estimator's variance using cluster sampling to its variance using simple random sampling. The design effect also can be expressed as $DEFF = [1 + (\overline{m} - 1)\rho_I]$ where $\overline{m}$ is the average cluster size and ρ_I is the intraclass correlation coefficient.

Intraclass correlation plays a fundamental role in many experimental designs that parallel its importance in survey sampling studies. For example, *cluster* or *group randomized trials* (Green 1998; Murray 1998) randomly allocate clusters rather than individual subjects to intervention conditions. Thus, community level randomization plans may be employed in trials to compare effectiveness of smoking cessation interventions where different combinations of advertisements, group lectures and drugs to attenuate nicotine craving are randomly allocated to communities. A subsample of subjects is selected within each community and, for logistic purposes, all participating subjects within a community receive the same protocol for intervention. Following the notation established above and recognizing that the number of clusters determines the residual degrees of freedom used to test the difference between two interventions, the usual formula for estimating the required total number of subjects per intervention is

$$n_{CS} = N_G \overline{m} = \left\{\left(z_\alpha + z_\beta\right)^2 \left(2\sigma^2\right)[1 + (\overline{m} - 1)\rho_I]\right\}/\Delta^2$$

where N_G is the number of clusters per intervention; z_α and z_β are the $100(1 - \alpha/2)$ and $100(1 - \beta)$ percentiles of the standard normal distribution as is appropriate for a two-directional test with significance level α and for power = $(1 - \beta)$; σ^2 is the applicable variance; and Δ is the anticipated outcome difference between groups. For these trials, it is of interest to compare interventions with respect to change in response between two observation times such as baseline to end of study. The variance for such changes can be expressed as $2\sigma_t^2(1 - \rho_t)$ where σ_t^2 is the outcome variance at a particular time t, ρ_t is the correlation between the outcome observations at two specified times, and ρ_I is

the intraclass correlation coefficient for change from baseline. The total required number of subjects in this context is

$$n_{CS} = N_G\overline{m} = \left\{\left(z_\alpha + z_\beta\right)^2\left(4\sigma_t^2\right)(1-\rho_t) \times \left[1+(\overline{m}-1)\rho_I\right]\right\}/\Delta^2.$$

Inverse Gaussian Distribution

Kalev Pärna
President of the Estonian Statistical Society, Professor of Probability, Head of the Institute of Mathematical Statistics
University of Tartu, Tartu, Estonia

Introduction

The inverse Gaussian distribution (IG) (also known as **Wald distribution**) is a two-parameter continuous distribution given by its density function

$$f(x;\mu,\lambda) = \sqrt{\frac{\lambda}{2\pi}}x^{-3/2}\exp\left\{-\frac{\lambda}{2\mu^2 x}(x-\mu)^2\right\},\quad x>0.$$

The parameter $\mu > 0$ is the mean and $\lambda > 0$ is the shape parameter. For a random variable (r.v.) X with inverse Gaussian distribution we write $X \sim IG(\mu,\lambda)$.

The inverse Gaussian distribution describes the distribution of the time a Brownian motion (see ►Brownian Motion and Diffusions) with positive drift takes to reach a given positive level. To be precise, let $X_t = \nu t + \sigma W_t$ be a Brownian motion with drift $\nu > 0$ (here W_t is the standard Brownian motion). Let T_a be the first passage time for a fixed level $a > 0$ by X_t. Then T_a has inverse Gaussian distribution, $T_a \sim IG\left(\frac{a}{\nu}, \frac{a^2}{\sigma^2}\right)$.

The inverse Gaussian distribution was first derived by E. Schrödinger in 1915. It belongs to the wider family of Tweedie distributions.

Characteristics of IG Distribution

The cumulative distribution function (c.d.f.) of IG is

$$F(x) = \Phi\left(\sqrt{\frac{\lambda}{x}}\left(\frac{x}{\mu}-1\right)\right) + \exp\left(\frac{2\lambda}{\mu}\right)\Phi\left(-\sqrt{\frac{\lambda}{x}}\left(\frac{x}{\mu}+1\right)\right),$$

where $\Phi()$ is cumulative distribution function of the standard normal distribution. The characteristic function of IG is

$$\phi(t) = \exp\left\{\frac{\lambda}{\mu}\left(1-\sqrt{1-\frac{2\mu^2 it}{\lambda}}\right)\right\}$$

and the ►moment generating function is

$$m(t) = \exp\left\{\frac{\lambda}{\mu}\left(1-\sqrt{1-\frac{2\mu^2 t}{\lambda}}\right)\right\}.$$

Using the latter, the first four raw moments (i.e., $\alpha_n \equiv E(X^n) = \frac{\partial^n m(t)}{\partial t^n}|_{t=0}$) of the IG distribution are calculated as

$$\alpha_1 = \mu,$$
$$\alpha_2 = \mu^2 + \frac{\mu^3}{\lambda},$$
$$\alpha_3 = \mu^3 + \frac{3\mu^4}{\lambda} + \frac{3\mu^5}{\lambda^2},$$
$$\alpha_4 = \mu^4 + \frac{6\mu^5}{\lambda} + \frac{15\mu^6}{\lambda^2} + \frac{15\mu^7}{\lambda^3}.$$

Accordingly, the mean, variance, skewness, and kurtosis are obtained as

$$E(X) = \mu,$$
$$Var(X) = \frac{\mu^3}{\lambda},$$
$$Skewness\ (X) = 3\sqrt{\frac{\mu}{\lambda}},$$
$$Kurtosis\ (X) = 15\frac{\mu}{\lambda}.$$

Summation of IG-Distributed Random Variables

An important property of the IG distribution is that, with certain limitations, the sum of random variables with IG distribution is again IG distributed. More precisely, if X_i are independent and $X_i \sim IG\left(\mu_0 w_i, \lambda_0 w_i^2\right)$ then

$$\sum_{i=1}^{n} X_i \sim IG(\mu_0 \overline{w}, \lambda_0 \overline{w}^2),$$

where $\overline{w} = \sum_{i=1}^{n} w_i$. It follows, by taking $w_i \equiv 1/n$, that the inverse Gaussian distribution is infinitely divisible.

Estimation of Parameters

Let $X_1, \ldots, X_n$ be a random sample from the IG distribution $IG(\mu, \lambda)$. Then the maximum likelihood estimators for the parameters μ and λ are

$$\hat{\mu} = \frac{\sum_{i=1}^{n} X_i}{n}, \quad \frac{1}{\hat{\lambda}} = \frac{1}{n}\sum_{i=1}^{n}\left(\frac{1}{X_i} - \frac{1}{\hat{\mu}}\right).$$

The statistics $\hat{\mu}$ and $\hat{\lambda}$ are independent and their distributions are given by

$$\hat{\mu} \sim IG(\mu, n\lambda), \quad \frac{n}{\hat{\lambda}} \sim \chi^2_{n-1}.$$

Simulation from IG Distribution

In order to generate random numbers from the inverse Gaussian distribution, the following algorithm can be used:

1. Generate a random number z from a standard normal distribution $N(0,1)$. Let $y = z^2$.
2. Calculate $x = \mu + \frac{\mu^2 y}{2\lambda} - \frac{\mu}{2\lambda}\sqrt{4\mu\lambda y + \mu^2 y^2}$.
3. Generate a random number u from a uniform distribution $U(0,1)$.
4. If $u \le \frac{\mu}{\mu+x}$ then return x, else return μ^2/x.

Inverse Sampling

Man Lai Tang[1], Hon Keung Tony Ng[2]
[1]Associate Professor
Hong Kong Baptist University, Kowloon, Hong Kong
[2]Associate Professor
Southern Methodist University, Dallas, TX, USA

Introduction and Applications

The inverse sampling, first proposed by Haldane (1945), suggests one continues to sample subjects until a prespecified number of events of interest is observed. In contrast to the commonly used binomial sampling wherein the sample size is prefixed and the number of events of interest observed is random, the number of events of interest observed is prefixed for inverse sampling and the sample size is a random variable follows a negative binomial distribution. Therefore, inverse sampling is also known as *negative binomial sampling*. It is generally considered to be more appropriate than the usual binomial sampling when the subjects come sequentially, when the response probability is rare, and when maximum likelihood estimators of some epidemiological measures are undefined under binomial sampling. For instance, in epidemiological investigations, the estimation of the prevalence of a given disease on public health in a community or the variation of a disease distribution between geographical regions to locate the potential causes is one of the aims of biostatisticians, epidemiologists or medical researchers. The prevalence

here is referred to the population proportion of subjects having the disease. Usually, the estimation is done under the assumed case-binomial sampling. However, when the underlying disease is rare, the probability of obtaining only a few or zero cases in a sample under binomial sampling can be large or non-negligible. So the estimate of the population prevalence under binomial sampling can be subjected to a large relative error (Cochran 1977). To ensure that a reasonable number of cases are obtained, we may consider the use of inverse sampling.

Inverse sampling has long been appealing to practitioners and statisticians in various medical, biological and engineering research areas. For example, Smith et al. (1994) studied the level of HIV-1 mRNA-expressing (positive) mononuclear cells within the esophageal mucosa of patients with acquired immune deficiency syndrome (AIDS) and esophageal disease. Since the process of identifying positive cells could be quite tedious, they measured the prevalence of positive cells via inverse sampling. Briefly, in each slide of biopsy specimens nonoverlapping microscopic fields were examined until a field containing positive cells was found. Other applications of inverse sampling can be also found in haematological study (Haldane 1945), botanical study of plant diseases (Madden et al. 1996) and case-control study involving a rare exposure of maternal congenital heart disease (Kikuchi 1987). In software engineering, Singh et al. (1997) used the method of inverse sampling to develop a statistical procedure for quantifying the reliability of a piece of software. Their proposed procedure substantially reduced the average number of executions run over the traditional binomial sampling.

Statistical Model and Inference

Suppose that we consider a study under inverse sampling, in which we continue to collect subjects until the predetermined number r (≥ 1) of index subjects with certain attributes of interested are obtained. Let Y be the number of subjects without the attributes of interest finally accumulated in the sample before we obtain the first r index subjects. We denote the proportion p as the corresponding probability that a randomly chosen subject with the attributes of interest, where $0 < p < 1$. As a result, the random variable Y follows a negative binomial distribution with parameters r and p with probability mass function

$$f(y|p) = \Pr(Y = y|p) = \binom{r+y-1}{y} p^r (1-p)^y, \quad y = 0, 1, 2, \cdots.$$

In practice, p is usually the parameter of interest and different methods are proposed to estimate p. Two commonly used estimators of p are the maximum likelihood estimator (MLE) and the uniformly minimum variance unbiased estimator (UMVUE). The MLE of p is given by

$$\hat{p} = \frac{r}{N},$$

where $N = r + Y$ is the total number of trials required to obtain the predetermined number r. It can be shown that the variance of $\hat{p}$ is

$$Var(\hat{p}) = \frac{p^2(1-p)}{r}.$$

Note that the MLE is actually a biased estimator of p and an UMVUE of p can be obtained by

$$\tilde{p} = \frac{r-1}{N-1}.$$

The variance of $\tilde{p}$ can be shown to be

$$Var(\tilde{p}) = (r-1)(1-p)\left\{\sum_{k=1}^{r-1} \frac{(-p)^k}{(1-p)^k(r-k)} - \left(\frac{-p}{1-p}\right)^r \log(p)\right\} - p^2$$

and an unbiased estimator of $Var(\tilde{p})$ for $r > 2$ is given by

$$\widehat{Var}(\tilde{p}) = \frac{\tilde{p}(1-\tilde{p})}{N-2}.$$

For interval estimation of p, there are different types of confidence intervals available in the literature. For example, Wald-type confidence interval based on MLE or UMVUE (Lui 2004), exact confidence interval due to Casella and Berger (1990), confidence interval based on the fact that $2(r+Y)p$ follows a χ^2 distribution with $2r$ degrees of freedom (Bennett 1981), score confidence interval, likelihood ratio based confidence interval saddle-point approximation based confidence interval. For a detail review on different confidence intervals for parameter p and comparative study among these methods, one may refer the Tian et al. (2009).

Extensions to two negative binomial proportions comparison have been recently studied. For instance, Tang et al. (2007) proposed different asymptotic procedures for testing negative binomial proportion ratio. Tang et al. (2008) considered exact unconditional procedures for risk ratio under standard inverse sampling. Tian et al. (2009) derived an asymptotically reliable saddle-point approximate confidence interval for risk ratio under inverse sampling. Tang and Tian (2009, 2010) proposed various asymptotic and approximate confidence intervals for proportion difference under inverse sampling.

Inversion of Bayes' Formula for Events

Kai Wang Ng
Professor and Head
The University of Hong Kong, Hong Kong, China

In standard notation, let $\{H_1, H_2, \cdots, H_m\}$ and $\{A_1, A_2, \cdots, A_n\}$ be two distinct partitions of the sample space, or equivalently two sets of events satisfying three properties: (i) each event is non-void, (ii) events in the same set are mutually exclusive (i.e., $P(H_j \cup H_k) = P(H_j) + P(H_k)$ for $j \neq k$), and (iii) each set is collectively exhaustive, (i.e., $P(\cup_{i=1}^{m} H_j) = 1$). The *Bayes' formula* in general form is, for $j = 1, \cdots, m, i = 1, \cdots, n$,

$$P(H_j|A_i) = \frac{P(A_i|H_j)P(H_j)}{P(A_i)} = \frac{P(A_i|H_j)P(H_j)}{\sum_{k=1}^{m} P(A_i|H_k)P(H_k)}, \quad (1)$$

where the last substitution is by virtue of the so-called *formula of total probability*,

$$P(A_i) = \sum_{k=1}^{m} P(A_i|H_k)P(H_k), \quad i = 1, \cdots, n, \quad (2)$$

which is valid due to properties (i) to (iii).

In Bayesian inference, which is the first paradigm of statistical inference in history, $\{H_1, H_2, \cdots, H_m\}$ are antecedent events viewed as competing hypotheses and $P(A_i|H_j)$ is the probability that the event A_i occurs as an outcome of the jth hypothesis. The investigator assigns $P(H_j)$, called the *prior probability*, to the jth hypothesis based on available information to him/her or in accordance with his/her belief on the odds of the competing hypotheses. Given that A_i occurs, Bayes' formula (1) gives the revised probability, called the *posterior probability*, of the jth competing hypothesis.

We put all the above probabilities in the combined two-way table on the top of next page, (Table 1). Where the posteriors $P_{ij} = P(H_j|A_i)$ and the likelihoods $L_{ij} = P(A_i|H_j)$ are respectively in the upper part and lower part of the (i,j) cell, while the priors $p_j = P(H_j)$ and the Bayes' factors $q_i = P(A_i)$ are in the two margins.

Now consider the question whether we can prescribe the posterior probabilities which we want to get in the end and work out the prior probabilities. In terms of the table, the question is equivalent to finding the values on margins, given all pairs of values in the cells.

A practical need leading to the above question, which seems to be the first, arises in the *Data Augmentation Algorithm* of Tanner and Wong (1987) for Bayesian inference in probability density function (pdf) setting; see also

Inversion of Bayes' Formula for Events. Table 1

$P(H_j\|A_i)$ / $P(A_i\|H_j)$	H_1	⋯	H_j	⋯	H_m	$P(A_i)$
A_1	P_{11} / L_{11}	⋯	P_{1j} / L_{1j}	⋯	P_{1m} / L_{1m}	q_1
⋮	⋮	⋮	⋮	⋮	⋮	⋮
A_i	P_{i1} / L_{i1}	⋯	P_{ij} / L_{ij}	⋯	P_{im} / L_{im}	q_i
⋮	⋮	⋮	⋮	⋮	⋮	⋮
A_n	P_{n1} / L_{n1}	⋯	P_{nj} / L_{nj}	⋯	P_{nm} / L_{nm}	q_n
$P(H_j)$	p_1	⋯	p_j	⋯	p_m	1

Tanner (1996, Chap. 5) for more detail. But it was not recognized as an inversion of Bayes' formula until the author of this article revisited the integral equation for which the Algorithm aimed to solve by successive substitution; see Tan et al. (2009, pp. 1–3, 9) for a detailed account and Ng (1995a, 1997b) for original reference. Beyond the context of Bayesian inference, the inversion of Bayes' formula (*IBF*) is mathematically equivalent to de-conditioning (*DC*) in the sense of finding unconditional probabilities given the conditional ones. Note that *IBF* is also used for "*Inverse Bayes Formulae*" as in Ng (1995b, 1997a) in reference to those de-conditioning formulae in pdf setting. If the inversion is through an algorithm, as discussed by Ng (1996) for those cases of the above two-way table where r_{ij} are defined only in certain cells in haphazard patterns, we shall call it an *IBF Algorithm*, or a *DC Algorithm*.

Note that the given values in the cells are assumed to be from an existing set of joint probabilities, $P(A_i \cap H_j)$, which are not known to us. This assumption is called *compatibility* or *consistency* and needs be confirmed in applications; see Arnold et al. (1999). If we have found all p_j or all q_i, we can construct $P(A_i \cap H_j)$ and hence reconstruct all the $P(H_j|A_i)$ and $P(A_i|H_j)$. *If the given P_{ij} and L_{ij} are not identical to the reconstructed conditional probabilities, they are not compatible by contradiction; otherwise we have a constructive proof that they are.* So when an IBF or IBF algorithm is available, checking compatibility is just a natural flow of the aftermath-checking and hence we shall omit this trivial part in the article.

Although A_i and H_j are non-void events, their intersection $A_i \cap H_j$ may be void and hence the conditional probabilities concerning them may be zero. This does not matter at all in Bayes' formula, but it does in its inversion because probability ratios are the key quantities. We summarize in the following lemma some self-explaining results which we shall need in the sequel.

Lemma 1 (Preliminary facts) The following are true if A_i and H_j satisfy the aforesaid properties (i)-(iii) and if $P_{ij} = P(H_j|A_i)$ and $L_{ij} = P(A_i|H_j)$ as assumed in the table.

(a) In each cell of the table, P_{ij} and L_{ij} are simultaneously both zero if and only if $A_i \cap H_j = \emptyset$ and both positive if and only if $A_i \cap H_j \neq \emptyset$. Thus the ratio $r_{ij} = P_{ij}/L_{ij}$ is well-defined in at least one cell in each row and each column, resulting in a system of equations,

$$p_j/q_i = r_{ij} \equiv P_{ij}/L_{ij}, \quad i = 1, 2, \cdots, n;\ j = 1, \cdots, m, \tag{3}$$

for the $m + n - 2$ effective unknowns, namely p_j and q_i subject to constraints $\sum_{j=1}^{m} p_j = 1$ and $\sum_{i=1}^{n} q_i = 1$, in as many number of equations as the number of well-defined r_{ij}.

(b) If $\{p_j\}$ are determined, so are $\{q_i\}$ by (3), and vice versa. Furthermore, we may always swap the roles of rows and columns for purpose of de-conditioning without loss of generality.

(c) The $\{p_j\}$ are uniquely determined if their relative proportions can be obtained; in this case we shall say they are *completely proportionable*. For example, given the complete set of proportions relative to a common denominator p_{j^*}, $(p_1/p_{j^*}, \cdots, p_{(j^*-1)}/p_{j^*}, 1, p_{(j^*+1)}/p_{j^*}, \cdots, p_m/p_{j^*})$, we can express p_j in terms of the proportions:

$$p_j = \frac{p_j}{p_{j^*}} \left\{ \sum_{j=1}^{m} \frac{p_j}{p_{j^*}} \right\}^{-1}, \quad j = 1, 2, \cdots, m. \tag{4}$$

Furthermore, if the complete consecutive ratios $(p_1/p_2, p_2/p_3, \cdots, p_{m-1}/p_m)$ are given, we can obtain

the proportions against a common denominator by chained multiplications; for instance,

$$\frac{p_1}{p_m} = \prod_{j=1}^{m-1} \frac{p_j}{p_{j+1}}, \frac{p_2}{p_m} = \prod_{j=2}^{m-1} \frac{p_j}{p_{j+1}}, \cdots \frac{p_{m-1}}{p_m} = \prod_{j=m-1}^{m-1} \frac{p_j}{p_{j+1}}. \tag{5}$$

Finally, the analogous results concerning $q_i, i = 1, \cdots, n$, are also valid.

(d) If in a particular row i, a subset of the ratios, $r_{ij_1}, r_{ij_2}, \cdots, r_{ij_k}$, are defined, the proportions between the corresponding marginal probabilities, $p_{j_1}, p_{j_2}, \cdots, p_{j_k}$, are readily available and we shall say that $p_{j_1}, p_{j_2}, \cdots,$ and p_{j_k} are *proportionable* in row i; in notation, $[p_{j_1}(i)p_{j_2}(i)\cdots(i)p_{j_k}]$, where the order is immaterial, or $[j_1(i)j_2(i)\cdots(i)j_k]$ for short. For example, the proportions relative to p_{j_k} are:

$$\begin{aligned} p_{j_1}/p_{j_k} &= r_{ij_1}/r_{ij_k}, p_{j_2}/p_{j_k} = r_{ij_2}/r_{ij_k}, \cdots, p_{j_{k-1}}/p_{j_k} \\ &= r_{ij_{k-1}}/r_{ij_k}. \end{aligned} \tag{6}$$

The analogous conclusion about a subset of q_i at a particular column j is also valid.

So the key of inversion of Bayes' formula is to determine the relative proportions of the marginal probabilities. Now if there is one row where all ratios are defined, all $\{p_j\}$ are completely proportionable in that row according to (3), hence determining all p_j. And similarly for the q_i.

Proposition 1 (IBF: completely defined ratios in one row or column) If P_{ij} and L_{ij} are compatible, the following hold:

(a) If there is a particular row, say the i^*th row, where all ratios r_{i^*j} are defined, we have

$$\begin{aligned} p_j &= r_{i^*j}\left\{\sum_{j=1}^{m} r_{i^*j}\right\}^{-1}, \ j = 1, \cdots, m; \\ q_i &= \frac{r_{i^*j}}{r_{ij}}\left\{\sum_{j=1}^{m} r_{i^*j}\right\}^{-1}, i = 1, \cdots, n. \end{aligned} \tag{7}$$

(b) If there is a particular column, say the j^*th column, where all ratios r_{ij^*} are defined, we have

$$\begin{aligned} q_i &= r_{ij^*}^{-1}\left\{\sum_{i=1}^{n} r_{ij^*}^{-1}\right\}^{-1}, \ i = 1, \cdots, n; \\ p_j &= r_{ij}r_{ij^*}^{-1}\left\{\sum_{i=1}^{n} r_{ij^*}^{-1}\right\}^{-1}, \ j = 1, \cdots, m. \end{aligned} \tag{8}$$

(c) Under the so-called **positivity condition** where all r_{ij} are defined, the following are valid:

$$\begin{aligned} p_j &= 1/\sum_{i=1}^{n} r_{ij}^{-1} = r_{ij}\left\{\sum_{j=1}^{m} r_{ij}\right\}^{-1}, \ j = 1, \cdots, m, \\ &\quad \text{regardless any } i = 1, \cdots, n; \end{aligned} \tag{9}$$

$$\begin{aligned} q_i &= 1/\sum_{j=1}^{m} r_{ij} = r_{ij}^{-1}\left\{\sum_{i=1}^{n} r_{ij}^{-1}\right\}^{-1}, \ i = 1, \cdots, n, \\ &\quad \text{regardless any } j = 1, \cdots, m. \end{aligned} \tag{10}$$

Proof For part (a), we have all the proportions $p_j/p_m = r_{i^*j}/r_{i^*m}$ according to Lemma 1(d). By substituting them in (4) and simplifying we get the first identity, and then the second, of (7). For part (b), flip over the ratio in (3) for the particular $j = j^*$, obtaining $q_i/p_{j^*} = r_{ij^*}^{-1}$, and proceed as in the proof for part (a). Since the assumption in (c) implies that (7) is true for every $i^* = 1, \cdots, n$, we immediately have the second identity of (9) and the first identity in (10). The same assumption implies (8) for every $j^* = 1, \cdots, m$, so we have the second identity in (10) and the first identity of (9).

There are situations where each row and each column has one undefined r_{ij}, or more, so that Proposition 1 does not apply. We can still consider making $\{p_j\}$ completely proportionable using more than one row, and all q_i using more than one column. This process, however, would lead to algorithms instead of nice and neat formulae as in Proposition 1. In view of Lemma 1(b), we shall concentrate on finding p_j.

Proposition 2 (IBF: at least one ratio undefined in every row and every column) If P_{ij} and L_{ij} are compatible, the following hold:

(a) Let $(p_{j_1}, p_{j_2}, \cdots, p_{j_m})$ be any permutation of $\{p_j\}$. If p_{j_1} and p_{j_2} are proportionable in row i_1, p_{j_2} and p_{j_3} proportionable in row i_2, $\cdots, p_{j_{(m-1)}}$ and p_{j_m} proportionable in row $i_{(m-1)}$, or in notation,

$$[p_{j_1}(i_1)p_{j_2}(i_2)p_{j_3}(i_3)\cdots p_{j_{(m-1)}}(i_{(m-1)})p_{j_m}], \tag{11}$$

then $\{p_j\}$ are completely proportionable. For example, the consecutive proportions are given by

$$\frac{p_{j_1}}{p_{j_2}} = \frac{r_{i_1j_1}}{r_{i_1j_2}}, \frac{p_{j_2}}{p_{j_3}} = \frac{r_{i_2j_2}}{r_{i_2j_3}}, \cdots, \frac{p_{j_{(m-1)}}}{p_{j_m}} = \frac{r_{i_{(m-1)}j_{(m-1)}}}{r_{i_{(m-1)}j_m}}, \tag{12}$$

and we can then determine $\{p_j\}$ by (5) and (4). In practice, as shown in examples below, a common denominator would suggest itself for less work of finding the proportions.

Inversion of Bayes Formula for Events. Table 2

	p_1	p_2	p_3	p_4	p_5	p_6
q_1				r_{14}		r_{16}
q_2		r_{22}	r_{23}		r_{25}	
q_3						r_{36}
q_4	r_{41}				r_{45}	
q_5			r_{53}			
q_6		r_{62}			r_{65}	
q_7	r_{71}			r_{74}		

Lemma 1(d)	Available proportions
[4(1)6]	$p_6/p_4 = r_{16}/r_{14}$
[2(2)3(2)5]	$p_2/p_5 = r_{22}/r_{25}$, $p_3/p_5 = r_{23}/r_{25}$
[1(4)5]	$p_1/p_5 = r_{41}/r_{45}$
[2(6)5]	Done in row 2
[1(7)4]	$p_4/p_5 = (r_{74}/r_{71})(p_1/p_5)$, $p_6/p_5 = (p_6/p_4)(p_4/p_5)$.

(b) The solution for $\{p_j\}$ is not unique if the following situation happens after going down the table row by row in search for proportionable $\{p_j\}$:

The process ends up with two or more subsets of $\{p_j\}$ whose union equals the whole set of $\{p_j\}$ and which satisfy two conditions: (i) each member of one subset is found not proportionable with any member of another subset and (ii) members within the same subset are proportionable unless the subset is a singleton.

Proof (a) is straightforward. In (b), first consider the case of two subsets. We can assign an arbitrary weight, a $(0 < a < 1)$, to the sum of one subset and $1 - a$ to the sum of the other, producing a solution for $\{p_j\}$. Then we have $\{q_i\}$ by Lemma 1(b). Other cases of more than two subsets are similar.

In the following examples, all well-defined $r_{ij} = P_{ij}/L_{ij}$ are shown, while an empty cell means that the ratio is not defined for a pair of zeros. We need only demonstrate finding $\{p_j\}$.

Example 1 *(IBF for haphazard patterns of well-defined ratios)* For a haphazard pattern, we can apply Lemma 1(d) row by row to accumulate available proportions of $\{p_j\}$, with the aid of a work-sheet as illustrated in Table 2.

The first column on the right side of the table (Table 2) shows proportionable columns by each row. The results in this column suggest using p_5 as the common denominator, because it is directly proportionable to more p_j than any other choice. Then on the next column, we accumulate available proportions relative to p_5. The results from row 1 to row 6 are straightforward. Row 7 provides proportion $p_4/p_1 = r_{74}/r_{71}$, which is multiplied by (p_1/p_5) (of row 4) to yield p_4/p_5. Then p_6/p_4 from row 1 and the newly found p_4/p_5 yields p_6/p_5. At this point, all 5 proportions to p_5 are ready to yield the 6 marginal probabilities by (4) in Lemma 1(c).

Now suppose the last row is dropped and we are dealing with a 6×6 table. The above process stops at the 6th row and there are two subsets, [4(1)6] and [2(2)3(2)5(4)1], as stipulated in part (b) of proposition 2. Although the proportions within subsets are determined as before, there are infinitely many possible proportions, $a : (1 - a), 0 < a < 1$, to be allocated to the two subsets, each being as good as another in reproducing the supposedly compatible P_{ij} and L_{ij} which define r_{ij}.

Example 2 *(IBF for zigzag paths of well-defined ratios)* The two examples (Table 3) are quite straightforward in reaching (11), so we don't need a work-sheet as in the last example.

For the left table, we have $[p_1(3)p_2(3)p_3]$ with consecutive ratios, $p_1/p_2 = r_{31}/r_{32}$ and $p_2/p_3 = r_{32}/r_{33}$. Next, we have $[p_3(5)p_4(5)p_5(5)p_6]$ with consecutive ratios, $p_3/p_4 = r_{53}/r_{54}$, $p_4/p_5 = r_{54}/r_{55}$ and $p_5/p_6 = r_{55}/r_{56}$. So we can plug in (5) and then (4) to get all p_i. An alternative route is $[p_1(3)p_2(3)p_3(4)p_5(5)p_4(5)p_6]$. For the right table, we can abbreviate the situation as $[p_1(2)p_2(3)p_3(4)p_4(5)p_5(6)p_6]$, which obviously provides consecutive ratios of p_1 to p_6 and is thus completely proportionable. Note that an alternative route is $[p_1(2)p_2(3)p_3(4)p_4(6)p_5(6)p_6]$.

The Bayes' formula was developed in a manuscript by Reverend Thomas Bayes and, after his death in 1761,

Inversion of Bayes Formula for Events. Table 3

	p_1	p_2	p_3	p_4	p_5	p_6
q_1						r_{16}
q_2					r_{25}	
q_3	r_{31}	r_{32}	r_{33}			
q_4			r_{43}		r_{45}	
q_5			r_{53}	r_{54}	r_{55}	r_{56}
q_6		r_{62}				
q_7	r_{71}					

	p_1	p_2	p_3	p_4	p_5	p_6
q_1	r_{11}					
q_2	r_{21}	r_{22}				
q_3		r_{32}	r_{33}			
q_4			r_{43}	r_{44}		
q_5				r_{54}	r_{55}	
q_6				r_{64}	r_{65}	r_{66}
q_7						r_{76}

was submitted by his friend to the Royal Society for posthumous publication in 1763. It is still a puzzle as why Bayes, who "was for twenty years a Fellow of the Royal Society" (Fisher 1973, p. 8), did not submit his fine essay. Fisher (1973, p. 9) wrote: "it seems clear that Bayes had recognized that the postulate proposed in his argument (though not used in his central theorem) would be thought disputable by a critical reader, and there can be little doubt that this was the reason why his treatise was not offered for publication in his own lifetime." Stigler (1983) provided another conjecture. The mathematicians at Bayes' time, and of his standing, would usually ponder and explore all possible converses and corollaries of a theorem of importance, especially a theorem of one's own. And the converses as described above are well within Bayes' capacity and do not require any new mathematics invented after his time. It is a conjecture of the author of this article that, after finishing the manuscript, Bayes recognized, or sensed, the inversion of his formula. His prior probabilities, therefore, could be perceived as the results of reverse-engineering. So he had to think about the implications of the argument and needed more time to re-write his essay (hand-written with feather and ink at that time).

About the Author

Kai Wang Ng (http://www.hku.hk/statistics/staff/kaing/) is presently Professor & Head, Department of Statistics & Actuarial Science, The University of Hong Kong. This is his 4th Headship in the same Department and he has been instrumental in the Department's growth of enrolment and other developments since 1991. He switched his early interest in functional analysis to statistical inference and completed his Ph.D. under Prof. D.A.S. Fraser in 1975. His first book in 1990, coauthored with K.T. Fang and S. Kotz, *Symmetric and Related Multivariate Analysis* (No. 36 in Chapman & Hall Monographs on Statistics and Applied probability), has roots in his 1980 paper with D.A.S. Fraser, which shows that the inference of the regression coefficients in a univariate/multivariate linear model with a spherically symmetric error vector/ matrix should be identical with i.i.d. normal errors according to the structural approach of inference. The book has been cited by about 500 articles in more than 140 international journals in diverse fields listed in ISI Science. The Google Scholar search provides more than a thousand citations. In 2009, his book *Bayesian Missing Data Problems: EM, Data Augmentation and Noniterative Computation* (with Ming T. Tan and Guo-Liang Tian), was published as No. 32 in Chapman & Hall/CRC Biostatistics Series. The methods introduced in the book are based on his 1995 discovery of the inversion of Bayes' formula in PDF form in the process of obtaining an explicit solution for the underlying integral equation of the Data Augmentation Algorithm of Tanner & Wong – considered as the Bayesian counter-part of the EM Algorithm in likelihood approach for handling incomplete data. This article presents a complete solution of this inversion in the most basic form – events.

Itô Integral

Boris L. Rozovskiĭ
Ford Foundation Professor of Applied Mathematics
Brown University, Providence, RI, USA

It was established in the first half of the twentieths century that Brownian motion (Wiener process, see ▶Brownian Motion and Diffusions) $B(s)$ is of fundamental importance for stochastic modeling of many real life processes ranging from diffusion of pollen on a water surface to volatility of financial markets. Further development of stochastic modeling brought up more complicated mathematical tools, including integrals with respect to Brownian motion. The task of constructing such an integral is not trivial. Since Brownian motion is not differentiable at any point and its quadratic variation is infinite, the classical Riemann-Stielltjes integral does not provide an appropriate framework. The first successful construction of stochastic integral

$$I_t(f) = \int_0^t f(s)\, dB(s)$$

with respect to Brownian motion was proposed by N. Wiener. Wiener's integral was defined for deterministic functions $f(s) \in L_2[0,\infty)$. Wiener has also established an important isometry

$$E\left(\int_0^t f(s)\, dB(s)\right)^2 = \int_0^t f^2(s)\, ds. \tag{1}$$

In 1944–1946, K. Itô extended the Wiener integral to a large class, written $\mathcal{J}$, of random functions $f(t)$. The elements of class $\mathcal{J}$ must be non-anticipating. Roughly speaking, the latter means that $f(t)$ must be a reasonably nice (appropriately measurable) function of t and/or the path of $B(s)$ for $s \le t$. In other words, the integrand at point t may depend only on the "past" and "present" of $B(s)$ but not on the "future". In addition, the elements of $\mathcal{J}$ must be square-integrable, which means that $E\left(\int_0^\infty f^2(s)\, ds\right) < \infty$. A function $f(t)$ from class $\mathcal{J}$ is called simple if there exists a partition $0 = s_0 \le s_1 \le \ldots$ such that $f(s) = f(s_i)$ for $s \in [s_i, s_{i+1})$. The Itô integral for a simple function $f(s)$ is defined by

$$I_t(f) := \int_0^t f(s)\, dB(s) = \sum_{s_i \le t} f(s_i)\left(B(s_{i+1}) - B(s_i)\right). \tag{2}$$

It is not difficult to see that if f is a simple function from class $\mathcal{J}$, then

$$E\left|\int_0^\infty f(s)\, dB(s)\right|^2 = \int_0^\infty E|f(s)|^2\, ds. \tag{3}$$

By making use of property (3), Itô extended his integral to any $f(s)$ such that for some sequence f_n of simple functions

$$E\int_0^\infty |f(s) - f_n(s)|^2\, ds \longrightarrow 0.$$

Other important properties of Itô's integral include: (a) $E\int_0^\infty f(s)\, dB(s) = 0$; (b) $I_t(f)$ is a continuous function of t with probability 1; (c) $I_t(f)$ is a continuous martingale.

Note, that in contrast to the Riemann integral, Itô integral is sensitive to shifts of the argument of f in the right hand part of (2). In particular, if $f(s)$ is a

smooth deterministic function, $s_i^* = (s_{i+1} + s_i)/2$, and $\max_i |s_{i+1} - s_i| \longrightarrow 0$, then

$$\sum_{s_i \le t} f\left(B\left(s_i^*\right)\right)\left(B\left(s_{i+1}\right) - B\left(s_i\right)\right) \longrightarrow \int_0^t f\left(B\left(s\right)\right) \circ dB\left(s\right) := \int_0^t f\left(B\left(s\right)\right) dB\left(s\right) + \frac{1}{2}\int_0^t f'\left(B\left(s\right)\right) ds.$$

The chain rule for functions of Brownian motion, usually referred to as the Itô formula, is given by

$$f\left(B(t)\right) - f\left(B(s)\right) = \int_s^t f'\left(B(r)\right) dB\left(r\right) + \frac{1}{2}\int_s^t f''\left(B\left(r\right)\right) dr.$$

Write $X_t = X^0 \exp\{\sigma B\left(t\right) + \mu t - \sigma^2 t/2\}$, where X^0, σ and μ are constants. This process is called geometric Brownian motion. It plays fundamental role in modeling of the dynamics of financial assets. By Itô formula, one can show that X_t is a solution of the following stochastic differential equation:

$$dX_t = \mu X_t dt + \sigma X_t dB\left(t\right). \tag{4}$$

The ratio dX_t/X_t models the rate of return on the asset X_t, μ is the mean rate of return, and σ represents the volatility of the asset. The Black-Scholes option pricing formula is based on Eq. (4).

Jackknife

Yoshihiko Maesono
Professor, Faculty of Mathematics
Kyushu University, Fukuoka, Japan

Introduction

The jackknife method was introduced by Quenouille (1949) for reducing a bias of a correlation estimator. Tukey (1958) extended his idea to make confidence intervals. Further, Efron (1979) proposed the bootstrap method (see ►Bootstrap Methods) as an extension of the jackknife inference. Using these resampling methods, we can make statistical inferences without assuming underlying distribution of the data.

Let $X_1, \ldots, X_n$ be independently and identically distributed random variables with distribution function F_θ. Quenouille (1949) proposed a technique for reducing the bias, splitting the sample into two half-samples, and in 1956 he extended this technique which split the sample into g groups of size h, where $n = gh$. Let $\hat{\theta}_n$ be an estimator of a parameter θ based on n observations, and $\hat{\theta}^{(i)}_{(g-1)h}$ be the corresponding estimator based on $(g-1)h$ observations for $i = 1, \cdots, g$. Let us define

$$\tilde{\theta}^{(i)} = g\hat{\theta}_n - (g-1)\hat{\theta}^{(i)}_{(g-1)h}.$$

Using $\tilde{\theta}^{(i)}$, Quenouille discussed the bias reduction. Tukey (1958) called $\tilde{\theta}^{(i)}$ a pseudo-value and proposed a confidence interval, using the idea that

$$\frac{\sqrt{g}(\tilde{\theta}_n - \theta)}{\sqrt{\sum_{i=1}^{g}(\tilde{\theta}^{(i)} - \tilde{\theta}_n)^2/(g-1)}}$$

should have approximate t-distribution with $g-1$ degrees of freedom, where $\tilde{\theta}_n = \sum_{i=1}^{g}\tilde{\theta}^{(i)}/g$. His idea was based on the conjecture that $\tilde{\theta}^{(i)} (i = 1, \cdots, g)$ could be treated as approximately independent and identically distributed random variables. After their introduction of the jackknife method, many papers discussed applications to statistical inferences. Let us discuss the bias reduction, and variance and higher order moment estimation.

Bias Reduction

Let us consider an estimator $\hat{\theta}_n = \hat{\theta}_n(X_1, \cdots, X_n)$ of the parameter θ, and

$$\hat{\theta}^{(i)}_{n-1} = \hat{\theta}_{n-1}(X_1, \cdots, X_{i-1}, X_{i+1}, \cdots, X_n)$$

denotes a corresponding estimator based on $n-1$ observations with X_i omitted. Then a bias corrected estimator is given by

$$\tilde{\theta}_J = n\hat{\theta}_n - (n-1)\overline{\theta}_n$$

where $\overline{\theta}_n = \sum_{i=1}^{n}\hat{\theta}^{(i)}_{n-1}/n$. Let us assume that $\hat{\theta}_n$ has the following bias

$$E(\hat{\theta}_n) - \theta = \frac{a_1(F)}{n} + \frac{a_2(F)}{n^2} + O(n^{-3})$$

where $a_1(F)$ and $a_2(F)$ depend on F but not on n. Then we can show that

$$E(\tilde{\theta}_J) - \theta = -\frac{a_2(F)}{n(n-1)} + O(n^{-2}) = O(n^{-2}).$$

Variance Estimation

The most popular jackknife variance estimator of $Var(\hat{\theta}_n)$ is given by

$$V_{J(1)} = \frac{n-1}{n}\sum_{i=1}^{n}\left(\hat{\theta}^{(i)}_{n-1} - \hat{\theta}_n\right)^2,$$

which is called a delete-1 jackknife variance estimator. If the estimator $\hat{\theta}_n$ is smooth enough, $V_{J(1)}$ is asymptotically consistent. But if the estimator is not smooth, it may be inconsistent. The best known example is the sample quantile (see Miller (1974)). To recover this inconsistency, Shao (1988) and Shao and Wu (1989) proposed the delete-d jackknife variance estimator. Let d be an integer less than n and $\mathbf{S}_{n,d}$ to be the collection of subsets of $\{1, \ldots, n\}$ with size d. For any $\delta = \{i_1, \ldots, i_d\} \in \mathbf{S}_{n,d}$, let $\hat{\theta}^{(\delta)}_{n-d}$ be the value of $\hat{\theta}_n$ when $X_{i_1}, \ldots, X_{i_d}$ are deleted from the sample. Then the delete-d jackknife variance estimator is given by

$$V_{J(d)} = \frac{n-d}{dN}\sum_{\delta}\left(\hat{\theta}^{(\delta)}_{n-d} - \hat{\theta}_n\right)^2,$$

where $N = \binom{n}{d}$ and $\sum_\delta$ is the summation over all the subsets in $\mathbf{S}_{n,d}$. For the estimators of the sample quantile, Shao

Miodrag Lovric (ed.), *International Encyclopedia of Statistical Science*, DOI 10.1007/978-3-642-04898-2,

and Wu (1989) proved that $V_{J(d)}$ is consistent and asymptotically unbiased when $n^{1/2}/d \to 0$ and $n - d \to \infty$. When the estimator is smooth enough, like ►U-statistics, Maesono (1996) has proved that $v_{J(d-1)} \leq v_{J(d)}$ for any sample point $(x_1, \ldots, x_n)$. Efron and Stein (1981) showed that the jackknife variance estimator $V_{J(1)}$ has a positive bias. Then the bias of the delete-d jackknife variance estimator is at least as large as the bias of the delete-1 estimator in the case of the smooth original estimator.

Higher Order Moment Estimation

Let us consider the following *ANOVA*- or H-decomposition (Hoeffding):

$$\hat{\theta}_n = \theta + n^{-1}\delta + n^{-1}\sum_{i=1}^{n} g_1(X_i) + n^{-2}\sum_{1\le i<j\le n} g_2(X_i, X_j) + n^{-3}\sum_{1\le i<j<k\le n} g_3(X_i, X_j, X_k) + \cdots \quad (1)$$

where $E[g_1(X_1)] = 0$, $E[g_2(X_1, X_2)|X_1] = E[g_3(X_1, X_2, X_3)|X_1, X_2] = 0$ *a.s.* Using the von Mises expansion or H-decomposition, we can show that many statistics satisfy the equation (1). The jackknife variance estimator $nV_{J(1)}$ is consistent to $E\left[g_1^2(X_1)\right]$, which is a main term of an asymptotic variance. Hinkley (1978) and Efron and Stein (1981) studied bias reductions of the jackknife variance estimator $V_{J(1)}$, using an estimator of $E\left[g_2^2(X_1, X_2)\right]$. Lai and Wang (1993) obtained an Edgeworth expansion which includes higher order moments. $n^{-1/2}$ term of the expansion is

$$\kappa_3 = E\left[g_1^3(X_1)\right] + 3E[g_1(X_1)g_1(X_2)g_2(X_1, X_2)].$$

In order to estimate these moments, we need pseudo values of $g_1(X_i)$ and $g_2(X_i, X_j)$. They are given by

$$\hat{g}_1(X_i) = n\hat{\theta}_n - (n-1)\hat{\theta}_{n-1}^{(i)}$$

and

$$\hat{g}_2(X_i, X_j) = (n-2)\left\{n\hat{\theta}_n - (n-1)\left(\hat{\theta}_{n-1}^{(i)} + \hat{\theta}_{n-1}^{(j)}\right) + (n-2)\hat{\theta}_{n-2}^{(i,j)}\right\}$$

where $\hat{\theta}_{n-2}^{(i,j)}$ is a corresponding statistic based on $n-2$ observations with X_i and X_j omitted. For these pseudo values, we can show that

$$\hat{g}_1(X_i) = g_1(X_i) + O_p(n^{-1}) \quad \text{and}$$
$$\hat{g}_2(X_i, X_j) = g_2(X_i, X_j) + O_p(n^{-1})$$

and then we have

$$\frac{2}{n(n-1)}\sum_{1\le i<j\le n}\hat{g}_2^2(X_i, X_j) \xrightarrow{P} E\left[g_2^2(X_i, X_j)\right]$$

and

$$\frac{1}{n}\sum_{i=1}^{n}\hat{g}_1^3(X_i) + \frac{6}{n(n-1)}\sum_{1\le i<j\le n}\hat{g}_1(X_i)\hat{g}_1(X_j) \times \hat{g}_2(X_i, X_j) \xrightarrow{P} \kappa_3.$$

Similarly, a pseudo value of $g_3(X_i, X_j, X_k)$ is given by

$$\hat{g}_3(X_i, X_j, X_k) = (n-4)(n-5)\left\{n\hat{\theta}_n - (n-1) \times \left(\hat{\theta}_{n-1}^{(i)} + \hat{\theta}_{n-1}^{(j)} + \hat{\theta}_{n-1}^{(k)}\right) + (n-2)\left(\hat{\theta}_{n-2}^{(i,j)} + \hat{\theta}_{n-2}^{(j,k)} + \hat{\theta}_{n-2}^{(i,k)}\right) - (n-3)\hat{\theta}_{n-3}^{(i,j,k)}\right\}$$

where $\hat{\theta}_{n-3}^{(i,j,k)}$ is a corresponding statistic based on $n-3$ observations with X_i, X_j and X_k omitted. Using the pseudo values $\hat{g}_1, \hat{g}_2$ and $\hat{g}_3$, we can make consistent estimators of the higher order moments which appear in the fourth cumulant κ_4.

James–Stein Estimator

Christian Heumann
Ludwig Maximilian University, Munich, Germany

James–Stein Estimator in the Original Problem

The James–Stein estimator was developed in the seminal work of Charles Stein in 1956 (Stein 1956), and James and Stein in 1961 (James and Stein 1961). They showed that the ordinary least squares estimator (in a special situation as described below) is dominated by the James–Stein estimator if the dimension of the parameter vector is greater than two. Many statisticians were first not believing this phenomenon often called Stein's phenomenon or Stein's paradox. One has to realize that the James–Stein estimator is a nonlinear estimator and therefore falls outside the class of linear estimators (linear in the data y). Second it is a biased estimator and domination of the ordinary least squares is defined in terms of the scalar mean squared error criterion (MSE). The situation that was studied by James and Stein is the following: consider a parameter vector $\beta = (\beta_1, \ldots, \beta_p)$ of dimension p which is the mean of a mutivariate normal distribution (see ▶Multivariate Normal Distributions) with $p \times p$ covariance matrix $\sigma^2 I_p$, where I is the identity matrix of dimension p (ones on the diagonal, zero elsewhere). Now consider a sample y of size $n = 1$ of that multivariate normal distribution:

$$y \sim N_p(\beta, \sigma^2 I_p)\,. \tag{1}$$

It is then clear that the components of y, y_j, $j = 1, \ldots, p$, are independent normally distributed random variables with mean β_j and known homoscedastic variance σ^2. The ordinary least squares estimator, which equals the maximum likelihood estimator in the normal case, is simply

$$\hat{\beta}_{ML} = y\,. \tag{2}$$

To see this, simply write the problem as a regression model:

$$y = I_p\beta + \epsilon\,, \tag{3}$$

where $\epsilon \sim N(0, \sigma^2 I_p)$ and apply the usual ordinary least squares formula:

$$\hat{\beta}_{OLS} = \left(I_p' I_p\right)^{-1} I_p' y = y\,. \tag{4}$$

Now consider the scalar mean squared error of *all* components of an estimator $\hat{\beta}$ of β. It is defined as

$$MSE(\beta, \hat{\beta}) = E(\hat{\beta} - \beta)'(\hat{\beta} - \beta) = \sum_{j=1}^{p} E(\hat{\beta}_j - \beta_j)^2\,. \tag{5}$$

It is easily seen that for the OLS (or ML) estimator, we get

$$MSE(\beta, \hat{\beta}) = \sum_{j=1}^{p} E(y_j - \beta_j)^2 = p\sigma^2\,. \tag{6}$$

James and Stein now showed that the estimator

$$\hat{\beta}_{JS} = \left(1 - \frac{(p-2)\sigma^2}{y'y}\right) y = \left(1 - \frac{(p-2)\sigma^2}{\sum_{j=1}^{p} y_j^2}\right) y \tag{7}$$

dominates the OLS (ML) with respect to the MSE criterion above which means that it always has lower MSE than the OLS independent of the true β if $p > 2$. Therefore the OLS is inadmissible in that case. We can write the JS estimator also as a function of the OLS or ML estimator:

$$\left(1 - \frac{(p-2)\sigma^2}{\hat{\beta}_{ML}' \hat{\beta}_{ML}}\right) \hat{\beta}_{ML}\,. \tag{8}$$

Note, that if $(p-2)\sigma^2 < \sum_{j=1}^{p} y_j^2$, the JS estimator shrinks the estimator y towards the origin 0. That it why it is sometimes called a shrinkage estimator. James and Stein then showed that, if $p > 2$,

$$MSE(\hat{\beta}_{JS}, \beta) = p\sigma^2 - (p-2)\sigma^2 \exp\left(-\frac{\beta'\beta}{2\sigma^2}\right) \cdot F\,, \tag{9}$$

where $F = F(\beta, \sigma^2, p)$ is some positive complicated sum. It is easily seen that $MSE(\hat{\beta}_{JS}, \beta)$ is lower than $MSE(\hat{\beta}_{OLS}, \beta)$ if $p > 2$. Since F is zero if $\beta = 0$, the $MSE(\hat{\beta}_{JS}, \beta)$ reaches its minimum at $\beta = 0$ with the value $p\sigma^2 - (p-2)\sigma^2 = 2\sigma^2$. In fact, a number of modifications are possible. For example the Stein type estimator

$$\hat{\beta}_{JS} = \left(1 - \frac{c\sigma^2}{y'y}\right) y = \left(1 - \frac{c\sigma^2}{\sum_{j=1}^{p} y_j^2}\right) \tag{10}$$

can be shown to dominate the OLS as long as $0 < c < 2(p-2)$ for $p > 2$. Note, that for $p \leq 2$, the OLS is admissible. Another modification is to use some "guess" vector for β, lets say, μ. Then the JS estimator can be formulated as

$$\hat{\beta}_{JS} = \left(1 - \frac{(p-2)\sigma^2}{\sum_{j=1}^{p} (y_j - \mu_j)^2}\right) (y - \mu) + \mu\,. \tag{11}$$

Then the improvement of the JS estimator is small if $(\beta - \mu)'(\beta - \mu)$ is big and big if our guess was good, i.e., $(\beta - \mu)'(\beta - \mu)$ is small.

Summarizing the result of James and Stein we can say that, when there are three or more unrelated measurements of parameters, the MSE as defined above can be reduced by using a combined estimator as the JS estimator. But this may not be true for each single component of β. That is, the estimate may be bad for a single component and only better if we look at all components as a whole, i.e., if we look at the sum of all single MSE measures. This is an important aspect to be considered when applying such type of estimators. For each single component the OLS is admissible. A second aspect is that σ^2 is assumed to be known in all formulas. Third, the JS estimator itself is inadmissible.

The James–Stein Estimator as an Empirical Bayes Estimator

In the following we think of β as random variable with prior density

$$\beta \sim N(0, \tau^2 I_p)\,, \tag{12}$$

where τ^2 is a scalar value. The Bayes estimator can then be derived as

$$\hat{\beta}_B = \frac{\tau^2}{\tau^2 + \sigma^2} y = \left(1 - \frac{\sigma^2}{\tau^2 + \sigma^2}\right) y\,. \tag{13}$$

Now consider the case that τ is unknown. But instead of estimating τ, one can estimate the ratio

$$\frac{\sigma^2}{\tau^2 + \sigma^2} \tag{14}$$

as a whole. It can be shown that (again assuming σ^2 to be known)

$$\frac{(p-2)\sigma^2}{y'y} \tag{15}$$

is an unbiased estimator of the ratio above. If this estimator is substituted into (13), the JS estimator is obtained.

Further Modifications

Further modifications have been made by M. E. Bock in 1975 (Bock 1975) for the case that $y \sim N(\beta, \Sigma)$ where Σ is an arbitrary $p \times p$ symmetric positive definite covariance matrix. The JS estimator in this case is

$$\hat{\beta} = \left(1 - \frac{p^* - 2}{y'\Sigma^{-1}y}\right) y\,, \tag{16}$$

where p^* is defined as

$$p^* = \frac{trace(\Sigma)}{\lambda_{max}(\Sigma)}\,, \tag{17}$$

with $\lambda_{max}(\Sigma)$ the maximum eigenvalue of Σ.

Another modification is the positive–part JS estimator introduced by Baranchik in 1964 (Baranchik 1964). It is given by

$$\hat{\beta}_{JS+} = \left(1 - \frac{(p-2)\sigma^2}{y'y}\right)^+ y \tag{18}$$

where the + sign is defined as

$$z^+ = \begin{cases} x, & x \geq 0 \\ 0, & x < 0 \end{cases}\,. \tag{19}$$

Thus, the effect that the factor in brackets can be negative if $y'y$ is small can be avoided. The JS+ estimator dominates the JS estimator but is itself inadmissible since it is not a smooth estimator. The other mentioned modifications can also be applied to this estimator.

Stein Type Estimators in Regression

In the usual regression setup

$$y = X\beta + \epsilon\,, \tag{20}$$

where X is a $T \times K$ matrix of covariates, Stein-type estimators are defined as

$$\hat{\beta}_{ST} = \left(1 - \frac{cs^2}{b'X'Xb}\right) b\,, \tag{21}$$

where b is the ordinary least squares estimator

$$b = (X'X)^{-1}X'y\,, \tag{22}$$

s^2 is the usual sum of squared residuals

$$s^2 = (y - Xb)'(y - Xb)\,, \tag{23}$$

and c is some constant. See e.g., Judge et al. (1985). It can be shown that the estimator is minimax if

$$0 \leq c \leq \frac{2}{T - K + 2}\left\{trace(X'X)^{-1} \cdot \frac{1}{\lambda_{max}[(X'X)^{-1}]} - 2\right\}\,. \tag{24}$$

Jarque-Bera Test

Carlos M. Jarque
Inter American Development Bank, Paris, France

Testing Normality of Observations

In statistical analysis the assumption of data coming from a normal distribution is often made. In fact, up until the end of the nineteenth century, many people were convinced that there was no need for curves other than the normal distribution. Later, by the beginning of the twentieth century, most informed opinion had accepted that populations might be non-normal. This led to the development of other distribution functions and very importantly to normality testing (see Jarque and Bera (1980), and Ord (1972)). Presently, testing the normality of observations has become a standard feature in statistical work. The Jarque-Bera test is a goodness-of-fit test of departure from normality, based on the sample skewness and kurtosis.

Consider having $v_1, \ldots, v_N$ observations and the wish to test if they come from a normal distribution. The test statistic JB is defined as

$$JB = \frac{N}{6}\left(W^2 + \frac{(K-3)^2}{4}\right)$$

where N is the number of observations, W is the sample skewness, and K is the sample kurtosis, defined as

$$W = \frac{\hat{\mu}_3}{\hat{\sigma}^3} = \frac{\hat{\mu}_3}{(\hat{\sigma}^2)^{3/2}}$$

$$K = \frac{\hat{\mu}_4}{\hat{\sigma}^4} = \frac{\hat{\mu}_4}{(\hat{\sigma}^2)^2}.$$

In this formula $\hat{\mu}_3$ and $\hat{\mu}_4$ are the estimates of the third and fourth central moments, respectively, and $\bar{v}$ is the sample mean:

$$\hat{\mu}_3 = \frac{1}{N}\sum_{i=1}^{N}(v_i - \bar{v})^3$$

$$\hat{\mu}_4 = \frac{1}{N}\sum_{i=1}^{N}(v_i - \bar{v})^4.$$

In turn, $\hat{\sigma}^2$ is the estimate of the second central moment, i.e., the sample variance

$$\hat{\sigma}^2 = \frac{1}{N}\sum_{i=1}^{N}(v_i - \bar{v})^2.$$

The hypothesis tested is if skewness is 0 and kurtosis is 3, which are the values for a normal distribution. The test statistic JB follows asymptotically ▶Chi-Square distribution with two degrees of freedom. Normality is rejected if JB is large. It has maximum asymptotic local power. For small sample sizes, significance points for $\alpha = 0.10$ and $\alpha = 0.05$ are given in the table below or may be obtainedas a routine in most statistical computer softwares (Table 1).

Testing Normality of Unobserved Regression Residuals

Now consider the linear regression model (see ▶Linear Regression Models) $y_i = x_i'\beta + u_i$ for $i = 1, \ldots, N$, where y_i is the dependent variable, x_i' a 1 by K vector of observations on K fixed regressors $(X_1, X_2, \ldots, X_K)$, u_i is the ith *unobservable* residual or disturbance, and β is a K by 1 vector of unknown parameters. Assume the model contains a constant term so $X_1 = 1$ for all i.

A traditional assumption is statistical and econometric work is that u_i is normally distributed (with zero mean and constant variance σ^2). This model has wide, everyday application. It is used to model phenomena in many sectors: economic, financial, social, technological, natural sciences, etc. The consequences of u_i not being normally

Source: Jarque and Bera (1987)

distributed are many, in terms of validity of inferential processes (e.g., traditional t and F-tests are sensitive to non-normality); efficiency of estimates used (the ordinary least squares estimator of β may be very sensitive to non-normality, particularly in long tailed distributions); and efficiency in forecasting techniques. This may lead to research and studies that arrive at wrong conclusions and to incorrect decision making, be it a policy prescription or a scientific finding.

As shown in Jarque and Bera (1980), formulating the distribution of u_i as a member of the Pearson Family of Distributions and applying the Lagrange Multiplier principle to test for normality of u_i within this overarching family of distributions, then the *JB* statistic is obtained. In this case, the test would be computed using the OLS residuals $\hat{u}_1, \ldots, \hat{u}_N$ (i.e., substitute v_i for $\hat{u}_i$ in *JB*), where $\hat{u}_i = y_i - x_i' b$ and where b in the OLS estimate of β

$$b = \left(X'X\right)^{-1} X'y \text{ and with } y = (y_1, \ldots, y_N)' \text{ and } X' = (x_1, \ldots, x_N).$$

The *JB* test applied with OLS residuals is simple to compute and has maximum local asymptotic power. It is asymptotically distributed as Chi-Square with two degrees of freedom. For small samples, in any regression model, the approximation to the finite sample distribution of the test can be easily obtained by computer simulation. Regression residual normality is rejected for large values of *JB*. Naturally the test may also be applied even if the distribution of u_i is outside the Pearson Family of Distributions. Due to its simplicity and good power properties it has wide use in statistical regression analysis.

About the Author

Carlos M. Jarque graduated in 1976 with a degree in Actuarial Science, at Anáhuac University, Mexico. He then obtained a Posgraduate Diploma and a Master's Degree from the London School of Economics and Political Science. He also undertook graduate studies in planning and economic policy at the University of Oslo. He holds a Doctorate in Economics from the Australian National University, and obtained a posdoctorate in Econometrics at Harvard University. Dr. Jarque has taught at the Australian National University, and at Harvard University. Dr. Jarque was Director and Vice-President of the International Statistical Institute. He was also elected Chairman of the United Nations Statistical Commission, and President of the U.N. Cartographic Conference. He was the Minister of Social Development in Mexico, Secretary for the National Development Plan of Mexico (1995–2000), and President of the National Institute of Statistics, Geography and Informatics of Mexico. From January 2001 to December 2005, he was Manager of the Sustainable Development Department of the Inter-American Development Bank, and from December 2005 to August 2007, the Secretary of the IDB. He is currently the IDB Representative in Europe and Israel, and Principal Advisor of the IDB President. Dr. Jarque is the author of over a hundred academic articles on economics, social development, planning and technology. He is well known in statistics and econometrics, among other contributions, for his paper (with Anil K. Bera) *Efficient tests for normality, homoscedasticity and serial independence of regression residuals* (*Economic Letters*, Volume 6, Issue 3, 1980, pp. 255–259), where a test was proposed, that is today known as Jarque-Bera test. He has received numerous distinctions and honors, including Mexico's National Award in Science and Technology, the President Benito Juárez Medal of Merit, the Henri Willen Methorst Medal, and the Adolf Quetelet Medal.

Jump Regression Analysis

Peihua Qiu
Professor
University of Minnesota, Minneapolis, MN, USA

Nonparametric regression analysis provides statistical tools for estimating regression curves or surfaces from noisy data. Conventional nonparametric regression procedures, however, are only appropriate for estimating continuous regression functions. When the underlying regression function has jumps, functions estimated by the conventional procedures are not statistically consistent at

the jump positions. Recently, regression analysis for estimating jump regression functions is under rapid development (Qiu 2005), which is briefly introduced here.

1-D Jump Regression Analysis

In one-dimensional (1-D) cases, the *jump regression analysis (JRA)* model has the form

$$y_i = f(x_i) + \varepsilon_i, \quad \text{for } i = 1, 2, \ldots, n, \tag{1}$$

where $\{y_i,\ i = 1, 2, \ldots, n\}$ are observations of the response variable y at design points $\{x_i,\ i = 1, 2, \ldots, n\}$, f is an unknown regression function, and $\{\varepsilon_i,\ i = 1, 2, \ldots, n\}$ are random errors. For simplicity, we assume that the design interval is $[0, 1]$. In (1), f is assumed to have the expression

$$f(x) = g(x) + \sum_{j=1}^{p} d_j I(x > s_j), \text{ for } x \in [0, 1], \tag{2}$$

where g is a continuous function in the entire design interval, p is the number of jump points, $\{s_j,\ j = 1, 2, \ldots, p\}$ are the jump positions, and $\{d_j,\ j = 1, 2, \ldots, p\}$ are the corresponding jump magnitudes. If $p = 0$, then f is continuous in the entire design interval. In (2), the function g is called the *continuity part* of f, and the summation $\sum_{j=1}^{p} d_j I(x > s_j)$ is called the *jump part* of f. The major goal of JRA is to estimate g, p, $\{s_j,\ j = 1, 2, \ldots, p\}$ and $\{d_j,\ j = 1, 2, \ldots, p\}$ from the observed data $\{(x_i, y_i),\ i = 1, 2, \ldots, n\}$.

A natural jump detection criterion is

$$M_n(x) = \frac{1}{nh_n} \sum_{i=1}^{n} Y_i K_1\left(\frac{x_i - x}{h_n}\right) - \frac{1}{nh_n} \sum_{i=1}^{n} Y_i K_2\left(\frac{x_i - x}{h_n}\right), \tag{3}$$

where h_n is a positive bandwidth parameter, K_1 and K_2 are two density kernel functions with supports $[0, 1]$ and $[-1, 0)$, respectively. Obviously, $M_n(x)$ is a difference of two *one-sided* kernel estimators. The first kernel estimator in equation (3) is right-sided; it is a weighted average of the observations in the right-sided neighborhood $[x, x + h_n]$. Similarly, the second kernel estimator in (3) is left-sided; it is a weighted average of the observations in the left-sided neighborhood $[x-h_n, x)$. Intuitively, $M_n(x)$ would be large if x is a jump point, and small otherwise. So, if we know that there is only one jump point (i.e., $p = 1$) in the design interval $[0, 1]$, then the jump point s_1 can be estimated by the maximizer of $|M_n(x)|$ over $x \in [h_n, 1 - h_n]$, denoted as $\widehat{s}_1$, and d_1 can be estimated by $M_n(\widehat{s}_1)$. In cases when $p > 1$ and p is known, the jump positions $\{s_j, j = 1, 2, \ldots, p\}$ and the jump magnitudes $\{d_j, j = 1, 2, \ldots, p\}$ can be estimated in a similar way. Let s_j^* be the maximizer of $|M_n(x)|$ over the range

$$x \in [h_n, 1 - h_n] \setminus \left(\bigcup_{\ell=1}^{j-1} [s_\ell^* - h_n, s_\ell^* + h_n] \right)$$

for $j = 1, 2, \ldots, p$. The ▶order statistics of $\{s_j^*, j = 1, 2, \ldots, p\}$ are denoted by $s_{(1)}^* \le s_{(2)}^* \le \ldots \le s_{(p)}^*$. Then we define $\widehat{s}_j = s_{(j)}^*$ and $\widehat{d}_j = M_n\left(s_{(j)}^*\right)$, for $j = 1, 2, \ldots, p$.

When the number of jumps p is unknown, people often use a threshold value u_n and flag all design points in $\{x_i : |M_n(x_i)| \ge u_n\}$ as candidate jumps. Then, certain deceptive candidate jumps need to be deleted using a modification procedure (cf., Qiu 2005, Sect. 3.3.3). An alternative approach is to perform a series of hypothesis tests for $H_0 : p = j$ versus $H_1 : p > j$, for $j = 0, 2, \ldots$, until the first "fail to reject H_0" (cf., Qiu 2005, Sect. 3.3.2).

The jump detection criterion $M_n(x)$ in (3) can be regarded as an estimator of the first-order derivative $f'(x)$ of f. It is based on local constant kernel estimation of the one-sided limits $f_-(x)$ and $f_+(x)$. Alternative jump detection criteria, based on other estimators of $f'(x)$ or based on estimators of both the first-order and the second-order derivatives of f, also exist. See Joo and Qiu (2009) for a recent discussion on this topic and on estimation of the continuity part g after jump points being detected.

2-D Jump Regression Analysis

In two-dimensional (2-D) cases, the regression model becomes

$$Z_i = f(x_i, y_i) + \varepsilon_i,\ i = 1, 2, \ldots, n, \tag{4}$$

where n is the sample size, $\{(x_i, y_i), i = 1, 2, \ldots, n\}$ are the design points in the design space, f is the 2-D regression function, $\{Z_i, i = 1, 2, \ldots, n\}$ are n observations of the response variable Z, and $\{\varepsilon_i, i = 1, 2, \ldots, n\}$ are random errors. For simplicity, we assume that the design space is the unit square $[0, 1] \times [0, 1]$. In such cases, jump positions of f are curves in the design space, which are called the *jump location curves (JLCs)*. Because jumps are an important structure of f, 2-D JRA is mainly for estimating JLCs and for estimating f with the jumps at the JLCs preserved, which are referred to as *jump detection* and *jump-preserving surface estimation*, respectively, in the literature (cf., Qiu 2005, Chaps. 4 and 5).

Early 2-D jump detection methods assume that the number of JLCs is known; they are usually the generalized versions of their 1-D counterparts, based on estimation of certain first-order directional derivatives of f. In Qiu and Yandell (1997), Qiu and Yandell describe the JLCs as *a pointset* in the design space, and suggest estimating the JLCs by another pointset in the same design space. Since points in a pointset need not form curves, the connection among the points of a pointset is much more flexible than the connection among the points on curves, which makes detection of arbitrary JLCs possible. For instance, Qiu and

Yandell (1997) suggest flagging a design point as a candidate jump point if the estimated gradient magnitude of f at this point is larger than a threshold. In that paper, we also suggest two modification procedures to remove certain deceptive jump candidates. Various other jump detection procedures, based on estimation of the first-order derivatives of f, or the second-order derivatives of f, or both, have been proposed in the literature. See Sun and Qiu (2007) for a recent discussion on this topic.

In the literature, there are two types of jump-preserving surface estimation methods. Methods of the first type usually estimate the surface after jumps are detected (Qiu 1998). Around the detected jumps, the surface estimator at a given point is often defined by a weighted average of the observations whose design points are located on the same side of the estimated JLC as the given point in a neighborhood of the point. Potential jumps can thus be preserved in the estimated surface. The second type of methods estimates the surface without detecting the jumps explicitly, using the so-called adaptive local smoothing. Adaptive local smoothing procedures obtain certain evidence of jumps from the observed data directly, and adapt to such evidence properly to preserve jumps while removing noise (Gijbels et al. 2006).

2-D Jump Regression Analysis and Image Processing

Model (4) can be used in cases with arbitrary 2-D design points. In certain applications (e.g., image processing), design points are regularly spaced in the 2-D design space. In such cases, a simpler model would be

$$Z_{ij} = f(x_i, y_j) + \varepsilon_{ij},\ i = 1, 2, \ldots, n_1;\ j = 1, 2, \ldots, n_2, \quad (5)$$

where $\{Z_{ij},\ i = 1, 2, \ldots, n_1;\ j = 1, 2, \ldots, n_2\}$ are observations of the response variable Z observed at design points $\{(x_i, y_j),\ i = 1, 2, \ldots, n_1;\ j = 1, 2, \ldots, n_2\}$, and $\{\varepsilon_{ij},\ i = 1, 2, \ldots, n_1;\ j = 1, 2, \ldots, n_2\}$ are random errors.

Model (5) is ideal for describing a monochrome digital image. In the setup of a monochrome digital image, x_i denotes the ith row of pixels, y_j denotes the jth column of pixels, f is the image intensity function, $f(x_i, y_j)$ is the true image intensity level at the (i, j)th pixel, ε_{ij} denotes the noise at the (i, j)th pixel, and Z_{ij} is the observed image intensity level at the (i, j)th pixel. The image intensity function f often has jumps at the outlines of objects. Therefore, 2-D JRA can provide a powerful statistical tool for image processing. In the image processing literature, positions at which f has jumps are called *step edges*, and positions at which the first-order derivatives of f have jumps are called *roof edges* (cf., Qiu 2005, Chap. 6). Edge detection and edge-preserving image restoration are two major problems in image processing, which are essentially the same problems as jump detection and jump-preserving surface estimation in 2-D JRA. See Qiu (2007) for a recent discussion about the connections and differences between the two areas.

About the Author

Dr. Peihua Qiu is a Professor, School of Statistics, University of Minnesota, USA. He is an Elected fellow of the American Statistical Association, an Elected fellow of the Institute of Mathematical Statistics, and an Elected member of the International Statistical Institute. He has authored and co-authored more than 70 papers and book chapters. His research monograph titled *Image Processing and Jump Regression Analysis* (John Wiley & Sons, 2005) won the inaugural Ziegel prize sponsored by Technometrics. Currently, he is an Associate editor for *Journal of the American Statistical Association* (2006–present) and *Technometrics* (2007–present).

Kalman Filtering

Mohinder S. Grewal
Professor
California State University, Fullerton, CA, USA

Theoretically, a Kalman filter is an estimator for what is called the linear quadratic Gaussian (*LQG*) problem, which is the problem of estimating the instantaneous "state" of a linear dynamic system perturbed by Gaussian white noise, by using measurements linearly related to the state, but corrupted by Gaussian white noise. The resulting estimator is statistically optimal with respect to any quadratic function of estimation error. R. E. Kalman introduced the "filter" in 1960 (Kalman 1960).

Practically, the Kalman filter is certainly one of the greater discoveries in the history of statistical estimation theory, and one of the greatest discoveries in the twentieth century. It has enabled humankind to do many things that could not have been done without it, and it has become as indispensable as silicon in the makeup of many electronic systems. The Kalman filter's most immediate applications have been for the control of complex dynamic systems, such as continuous manufacturing processes, aircraft, ships, spacecraft, and satellites.

In order to control a dynamic system, one must first know what the system is doing. For these applications, it is not always possible or desirable to measure every variable that one wants to control. The Kalman filter provides a means for inferring the missing information from indirect (and noisy) measurements. In such situations, the Kalman filter is used to estimate the complete state vector from partial state measurements and is called an observer. The Kalman filter is also used to predict the outcome of dynamic systems that people are not likely to control, such as the flow of rivers during flood conditions, the trajectories of celestial bodies, or the prices of traded commodities.

Kalman filtering is an algorithm made from mathematical models. The Kalman filter makes it easier to solve a problem, but it does not solve the problem all by itself. As with any algorithm, it is important to understand its use and function before it can be applied effectively.

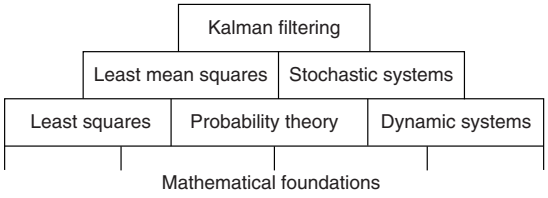
The Kalman filter is a recursive algorithm. It has been called "ideally suited to digital computer implementation," in part because it uses a finite representation of the estimation problem-by a finite number of variables (Gelb et al. 1974). It does, however, assume that these variables are real numbers with infinite precision. Some of the problems encountered in its use arise from the distinction between finite dimension and finite information, and the distinction between finite and manageable problem sizes. These are all issues on the practical side of Kalman filtering that must be considered along with the theory.

It is a complete statistical characterization of an estimation problem. The Kalman filter is much more than an estimator, because it propagates the entire probability distribution of the variables it is tasked to estimate. This is a complete characterization of the current state of knowledge of the dynamic system, including the influence of all past measurements. These probability distributions are also useful for statistical analysis and predictive design of sensor systems.

In a limited context, the Kalman filter is a learning process. It uses a model of the estimation problem that distinguishes between phenomena (what we are able to observe), noumena (what is really going on), and the state of knowledge about the noumena that we can deduce from the phenomena. That state of knowledge is represented by probability distributions. To the extent that those probability distributions represent knowledge of the real world, and the cumulative processing of knowledge is learning, this is a learning process. It is a fairly simple one, but quite effective in many applications. Figure 1 depicts the essential subjects forming the foundations for Kalman filtering theory. Although this shows Kalman filtering as the apex of a pyramid, it is but part of the foundations of another discipline-modern control theory-and a proper subset of statistical decision theory (Grewal and Andrews 2008).

Applications of Kalman filtering encompass many fields. As a tool, the algorithm is used almost exclusively for estimation and performance analysis of estimators and as observers for control of a dynamical system. Except for a few fundamental physical constants, there is hardly anything in the universe that is truly constant. The orbital parameters of the asteroid Ceres are not constant, and

Miodrag Lovric (ed.), *International Encyclopedia of Statistical Science*, DOI 10.1007/978-3-642-04898-2,



Kalman Filtering. Fig. 1 Foundational concepts in Kalman filtering

even the "fixed" stars and continents are moving. Nearly all physical systems are dynamic to some degree. If we want very precise estimates of their characteristics over time, then we must take their dynamics into consideration.

We do not always know the dynamics very precisely. Given this state of partial ignorance, the best we can do is express ignorance more precisely-using probabilities. The Kalman filter allows us to estimate the state of such systems with certain types of random behavior by using such statistical information. A few examples of common estimation problems are shown in Table 1. The third column lists some sensor types that we might use to estimate the state of the corresponding dynamic systems. The objective of design analysis is to determine how best to use these sensor types for a given set of design criteria. These criteria are typically related to estimation accuracy and system cost.

Because the Kalman filter uses a complete description of the probability distribution of its estimation errors to determine the optimal filtering gains, this probability distribution may be used to assess its performance as a function of the design parameters of an estimation system, such as the types of sensors to be used, the locations and orientations of the various sensor types with respect to the system to be estimated, the allowable noise characteristics of the sensors, the prefiltering methods for smoothing sensor noise, the data sampling rates for the various sensor types, and the level of model simplification to reduce implementation requirements.

This analytical capability of the Kalman filter enables system designers to assign "error budgets" to subsystems of an estimation system and to trade off the budget allocations to optimize cost or other measures of performance while achieving a required level of estimation accuracy. Furthermore, it acts like an observer by which all the states not measured by the sensors can be constructed for use in the control system applications.

Linear Estimation

Linear estimation addresses the problem of estimating the state of a linear stochastic system by using measurements or sensor outputs that are linear functions of the state. We suppose that the stochastic systems can be represented by the types of plant and measurement models (for continuous and discrete time) shown as equations in Table 2, with dimensions of the vector and matrix quantities. The measurement and plant noise v_k and w_k, respectively, are assumed to be zero-mean ▶Gaussian processes, and the initial value x_o is a Gaussian random variable with known mean x_0 and known covariance matrix P_0. Although the noise sequences w_k and v_k are assumed to be uncorrelated, this restriction can be removed, modifying the estimator equations accordingly.

A summary of equations for the discrete-time Kalman estimator are shown in Table 3, where Q_k, R_k are process and measurement noise covariances, Φ_k is the state transition matrix, H_k is the measurement sensitivity matrix, $\overline{K}_k$ is the Kalman gain. $P_k(-), P_k(+)$ are covariances before and after measurement updates.

Implementation Methods

The Kalman filter's theoretical performance has been characterized by the covariance matrix of estimation uncertainty, which is computed as the solution of a matrix Riccati differential and difference equation. A relationship between optimal deterministic control and optimal estimation problems has been described via the separation principle.

Soon after the Kalman filter was first implemented on computers, it was discovered that the observed mean-square estimation errors were often much larger than the values predicted by the covariance matrix, even with simulated data. The variances of the filter estimation errors were observed to diverge from their theoretical values, and the solutions obtained for the Riccati equations were observed to have negative variances. Riccati equations should have positive or zero variances.

Current work on the Kalman filter primarily focuses on development of robust and numerically stable implementation methods. Numerical stability refers to robustness against roundoff errors. Numerically stable implementation methods are called square root filtering because they use factors of the covariance matrix of estimation uncertainty or its inverse, called the information matrix.

Numerical solution of the Riccati equation tends to be more robust against roundoff errors if Cholesky factors of a symmetrical nonnegative definite matrix P is a matrix C such that $CC^T = P$. Cholesky decomposition algorithms solve for C that is either upper triangular or lower triangular. Another method is modified Cholesky decomposition. Here, algorithms solve for diagonal factors and either a lower triangular factor L or an upper triangular

	z, v	$\ell \times 1$	H	$\ell \times n$
	R	$\ell \times \ell$	Δ, δ	Scalar

factor U such that $P = UD_uU^T = LD_LL^T$ where D_L and D_u are diagonal factors with nonnegative diagonal elements. Another implementation method uses square root information filters that use a symmetric product factorization of the information matrix P^{-1}. Another implementation with improved numerical properties is the "sigmaRho filter." Individual terms of the covariance matrix can be interpreted as $P_{ij} = \sigma_i\sigma_j\rho_{ij}$ where P_{ij} is the ijth of the covariance matrix, σ_i is the standard deviation of the estimate of the ith state component, and ρ_{ij} is the correlation coefficient between ith and jth state component (Grewal and Kain 2010).

Alternative Kalman filter implementations use these factors of the covariance matrix (or its inverse) in three types of filter operations: (1) temporal updates, (2) observation updates, and (3) combined updates (temporal and observation). The basic algorithm methods used in these alternative Kalman filter implementations fall into four general categories. The first three of these categories are concerned with decomposing matrices into triangular factors and maintaining the triangular form of the factors through all the Kalman filtering operation. The fourth category includes standard matrix operations (multiplication, inversion, etc.) that have been specialized for triangular

Kalman Filtering. Table 3 Discrete-time Kalman filter equations

System dynamic model	$x_k = \Phi_{k-1}x_{k-1} + w_{k-1}, \quad w_k \sim N(0, Q_k)$
Measurement model	$z_k = H_k x_k = v_k, \quad v_k \sim N(0, R_k)$
Initial conditions	$E\langle x_0\rangle = \widehat{x}_0, \quad E\left\langle \widetilde{x}_0 \widetilde{x}_0^T \right\rangle = P_0$
Independence assumption	$E\left\langle w_k v_j^T \right\rangle = 0$ for all k and j
State estimate extrapolation	$\widehat{x}_k(-) = \Phi_{k-1}\widehat{x}_{k-1}(+)$
Error covariance extrapolation	$P_k(-) = \Phi_{k-1}P_{k-1}(+)\Phi_{k-1}^T + Q_{k-1}$
State estimate observational update	$\widehat{x}(+) = \widehat{x}_k(-) + \overline{K}_k[z_k - H_k\widehat{x}_k(-)]$
Error covariance update	$P_k(+) = [I - \overline{K}_k H_k]P_k(-)$
Kalman gain matrix	$\overline{K}_k = P_k(-)H_k^T\left[H_k P_k(-)H_k^T + R_k\right]^{-1}$

matrices. These implementation methods have succeeded where the conventional Kalman filter implementations have failed (Grewal and Andrews 2008).

Even though uses are being explored in virtually every discipline, research is particularly intense on successful implementation of Kalman filtering to global positioning systems (GPS), inertial navigation systems (INS), and guidance and navigation. GPS is a satellite-based system that has demonstrated unprecedented levels of positioning accuracy, leading to its extensive use in both military and civil arenas. The central problem for GPS receivers is the precise estimation of position, velocity, and time, based on noisy observations of satellite signals. This provides an ideal setting for the use of Kalman filtering. GPS technology is used in automobile, aircraft, missiles, ships, agriculture, and surveying. Currently, the Federal Aviation Agency (FAA) is sponsoring research on the development of wide-area augmentation system (WAAS) for precision landing and navigation of commercial aircraft (Grewal et al. 2007).

Kalman filters are used in bioengineering, traffic systems, photogrammetry, and myriad process controls. The Kalman filter is observer, parameter identifier in modeling, predictor, filter, and smoother in a wide variety of applications. It has become integral to twenty-first century technology (Grewal and Kain 2010; Grewal et al. 2007).

About the Author

Dr. Mohinder S. Grewal, P.E., coauthored *Kalman Filtering: Theory & Practice Using MATLAB* (with A.P. Andrews, 3rd edition, Wiley & Sons 2008) and *Global Positioning Systems, Inertial Navigation, & Integration* (with L.R. Weill and A.P. Andrews, 2nd edition, Wiley & Sons 2007). Dr. Grewal has consulted with Raytheon Systems, Geodetics, Boeing Company, Lockheed-Martin, and Northrop on application of Kalman filtering. He has published over 60 papers in IEEE and ION refereed journals and proceedings, including the Institute of Navigation's Redbook. Currently, Dr. Grewal is Professor of Electrical Engineering at California State University, Fullerton, in Fullerton, California, where he received the 2009 Outstanding Professor award. He is an architect of the GEO Uplink Subsystem (GUS) for the Wide Area Augmentation System (WAAS), including the GUS clock steering algorithms, and holds two patents in this area. His current research interest is in the area of application of GPS, INS integration to navigation. Dr. Grewal is a member of the Institute of Navigation, Senior Member of IEEE, and a Fellow of the Institute for the Advancement of Engineering.

Kaplan-Meier Estimator

Irène Gijbels
Professor, Head of Statistics Section
Katholieke Universiteit Leuven, Leuven, Belgium

The Kaplan-Meier estimator estimates the distribution function of a lifetime T based on a sample of randomly right censored observations. In survival analysis the lifetime T is a nonnegative random variable describing the time until a certain event of interest happens. In medical applications examples of such events are the time till death of a patient suffering from a specific disease, the time till recovery of a disease after the start of the treatment, or the time till remission after the curing of a patient. A typical difficulty in survival analysis is that the observations might be incomplete. For example, when studying the time till death of a patient with a specific disease, the patient might die from another cause. As a consequence the lifetime of this patient is not observed, and is only known to be larger than the time till the patient was "censored" by the other cause of death. Such a type of censoring mechanism is called right random censorship. Other areas of applications in which one encounters this type of data are reliability in industry and analysis of duration data in economics, to just name a few.

Let $T_1, T_2, \cdots, T_n$ denote n independent and identically distributed random variables, all having the same distribution as the lifetime T. Denote by $F(t) = P\{T \le t\}$ the cumulative distribution function of T. Due to the right random censoring, the lifetime T might be censored by a censoring time C, having cumulative distribution function G. Associated at each lifetime T_i there is a censoring time C_i. Under a right random censorship model the observations consist of the pairs

$$(Z_i, \delta_i) \quad \text{where} \quad Z_i = \min(T_i, C_i) \quad \text{and} \quad \delta_i = I\{T_i \le C_i\} \qquad i = 1, \cdots, n.$$

The indicator random variable $\delta = I\{T \le C\}$ takes value 1 when the lifetime T is observed, and is 0 when the censoring time is observed instead. A crucial assumption in this model is that the lifetime T_i (also often called survival time) is independent of the censoring time C_i for all individuals. An observation (Z_i, δ_i) is called uncensored when $\delta_i = 1$ and hence the survival time T_i for individual i has been observed. When $\delta_i = 0$ the observed time is the censoring time C_i and one only has the incomplete observation that $T_i > C_i$.

Kaplan and Meier (1958) studied how to estimate the survival function $S(t) = 1 - F(t) = P\{T > t\}$, based on observations $(Z_1, \delta_1), \cdots, (Z_n, \delta_n)$ from n patients. The estimation method does not make any assumptions about a specific form of the cumulative distribution functions F and G, and is therefore a nonparametric estimate. When there are no tied observations the estimate is defined as

$$\widehat{S}(t) = \begin{cases} \prod_{j:Z_{(j)} \le t} \left(\frac{n-j}{n-j+1} \right)^{\delta_{(j)}} & \text{if} \quad t < Z_{(n)} \\ 0 & \text{if} \quad t \ge Z_{(n)}, \end{cases}$$

where $Z_{(1)} \le Z_{(2)} \cdots \le Z_{(n)}$ denote the ordered Z_i's, and $\delta_{(i)}$ is the indicator variable associated with $Z_{(i)}$. In case of a tie between a censored and an uncensored observation, the convention is that the uncensored observation happened just before the censored observation. An equivalent expression, for $t < Z_{(n)}$, is

$$\widehat{S}(t) = \prod_{j:Z_{(j)} \le t} \left(1 - \frac{\delta_{(j)}}{n-j+1} \right).$$

In case of n complete observations, $\delta_{(i)} = 1$ for all individuals, and the Kaplan-Meier estimate reduces to $S_n(t) = 1 - \#\{j : Z_j \le t\}/n$, i.e., one minus the empirical cumulative distribution function. The latter estimate is a decreasing step function with downward jumps of size $1/n$ at each observation $Z_j = T_j$.

Suppose now that there are tied observations, and that there are only r distinct observations. Denote by $Z_{(1)} \le Z_{(2)} \le Z_{(r)}$ the r ordered different observations, and by d_j the number of times that $Z_{(j)}$ has been observed. Then, for $t < Z_{(r)}$, the Kaplan-Meier estimate is defined as

$$\prod_{j:Z_{(j)} \le t} \left(1 - \frac{d_j}{n_j} \right)^{\delta_{(j)}},$$

where n_j denotes the number of individuals in the sample that are at risk at time point $Z_{(j)}$, i.e., the set of individuals that are still "alive" just before the time point $Z_{(j)}$. The Kaplan-Meier estimate is also called the product-limit estimate.

In studies of life tables (see ▶Life Table), the actuarial estimate for the survival function was already around much earlier. One of the first references for the product-limit estimate, obtained as a limiting case of the actuarial estimate, is Bähmer (1912).

The Kaplan-Meier estimate of the survival function $S = 1 - F$ is a decreasing step function, which jumps at the uncensored observations but remains constant when passing a censored observation. In contrast to the empirical estimate S_n based on a complete sample of size n, the sizes of the jumps are random.

The construction of the Kaplan-Meier estimate $\widehat{S}(t)$ also has a very simple interpretation due to Efron (1967). The mass $1/n$ that is normally attached to each observation in the empirical estimate for S, is now for a censored observation redistributed equally over all observations that are larger than the considered one.

Kaplan and Meier (1958) give the maximum likelihood derivation of the product-limit estimate and discuss mean and variance properties of it. An estimate for the variance of $\widehat{S}(t)$ was already established by Greenwood (1926). Greenwood's formula estimates the variance of $\widehat{S}(t)$ by

$$\widehat{\mathrm{Var}}\left(\widehat{S}(t)\right) = \left(\widehat{S}(t)\right)^2 \sum_{j:Z_{(j)} \le t} \frac{d_j}{n_j(n_j - d_j)}.$$

This estimate can be used to construct confidence intervals.

The theoretical properties of the Kaplan-Meier estimate have been studied extensively. For example, weak convergence of the process $\sqrt{n}\left(\widehat{S}(t) - S(t)\right)$ to a Gaussian process was established by Breslow and Crowley (1974), and uniform strong consistency of the Kaplan-Meier estimate was proven by Winter et al. (1978).

The Kaplan-Meier estimate is implemented in most statistical software packages, and is a standard statistical tool in survival analysis.

Kappa Coefficient of Agreement

Tarald O. Kvålseth
Professor Emeritus
University of Minnesota, Minneapolis, MN, USA

Introduction

When two (or more) observers are independently classifying items or observations into the same set of k mutually exclusive and exhaustive categories, it may be of interest to use a measure that summarizes the extent to which the observers agree in their classifications. The Kappa coefficient first proposed by Cohen (1960) is one such measure.

In order to define this measure, let p_{ij} be the proportion of items assigned to category i by Observer 1 and to category j by Observer 2. Furthermore, let p_{i+} be the proportion of items assigned to category i by Observer 1 and p_{+j} the proportion of items assigned to category j by Observer 2. If these proportions or sample probabilities are represented in terms of a two-way contingency table with k rows and k columns, then p_{ij} becomes the probability in the cell corresponding to row i and column j. With row i being the same as column i for $i = 1, \ldots, k$, the diagonal of this table with probabilities p_{ii} $(i = 1, \ldots, k)$ represents the agreement probabilities, whereas the off-diagonal entries represent the disagreement probabilities.

The observed probability of agreement $P_{ao} = \sum_{i=1}^{k} p_{ii}$ could, of course, be used as an agreement measure. However, since there may be some agreement between the two observers based purely on chance, it seems reasonable that a measure of interobserver agreement should also account for the agreement expected by chance. By defining chance-expected agreement probability as $P_{ac} = \sum_{i=1}^{k} p_{i+}p_{+i}$ and based on independent classifications between the two observers, Cohen (1960) introduced the Kappa coefficient as

$$K = \frac{P_{ao} - P_{ac}}{1 - P_{ac}} \qquad (1)$$

where $K \le 1$, with $K = 1$ in the case of perfect agreement, $K = 0$ when the observed agreement probability equals that due to chance, and $K < 0$ if the observed agreement probability is less than the chance-expected one.

Kappa can alternatively be expressed in terms of the observed probability of disagreement P_{do} and the chance-expected probability of disagreement P_{dc} as

$$K = 1 - \frac{P_{do}}{P_{dc}}; \quad P_{do} = \sum_{\substack{i=1}}^{k}\sum_{\substack{j=1 \\ i \neq j}}^{k} p_{ij}, \quad P_{dc} = \sum_{\substack{i=1}}^{k}\sum_{\substack{j=1 \\ i \neq j}}^{k} p_{i+}p_{+j} \quad (2)$$

The form of K in (1) is the most frequently used one. However, it should be pointed out that the normalization used in (1), i.e., using the dominator $1 - P_{ac}$ such that $K \leq 1$, is not unique. In fact, there are infinitely many such normalizations. Thus, for any given marginal probability distributions $\{p_{i+}\}$ and $\{p_{+j}\}$, one could, for example, instead of the denominator in (1), use $\sum_{i=1}^{k}\left(\frac{1}{2}p_{i+}^{\alpha} + \frac{1}{2}p_{+i}^{\alpha}\right)^{1/\alpha} - P_{ac}$ for any real value of α. For $\alpha \to -\infty$, this alternative denominator would become $\sum_{i=1}^{k}\min\{p_{i+}, p_{+i}\} - P_{ac}$. No such non-uniqueness issue would arise by using the form of K in (2). This K also has the simple interpretation of being the proportional difference between the chance and observed disagreement probabilities, i.e., the relative extent to which P_{do} is less than P_{dc}.

Weighted Kappa

In the case when the $k > 2$ categories are ordinal, or also possibly in some cases involving nominal categories, some disagreements may be considered more serious than others. Consequently, the weighted Kappa (K_w) was introduced (Cohen 1968). In terms of the set of nonnegative agreement weights $v_{ij} \in [0,1]$ and disagreement weights $w_{ij} \in [0,1]$ for all i and j, K_w can be defined as

$$K_w = \frac{\sum_{i=1}^{k}\sum_{j=1}^{k} v_{ij}p_{ij} - \sum_{i=1}^{k}\sum_{j=1}^{k} v_{ij}p_{i+}p_{+j}}{1 - \sum_{i=1}^{k}\sum_{j=1}^{k} v_{ij}p_{i+}p_{+j}} \quad (3)$$

$$= 1 - \frac{\sum_{i=1}^{k}\sum_{j=1}^{k} w_{ij}p_{ij}}{\sum_{i=1}^{k}\sum_{j=1}^{k} w_{ij}p_{i+}p_{+j}} \quad (4)$$

where $w_{ij} = 1 - v_{ij}, w_{ij} = w_{ji}$ for all i and j, and $w_{ij} = 0$ for all $i = j$. Of course, when w_{ij} is the same for all $i \neq j$, K_w reduces to K in (1) – (2). From (4), which seems to be the most intuitive and preferred form of K_w, it is clear that $K_w \leq 1$, with $K_w = 1$ if, and only if, $p_{ij} = 0$ for all $i \neq j$ (i.e., if all disagreement cells have zero probability), $K_w = 0$ under independence (i.e., $p_{ij} = p_{i+}p_{+j}$ for all i and j), and K_w may also take on negative values. Unless there are particular justifications to the contrary, the most logical choice of weights would seem to be $w_{ij} = |i-j|/(k-1)$ or $w_{ij} = (i-j)^2/(k-1)^2$ for all i and j.

Specific Category Kappa

Besides measuring the overall agreement between two observers, it may be of interest to determine their extent of agreement on specific categories. As first proposed by Spitzer et al. (1967) (see also (Fleiss et al. 2003)), such measurement required the original $k \times k$ table to be collapsed into 2×2 tables, one for each specific category. Thus, to measure the agreement on a specific category s, the original $k \times k$ table would need to be collapsed into a 2×2 table with one category being the original s category and the other category being "all others". The agreement measurement K_s was then obtained by computing the value of K in (1) based on the collapsed 2×2 table.

As an alternative way of obtaining the agreement K_s on the specific category s, without the need to collapse the original $k \times k$ table, Kvålseth (1989) proposed the specific – category Kappa as

$$K_s = \frac{p_{ss} - p_{s+}p_{+s}}{\bar{p}_s - p_{s+}p_{+s}}, \quad \bar{p}_s = \frac{p_{s+} + p_{+s}}{2} \quad (5)$$

The K_s can alternatively be expressed as

$$K_s = 1 - \frac{\sum\sum_{D_s} p_{ij}}{\sum\sum_{D_s} p_{i+}p_{+j}} \quad (6)$$

where $\sum\sum_{D_s}$ denotes the summation over all disagreement cells for category s, i.e.,

$$D_s = \{(s,j) \text{ for all } j \neq s \text{ and } (i,s) \text{ for all } i \neq s\} \quad (7)$$

From (6), K_s is the proportional difference between the chance - expected disagreement and the observed disagreement for the specific category s. Note that K in (1) and (2) are weighted arithmetic means of K_s in (5) and (6), respectively, for $s = 1, \ldots, k$, with the weights being based on the denominators in (6) – (7).

When K_s is expressed as in (6), an extension to the case when disagreements should be unequally weighted is rather obvious. Thus, for disagreement weights $w_{ij} \in [0,1]$ for all i and j, with $w_{ij} = 0$ for all $i = j$, the following weighted specific – category Kappa has been proposed (Kvålseth 2003):

$$K_{ws} = 1 - \frac{\sum\sum_{D_s} w_{ij}p_{ij}}{\sum\sum_{D_s} w_{ij}p_{i+}p_{+j}} \quad (8)$$

where D_s is the set of disagreement cells in (7). When w_{ij} is the same for all $(i,j) \in D_s$, (8) reduces to (6). Note also that

K_w in (4) is a weighted arithmetic mean of the K_{ws} for $s = 1, \ldots, k$, with the weights based on the denominator in (8).

The possible values of K_s and K_{ws} range from 1 (when the disagreement probabilities for category s are all zero), through 0 (under the independence $p_{sj} = p_{s+}p_{+j}$ for all j and $p_{is} = p_{i+}p_{+s}$ for all i), and to negative values when observed disagreement exceeds chance - expected disagreement for category s.

Conditional and Asymmetric Kappa

Light (1971) considered the agreement between two observers for only those items (observations) that Observer 1 assigned to category i, with the conditional Kappa defined as

$$K_{2|1}^{(i)} = \frac{p_{ii}/p_{i+} - p_{+i}}{1 - p_{+i}} \tag{9}$$

This measure can also be expressed as

$$K_{2|1}^{(i)} = 1 - \frac{\sum_{\substack{j=1 \\ j \neq i}}^{k} p_{ij}}{\sum_{\substack{j=1 \\ j \neq i}}^{k} p_{i+}p_{+j}} \tag{10}$$

which immediately suggests the following weighted form (Kvålseth 1985):

$$K_{2|1,w}^{(i)} = 1 - \frac{\sum_{\substack{j=1 \\ j \neq i}}^{k} w_{ij}p_{ij}}{\sum_{\substack{j=1 \\ j \neq i}}^{k} w_{ij}p_{i+}p_{+j}} \tag{11}$$

Whereas K in (1) – (2) and K_w in (3) – (4) treat the two observers equivalently, i.e., these measures are effectively symmetric, asymmetric versions of Kappa may be defined in terms of the weighted means of the measures in (9) – (11) as

$$\overline{K}_{2|1} = \sum_{i=1}^{k} p_{i+}K_{2|1}^{(i)}, \; \overline{K}_{2|1,w} = \sum_{i=1}^{k} p_{i+}K_{2|1,w}^{(i)} \tag{12}$$

Such measures as in (12) may be appropriate if Observer 1 is to be designated as the "standard" against which classifications by Observer 2 are to be compared (Kvålseth 1991).

Statistical Inferences

Consider now that the above Kappa coefficients are estimates (and estimators) based on sample probabilities (proportions) $p_{ij} = n_{ij}/N$ for $i = 1, \ldots, k$ and $j = 1, \ldots, k$ and sample size $N = \sum_{i=1}^{k}\sum_{j=1}^{k} n_{ij}$, with $\{\pi_{ij}\}$ being the corresponding population probabilities. It may then be of interest to make statistical inferences, especially confidence - interval construction, about the corresponding $\{\pi_{ij}\}$ – based population coefficients or measures. Such approximate inferences can be made based on the *delta method* (Bishop et al. 1975).

Consequently, under multinomial sampling and when N is reasonably large, the various Kappa coefficients introduced above are approximately normally distributed with means equal to the corresponding population coefficients and with variances that can be determined as follows. Since those Kappa coefficients can all be expressed in terms of K_w in (4) by special choices among the set of weights $\{w_{ij}\}$, it is sufficient to determine the variance of (the estimator) K_w. For instance, in the case of K_s in (6) and K_{ws} in (8), one can simply set $w_{ij} = 0$ in (4) for all cells that do not belong to D_s in (7). Thus, the estimated variance of K_w has been given in (Kvålseth 2003) as

$$\mathrm{Var}(K_w) = \left(NF_w^2\right)^{-1}\left\{\sum_{i=1}^{k}\sum_{j=1}^{k} p_{ij}E_{ij}^2 - \left[K_w - (1 - F_w)(1 - K_w)\right]^2\right\} \tag{13a}$$

where

$$E_{ij} = 1 - w_{ij} - (2 - \overline{w}_{i+} - \overline{w}_{+j})(1 - K_w) \tag{13b}$$

$$\overline{w}_{i+} = \sum_{j=1}^{k} w_{ij}p_{+j}, \; \overline{w}_{+j} = \sum_{i=1}^{k} w_{ij}p_{i+}, \; F_w = \sum_{i=1}^{k}\sum_{j=1}^{k} w_{ij}p_{i+}p_{+j}. \tag{13c}$$

Note that F_w is the dominator of K_w in (4).

Example As an example of this inference procedure, consider the (fictitious) probabilities (proportions) in Table 1.

In the case of category 1, e.g., it follows from (5) or (6) and Table 1 that the interobserver agreement $K_1 = 0.72$.

Kappa Coefficient of Agreement. Table 1 Results from two observers' classifications with three categories

	Observer 2			
Observer 1	1	2	3	Total
1	0.40	0.07	0.01	0.48
2	0.04	0.20	0.06	0.30
3	0.02	0.05	0.15	0.22
Total	0.46	0.32	0.22	1.00

If, however, the categories in Table 1 are ordinal and the weights $w_{ij} = |i - j|/(k - 1)$ are used, it is found from (7) – (8) and Table 1, with D_1 consisting of the cells (1,2), (1,3), (2,1), and (3,1), that $K_{w1} = 0.76$. Similarly, $K_2 = 0.49, K_3 = 0.59$, $K_{w2} = 0.49$, and $K_{w3} = 0.69$, whereas, from (1) – (4), $K = 0.61$ and $K_w = 0.67$.

In order to construct a confidence interval for the population equivalent of K_{w1}, (13) can be used by (a) setting $w_{ij} = 0$ for those cells that do not belong to D_1 in (7), i.e., the cells (2,2), (2,3), (3,2) and (3,3) and (b) replacing K_w and F_w with K_{ws} and F_{ws} (the denominator of K_{ws}). Thus, with $K_{w1} = 1 - 0.0850/0.3526 = 0.7589$ (and $F_{w1} = 0.3526$), it is found from (13b) – (13c) that $E_{11} = 0.6986$, $E_{12} = 0.1673, \ldots, E_{33} = 0.7444$ so that, from (13a), if the data in Table 1 are based on sample size $N = 100$, it is found that $\mathrm{Var}(K_{w1}) = 0.0042$. Consequently, an approximate 95% confidence interval for the population equivalent of K_{w1} becomes $0.76 \pm 1.96\sqrt{0.0042}$, or $(0.63, 0.89)$. By comparison, setting $w_{12} = w_{13} = w_{21} = w_{31} = 1$ and all other $w_{ij} = 0$, it is found in (Kvålseth 2003) that a 95% confidence interval for the population equivalent of the unweighted K_1 is (0.58, 0.86).

Concluding Comment

While the overall Kappa and its weighted form in (1) – (4) are the most popular measures of interobserver agreement, they are not without some criticism or controversy. In particular, they depend strongly on the marginal distributions $\{p_{i+}\}$ and $\{p_{+j}\}$ so that, when those distributions are highly uneven (non-uniform), values of Kappa tend to be unreasonably small. Also, since the p_{ii} $(i = 1, \ldots, k)$ are included in the marginal distributions, the agreement probabilities enter into both the overall probability of agreement as observed and as expected by chance.

Kendall's Tau

Llukan Puka
Professor
University of Tirana, Tirana, Albania

K

Kendall's *Tau* is a nonparametric measure of the degree of correlation. It was introduced by Maurice Kendall in 1938 (Kendall 1938).

Kendall's *Tau* measures the strength of the relationship between two ordinal level variables. Together with Spearman's rank correlation coefficient, they are two widely accepted measures of rank correlations and more popular rank correlation statistics.

It is required that the two variables, X and Y, are paired observations. Then, provided both variables are at least ordinal, it would be possible to calculate the correlation between them. In general, application of the product-moment correlation coefficient is limited by the requirement that the trend must be linear. A less restrictive measure of correlation is based on the probabilistic notion that the correlation between variables X and Y is strong if on average, there is a high probability that an increase in X will be accompanied by an increase in Y (or decrease in Y). Then the only limitation imposed on the trend line is that it should be either continually increasing or continually decreasing.

One of the properties of coefficients that adopt this notion of correlation, like *Kendall's Tau* coefficient, is that the definition of the correlation depends only on the ranks of the data values and not on the numerical values. To this end, they can be applied either to data from scaled variables that has been converted to ranks, or to ordered categorical variables.

Formula for Calculation of Kendall's Tau Coefficient, (Hollander and Wolfe 1998)

For any sample of n paired observations of a bivariate variables (X, Y), there are $m = \frac{n(n-1)}{2}$ possible comparisons of points (X_i, Y_i) and (X_j, Y_j). A pair of observation data set (X_i, Y_i), (X_j, Y_j) is called concordant if $X_j - X_i$ and $Y_j - Y_i$ has the same sign. Otherwise, if they have opposite signs, the pair is called discordant. If $X_i = X_j$, or $Y_i = Y_j$ or both, the comparison is called a "tie." Ties are not counted as concordant or discordant.

If C is the number of pairs that are concordant and D is the number of pairs that are discordant, then the value *Tau* of Kendall's *Tau* is

$$Tau = \frac{C - D}{m}$$

The quantity $S = C - D$ is known as Kendall S. A predominance of concordant pairs resulting in a large positive value of S indicates a strong positive relationship between X and Y; a predominance of discordant pairs resulting in a large negative value of S indicates a strong negative relationship between X and Y.

The denominator m is a normalizing coefficient such that the *Kendall's Tau* coefficient can assume values between −1 and +1: $-1 \le Tau \le 1$.

The interpretation of *Kendall's Tau* value is similar as for the other correlation coefficients: when the value is +1, then the two rankings are the same (the concordance between two variables is perfect); when the value is −1, the discordance is perfect (the ranking of one of variables is reverse to the other); and finally any other value between −1 and +1 is interpreted as a sign of the level of relationship, a positive relationship (*Kendall's Tau* > 0, both variables increase together), or a negative relationship (*Kendall's Tau* < 0, the rank of one variable increases, the other one decreases); the value 0 is an indication for non relationship.

If there are a large number of ties, then the dominator has to be corrected by $\sqrt{(m - n_x)(m - n_y)}$ where n_x is the number of ties involving X and n_y is the number of ties involving Y.

For inferential purposes, *Kendall's Tau* coefficient is used to test the hypothesis that X and Y are independent, $Tau = 0$, against one of the alternatives: $Tau \neq 0$, $Tau > 0$, $Tau < 0$. Critical values are tabulated, Daniel (1990), Abdi (2007). The problem of ties is considered also by Sillitto (1947), Burr (1960).

In large samples, the statistic

$$\frac{3 \times Kendall's\ Tau \times \sqrt{n(n-1)}}{\sqrt{2(2n+5)}}$$

has approximately a normal distribution with mean 0 and standard deviation 1, and therefore can be used as a test statistic for testing the null hypothesis of zero correlation. It can be used also to calculate the confidence intervals (Noether 1967).

Kendall's *Tau* and Spearman's *Rho*

Kendall's *Tau* is equivalent to Spearman's *Rho*, with regard to the underlying assumptions. But they differ in their underlying logic and also computational formulas are quite different. The relationship between the two measures is given by

$$-1 \le \{(3 \times \text{Kendall's } Tau) - (2 \times \text{Spearman's } Rho)\} \le +1.$$

Their values are very similar in most cases, and when discrepancies occur, it is probably safer to interpret the lower value. More importantly, Kendall's *Tau* and Spearman's *Rho* imply different interpretations. Spearman's *Rho* is considered as the regular Pearson's correlation coefficient in terms of the proportion of variability accounted for, whereas Kendall's *Tau* represents a probability, i.e., the difference between the probabilities that the observed data are in the same order versus the probability that the observed data are not in the same order.

The distribution of Kendall's *Tau* has better statistical properties. In most of the situations, the interpretations of Kendall's *Tau* and Spearman's rank correlation coefficient are very similar and thus invariably lead to the same inferences. In fact neither statistics has any advantage in being easier to apply (since both are freely available in statistical packages) or easier to interpret. However Kendall's statistics structure is much simpler than that of the Spearman coefficient and has the advantage that it can be extended to explore the influence of a third variable on the relationship.

There are two different variations of Kendall's *Tau* that make adjustment for ties: *Tau b* and *Tau c*. These measures differ only as to how tied ranks are handled.

Kendall's *Tau-b*

Kendall's *Tau-b* is a nonparametric measure of correlation for ordinal or ranked variables that take ties into account. The sign of the coefficient indicates the direction of the relationship, and its absolute value indicates the strength, with larger absolute values indicating stronger relationships. Possible values ranges from −1 to 1. The calculation formula for *Kendall's Tau-b* is given by the following:

$$Tau - b = \frac{C - D}{\sqrt{(C + D + X_0)(C + D + Y_0)}}$$

where X_0 is the number of pairs tied only on the X variable, Y_0 is the number of pairs tied only on the Y variable. When

there are no ties, the values of Kendall's *Tau* and Kendall's *Tau b* are identical.

The *Kendall's Tau-b* has properties similar to the properties of the *Spearman Rho*. Because it does estimate a population parameter, many statisticians prefer the Kendall's *Tau-b* to the Spearman rank correlation coefficient.

Kendall's *Tau-c*

Kendall's *Tau-c*, is a variant of *Tau-b* used for situations of unequal-sized sets of ordered categories. It equals the excess of concordant over discordant pairs, multiplied by a term representing an adjustment for the size of the table. It is also called *Kendall–Stuart Tau-c* (or Stuart's Tau-c) and is calculated by formula

$$Tau - c = \frac{2m \times (C - D)}{n^2(m-1)}$$

where m is the smaller of the number of rows and columns, and n is the sample size.

Kendall's *Tau-b* and Kendall's *Tau-c* are superior to other measures of ordinal correlation when a test of significance is required.

About the Author

Dr. Llukan Puka is a Professor, Department of Mathematics, Faculty of Natural Science, University of Tirana, Albania. He was the Head of Statistics and Probability Section at the Faculty, Head of Mathematics Department too. During 1997–2007, he was the Dean of the Faculty. Professor Puka is an Elected Member of the ISI, associated to the IASC. He has authored and coauthored more than 30 papers and 15 textbooks, university level and high school level, mainly concerning probability, statistics, and random processes. He was the Head of National Council of Statistics (2001–2005). Professor Puka is the President of the Albanian Actuarial Association.

Michigan State University, East Lansing, MI, USA

Background

Consider the problem of testing the null hypothesis that a set of random variables $X_i, i = 1, \ldots, n$, is a random sample from a specified continuous distribution function (d.f.) F. Under the null hypothesis, the empirical d.f.

$$F_n(x) = \frac{1}{n}\sum_{i=1}^{n} \mathbb{I}\{X_i \le x\}$$

must "agree" with F. One way to measure this agreement is to use omnibus test statistics from the empirical process (see ►Empirical Processes)

$$v_n(x) = \sqrt{n}(F_n(x) - F(x)).$$

The time transformed uniform empirical process

$$u_n(t) = v_n(x), \quad t = F(x)$$

is an empirical process based on random variables $U_i = F(X_i), i = 1, \ldots, n$, that are uniformly distributed on $[0,1]$ under the null hypothesis. Hence, although the construction of u_n depends on F, the null distribution of this process does not depend on F any more (Kolmogorov (1933), Doob (1949)). From this sprang a principle, universally accepted in goodness of fit testing theory, that one should choose tests of the above hypothesis based on statistics $A(v_n, F)$ which can be represented as statistics $B(u_n)$ just from u_n. Any such statistic, like, for example, weighted Cramér-von Mise statistics $\int v_n^2(x)\alpha(F(x))dF(x)$, or Kolmogorov-Smirnov statistics $\max_x |v_n(x)|/\alpha(F(x))$, will have a null distribution free

from F, and hence this distribution can be calculated once and used for many different F – still a very desirable property in present times, in spite of great advantages in computational power. It is called the distribution free property of the test statistic.

However, as first clarified by Gikhman (1954) and Kac et al. (1955), this property is lost even asymptotically as soon as one is fitting a family of parametric d.f.'s. More precisely, suppose one is given a parametric family of d.f.'s F_θ, θ a k-dimensional Euclidean parameter, and one wishes to test the hypothesis that $X_i, i = 1, \dots, n$, is a random sample from some F_θ. Denoting $\hat{\theta}_n$ a $n^{1/2}$-consistent estimator of θ, the relevant process here is the parametric empirical process

$$\hat{v}_n(x) = \sqrt{n}(F_n(x) - F_{\hat{\theta}_n}(x)).$$

To describe the effect of estimation of θ on $\hat{v}_n$, let $\dot{F}_\theta(x) = \partial F_\theta(x)/\partial\theta$ and y^T denote the transpose of a k-vector y. Under simple regularity conditions,

$$\begin{aligned}\hat{v}_n(x) &= \sqrt{n}(F_n(x) - F_{\hat{\theta}_n}(x)) \\ &= v_n(x) - \dot{F}_\theta(x)^T\sqrt{n}(\hat{\theta}_n - \theta) + o_P(1).\end{aligned}$$

If additionally, for a k-vector of square integrable functions ψ,

$$\sqrt{n}(\hat{\theta}_n - \theta) = \int \psi dv_n + o_P(1),$$

then $\hat{v}_n$ converges weakly to a mean zero Gaussian process $\hat{v}$, different from the weak limit of v_n, with a covariance function that depends on the unknown parameter θ via F_θ and ψ in a complicated fashion (Durbin (1973), Khmaladze (1979)). Critical values of any test based on this process are difficult to find even for large samples. Thus the goodness of fit testing theory was in danger of being fragmented into large number of particular cases and becoming computationally heavy and complex.

Khmaladze Transformation

To overcome this shortcoming, Khmaladze devised a transformation of $\hat{v}_n$ whose asymptotic null distribution under the parametric null hypothesis is distribution free while at the same time this transformed process stays in one-to-one correspondence with the process $\hat{v}_n$ without the loss of any "statistical information."

To describe this transformation, let f_θ denote density of F_θ and $\psi_\theta = \partial \log f_\theta/\partial\theta$ and let v denote the limit in distribution of empirical process v_n. Equip the process $\hat{v}$ with filtration $\mathcal{H} = \{\mathcal{H}_x, -\infty < x < \infty\}$, where each σ-field $\mathcal{H}_x = \sigma\{v(y), y \le x, \int \psi_\theta dv\}$ is generated not only by the "past" of v but also $\int \psi_\theta dv$, which contains a "little bit of a future" as well. This filtration is not an intrinsic part of the testing problem as it is usually formulated in statistics. Nevertheless, Khmaladze (1981) suggested to use it, because then it is natural to speak about martingale part $\{w, \mathcal{H}\}$ of the resulting semi-martingale $\{\hat{v}, \mathcal{H}\}$. Let $h_\theta^T(x) = (1, \psi_\theta(x))$ be "extended" score function and let $\Gamma_{x,\theta}$ be covariance matrix of $\int_x h_\theta dv$. Then this martingale part has the form

$$w(x) = v(x) - \int^x h_\theta(y)\Gamma_{y,\theta}^{-1}\int_y h_\theta dv\, dF_\theta(y). \qquad (1)$$

The change of time $t = F_\theta(x)$ will transform it to a standard Brownian motion (see ▶Brownian Motion and Diffusions) on $[0,1]$ – a convenient limiting process, with the distribution independent from F_θ. The substitution of $\hat{v}_n$ in (1) produces a version of empirical process w_n, which, basically, is the Khmaladze transform (KhT hence forth). It was shown to possess the following asymptotic properties: it will not change, regardless of which function ψ, or which estimator $\hat{\theta}_n$, was used in $\hat{v}_n$; it stays in one-to-one correspondence with $\hat{v}_n$, if $\hat{\theta}_n$ is the maximum likelihood estimator; and also the centering of empirical distribution function F_n in empirical process is unnecessary. Hence, the final form of KhT for parametric hypothesis is

$$w_{n,\theta}(x) = \sqrt{n}\left[F_n(x) - \int^x h_\theta(y)\Gamma_{y,\theta}^{-1}\int_y h_\theta dF_n\, dF_\theta(y)\right].$$

If the hypothesis is true, after time transformation $t = F_\theta(x)$, the processes $w_{n,\theta}$ and $w_{n,\hat{\theta}_n}$ converge weakly to standard Brownian motion. Consequently a class of tests based on time transformed $w_{n,\hat{\theta}_n}$ are asymptotically distribution free.

A slightly different point of view on $w_{n,\theta}$ is that its increment

$$dw_{n,\theta}(x) = \sqrt{n}\left[dF_n(x) - h_\theta(x)\Gamma_{x,\theta}^{-1}\int_x h_\theta dF_n\, dF_\theta(x)\right]$$

is (normalized) difference between $dF_n(x)$ and its linear regression on $F_n(x)$ and $\int_x h_\theta dF_n$.

If θ is known, i.e., if the hypothesis is simple, then $w_{n,\theta}$ reduces to what is called in the theory of empirical processes the basic martingale (see, e.g., Shorack and Wellner (1986)).

It is well known that the analog of Kolmogorov test is not distribution free when fitting a multivariate d.f. Khmaladze (1988, 1993) developed an analog of KhT in this case also, using the notion of so called scanning martingales.

Tsigroshvili (1998), and in some cases Khmaladze and Koul (2009), show that the KhT is well defined even if the matrix $\Gamma_{x,\theta}$ is not of full rank.

Some power properties of tests based on the $w_{n,\hat{\theta}_n}$ were investigated in a number of publications, including Janssen & Ünlü (2008), Koul and Sakhanenko (2005) and Nikitin (1995).

The specific form of $w_{n,\theta}$ and the practicality of its use for some particular parametric families was studied, e.g., in Koul and Sakhanenko (2005) and Haywood and Khmaladze (2007).

KhT for Counting Processes

If $N(t), t \geq 0$, is a point process (see ►Point Processes) then Aalen (1978) used an appropriate filtration and the corresponding random intensity function $\lambda(t)$ to create the martingale

$$M(t) = N(t) - \int_0^t \lambda(s)ds.$$

This in turn gave rise to broad and successful theory, especially in survival analysis with randomly censored observations, as explained in the monograph by Andersen et al. (1993). However, if the $\lambda = \lambda_\theta$ depends on unspecified parameter, which needs to be estimated using N itself, then the process $\hat{M}(t)$ is not a martingale any more and suffers from the same problems as the process $\hat{v}_n$.

Again, by including the estimator $\hat{\theta}$ in the filtration used, the KhT for $\hat{M}(t)$ was constructed in Maglaperidze et al. (1998), Nikabadze and Stute (1997), and later in O'Quigley (2003), Sun et al. (2001) and Scheike and Martinussen (2004).

KhT in Regression

The transformation was taken into new direction of the quantile regression problems in Koenker and Xiao (2002), where some additional problems were resolved. The practicality of the approach was demonstrated by the software, created by Roger Koenker and his colleagues. Recent extension to the case of autoregression is presented in discussion paper Koenker and Xiao (2006).

In the classical mean regression set up with covariate X and response Y, $Y = \mu(X) + \epsilon$, where error ϵ is independent of X, $E\epsilon = 0$, and $\mu(x) = E(Y|X = x)$. Let (X_i, Y_i), $i = 1, \cdots, n$, be a random sample from this model.

Here the two testing problems are of interest. One is the goodness-of-fit of an error d.f. and the second is the problem of lack-of-fit of a parametric regression function $m_\theta(x)$. In parametric regression model, tests for the first problem are based on the residual empirical process $\hat{v}_n(x)$ of the residuals $\hat{\epsilon}_i = Y_i - m_{\hat{\theta}_n}(X_i)$, $i = 1, \cdots, n$, where $\hat{\theta}_n$ is a $n^{1/2}$-consistent estimator of θ. Khmaladze and Koul (2004) develops the KhT of $\hat{v}_n$. Similar results were obtained for nonparametric regression models in Khmaladze and Koul (2009). It is shown, somewhat unexpectedly, that in nonparametric regression models, KhT not only leads to an asymptotically distribution free process, but also tests based on it have larger power than the tests based on $\hat{v}_n$ with non-parametric residuals $Y_i - \hat{m}_n(X_i)$.

Tests of lack-of-fit are typically based on the partial sum processes of the form

$$\sum_{i=1}^{n} g(\hat{\epsilon}_i) I\{X_i \leq x\},$$

for some known function g. However, again their limiting distribution depend on the form of the regression function, on the estimator $\hat{\theta}_n$ used and on the particular value of the parameter. Starting with Stute et al. (1998) this tradition was changed and KhT was introduced for these partial sum processes, which again, led to the process converging to standard Brownian motion. Khmaladze and Koul (2004) studied the analog of KhT for partial sum process when design variable is multi-dimensional.

Extension to some time series models are discussed in Koul and Stute (1999), Bai (2003) and Koul (2006). Koul and Song (2008, 2009, 2010), Dette and Hetzler (2008, 2009) illustrate use of KhT in some other problems in the context of interval censored data, Berkson measurement error regression models and fitting a parametric model to the conditional variance function.

About the Author

Dr. Hira Lal Koul is Professor and Chair, Department of Statistics and Probability, Michigan State University. He was President of the International Indian Statistical Association (2005–2006). He was awarded a Humboldt Research Award for Senior Scientists (1995). He is a Fellow of the American Statistical Association, Institute of Mathematical Statistics, and Elected member of the International Statistical Institute. He is Co-Editor in Chief of *Statistics and Probability Letters*, Associate Editor for *Applicable Analysis and Discrete Mathematics*, and Co-Editor of *The J. Mathematical Sciences* he has (co-)authored about 110 papers, and several monographs and books. He is joint editor of the text *Frontiers in Statistics* (with Jianqing Fan, dedicated to Prof. Peter J Bickel in honor of his 65th birthday, Imperial College Press, London, UK, 2006).

Kolmogorov-Smirnov Test

Raul H. C. Lopes
Research Fellow
Brunel University, Uxbridge, UK
Professor of Computer Science at UFES, Vitoria
Brazil

Applications of Statistics are frequently concerned with the question of whether two sets of data come from the same distribution function, or, alternatively, of whether a probabilistic model is adequate for a data set. As an example, someone might be interested in evaluating the quality of a computer random numbers generator, by testing if the sample is uniformly distributed. A test like that is generally called a goodness-of-fit test. Examples of it are the χ^2 test and the Kolmogorov-Smirnov test.

Generally given a sample $X = x_0, x_1, \ldots, x_{n-1}$ and a probability distrbution function $P(x)$ the target would be

to test the Null Hypothesis H_0 that P is the sample's distribution function. When testing with two data sets the Null Hypothesis H_0 states that they both have the same distribution functions.

The choice of a statistical test must take into account at least two factors: (1) whether the data is continuous or discrete, (2) and if the comparison to be performed uses two data sets or a one set against a fitting probability model. Testing that a set of computer generated pseudo-random real numbers follows a uniformly distributed model is an example of testing a continuous data set against a probabilistic model, while comparing the amount of Vitamin C in two different brands of orange juice would fit a comparison of two continuous data sets.

The χ^2 test was designed to test discrete data sets against a probability model. However, it could be applied in the test of the computer random numbers generator by discretising the sample. Given the set $X = x_0, x_1, \ldots, x_{n-1}$ of generated numbers, a set of k intervals (bins)

$$(-\infty, z_1), (z_1, z_2), \ldots, (z_{k-1}, \infty)$$

could be used to define a discrete function

$$X_j = i, \text{ when } x_j \in (z_{i-1}, z_i).$$

Kolmogorov (1933) and Smirnov (1948) proved a result, also Schmid (1958), that is the basis for a much more efficient goodness-of-fit test when continuous data is involved. The test starts with the definition of a function $F_{X,n}(x)$ that gives the fraction of points $x_i, i \in (0, \ldots, n-1)$, in a sample X that are below x as follows (E.W. Dijkstra's uniform notation for quantifiers is used, with $\#\, i : P(x_i)$ denoting the number of elements in the set satisfying the property $P(x_i)$, for all possible i.):

$$F_{X,n}(x) = \frac{\#i : x_i \leq x}{n}$$

Assuming that another sample $Y = y_0, y_1, \ldots, y_{m-1}$ is given, then its function can be defined:

$$F_{Y,m}(y) = \frac{\#i : y_i \leq y}{m}$$

And any statistic could be used to measure the difference between X and Y, by measuring the difference between $F_{X,n}(x)$ and $F_{Y,m}(x)$. Even the area between the curves defined by these functions could be used. The Kolmogorov-Smirnov distance, is defined as the maximum absolute value of the difference between $F_{X,n}(x)$ and $F_{Y,m}(x)$ for all possible values of x:

$$D = max\, x : -\infty < x < \infty : F_{X,n}(x) - F_{Y,m}(x)$$

In a test trying to fit one sample with a probabilistic model defined by the function $P(x)$, the distance, also called Kolmogorov-Smirnov statistic, would be defined as

$$D = max\, x : -\infty < x < \infty : F_{X,n}(x) - P(x)$$

The distribution of the Kolmogorov-Smirnov statistic in the case of a Null Hypothesis test can be computed, giving a significance level for the observed value. For that purpose, let $D^\star$ be the following function of the observed value:

$$D^\star(d) = \left[\sqrt{n_e} + 0.12 + 0.11/\sqrt{n_e}\right] d$$

In the definition of $D^\star$, the quantity n_e is defined as follows:

- n_e is the number of points in the sample, when doing a one-sample test.
- $n_e = \frac{n*m}{n+m}$, in the case of a two-sample test, with n and m being the sizes of the samples.

The significance level can then be computed using the function Q below (Stephens 1970):

$$Q(d) = 2\sum_{i=1}^{\infty}(-1)^{i-1}e^{-2i^2d^2}$$

Given a d, computed by the Kolmogorov-Smirnov distance, the significance level of d, which comes to be the probability that the null hypotheses (that the two distributions are the same) is invalid, is given by

$$\text{Probability}(D > d) = Q(D^\star(d))$$

The Kolmogorov-Smirnov test offers several advantages over the χ^2 test:

- It can be applied to continuous data.
- The distribution of its statistic is invariant under re-parametrisation and it can be easily implemented by computers.
- It can be extended to multivariate data.

Several statistics packages implement the Kolmogorov-Smirnov test. The package **R** (Crawley 2007), freely available (Software and documentation from http://www.r-project.org) for most operating systems, offers a Kolmogorov-Smirnov test in the function *ks.test*.

Adapting goodness-of-fit tests to multivariate data is considered a challenge. In particular, tests based on binning suffer from what has been described as the "curse of multi-dimensionality": the multi-dimensional space is essentially empty and binning tests tend to be ineffective even with large data sets.

Peacock in (Peacock 1983) introduced an extension of the Kolmogorov-Smirnov test to multivariate data. The idea consists in taking into account the distribution function of the two samples in all possible orderings, $2^d - 1$ orderings when d dimensional data is being considered. Given n points, in a two-dimensional space, Peacock proposed to compute the distribution functions in the $4n^2$ quadrants of the plane defined by all pairs (x_i, y_i), x_i and y_i being coordinates of all points of two given samples. This gives an algorithm of $\Omega(n^3)$ complexity. Fasano e Franceschini introduced in (Fasano and Franceschini 1987) an approximation of the Peacock's test that computes the statistic over all quadrants centred in each point of the given samples. Their test can be computed in time $\Omega(n^2)$. Lopes et alii introduced an algorithm (Available, under GPL license, from http://www.inf.ufes.br/ raul/cern.2dks.tar.bz2) based on range-counting trees that computes this last statistic in $O(n \lg n)$, which is a lower-bound for the test (Lopes et al. 2008).

Kullback-Leibler Divergence

James M. Joyce
Chair and Professor of Philosophy and of Statistics
University of Michigan, Ann Arbor, MI, USA

Kullback-Leibler divergence (Kullback and Leibler 1951) is an information-based measure of disparity among probability distributions. Given distributions P and Q defined over X, with Q absolutely continuous with respect to P, the *Kullback-Leibler divergence* of Q from P is the P-expectation of $-\log_2\{P/Q\}$. So, $D_{KL}(P,Q) = -\int_X \log_2(Q(x)/P(x))dP$. This quantity can be seen as the difference between the *cross-entropy for Q on P*, $H(P,Q) = -\int_X \log_2(Q(x))dP$, and the *self-entropy* (Shannon 1948) of P, $H(P) = H(P,P) = -\int_X \log_2(P(x))dP$. Since $H(P,Q)$ is the P-expectation of the number of bits of information, beyond those encoded in Q, that are needed to identify points in X, $D_{KL}(P,Q) = H(P) - H(P,Q)$ is the expected difference, from the perspective of P, between the information encoded in P and the information encoded in Q.

D_{KL} has a number of features that make it plausible as a measure of probabilistic divergence. Here are some of its key properties:

Premetric. $D_{KL}(P,Q) \geq 0$, with identity if and only if $P = Q$ a.e. with respect to P.

Convexity. $D_{KL}(P,Q)$ is convex in both P and Q.

Chain Rule. Given joint distributions $P(x,y)$ and $Q(x,y)$, define the KL-divergence conditional on x as $D_{KL}(P(y|x), Q(y|x)) = \int_X D_{KL}(P(y|x), Q(y|x))dP_x$ where P_x is P's x-marginal. Then,

$$D_{KL}(P(x,y), Q(x,y)) = D_{KL}(P_x, Q_x) + D_{KL}(P(y|x), Q(y|x)).$$

Independence. When X and Y are independent in both P and Q the Chain Rule assumes the simple form $D_{KL}(P(x,y), Q(x,y)) = D_{KL}(P_x, Q_x) + D_{KL}(P_y, Q_y)$, which reflects the well-known idea that independent information is additive.

It should be emphasized that KL-divergence is not a genuine metric: it is not symmetric and fails the triangle inequality. Thus, talk of Kullback-Leibler "distance" is misleading. While one can create a symmetric divergence measure by setting $D^*_{KL}(P,Q) = \frac{1}{2}D_{KL}(P,Q) + \frac{1}{2}D_{KL}(Q,P)$, this still fails the triangle inequality.

There is a close relationship between KL-divergence and a number of other statistical concepts. Consider, for example, *mutual information*. Given a joint distribution

$P(x,y)$ on $X \times Y$ with marginals P_X and P_Y, the mutual information of X and Y with respect to P is defined as $I_P(X,Y) = -\int_{X\times Y} \log_2(P(x,y)/[P_X(x)\cdot P_Y(y)])dP$. If we let $P_\perp(x,y) = P_X(x)\cdot P_Y(y)$ be the factorization of P, then $I_P(X,Y) = D(P,P_\perp)$. Thus, according to *KL*-divergence, mutual information measures the dissimilarity of a joint distribution from its factorization.

There is also a connection between *KL*-divergence and maximum likelihood estimation. Let $l_x(\theta) = p(x|\theta)$ be a likelihood function with parameter $\theta \in \Theta$, and imagine that enough data has been collected to make a certain empirical distribution $f(x)$ seem reasonable. In MLE one often hopes to find an estimate for θ that maximizes *expected log-likelihood* relative to one's data, i.e., we seek $\theta^\wedge = \text{argmax}_\theta E_f[\log_2(p(x|\theta)]$. To find this quantity it suffices to minimize the *KL*-divergence between $f(x)$ and $p(x|\theta^\wedge)$ since

$$\begin{aligned}
&\text{argmin}_\theta\, D_{KL}(f, p(\cdot|\theta^\wedge)) \\
&\quad = \text{argmin}_\theta - \int_X f(x)\cdot\log_2(p(x|\theta^\wedge)/f(x))dx \\
&\quad = \text{argmin}_\theta[H(f,f) - H(f,p(\cdot|\theta^\wedge))] \\
&\quad = \text{argmax}_\theta H(f,p(\cdot|\theta^\wedge)) \\
&\quad = \text{argmax}_\theta E_f[\log_2(p(x|\theta))].
\end{aligned}$$

In short, MLE minimizes Kullback-Leibler divergence from the empirical distribution.

Kullback-Leibler also plays a role in ▶model selection. Indeed, Akaike (1973) uses D_{KL} as the basis for his "information criterion" (AIC). Here, we imagine an unknown true distribution $P(x)$ over a sample space X, and a set Π_θ of models each element of which specifies a parameterized set of distributions $\pi(x|\theta)$ over X. The models in Π_θ are meant to approximate P, and the aim is to find the best approximation in light of data drawn from P. For each π and θ, $D_{KL}(P,\pi(x|\theta))$ measures the information lost when $\pi(x|\theta)$ is used to approximate P. If θ were known, one could minimize information loss by choosing π to minimize $D_{KL}(P,\pi(x|\theta))$. But, since θ is unknown one must estimate. For each body of data y and each π, let $\theta^\wedge_y$ be the MLE estimate for θ given y, and consider $D_{KL}(P,\pi(x|\theta^\wedge_y))$ as a random variable of y. Akaike maintained that one should choose the model that minimizes the expected value of this quantity, so that one chooses π to minimize $E_y[D_{KL}(P,\pi(x|\theta^\wedge_y))] = E_y[H(P,P) - H(P,\pi(\cdot|\theta^\wedge_y))]$. This is equivalent to maximizing $E_yE_x[\log_2(\pi(x|\theta^\wedge_y))]$. Akaike proved that $2k - \log_2(l_x(\theta^\wedge))$ is an unbiased estimate of this quantity for large samples, where $\theta^\wedge$ is the MLE estimate of θ and k is the number of estimated parameters. In this way, some have claimed, the policy of minimizing *KL*-divergence leads one to value simplicity in models since the "$2k$" term functions as a kind of penalty for complexity. (see Sober 2002).

KL-divergence also figures prominently in Bayesian approaches experimental design, where it is treated as a utility function. The objective in such work is to design experiments that maximize *KL*-divergence between the prior and posterior. The results of such experiments are interpreted as having a high degree of informational content. Lindley (1956) and De Groot (1962) are essential references here.

Bayesians have also appealed to *KL*-divergence to provide a rationale for Bayesian conditioning and related belief update rules, e.g., the probability kinematics of Jeffrey (1965). For example, Diaconis and Zabell (1982) show that the posterior probabilities prescribed by Bayesian conditioning or by probability kinematics minimize *KL*-divergence from the perspective of the prior. Thus, in the sense of information divergence captured by D_{KL}, these forms of updating introduce the least amount of new information consistent with the data received.

Kurtosis: An Overview

Edith Seier
Professor
East Tennessee State University, Johnson City, TN, USA

Pearson (1905) defined $\beta_2 = m_4/m_2^2$ (where m_i is the ith moment with respect to the mean) to compare other distributions to the normal distribution, for which $\beta_2 = 3$. He called $\eta = \beta_2 - 3$ the "degree of kurtosis" and mentioned that it "measures whether the frequency towards the mean is emphasized more or less than that required by the Gaussian law." In Greek, *kurtos* means convex, and *kurtosis* had been previously used to denote curvature both in mathematics and medicine. Pearson's development of the idea of kurtosis during the years previous to 1905 is examined by Fiori and Zenga (2009). "Coefficient of kurtosis" is the name usually given to β_2.

A sample estimator of β_2 is $b_2 = (\sum(x-\bar{x})^4/n)/s^4$. Statistical software frequently include an adjusted version of the estimator of η:

$$\frac{n(n+1)}{(n-1)(n-2)(n-3)}\frac{\left[\sum(x-\bar{x})^4\right]}{s^4} - \frac{3(n-1)(n-1)}{(n-2)(n-3)}.$$

The adjustment reduces the bias, at least in the case of nearly normal distributions. Byers (2000) proved that $b_2 \leq n - 2 + 1/(n-1)$. Simulation results indicate that when β_2 is large for the population of origin, b_2 will be small on average if the sample size is small.

Currently the word kurtosis is understood in a broader sense, not limited to β_2. Balanda and MacGillivray (1988) conclude that kurtosis is best defined as "the location- and scale-free movement of probability mass from the shoulders of a distribution into its center and tails." which can be formalized in many ways. Kurtosis is associated to both, the center and the tails of a distribution. Kurtosis is invariant under linear transformations or change of units of the variable. High kurtosis is linked to high concentration of mass in the center and/or the tails of the distribution. Heavy tails is a topic of interest in the analysis of financial data.

Several kurtosis measures have been defined. L-kurtosis (Hosking 1992) is popular in the field of hydrology. There are other measures defined in terms of distances between quantiles, ratios of spread measures, comparisons of sum of distances to the median, and expected values of functions of the standardized variable other than the fourth power that corresponds to β_2.

Ruppert (1987) proposed the use of the influence function to analyze kurtosis measures and points out that even those defined with the intention of measuring peakedness or tail weight alone, end up measuring both. There are measures that are more sensitive to the tails of the distribution than others: β_2 gives high importance to the tails because it is defined in terms of the fourth power of the deviations from the mean. For example, the value of β_2 is 1.8 for the uniform distribution and 3.53, 4.51, 36.2 and 82.1 for the $SU(0,\delta)$ distribution with $\delta = 3, 2, 1, 0.9$ respectively. For the same distributions, the values of L-kurtosis are 0,0.143,0.168, 0.293 and 0.329. The upper bound for L-kurtosis is 1, while β_2 is unbounded. The estimator b_2 is sensitive to ▶outliers; one single outlier can dramatically change its value.

Another approach to the study of kurtosis is the comparison of cumulative distribution functions. Van Zwet (1964) defined the convexity criterion ($\prec_S$): two symmetric distributions with cumulative distribution functions F and G are ordered and $F \prec_S G$ if $G^{-1}(F(x))$ is convex to the right of the common point of symmetry. If $F \prec_S G$, the value of β_2 for F is not larger than its value for G. The following distributions are ordered according to the convexity criterion:

U-shaped $\prec_S$ Uniform $\prec_S$ Normal $\prec_S$ Logistic $\prec_S$ Laplace.

Some families of distributions are ordered according to the convexity criterion, with the order associated (either directly or inversely) to the value of their parameter. Among those families are *beta*(α,α), *Tukey*(λ), Johnson's $SU(0,\delta)$, and the symmetric two-sided power family $TSP(\alpha)$. Balanda and MacGillivray (1990) defined the spread-spread functions to compare non-necessarily symmetric distributions. Additional ordering criteria have been defined. Any new measure of kurtosis that is defined needs to order distributions in agreement with some ordering based on distribution functions. The numerical value of a kurtosis measure can be obtained for most distributions but not all distributions are ordered according to a CDF based ordering criterion. For example, the *Laplace* and *t-Student*$_{(6)}$ distributions have known values for β_2 (6 and 9 respectively). However, they are not $\prec_S$ ordered because $G^{-1}(F(x))$ is neither convex, nor concave for $x > 0$. In particular, not all the distributions are ordered with respect

to the normal distribution according to the convexity criterion; but uniform $\prec_S$ unimodal distributions.

There are several ways of measuring kurtosis, there is also more than one way of thinking about peak and tails. One simple way of visualizing peak and tails in a unimodal probability distribution is to superimpose, on $f(x)$, a uniform density function with the same median and variance (Kotz and Seier 2008).

High kurtosis affects the behavior of inferential tools. Van Zwet (1964) proved that, when working with symmetric distributions, the median is more efficient than the mean as estimator of the center when the distribution has very high kurtosis. The variance of the sample variance is related to β_2. Simulations indicate that the power of some tests for the equality of variances diminishes (for small samples) when the distribution of the variable has high kurtosis.

Large Deviations and Applications

Francis Comets
Professor
Université Paris Diderot, Paris, France

Large deviations is concerned with the study of rare events and of small probabilities. Let $X_i, 1 \le i \le n$, be independent identically distributed (i.i.d.) real random variables with expectation m, and $\bar{X}_n = (X_1 + \ldots + X_n)/n$ their empirical mean. The law of large numbers shows that, for any Borel set $A \subset \mathbb{R}$ not containing m in its closure, $P(\bar{X}_n \in A) \to 0$ as $n \to \infty$, but does not tell us how fast the probability vanishes. Large deviations theory gives us the rate of decay, which is exponential in n. Cramér's theorem states that,

$$P(\bar{X}_n \in A) = \exp\big(-n\big(\inf\{I(x); x \in A\} + o(1)\big)\big)$$

as $n \to \infty$, for all interval A. The rate function I can be computed as the Legendre conjugate of the logarithmic moment generating function of X,

$$I(x) = \sup\{\lambda x - \ln E \exp(\lambda X_1); \lambda \in \mathbb{R}\},$$

and is called the Cramér transform of the common law of the X_i's. The natural assumption is the finiteness of the ►moment generating function in a neighborhood of the origin, i.e., the property of exponential tails. The function $I : \mathbb{R} \to [0, +\infty]$ is convex with $I(m) = 0$.

- In the Gaussian case $X_i \sim \mathcal{N}(m, \sigma^2)$, we find $I(x) = (x-m)^2/(2\sigma^2)$.
- In the Bernoulli case $P(X_i = 1) = p = 1 - P(X_i = 0)$, we find the entropy function $I(x) = x \ln(x/p) + (1-x) \ln(1-x)/(1-p)$ for $x \in [0,1]$, and $I(x) = +\infty$ otherwise.

To emphasize the importance of rare events, let us mention a consequence, the Erdös–Rényi law: consider an infinite sequence $X_i, i \ge 1$, of Bernoulli i.i.d. variables with parameter p, and let R_n denote the length of the longest consecutive run, contained within the first n tosses, in which the fraction of 1s is at least a ($a > p$). Erdös and Rényi proved that, almost surely as $n \to \infty$,

$$R_n / \ln n \longrightarrow I(a)^{-1},$$

with the function I from the Bernoulli case above. Though it may look paradoxical, large deviations are at the core of this event of full probability. This result is the basis of ►bioinformatics applications like sequence matching, and of statistical tests for sequence randomness.

The theory does not only apply to independent variables, but allows for many variations, including weakly dependent variables in a general state space, Markov or ►Gaussian processes, large deviations from ►ergodic theorems, non-asymptotic bounds, asymptotic expansions (Edgeworth expansions), etc.

Here is the formal definition. Given a Polish space (i.e., a separable complete metric space) $\mathcal{X}$, let $\{\mathbb{P}_n\}$ be a sequence of Borel probability measures on $\mathcal{X}$, let a_n be a positive sequence tending to infinity, and finally let $I : \mathcal{X} \to [0, +\infty]$ be a lower semicontinuous functional on X. We say that the sequence $\{\mathbb{P}_n\}$ satisfies a large deviation principle with speed a_n and rate I, if for each measurable set $E \subset X$

$$-\inf_{x \in E^\circ} I(x) \le \underline{\lim_n}\, a_n^{-1} \ln \mathbb{P}_n(E) \le \overline{\lim_n}\, a_n^{-1} \ln \mathbb{P}_n(E) \le -\inf_{x \in \bar{E}} I(x)$$

where $\bar{E}$ and E° denote respectively the closure and interior of E. The rate function can be obtained as

$$I(x) = -\lim_{\delta \searrow 0} \lim_{n \to \infty} a_n^{-1} \ln \mathbb{P}_n(B(x, \delta)),$$

with $B(x, \delta)$ the ball of center x and radius δ.

Sanov's theorem and sampling with replacement: let μ be a probability measure on a set Σ that we assume finite for simplicity, with $\mu(y) > 0$ for all $y \in \Sigma$. Let $Y_i, i \ge 1$, an i.i.d. sequence with law μ, and N_n the score vector of the n-sample,

$$N_n(y) = \sum_{i=1}^{n} \mathbf{1}_y(Y_i).$$

By the law of large numbers, $N_n/n \to \mu$ almost surely. From the ►multinomial distribution, one can check that, for all ν such that $n\nu$ is a possible score vector for the n-sample,

$$(n+1)^{-|\Sigma|} e^{-nH(\nu|\mu)} \le P(n^{-1}N_n = \nu) \le e^{-nH(\nu|\mu)},$$

where $H(\nu|\mu) = \sum_{y \in \Sigma} \nu(y) \ln \frac{\nu(y)}{\mu(y)}$ is the relative entropy of ν with respect to μ. The large deviations theorem holds

Miodrag Lovric (ed.), *International Encyclopedia of Statistical Science*, DOI 10.1007/978-3-642-04898-2,

for the empirical distribution of a general n-sample, with speed n and rate $I(\nu) = H(\nu|\mu)$ given by the natural generalization of the above formula. This result, due to Sanov, has many consequences in information theory and statistical mechanics (Dembo and Zeitouni 1998; den Hollander 2000), and for exponential families in statistics. Applications in statistics also include point estimation (by giving the exponential rate of convergence of M-estimators) and for hypothesis testing (Bahadur efficiency) (Kester 1985), and concentration inequalities (Dembo and Zeitouni 1998).

The *Freidlin–Wentzell theory* deals with diffusion processes with small noise,

$$dX_t^\epsilon = b\left(X_t^\epsilon\right) dt + \sqrt{\epsilon}\, \sigma\left(X_t^\epsilon\right) dB_t\,, \qquad X_0^\epsilon = y.$$

The coefficients b, σ are uniformly lipshitz functions, and B is a standard Brownian motion (see ►Brownian Motion and Diffusions). The sequence X^ϵ can be viewed as $\epsilon \searrow 0$ as a small random perturbation of the ordinary differential equation

$$dx_t = b(x_t)dt\,, \qquad x_0 = y.$$

Indeed, $X^\epsilon \to x$ in the supremum norm on bounded time-intervals. Freidlin and Wentzell have shown that, on a finite time interval $[0, T]$, the sequence X^ϵ with values in the path space obeys the LDP with speed ϵ^{-1} and rate function

$$I(\phi) = \frac{1}{2}\int_0^T \sigma(\phi(t))^{-2}\left(\dot{\phi}(t) - b(\phi(t))\right)^2 dt$$

if ϕ is absolutely continuous with square-integrable derivative and $\phi(0) = y$; $I(\phi) = \infty$ otherwise. (To fit in the above formal definition, take a sequence $\epsilon = \epsilon_n \searrow 0$, and for $\mathbb{P}_n$ the law of X^{ϵ_n}.)

The Freidlin–Wentzell theory has applications in physics (metastability phenomena) and engineering (tracking loops, statistical analysis of signals, stabilization of systems, and algorithms) (Freidlin and Wentzell 1998; Dembo and Zeitouni 1998; Olivieri and Vares 2005).

Laws of Large Numbers

Andrew Rosalsky
Professor
University of Florida, Gainesville, FL, USA

The *laws of large numbers* (LLNs) provide bounds on the fluctuation behavior of sums of random variables and, as we will discuss herein, lie at the very foundation of statistical science. They have a history going back over 300 years. The literature on the LLNs is of epic proportions, as this concept is indispensable in probability and statistical theory and their application.

Probability theory, like some other areas of mathematics such as geometry for example, is a subject arising from an attempt to provide a rigorous mathematical model for real world phenomena. In the case of probability theory, the real world phenomena are chance behavior of biological processes or physical systems such as gambling games and their associated monetary gains or losses.

The probability of an event is the abstract counterpart to the notion of the long-run relative frequency of the

occurence of the event through infinitely many replications of the experiment. For example, if a quality control engineer asserts that the probability is 0.98 that a widget produced by her production team meets specifications, then she is asserting that in the long-run, 98% of those widgets meet specifications. The phrase "in the long-run" requires the notion of *limit* as the sample size approaches infinity. The long-run relative frequency approach for describing the probability of an event is natural and intuitive but, nevertheless, it raises serious mathematical questions. Does the limiting relative frequency always exist as the sample size approaches infinity and is the limit the same irrespective of the sequence of experimental outcomes? It is easy to see that the answers are negative. Indeed, in the above example, depending on the sequence of experimental outcomes, the proportion of widgets meeting specifications could fluctuate repeatedly from near 0 to near 1 as the number of widgets sampled approaches infinity. So in what sense can it be asserted that the limit exists and is 0.98? To provide an answer to this question, one needs to apply a LLN.

The LLNs are of two types, viz., *weak* LLNs (WLLNs) and *strong* LLNs (SLLNs). Each type involves a different mode of convergence. In general, a WLLN (resp., a SLLN) involves convergence in probability (resp., convergence almost surely (a.s.)). The definitions of these two modes of convergence will now be reviewed.

Let $\{U_n, n \geq 1\}$ be a sequence of random variables defined on a probability space $(\Omega, \mathcal{F}, P)$ and let $c \in \mathbb{R}$. We say that U_n *converges in probability* to c (denoted $U_n \xrightarrow{P} c$) if

$$\lim_{n\to\infty} P(|U_n - c| > \varepsilon) = 0 \text{ for all } \varepsilon > 0.$$

We say that U_n *converges a.s.* to c (denoted $U_n \to c$ a.s.) if

$$P(\{\omega \in \Omega : \lim_{n\to\infty} U_n(\omega) = c\}) = 1.$$

If $U_n \to c$ a.s., then $U_n \xrightarrow{P} c$; the converse is not true in general.

The celebrated Kolmogorov SLLN (see, e.g., Chow and Teicher [1997], p. 125) is the following result. Let $\{X_n, n \geq 1\}$ be a sequence of independent and identically distributed (i.i.d.) random variables and let $c \in \mathbb{R}$. Then

$$\frac{\sum_{i=1}^n X_i}{n} \to c \text{ a.s. if and only if } EX_1 = c. \tag{1}$$

Using statistical terminology, the sufficiency half of (1) asserts that the *sample mean* converges a.s. to the *population mean* as the *sample size n* approaches infinity provided the population mean exists and is finite. This result is of fundamental importance in statistical science. It follows from (1) that

$$\text{if } EX_1 = c \in \mathbb{R}, \text{ then } \frac{\sum_{i=1}^n X_i}{n} \xrightarrow{P} c; \tag{2}$$

this result is the Khintchine WLLN (see, e.g., Petrov [1995], p. 134).

Next, suppose $\{A_n, n \geq 1\}$ is a sequence of independent events all with the same probability p. A special case of the Kolmogorov SLLN is the limit result

$$\hat{p}_n \to p \text{ a.s.} \tag{3}$$

where $\hat{p}_n = \sum_{i=1}^n I_{A_i}/n$ is the proportion of $\{A_1, \ldots, A_n\}$ to occur, $n \geq 1$. (Here I_{A_i} is the indicator function of $A_i, i \geq 1$.) This result is the first SLLN ever proved and was discovered by Emile Borel in 1909. Hence, with probability 1, the *sample proportion* $\hat{p}_n$ approaches the *population proportion* p as the sample size $n \to \infty$. It is this SLLN which thus provides the theoretical justification for the long-run relative frequency approach to interpreting probabilities. Note, however, that the convergence in (3) is not pointwise on Ω but, rather, is pointwise on some subset of Ω *having probability 1.* Consequently, any interpretation of $p = P(A_1)$ via (3) necessitates that one has *a priori* an intuitive understanding of the notion of an event having probability 1.

The SLLN (3) is a key component in the proof of the Glivenko–Cantelli theorem (see ▶Glivenko-Cantelli Theorems) which, roughly speaking, asserts that with probability 1, a population distribution function can be uniformly approximated by a sample (or empirical) distribution function as the sample size approaches infinity. This result is referred to by Rényi (1970, p. 400) as the *fundamental theorem of mathematical statistics* and by Loève (1977, p. 20) as the *central statistical theorem*.

In 1689, Jacob Bernoulli (1654–1705) proved the first WLLN

$$\hat{p}_n \xrightarrow{P} p. \tag{4}$$

Bernoulli's renowned book *Ars Conjectandi* (*The Art of Conjecturing*) was published posthumously in 1713, and it is here where the proof of his WLLN was first published. It is interesting to note that there is over a 200 year gap between the WLLN (4) of Bernoulli and the corresponding SLLN (3) of Borel.

An interesting example is the following modification of one of Stout (1974, p. 9). Suppose that the quality control engineer referred to above would like to estimate the proportion p of widgets produced by her production team

that meet specifications. She estimates p by using the proportion $\hat{p}_n$ of the first n widgets produced that meet specifications and she is interested in knowing if there will ever be a point in the sequence of examined widgets such that with probability (at least) a specified large value, $\hat{p}_n$ will be within ε of p *and stay* within ε of p as the sampling continues (where $\varepsilon > 0$ is a prescribed tolerance). The answer is affirmative since (3) is equivalent to the assertion that for a given $\varepsilon > 0$ and $\delta > 0$, there exists a positive integer $N_{\varepsilon,\delta}$ such that

$$P\left(\cap_{n=N_{\varepsilon,\delta}}^{\infty}[|\hat{p}_n - p| \le \varepsilon]\right) \ge 1 - \delta.$$

That is, the probability is arbitrarily close to 1 that $\hat{p}_n$ will be arbitrarily close to p simultaneously for all n beyond some point. If one applied instead the WLLN (4), then it could only be asserted that for a given $\varepsilon > 0$ and $\delta > 0$, there exists a positive integer $N_{\varepsilon,\delta}$ such that

$$P(|\hat{p}_n - p| \le \varepsilon) \ge 1 - \delta \text{ for all } n \ge N_{\varepsilon,\delta}.$$

There are numerous other versions of the LLNs and we will discuss only a few of them. Note that the expressions in (1) and (2) can be rewritten, respectively, as

$$\frac{\sum_{i=1}^n X_i - nc}{n} \to 0 \text{ a.s. and } \frac{\sum_{i=1}^n X_i - nc}{n} \xrightarrow{P} 0$$

thereby suggesting the following definitions. A sequence of random variables $\{X_n, n \ge 1\}$ is said to obey a general *SLLN* (resp., *WLLN*) with *centering sequence* $\{a_n, n \ge 1\}$ and *norming sequence* $\{b_n, n \ge 1\}$ (where $0 < b_n \to \infty$) if

$$\frac{\sum_{i=1}^n X_i - a_n}{b_n} \to 0 \text{ a.s.} \left(\text{resp., } \frac{\sum_{i=1}^n X_i - a_n}{b_n} \xrightarrow{P} 0\right).$$

A famous result of Marcinkiewicz and Zygmund (see, e.g., Chow and Teicher (1997), p. 125) extended the Kolmogorov SLLN as follows. Let $\{X_n, n \ge 1\}$ be a sequence of i.i.d. random variables and let $0 < p < 2$. Then

$$\frac{\sum_{i=1}^n X_i - nc}{n^{1/p}} \to 0 \text{ a.s. for some } c \in \mathbb{R} \text{ if and only if } E|X_1|^p < \infty.$$

In such a case, necessarily $c = EX_1$ if $p \ge 1$ whereas c is arbitrary if $p < 1$.

Feller (1946) extended the Marcinkiewicz–Zygmund SLLN to the case of a more general norming sequence $\{b_n, n \ge 1\}$ satisfying suitable growth conditions.

The following WLLN is ascribed to Feller by Chow and Teicher (1997, p. 128). If $\{X_n, n \ge 1\}$ is a sequence of i.i.d. random variables, then there exist real numbers $a_n, n \ge 1$ such that

$$\frac{\sum_{i=1}^n X_i - a_n}{n} \xrightarrow{P} 0 \tag{5}$$

if and only if

$$nP(|X_1| > n) \to 0 \text{ as } n \to \infty. \tag{6}$$

In such a case, $a_n - nE(X_1 I_{[|X_1| \le n]}) \to 0$ as $n \to \infty$.

The condition (6) is weaker than $E|X_1| < \infty$. If $\{X_n, n \ge 1\}$ is a sequence of i.i.d. random variables where X_1 has probability density function

$$f(x) = \begin{cases} \frac{c}{x^2 \log|x|}, & |x| \ge e \\ 0, & |x| < e \end{cases}$$

where c is a constant, then $E|X_1| = \infty$ and the SLLN $\sum_{i=1}^n X_i/n \to c$ a.s. fails for every $c \in \mathbb{R}$ but (6) and hence the WLLN (5) hold with $a_n = 0, n \ge 1$.

Klass and Teicher (1977) extended the Feller WLLN to the case of a more general norming sequence $\{b_n, n \ge 1\}$ thereby obtaining a WLLN analog of Feller's (1946) extension of the Marcinkiewicz–Zygmund SLLN.

Good references for studying the LLNs are the books by Révész (1968), Stout (1974), Loève (1977), Chow and Teicher (1997), and Petrov (1995). While the LLNs have been studied extensively in the case of independent summands, some of the LLNs presented in these books involve summands obeying a dependence structure other than that of independence.

A large literature of investigation on the LLNs for sequences of Banach space valued random elements has emerged beginning with the pioneering work of Mourier (1953). See the monograph by Taylor (1978) for background material and results up to 1978. Excellent references are the books by Vakhania, Tarieladze, and Chobanyan (1987) and Ledoux and Talagrand (1991). More recent results are provided by Adler et al. (1991), Cantrell and Rosalsky (2004), and the references in these two articles.

About the Author

Professor Rosalsky is Associate Editor, *Journal of Applied Mathematics and Stochastic Analysis* (1989–present), and Associate Editor, *International Journal of Mathematics and Mathematical Sciences* (1994–present). He has collaborated with research workers from 15 different countries. At the University of Florida, he twice received a Teaching Improvement Program Award and on five occasions was named an Anderson Scholar Faculty Honoree, an honor reserved for faculty members designated by undergraduate honor students as being the most effective and inspiring.

Learning Statistics in a Foreign Language

Khidir M. Abdelbasit
Sultan Qaboos University, Muscat, Sultanate of Oman

Background

The Sultanate of Oman is an Arabic-speaking country, where the medium of instruction in pre-university education is Arabic. In Sultan Qaboos University (SQU) all sciences (including Statistics) are taught in English. The reason is that most of the scientific literature is in English and teaching in the native language may leave graduates at a disadvantage. Since only few instructors speak Arabic, the university adopts a policy of no communication in Arabic in classes and office hours. Students are required to achieve a minimum level in English (about 4.0 IELTS score) before they start their study program. Very few students achieve that level on entry and the majority spends about two semesters doing English only.

Language and Cultural Problems

It is to be expected that students from a non-English-speaking background will face serious difficulties when learning in English especially in the first year or two. Most of the literature discusses problems faced by foreign students pursuing study programs in an English-speaking country, or a minority in a multi-cultural society (see for example Coutis P. and Wood L., Hubbard R, Koh E). Such students live (at least while studying) in an English-speaking community with which they have to interact on a daily basis. These difficulties are more serious for our students who are studying in their own country where English is not the official language. They hardly use English outside classrooms and avoid talking in class as much as they can.

My SQU Experience

Statistical concepts and methods are most effectively taught through real-life examples that the students appreciate and understand. We use the most popular textbooks in the USA for our courses. These textbooks use this approach with US students in mind. Our main problems are:

- Most of the examples and exercises used are completely alien to our students. The discussions meant to maintain the students' interest only serve to put ours off. With limited English they have serious difficulties understanding what is explained and hence tend not to listen to what the instructor is saying. They do not read the textbooks because they contain pages and pages of lengthy explanations and discussions they cannot follow. A direct effect is that students may find the subject boring and quickly lose interest. Their attention then turns to the art of passing tests instead of acquiring the intended knowledge and skills. To pass their tests they use both their class and study times looking through examples, concentrating on what formula to use and where to plug the numbers they have to get the answer. This way they manage to do the mechanics fairly well, but the concepts are almost entirely missed.

- The problem is worse with introductory probability courses where games of chance are extensively used as illustrative examples in textbooks. Most of our students have never seen a deck of playing cards and some may even be offended by discussing card games in a classroom.

The burden of finding strategies to overcome these difficulties falls on the instructor. Statistical terms and concepts such as parameter/statistic, sampling distribution, unbiasedness, consistency, sufficiency, and ideas underlying hypothesis testing are not easy to get across even in the students' own language. To do that in a foreign language is a real challenge. For the Statistics program to be successful, all (or at least most of the) instructors involved should be up to this challenge. This is a time-consuming task with little reward, other than self satisfaction. In SQU the problem is compounded further by the fact that most of the instructors are expatriates on short-term contracts who are more likely to use their time for personal career advancement, rather than time-consuming community service jobs.

What Can Be Done?

For our first Statistics course we produced a manual that contains very brief notes and many samples of previous quizzes, tests, and examinations. It contains a good collection of problems from local culture to motivate the students. The manual was well received by the students, to the extent that students prefer to practice with examples from the manual rather than the textbook.

Textbooks written in English that are brief and to the point are needed. These should include examples and exercises from the students' own culture. A student trying to understand a specific point gets distracted by lengthy explanations and discouraged by thick textbooks to begin with. In a classroom where students' faces clearly indicate that you have got nothing across, it is natural to try explaining more using more examples. In the end of semester evaluation of a course I taught, a student once wrote "The instructor explains things more than needed. He makes simple points difficult." This indicates that, when teaching in a foreign language, lengthy oral or written explanations are not helpful. A better strategy will be to explain concepts and techniques briefly and provide plenty of examples and exercises that will help the students absorb the material by osmosis. The basic statistical concepts can only be effectively communicated to students in their own language. For this reason textbooks should contain a good glossary where technical terms and concepts are explained using the local language.

I expect such textbooks to go a long way to enhance students' understanding of Statistics. An international project can be initiated to produce an introductory statistics textbook, with different versions intended for different geographical areas. The English material will be the same; the examples vary, to some extent, from area to area and glossaries in local languages. Universities in the developing world, naturally, look at western universities as models, and international (western) involvement in such a project is needed for it to succeed. The project will be a major contribution to the promotion of understanding Statistics and excellence in statistical education in developing countries. The international statistical institute takes pride in supporting statistical progress in the developing world. This project can lay the foundation for this progress and hence is worth serious consideration by the institute.

Least Absolute Residuals Procedure

Richard William Farebrother
Honorary Reader in Econometrics
Victoria University of Manchester, Manchester, UK

For $i = 1, 2, \ldots, n$, let $\{x_{i1}, x_{i2}, \ldots, x_{iq}, y_i\}$ represent the ith observation on a set of $q + 1$ variables and suppose that we wish to fit a linear model of the form

$$y_i = x_{i1}\beta_1 + x_{i2}\beta_2 + \cdots + x_{iq}\beta_q + \epsilon_i$$

to these n observations. Then, for $p > 0$, the L_p-norm fitting procedure chooses values for $b_1, b_2, \ldots, b_q$ to minimise the L_p-norm of the residuals $[\sum_{i=1}^{n} |e_i|^p]^{1/p}$ where, for $i = 1, 2, \ldots, n$, the ith residual is defined by

$$e_i = y_i - x_{i1}b_1 - x_{i2}b_2 - \ldots - x_{iq}b_q.$$

The most familiar L_p-norm fitting procedure, known as the ►least squares procedure, sets $p = 2$ and chooses values for $b_1, b_2, \ldots, b_q$ to minimize the sum of the squared residuals $\sum_{i=1}^{n} e_i^2$.

A second choice, to be discussed in the present article, sets $p = 1$ and chooses $b_1, b_2, \ldots, b_q$ to minimize the sum of the absolute residuals $\sum_{i=1}^{n} |e_i|$.

A third choice sets $p = \infty$ and chooses $b_1, b_2, \ldots, b_q$ to minimize the largest absolute residual $max_{i=1}^{n}|e_i|$.

Setting $u_i = e_i$ and $v_i = 0$ if $e_i \geq 0$ and $u_i = 0$ and $v_i = -e_i$ if $e_i < 0$, we find that $e_i = u_i - v_i$ so that the least absolute residuals (*LAR*) fitting problem chooses $b_1, b_2, \ldots, b_q$ to minimize the sum of the absolute residuals

$$\sum_{i=1}^{n}(u_i + v_i)$$

subject to

$$x_{i1}b_1 + x_{i2}b_2 + \cdots + x_{iq}b_q + U_i - v_i = y_i \quad \text{for } i = 1, 2, \ldots, n$$

$$\text{and} \quad U_i \geq 0, v_i \geq 0 \quad \text{for } i = 1, 2, \ldots, n.$$

The *LAR* fitting problem thus takes the form of a linear programming problem and is often solved by means of a variant of the dual simplex procedure.

Gauss has noted (when $q = 2$) that solutions of this problem are characterized by the presence of a set of q zero residuals. Such solutions are robust to the presence of outlying observations. Indeed, they remain constant under variations in the other $n - q$ observations provided that these variations do not cause any of the residuals to change their signs.

The *LAR* fitting procedure corresponds to the maximum likelihood estimator when the ϵ-disturbances follow a double exponential (Laplacian) distribution. This estimator is more robust to the presence of outlying observations than is the standard least squares estimator which maximizes the likelihood function when the ϵ-disturbances are normal (Gaussian). Nevertheless, the *LAR* estimator has an asymptotic normal distribution as it is a member of Huber's class of M-estimators.

There are many variants of the basic *LAR* procedure but the one of greatest historical interest is that proposed in 1760 by the Croatian Jesuit scientist Rugjer (or Rudjer) Josip Bošković (1711–1787) (Latin: Rogerius Josephus Boscovich; Italian: Ruggiero Giuseppe Boscovich). In his variant of the standard *LAR* procedure, there are two explanatory variables of which the first is constant $x_{i1} = 1$ and the values of b_1 and b_2 are constrained to satisfy the adding-up condition $\sum_{i=1}^{n}(y_i - b_1 - x_{i2}b_2) = 0$ usually associated with the least squares procedure developed by Gauss in 1795 and published by Legendre in 1805. Computer algorithms implementing this variant of the *LAR* procedure with $q \geq 2$ variables are still to be found in the literature.

For an account of recent developments in this area, see the series of volumes edited by Dodge (1987, 1992, 1997, 2002). For a detailed history of the *LAR* procedure, analyzing the contributions of Bošković, Laplace, Gauss, Edgeworth, Turner, Bowley and Rhodes, see Farebrother (1999). And, for a discussion of the geometrical and mechanical representation of the least squares and *LAR* fitting procedures, see Farebrother (2002).

About the Author

Richard William Farebrother was a member of the teaching staff of the Department of Econometrics and Social Statistics in the (Victoria) University of Manchester from 1970 until 1993 when he took early retirement (he has been blind since 1993). From 1993 until 2001 he was an Honorary Reader in Econometrics in the Department of Economic Studies of the same University. He has published three books: *Linear Least Squares Computations* in 1988, *Fitting Linear Relationships: A History of the Calculus of Observations 1750–1900* in 1999, and *Visualizing statistical Models and Concepts* in 2002. He has also published more than 140 research papers in a wide range of subject areas including econometric theory, computer algorithms, statistical distributions, statistical inference, and the history of statistics. Dr. Farebrother was also visiting Associate Professor (1982) at Monash University, Australia, and Visiting Professor (1990) at the Institute for Advanced Studies in Vienna, Austria.

Least Squares

Czesław Stępniak
Professor
Maria Curie-Skłodowska University, Lublin, Poland
University of Rzeszów, Rzeszów, Poland

Least Squares (LS) problem involves some algebraic and numerical techniques used in "solving" overdetermined systems $F(x) \approx b$ of equations, where $b \in R^n$ while $F(x)$ is a column of the form

$$F(x) = \begin{bmatrix} f_1(x) \\ f_2(x) \\ \dots \\ f_{m-1}(x) \\ f_m(x) \end{bmatrix}$$

with entries $f_i = f_i(x)$, $i = 1, \dots n$, where $x = (x_1, \dots, x_p)^T$. The LS problem is *linear* when each f_i is a linear function, and *nonlinear* – if not.

Linear LS problem refers to a system $Ax = b$ of linear equations. Such a system is overdetermined if $n > p$. If $b \notin range(A)$ the system has no proper solution and will be denoted by $Ax \approx b$. In this situation we are seeking for a solution of some optimization problem. The name "Least Squares" is justified by the l_2-norm commonly used as a measure of imprecision.

The LS problem has a clear statistical interpretation in regression terms. Consider the usual regression model

$$y_i = f_i(x_{i1}, \dots, x_{ip}; \beta_1, \dots, \beta_p) + e_i \text{ for } i = 1, \dots, n \qquad (1)$$

where x_{ij}, $i = 1, \dots n, j = 1, \dots p$, are some constants given by experimental design, f_i, $i = 1, \dots n$, are given functions depending on unknown parameters β_j, $j = 1, \dots, p$, while y_i, $i = 1, \dots, n$, are values of these functions, observed with some random errors e_i. We want to estimate the unknown parameters β_i on the basis of the data set $\{x_{ij}, y_i\}$.

In linear regression each f_i is a linear function of type $f_i = \sum_{j=1}^{p} c_{ij}(x_1, \dots, x_n)\beta_j$ and the model (1) may be presented in vector-matrix notation as

$$y = X\beta + e,$$

where $y = (y_1, \dots, y_n)^T$, $e = (e_1, \dots, e_n)^T$ and $\beta = (\beta_1, \dots, \beta_p)^T$, while X is a $n \times p$ matrix with entries x_{ij}. If $e_1, \dots, e_n$ are not correlated with mean zero and a common (perhaps unknown) variance then the problem of Best Linear Unbiased Estimation (BLUE) of β reduces to finding a vector $\widehat{\beta}$ that minimizes the norm $\left\| y - X\widehat{\beta} \right\|_2 = (y - X\widehat{\beta})^T (y - X\widehat{\beta})$

Such a vector is said to be the *ordinary* LS solution of the overparametrized system $X\beta \approx y$. On the other hand the last one reduces to solving the consistent system

$$X^T X\beta = X^T y$$

of linear equations called normal equations. In particular, if $rank(X) = p$ then the system has a unique solution of the form

$$\widehat{\beta} = (X^T X)^{-1} X^T y.$$

For linear regression $y_i = \alpha + \beta x_i + e_i$ with one regressor x the BLU estimators of the parameters α and β may be presented in the convenient form as

$$\widehat{\beta} = \frac{ns_{xy}}{ns^2 x} \quad \text{and} \quad \widehat{\alpha} = \bar{y} - \widehat{\beta}\bar{x},$$

where

$$ns_{xy} = \sum_i x_i y_i - \frac{(\sum_i x_i)(\sum_i y_i)}{n},$$

$$ns_x^2 = \sum_i x_i^2 - \frac{(\sum_i x_i)^2}{n}, \quad \bar{x} = \frac{\sum_i x_i}{n} \quad \text{and} \quad \bar{y} = \frac{\sum_i y_i}{n}$$

For its computation we only need to use a simple pocket calculator.

Example The following table presents the number of residents in thousands (x) and the unemployment rate in % (y) for some cities of Poland. Estimate the parameters β and α.

x_i	131	87	56	312	185	252	157
y_i	8.7	10.2	9.9	6.3	6.1	5.2	11.0

In this case $\sum_i x_i = 1,180$, $\sum_i y_i = 57.4$, $\sum_i x_i^2 = 247,588$ and $\sum_i x_i y_i = 8,713$. Therefore $ns_x^2 = 48,673.71$ and $ns_{xy} = -963$. Thus $\widehat{\beta} = -0.02$ and $\widehat{\alpha} = 11.77$ and hence $f(x) = -0.02x + 11.77$.

If the variance–covariance matrix of the error vector e coincides (except a multiplicative scalar σ^2) with a positive definite matrix V then the Best Linear Unbiased estimation reduces to the minimization of $(y - X\widehat{\beta})^T V(y - X\widehat{\beta})$, called the *weighed* LS problem. Moreover, if $rank(X) = p$ then its solution is given in the form

$$\widehat{\beta} = (X^T V^{-1} X)^{-1} X^T V^{-1} y.$$

It is worth to add that a nonlinear LS problem is more complicated and its explicit solution is usually not known. Instead of this some algorithms are suggested.

Total least squares problem. The problem has been posed in recent years in numerical analysis as an alternative for the LS problem in the case when all data are affected by errors.

Consider an overdetermined system of n linear equations $Ax \approx b$ with k unknown x. The TLS problem consists in minimizing the Frobenius norm

$$\left\| [A, b] - \left[\widehat{A}, \widehat{b}\right] \right\|_F$$

for all $\widehat{A} \in R^{n \times k}$ and $\widehat{b} \in range(\widehat{A})$, where the Frobenius norm is defined by $\|(a_{ij})\|_F = \sum_{i,j} a_{ij}$. Once a minimizing $\left[\widehat{A}, \widehat{b}\right]$ is found, then any x satisfying $\widehat{A}x = \widehat{b}$ is called a *TLS solution* of the initial system $Ax \approx b$.

The trouble is that the minimization problem may not be solvable, or its solution may not be unique. As an example one can set

$$A = \begin{bmatrix} 1 & 0 \\ 0 & 0 \end{bmatrix} \text{ and } b = \begin{bmatrix} 0 \\ 2 \end{bmatrix}.$$

It is known that the TLS solution (if exists) is always better than the ordinary LS in the sense that the correction $b - A\widehat{x}$ has smaller l_2-norm. The main tool in solving the TLS problems is the following Singular Value Decomposition:

For any matrix A of $n \times k$ with real entries there exist orthonormal matrices $P = \left[p_1, \ldots, p_n\right]$ and $Q = \left[q_1, \ldots, q_k\right]$ such that

$$P^T AQ = diag(\sigma_1, \ldots, \sigma_m), \text{ where } \sigma_1 \geq \cdots \geq \sigma_m \text{ and } m = \min\{n, k\}.$$

Lévy Processes

Mohamed Abdel-Hameed
Professor
United Arab Emirates University, Al Ain, United Arab Emirates

Introduction

Lévy processes have become increasingly popular in engineering (reliability, dams, telecommunication) and mathematical finance. Their applications in reliability stems from the fact that they provide a realistic model for the degradation of devices, while their applications in the mathematical theory of dams as they provide a basis for describing the water input of dams. Their popularity in finance is because they describe the financial markets in a more accurate way than the celebrated Black–Scholes model. The latter model assumes that the rate of returns on assets are normally distributed, thus the process describing the asset price over time is continuous process. In reality, the asset prices have jumps or spikes, and the asset returns exhibit fat tails and ►skewness, which negates the normality assumption inherited in the Black–Scholes model.

Because of the deficiencies in the Black–Scholes model researchers in mathematical finance have been trying to find more suitable models for asset prices. Certain types of Lévy processes have been found to provide a good model for creep of concrete, fatigue crack growth, corroded steel gates, and chloride ingress into concrete. Furthermore, certain types of Lévy processes have been used to model the water input in dams.

In this entry, we will review Lévy processes and give important examples of such processes and state some references to their applications.

Lévy Processes

A stochastic process $X = \{X_t, t \geq 0\}$ that has right continuous sample paths with left limits is said to be a Lévy process if the following hold:

1. X has *stationary increments*, i.e., for every $s, t \geq 0$, the distribution of $X_{t+s} - X_t$ is independent of t.
2. X has independent increments, i.e., for every $t, s \geq 0$, $X_{t+s} - X_t$ is independent of $(X_u, u \leq t)$.
3. X is stochastically continuous, i.e., for every $t \geq 0$ and $\epsilon > 0$:

$$lim_{s \to t} P(|X_t - X_s| > \epsilon) = 0.$$

That is to say a Lévy process is a stochastically continuous process with stationary and independent increments whose sample paths are right continuous with left hand limits.

If $\Phi(z)$ is the characteristic function of a Lévy process, then its characteristic component $\varphi(z) \stackrel{def}{=} \frac{\ln \Phi(z)}{t}$ is of the form

$$\left\{ iza - \frac{z^2 b}{2} + \int_R [\exp(izx) - 1 - izx I_{\{|x|<1\}}] v(dx) \right\}$$

where $a \in R$, $b \in R_+$ and v is a measure on R satisfying $v(\{0\}) = 0, \int_R (1 \wedge x^2) v(dx) < \infty$.

The measure v characterizes the size and frequency of the jumps. If the measure is infinite, then the process has infinitely many jumps of very small sizes in any small interval. The constant a defined above is called the drift term of the process, and b is the variance (volatility) term.

The Lévy–Itô decomposition identify any Lévy process as the sum of three independent processes, it is stated as follows:

Given any $a \in R$, $b \in R_+$ and measure v on R satisfying $v(\{0\}) = 0, \int_R (1 \wedge x^2) v(dx) < \infty$, there exists a probability space (Ω, F, P) on which a *Lévy* process X is defined. The process X is the sum of three independent processes $\overset{(1)}{X}$, $\overset{(2)}{X}$, and $\overset{(3)}{X}$, where $\overset{(1)}{X}$ is a Brownian motion with drift a and volatility b (in the sense defined below), $\overset{(2)}{X}$ is a compound Poisson process, and $\overset{(3)}{X}$ is a square integrable martingale. The characteristic components of $\overset{(1)}{X}$, $\overset{(2)}{X}$, and $\overset{(3)}{X}$ (denoted by $\overset{(1)}{\varphi}(z)$, $\overset{(2)}{\varphi}(z)$ and $\overset{(3)}{\varphi}(z)$, respectively) are as follows:

$$\overset{(1)}{\varphi}(z) = iza - \tfrac{z^2 b}{2},$$
$$\overset{(2)}{\varphi}(z) = \int_{\{|x| \geq 1\}} (\exp(izx) - 1) v(dx),$$
$$\overset{(3)}{\varphi}(z) = \int_{\{|x|<1\}} (\exp(izx) - 1 - izx) v(dx).$$

Examples of the Lévy Processes

The Brownian Motion

A Lévy process is said to be a Brownian motion (see ►Brownian Motion and Diffusions) with drift μ, and volatility rate σ^2, if $\mu = a$, $b = \sigma^2$, and $v(R) = 0$. Brownian motion is the only nondeterministic Lévy processes with continuous sample paths.

The Inverse Brownian Process

Let X be a Brownian motion with $\mu > 0$ and volatility rate σ^2. For any $x > 0$, let $T_x = \inf\{t : X_t > x\}$. Then T_x is an increasing Lévy process (called inverse Brownian motion), its Lévy measure is given by

$$v(dx) = \frac{1}{\sqrt{2\pi\sigma^2 x^3}} \exp\left(\frac{-x\mu^2}{2\sigma^2}\right).$$

The Compound Poisson Process

The compound Poisson process (see ►Poisson Processes) is a Lévy process where $b = 0$ and v is a finite measure.

The Gamma Process

The gamma process is a nonnegative increasing Lévy process X, where $b = 0$, $a - \int_0^1 x v(dx) = 0$ and its Lévy measure is given by

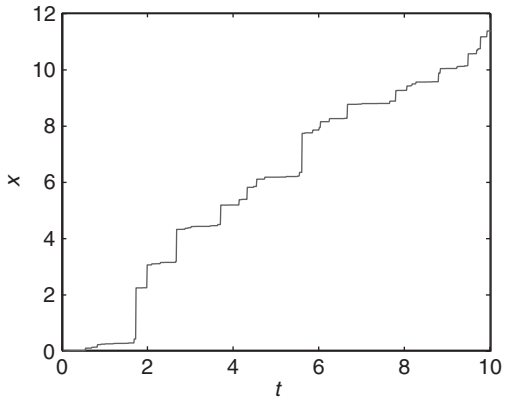
$$v(dx) = \frac{\alpha}{x} exp(-x/\beta) dx, \qquad x > 0$$

where $\alpha, \beta > 0$. It follows that the mean term $(E(X_1))$ and the variance term $(V(X_1))$ for the process are equal to $\alpha\beta$ and $\alpha\beta^2$, respectively.

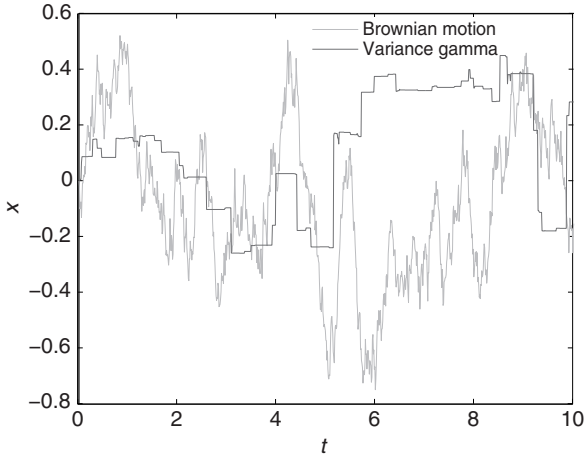
The following is a simulated sample path of a gamma process, where $\alpha = 2$ and $\beta = 0.5$ (Fig. 1).

The Variance Gamma Process

The variance gamma process is a Lévy process that can be represented as either the difference between two independent gamma processes or as a Brownian process subordinated by a gamma process. The latter is accomplished by a random time change, replacing the time of the Brownian process by a gamma process, with a mean term equal to 1. The variance gamma process has three parameters: μ – the



Lévy Processes. Fig. 1 Gamma process



Lévy Processes. Fig. 2 Brownian motion and variance gamma sample paths

Brownian process drift term, σ – the volatility of the Brownian process, and v – the variance term of the the gamma process.

The following are two simulated sample paths, one for a Brownian motion with a drift term $\mu = 0.2$ and volatility term $\sigma = 0.5$ and the other is for a variance gamma process with the same values for the drift term and the volatility terms and $v = 1$ (Fig. 2).

Life Expectancy

Maja Biljan-August
Full Professor
University of Rijeka, Rijeka, Croatia

Life expectancy is defined as the average number of years a person is expected to live from age x, as determined by statistics.

Statistics on life expectancy are derived from a mathematical model known as the ►life table. In order to calculate this indicator, the mortality rate at each age is assumed to be constant. Life expectancy (e_x) can be evaluated at any age and, in a hypothetical stationary population, can be written in discrete form as:

$$e_x = \frac{T_x}{l_x}$$

where x is age; T_x is the number of person-years lived aged x and over; and l_x is the number of survivors at age x according to the life table.

Life expectancy can be calculated for combined sexes or separately for males and females. There can be significant differences between sexes.

Life expectancy at birth (e_0) is the average number of years a newborn child can expect to live if current mortality trends remain constant:

$$e_0 = \frac{T_0}{l_0}$$

where T_0 is the total size of the population and l_0 is the number of births (the original number of persons in the birth cohort).

Life expectancy declines with age. Life expectancy at birth is highly influenced by infant mortality rate. *The paradox of the life table* refers to a situation where life expectancy at birth increases for several years after birth ($e_0 < e_1 < \ldots e_5$ and even beyond). The paradox reflects the higher rates of infant and child mortality in populations in pre-transition and middle stages of the demographic transition.

Life expectancy at birth is a summary measure of mortality in a population. It is a frequently used indicator of health standards and socio-economic living standards. Life expectancy is also one of the most commonly used indicators of social development. This indicator is easily comparable through time and between areas, including countries. Inequalities in life expectancy usually indicate inequalities in health and socio-economic development.

Life expectancy rose throughout human history. In ancient Greece and Rome, the average life expectancy was below 30 years; between the years 1800 and 2000, life expectancy at birth rose from about 30 years to a global average of 67 years, and to more than 75 years in the richest countries (Riley 2001). Furthermore, in most industrialized countries, in the early twenty-first century, life expectancy averaged at about 78 years (WHO). These changes, called the "health transition," are essentially the result of improvements in public health, medicine, and nutrition.

Life expectancy varies significantly across regions and continents: from life expectancies of about 40 years in some central African populations to life expectancies of 80 years and above in many European countries. The more developed regions have an average life expectancy of 76 years, while the population of less developed regions is at birth expected to live an average 12 years less. The two continents that display the most extreme differences in life expectancies are North America (77.6 years) and Africa (49.1 years) where, as of recently, the gap between life expectancies amounts to 29 years (UN, 2000–2005 data).

Countries with the highest life expectancies in the world (82 years) are Australia, Iceland, Italy, Switzerland, and Japan (83 years); Japanese men and women live an average of 79 and 86 years, respectively (WHO 2009).

In countries with a high rate of HIV infection, principally in Sub-Saharan Africa, the average life expectancy is 45 years and below. Some of the world's lowest life expectancies are in Sierra Leone (41 years), Afghanistan (42 years), Lesotho (45 years), and Zimbabwe (45 years).

In nearly all countries, women live longer than men. The world's average life expectancy at birth is 65 years for males and 70 years for females; the gap is about five years. The female-to-male gap is expected to narrow in the more developed regions and widen in the less developed regions. The Russian Federation has the greatest difference in life expectancies between the sexes (13 years less for men), whereas in Tonga, life expectancy for males exceeds that for females by 2 years (WHO 2009).

Life expectancy is assumed to rise continuously. According to estimation by the UN, global life expectancy at birth is likely to rise to an average 74 years by 2045–2050. By 2100, life expectancy is expected to vary across countries from 66 to 97 years. Long-range United Nations population projections predict that by 2300, on average, people can expect to live more than 95 years, from 87 (Liberia) up to 106 years (Japan).

For more details on the calculation of life expectancy, including continuous notation, see Keyfitz (1968, 2005) and Preston et al. (2003).

Life Table

Jan M. Hoem
Professor, Director Emeritus
Max Planck Institute for Demographic Research, Rostock, Germany

The life table is a classical tabular representation of central features of the distribution function F of a positive variable, say X, which normally is taken to represent the lifetime of a newborn individual. The life table was introduced well before modern conventions concerning statistical distributions were developed, and it comes with some special terminology and notation, as follows. Suppose that F has a density $f(x) = \frac{d}{dx}F(x)$ and define *the force of mortality* or *death intensity* at age x as the function

$$\mu(x) = -\frac{d}{dx}\ln\{1 - F(x)\} = \frac{f(x)}{\{1 - F(x)\}}.$$

Heuristically, it is interpreted by the relation $\mu(x)\mathrm{d}x = P\{x < X < x + \mathrm{d}x | X > x\}$. Conversely $F(x) = 1 - \exp\left\{-\int_0^x \mu(s)ds\right\}$. The *survivor function* is defined as $\ell(x) = \ell(0)\{1 - F(x)\}$, normally with $\ell(0) = 100,000$. In mortality applications $\ell(x)$ is the expected number of survivors to exact age x out of an original cohort of 100,000 newborn babies. The *survival probability* is

$$\begin{aligned} {}_tp_x &= P\{X > x + t | X > x\} = \ell(x + t)/\ell(x) \\ &= \exp\left\{-\int_0^t \mu(x + s)ds\right\}, \end{aligned}$$

and the non-survival probability is (the converse) ${}_tq_x = 1 - {}_tp_x$. For $t = 1$ one writes $q_x = {}_1q_x$ and $p_x = {}_1p_x$. In particular, we get $\ell(x + 1) = \ell(x)p_x$. This is a practical recursion formula that permits us to compute all values of $\ell(x)$ once we know the values of p_x for all relevant x.

The life expectancy is $e_0^o = EX = \int_0^\infty \ell(x)dx/\ell(0)$ (The subscript 0 in e_0^o indicates that the expected value is computed at age 0 (i.e., for newborn individuals) and the superscript o indicates that the computation is made in the continuous mode.). The remaining life expectancy at age x is:

$$e_x^o = E(X - x | X > x) = \int_0^\infty \ell(x + t)dt/\ell(x),$$

i.e., it is the expected lifetime remaining to someone who has attained age x.

To turn to the statistical estimation of these various quantities, suppose that the function $\mu(x)$ is piecewise constant, which means that we take it to equal some constant, say μ_j, over each interval (x_j, x_{j+1}) for some partition $\{x_j\}$ of the age axis. For a collection $\{X_i\}$ of independent observations of X, let D_j be the number of X_i that fall in the interval (x_j, x_{j+1}). In mortality applications, this is the number of deaths observed in the given interval. For the cohort of the initially newborn, D_j is the number of individuals who die in the interval (called the *occurrences* in the interval). If individual i dies in the interval, he or she will of course have lived for $X_i - x_j$ time units *during* the interval. Individuals who survive the interval, will have lived for $x_{j+1} - x_j$ time units in the interval, and individuals who do not survive to age x_j, will not have lived during this interval at all. When we aggregate the time units lived in (x_j, x_{j+1}) over all individuals, we get a total R_j which is called the *exposures* for the interval, the idea being that individuals are *exposed to the risk* of death for as long as they live in the interval. In the simple case where there are no relations between the individual parameters μ_j, the collection $\{D_j, R_j\}$ constitutes a statistically sufficient set of observations with a likelihood Λ that satisfies the relation $\ln\Lambda = \sum_j\{-\mu_j R_j + D_j \ln\mu_j\}$ which is easily seen to be maximized by $\hat{\mu}_j = D_j/R_j$. The latter fraction is therefore the maximum-likelihood estimator for μ_j (In some connections an age schedule of mortality will be specified, such as the classical Gompertz–Makeham function $\mu_x = a + bc^x$, which does represent a relationship between the intensity values at the different ages x, normally for single-year age groups. Maximum likelihood estimators can then be found by plugging this functional specification of the intensities into the likelihood function, finding the values $\hat{a}, \hat{b}$, and $\hat{c}$ that maximize Λ, and using $\hat{a} + \hat{b}\hat{c}^x$ for the intensity in the rest of the life table computations. Methods that do not amount to maximum likelihood estimation will sometimes be used because they involve simpler computations. With some luck they provide starting values for the iterative process that must usually be applied to produce the maximum likelihood estimators. For an example, see Forsén (1979)). This whole schema can be extended trivially to cover censoring (*withdrawals*) provided the censoring mechanism is unrelated to the mortality process.

If the force of mortality is constant over a single-year age interval $(x, x+1)$, say, and is estimated by $\hat{\mu}_x$ in this interval, then $\hat{p}_x = e^{-\hat{\mu}_x}$ is an estimator of the single-year survival probability p_x. This allows us to estimate the survival function recursively for all corresponding ages, using $\hat{\ell}(x+1) = \hat{\ell}(x)\hat{p}_x$ for $x = 0, 1, \ldots$, and the rest of the life table computations follow suit. Life table construction consists in the estimation of the parameters and the tabulation of functions like those above from empirical data. The data can be for age at death for individuals, as in the example indicated above, but they can also be observations of duration until recovery from an illness, of intervals between births, of time until breakdown of some piece of machinery, or of any other positive duration variable.

So far we have argued as if the life table is computed for a group of mutually independent individuals who have all been observed in parallel, essentially a cohort that is followed from a significant common starting point (namely from birth in our mortality example) and which is diminished over time due to *decrements* (*attrition*) caused by the risk in question and also subject to reduction due to censoring (withdrawals). The corresponding table is then called a *cohort life table*. It is more common, however, to estimate a $\{p_x\}$ schedule from data collected for the members of a population during a limited time period and to use the mechanics of life-table construction to produce a *period life table* from the p_x values.

Life table techniques are described in detail in most introductory textbooks in actuarial statistics, ►biostatistics, ►demography, and epidemiology. See, e.g., Chiang (1984), Elandt-Johnson and Johnson (1980), Manton and Stallard (1984), Preston et al. (2001). For the history of the topic, consult Seal (1977), Smith and Keyfitz (1977), and Dupâquier (1996).

Likelihood

Nancy Reid
Professor
University of Toronto, Toronto, ON, Canada

Introduction

The likelihood function in a statistical model is proportional to the density function for the random variable to be observed in the model. Most often in applications of likelihood we have a parametric model $f(y;\theta)$, where the parameter θ is assumed to take values in a subset of $\mathbb{R}^k$, and the variable y is assumed to take values in a subset of $\mathbb{R}^n$: the likelihood function is defined by

$$L(\theta) = L(\theta; y) = cf(y;\theta), \tag{1}$$

where c can depend on y but not on θ. In more general settings where the model is semi-parametric or non-parametric the explicit definition is more difficult, because the density needs to be defined relative to a dominating measure, which may not exist: see Van der Vaart (1996) and Murphy and Van der Vaart (1997). This article will consider only finite-dimensional parametric models.

Within the context of the given parametric model, the likelihood function measures the relative plausibility of various values of θ, for a given observed data point y. Values of the likelihood function are only meaningful relative to each other, and for this reason are sometimes standardized by the maximum value of the likelihood function, although other reference points might be of interest depending on the context.

If our model is $f(y;\theta) = \binom{n}{y}\theta^y(1-\theta)^{n-y}, y = 0, 1, \ldots, n;$ $\theta \in [0,1]$, then the likelihood function is (any function proportional to)

$$L(\theta; y) = \theta^y(1-\theta)^{n-y}$$

and can be plotted as a function of θ for any fixed value of y. The likelihood function is maximized at $\theta = y/n$. This model might be appropriate for a sampling scheme which recorded the number of successes among n independent trials that result in success or failure, each trial having the same probability of success, θ. Another example is the likelihood function for the mean and variance parameters when sampling from a normal distribution with mean μ and variance σ^2:

$$L(\theta; y) = \exp\{-n \log \sigma - (1/2\sigma^2)\Sigma(y_i - \mu)^2\},$$

where $\theta = (\mu, \sigma^2)$. This could also be plotted as a function of μ and σ^2 for a given sample $y_1, \ldots, y_n$, and it is not difficult to show that this likelihood function only depends on the sample through the sample mean $\bar{y} = n^{-1}\Sigma y_i$ and sample variance $s^2 = (n-1)^{-1}\Sigma(y_i - \bar{y})^2$, or equivalently through Σy_i and Σy_i^2. It is a general property of likelihood functions that they depend on the data only through the minimal sufficient statistic.

Inference

The likelihood function was defined in a seminal paper of Fisher (1922), and has since become the basis for most methods of statistical inference. One version of likelihood inference, suggested by Fisher, is to use some rule such as $L(\hat{\theta})/L(\theta) > k$ to define a range of "likely" or "plausible" values of θ. Many authors, including Royall (1997) and Edwards (1960), have promoted the use of plots of the likelihood function, along with interval estimates of plausible values. This approach is somewhat limited, however, as it requires that θ have dimension 1 or possibly 2, or that a likelihood function can be constructed that only depends on a component of θ that is of interest; see section "►Nuisance Parameters" below.

In general, we would wish to calibrate our inference for θ by referring to the probabilistic properties of the inferential method. One way to do this is to introduce a probability measure on the unknown parameter θ, typically called a prior distribution, and use Bayes' rule for conditional probabilities to conclude

$$\pi(\theta \mid y) = L(\theta; y)\pi(\theta) / \int_\theta L(\theta; y)\pi(\theta)d\theta,$$

where $\pi(\theta)$ is the density for the prior measure, and $\pi(\theta \mid y)$ provides a probabilistic assessment of θ after observing $Y = y$ in the model $f(y; \theta)$. We could then make conclusions of the form, "having observed 5 successes in 20 trials, and assuming $\pi(\theta) = 1$, the posterior probability that $\theta > 0.5$ is 0.013," and so on.

This is a very brief description of Bayesian inference, in which probability statements refer to that generated from the prior through the likelihood to the posterior. A major difficulty with this approach is the choice of prior probability function. In some applications there may be an accumulation of previous data that can be incorporated into a probability distribution, but in general there is not, and some rather *ad hoc* choices are often made. Another difficulty is the meaning to be attached to probability statements about the parameter.

Inference based on the likelihood function can also be calibrated with reference to the probability model $f(y; \theta)$, by examining the distribution of $L(\theta; Y)$ as a random function, or more usually, by examining the distribution of various derived quantities. This is the basis for likelihood inference from a frequentist point of view. In particular, it can be shown that $2\log\{L(\hat{\theta}; Y)/L(\theta; Y)\}$, where $\hat{\theta} = \hat{\theta}(Y)$ is the value of θ at which $L(\theta; Y)$ is maximized, is approximately distributed as a χ^2_k random variable, where k is the dimension of θ. To make this precise requires an asymptotic theory for likelihood, which is based on a central limit theorem (see ►Central Limit Theorems) for the *score function*

$$U(\theta; Y) = \frac{\partial}{\partial\theta} \log L(\theta; Y).$$

If $Y = (Y_1, \ldots, Y_n)$ has independent components, then $U(\theta)$ is a sum of n independent components, which under mild regularity conditions will be asymptotically normal. To obtain the χ^2 result quoted above it is also necessary to investigate the convergence of $\hat{\theta}$ to the true value governing the model $f(y; \theta)$. Showing this convergence, usually in probability, but sometimes almost surely, can be difficult: see Scholz (2006) for a summary of some of the issues that arise.

Assuming that $\hat{\theta}$ is consistent for θ, and that $L(\theta; Y)$ has sufficient regularity, the follow asymptotic results can be established:

$$(\hat{\theta} - \theta)^T i(\theta)(\hat{\theta} - \theta) \xrightarrow{d} \chi^2_k, \tag{2}$$

$$U(\theta)^T i^{-1}(\theta) U(\theta) \xrightarrow{d} \chi^2_k, \tag{3}$$

$$2\{\ell(\hat{\theta}) - \ell(\theta)\} \xrightarrow{d} \chi^2_k, \tag{4}$$

where $i(\theta) = E\{-\ell''(\theta; Y); \theta\}$ is the expected Fisher information function, $\ell(\theta) = \log L(\theta)$ is the log-likelihood function, and χ^2_k is the ►chi-square distribution with k degrees of freedom.

These results are all versions of a more general result that the log-likelihood function converges to the quadratic form corresponding to a multivariate normal distribution (see ►Multivariate Normal Distributions), under suitably stated limiting conditions. There is a similar asymptotic result showing that the posterior density is asymptotically

normal, and in fact asymptotically free of the prior distribution, although this result requires that the prior distribution be a proper probability density, i.e., has integral over the parameter space equal to 1.

Nuisance Parameters

In models where the dimension of θ is large, plotting the likelihood function is not possible, and inference based on the multivariate normal distribution for $\hat{\theta}$ or the χ^2_k distribution of the log-likelihood ratio doesn't lead easily to interval estimates for components of θ. However it is possible to use the likelihood function to construct inference for parameters of interest, using various methods that have been proposed to eliminate nuisance parameters.

Suppose in the model $f(y;\theta)$ that $\theta = (\psi, \lambda)$, where ψ is a k_1-dimensional parameter of interest (which will often be 1). The *profile log-likelihood* function of ψ is

$$\ell_P(\psi) = \ell(\psi, \hat{\lambda}_\psi),$$

where $\hat{\lambda}_\psi$ is the *constrained* maximum likelihood estimate: it maximizes the likelihood function $L(\psi, \lambda)$ when ψ is held fixed. The profile log-likelihood function is also called the concentrated log-likelihood function, especially in econometrics. If the parameter of interest is not expressed explicitly as a subvector of θ, then the constrained maximum likelihood estimate is found using Lagrange multipliers.

It can be verified under suitable smoothness conditions that results similar to those at (2 – 4) hold as well for the profile log-likelihood function: in particular

$$2\{\ell_P(\hat{\psi}) - \ell_P(\psi)\} = 2\{\ell(\hat{\psi}, \hat{\lambda}) - \ell(\psi, \hat{\lambda}_\psi)\} \xrightarrow{d} \chi^2_{k_1},$$

This method of eliminating nuisance parameters is not completely satisfactory, especially when there are many nuisance parameters: in particular it doesn't allow for errors in estimation of λ. For example the profile likelihood approach to estimation of σ^2 in the linear regression model (see ▶Linear Regression Models) $y \sim N(X\beta, \sigma^2)$ will lead to the estimator $\hat{\sigma}^2 = \Sigma(y_i - \hat{y}_i)^2/n$, whereas the estimator usually preferred has divisor $n-p$, where p is the dimension of β.

Thus a large literature has developed on improvements to the profile log-likelihood. For Bayesian inference such improvements are "automatically" included in the formulation of the marginal posterior density for ψ:

$$\pi_M(\psi \mid y) \propto \int \pi(\psi, \lambda \mid y) d\lambda,$$

but it is typically quite difficult to specify priors for possibly high-dimensional nuisance parameters. For non-Bayesian inference most modifications to the profile log-likelihood are derived by considering conditional or marginal inference in models that admit factorizations, at least approximately, like the following:

$$f(y;\theta) = f_1(y_1;\psi) f_2(y_2 \mid y_1;\lambda), \quad \text{or}$$
$$f(y;\theta) = f_1(y_1 \mid y_2;\psi) f_2(y_2;\lambda).$$

A discussion of conditional inference and density factorisations is given in Reid (1995). This literature is closely tied to that on higher order asymptotic theory for likelihood. The latter theory builds on saddlepoint and Laplace expansions to derive more accurate versions of (2–4): see, for example, Severini (2000) and Brazzale et al. (2007). The direct likelihood approach of Royall (1997) and others does not generalize very well to the nuisance parameter setting, although Royall and Tsou (2003) present some results in this direction.

Extensions to Likelihood

The likelihood function is such an important aspect of inference based on models that it has been extended to "likelihood-like" functions for more complex data settings. Examples include nonparametric and semi-parametric likelihoods: the most famous semi-parametric likelihood is the proportional hazards model of Cox (1972). But many other extensions have been suggested: to empirical likelihood (Owen 1988), which is a type of nonparametric likelihood supported on the observed sample; to quasi-likelihood (McCullagh 1983) which starts from the score function $U(\theta)$ and works backwards to an inference function; to bootstrap likelihood (Davison et al. 1992); and many modifications of profile likelihood (Barndorff-Nielsen and Cox 1994; Fraser 2003). There is recent interest for multi-dimensional responses Y_i in composite likelihoods, which are products of lower dimensional conditional or marginal distributions (Varin 2008). Reid (2000) concluded a review article on likelihood by stating:

> From either a Bayesian or frequentist perspective, the likelihood function plays an essential role in inference. The maximum likelihood estimator, once regarded on an equal footing among competing point estimators, is now typically the estimator of choice, although some refinement is needed in problems with large numbers of nuisance parameters. The likelihood ratio statistic is the basis for most tests of hypotheses and interval estimates. The emergence of the centrality of the likelihood function for inference, partly due to the large increase in computing power, is one of the central developments in the theory of statistics during the latter half of the twentieth century.

Further Reading

The book by Cox and Hinkley (1974) gives a detailed account of likelihood inference and principles of statistical inference; see also Cox (2006). There are several book-length treatments of likelihood inference, including Edwards (1960), Azzalini (1998), Pawitan (2000), and Severini (2000): this last discusses higher order asymptotic theory in detail, as does Barndorff-Nielsen and Cox (1994), and Brazzale, Davison and Reid (2007). A short review paper is Reid (2000). An excellent overview of consistency results for maximum likelihood estimators is Scholz (2006); see also Lehmann and Casella (1998). Foundational issues surrounding likelihood inference are discussed in Berger and Wolpert (1980).

About the Author

Professor Reid is a Past President of the Statistical Society of Canada (2004–2005). During (1996–1997) she served as the President of the Institute of Mathematical Statistics. Among many awards, she received the Emanuel and Carol Parzen Prize for Statistical Innovation (2008) "for leadership in statistical science, for outstanding research in theoretical statistics and highly accurate inference from the likelihood function, and for influential contributions to statistical methods in biology, environmental science, high energy physics, and complex social surveys." She was awarded the Gold Medal, Statistical Society of Canada (2009) and Florence Nightingale David Award, Committee of Presidents of Statistical Societies (2009). She is Associate Editor of *Statistical Science*, (2008–), *Bernoulli* (2007–) and *Metrika* (2008–).

Limit Theorems of Probability Theory

Alexandr Alekseevich Borovkov
Professor, Head of Probability and Statistics Chair at the Novosibirsk University
Novosibirsk University, Novosibirsk, Russia

Limit Theorems of Probability Theory is a broad name referring to the most essential and extensive research area in Probability Theory which, at the same time, has the greatest impact on the numerous applications of the latter.

By its very nature, Probability Theory is concerned with asymptotic (limiting) laws that emerge in a long series of observations on random events. Because of this, in the early twentieth century even the very definition of probability of an event was given by a group of specialists (R. von Mises and some others) as the limit of the relative frequency of the occurrence of this event in a long row of independent random experiments. The "stability" of this frequency (i.e., that such a limit always exists) was postulated. After the 1930s, Kolmogorov's axiomatic construction of probability theory has prevailed. One of the main assertions in this axiomatic theory is the *Law of Large Numbers* (LLN) on the convergence of the averages of large numbers of random variables to their expectation. This law implies the aforementioned stability of the relative frequencies and their convergence to the probability of the corresponding event.

The LLN is the simplest limit theorem (LT) of probability theory, elucidating the physical meaning of probability. The LLN is stated as follows: if $X, X_1, X_2, \ldots$ is a sequence of i.i.d. random variables,

$$S_n := \sum_{j=1}^{n} X_j,$$

and the expectation $a := \mathbf{E}X$ exists then $n^{-1}S_n \xrightarrow{a.s.} a$ (almost surely, i.e., with probability 1). Thus the value na can be called the *first order approximation* for the sums S_n. The *Central Limit Theorem* (CLT) gives one a more precise approximation for S_n. It says that, if $\sigma^2 := \mathbf{E}(X-a)^2 < \infty$, then the distribution of the standardized sum $\zeta_n := (S_n - na)/\sigma\sqrt{n}$ converges, as $n \to \infty$, to the standard normal (Gaussian) law. That is, for all x,

$$\mathbf{P}(\zeta_n < x) \to \Phi(x) := \frac{1}{\sqrt{2\pi}} \int_{-\infty}^{x} e^{-t^2/2}\,dt.$$

The quantity $n\mathbf{E}\xi + \zeta\sigma\sqrt{n}$, where ζ is a standard normal random variable (so that $\mathbf{P}(\zeta < x) = \Phi(x)$), can be called *the second order approximation* for S_n.

The first LLN (for the Bernoulli scheme) was proved by Jacob Bernoulli in the late 1690s (published posthumously in 1713). The first CLT (also for the Bernoulli scheme) was established by A. de Moivre (first published in 1738 and referred nowadays to as the de Moivre–Laplace theorem). In the beginning of the nineteenth century, P.S. Laplace and C.F. Gauss contributed to the generalization of these assertions and appreciation of their enormous applied importance (in particular, for the *theory of errors of observations*), while later in that century further breakthroughs in both methodology and applicability range of the CLT were achieved by P.L. Chebyshev (1887) and A.M. Lyapunov (1900).

The main directions in which the two aforementioned main LTs have been extended and refined since then are:

1. Relaxing the assumption $\mathbf{E}X^2 < \infty$. When the second moment is infinite, one needs to assume that the "tail" $P(x) := \mathbf{P}(X > x) + \mathbf{P}(X < -x)$ is a function regularly varying at infinity such that the limit $\lim_{x\to\infty} \mathbf{P}(X > x)/P(x)$ exists. Then the distribution of the normalized sum $S_n/\sigma(n)$, where $\sigma(n) := P^{-1}(n^{-1})$, P^{-1} being the generalized inverse of the function P, and we assume that $\mathbf{E}\xi = 0$ when the expectation is finite, converges to one of the so-called stable laws as $n \to \infty$. The ▶characteristic functions of these laws have simple closed-form representations.
2. Relaxing the assumption that the X_j's are identically distributed and proceeding to study the so-called *triangular array scheme*, where the distributions of the summands $X_j = X_{j,n}$ forming the sum S_n depend not only on j but on n as well. In this case, the class of all limit laws for the distribution of S_n (under suitable normalization) is substantially wider: it coincides with the class of the so-called infinitely divisible distributions. An important special case here is the Poisson limit theorem on convergence in distribution of the number of occurrences of rare events to a Poisson law.
3. Relaxing the assumption of independence of the X_j's. Several types of "weak dependence" assumptions on X_j under which the LLN and CLT still hold true have been suggested and investigated. One should also mention here the so-called ergodic theorems (see ▶Ergodic Theorem) for a wide class of random sequences and processes.
4. Refinement of the main LTs and derivation of asymptotic expansions. For instance, in the CLT, bounds of the rate of convergence $\mathbf{P}(\zeta_n < x) - \Phi(x) \to 0$ and

asymptotic expansions for this difference (in the powers of $n^{-1/2}$ in the case of i.i.d. summands) have been obtained under broad assumptions.

5. Studying large deviation probabilities for the sums S_n (theorems on rare events). If $x \to \infty$ together with n then the CLT can only assert that $\mathbf{P}(\zeta_n > x) \to 0$. Theorems on large deviation probabilities aim to find a function $P(x,n)$ such that

$$\frac{\mathbf{P}(\zeta_n > x)}{P(x,n)} \to 1 \quad \text{as} \quad n \to \infty, \quad x \to \infty.$$

The nature of the function $P(x,n)$ essentially depends on the rate of decay of $\mathbf{P}(X > x)$ as $x \to \infty$ and on the "deviation zone," i.e., on the asymptotic behavior of the ratio x/n as $n \to \infty$.

6. Considering observations $X_1, \ldots, X_n$ of a more complex nature – first of all, multivariate random vectors. If $X_j \in \mathbb{R}^d$ then the role of the limit law in the CLT will be played by a d-dimensional normal (Gaussian) distribution with the covariance matrix $\mathbf{E}(X - \mathbf{E}X)(X - \mathbf{E}X)^T$.

The variety of application areas of the LLN and CLT is enormous. Thus, *Mathematical Statistics* is based on these LTs. Let $X_n^* := (X_1, \ldots, X_n)$ be a sample from a distribution F and $F_n^*(u)$ the corresponding empirical distribution function. The fundamental Glivenko–Cantelli theorem (see ▶Glivenko-Cantelli Theorems) stating that $\sup_u |F_n^*(u) - F(u)| \xrightarrow{a.s.} 0$ as $n \to \infty$ is of the same nature as the LLN and basically means that the unknown distribution F can be estimated arbitrary well from the random sample X_n^* of a large enough size n.

The existence of consistent estimators for the unknown parameters $a = \mathbf{E}\xi$ and $\sigma^2 = \mathbf{E}(X - a)^2$ also follows from the LLN since, as $n \to \infty$,

$$a^* := \frac{1}{n}\sum_{j=1}^n X_j \xrightarrow{a.s.} a, \quad (\sigma^2)^* := \frac{1}{n}\sum_{j=1}^n (X_j - a^*)^2$$
$$= \frac{1}{n}\sum_{j=1}^n X_j^2 - (a^*)^2 \xrightarrow{a.s.} \sigma^2.$$

Under additional moment assumptions on the distribution F, one can also construct asymptotic confidence intervals for the parameters a and σ^2, as the distributions of the quantities $\sqrt{n}(a^* - a)$ and $\sqrt{n}\big((\sigma^2)^* - \sigma^2\big)$ converge, as $n \to \infty$, to the normal ones. The same can also be said about other parameters that are "smooth" enough functionals of the unknown distribution F.

The theorem on the ▶asymptotic normality and asymptotic efficiency of maximum likelihood estimators is another classical example of LTs' applications in mathematical statistics (see e.g., Borovkov 1998). Furthermore, in estimation theory and hypotheses testing, one also needs theorems on large deviation probabilities for the respective statistics, as it is statistical procedures with small error probabilities that are often required in applications.

It is worth noting that summation of random variables is by no means the only situation in which LTs appear in Probability Theory.

Generally speaking, the main objective of Probability Theory in applications is finding appropriate stochastic models for objects under study and then determining the distributions or parameters one is interested in. As a rule, the explicit form of these distributions and parameters is not known. LTs can be used to find suitable approximations to the characteristics in question.

At least two possible approaches to this problem should be noted here.

1. Suppose that the unknown distribution F_θ depends on a parameter θ such that, as θ approaches some "critical" value θ_0, the distributions F_θ become "degenerate" in one sense or another. Then, in a number of cases, one can find an approximation for F_θ which is valid for the values of θ that are close to θ_0. For instance, in actuarial studies, ▶queueing theory and some other applications one of the main problems is concerned with the distribution of $\overline{S} := \sup_{k \geq 1}(S_k - \theta k)$, under the assumption that $\mathbf{E}X = 0$. If $\theta > 0$ then $\overline{S}$ is a proper random variable. If, however, $\theta \to 0$ then $\overline{S} \xrightarrow{a.s.} \infty$. Here we deal with the so-called "transient phenomena." It turns out that if $\sigma^2 := \mathrm{Var}\,(X) < \infty$ then there exists the limit

$$\lim_{\theta \downarrow 0} \mathbf{P}(\theta \overline{S} > x) = e^{-2x/\sigma^2}, \quad x > 0.$$

This (Kingman–Prokhorov) LT enables one to find approximations for the distribution of $\overline{S}$ in situations where θ is small.

2. Sometimes one can estimate the "tails" of the unknown distributions, i.e., their asymptotic behavior at infinity. This is of importance in those applications where one needs to evaluate the probabilities of rare events. If the equation $\mathbf{E}e^{\mu(X-\theta)} = 1$ has a solution $\mu_0 > 0$ then, in the above example, one has

$$\mathbf{P}(\overline{S} > x) \sim ce^{-\mu_0 x}, \quad x \to \infty,$$

where c is a known constant. If the distribution F of X is *subexponential* (in this case, $\mathbf{E}e^{\mu(X-\theta)} = \infty$ for any $\mu > 0$) then

$$\mathbf{P}(\overline{S} > x) \sim \frac{1}{\theta}\int_x^\infty (1 - F(t))\,dt, \quad x \to \infty.$$

This LT enables one to find approximations for $\mathbf{P}(\overline{S} > x)$ for large x.

For both approaches, the obtained approximations can be refined.

An important part of Probability Theory is concerned with LTs for *random processes*. Their main objective is to find conditions under which random processes converge, in some sense, to some limit process. An extension of the CLT to that context is the so-called *Functional CLT* (a.k.a. the Donsker–Prokhorov invariance principle) which states that, as $n \to \infty$, the processes $\{\zeta_n(t) := (S_{\lfloor nt \rfloor} - ant)/\sigma\sqrt{n}\}_{t\in[0,1]}$ converge in distribution to the standard Wiener process $\{w(t)\}_{t\in[0,1]}$. The LTs (including large deviation theorems) for a broad class of functionals of the sequence (►random walk) $\{S_1, \ldots, S_n\}$ can also be classified as LTs for ►stochastic processes. The same can be said about Law of iterated logarithm which states that, for an arbitrary $\varepsilon > 0$, the random walk $\{S_k\}_{k=1}^{\infty}$ crosses the boundary $(1-\varepsilon)\sigma\sqrt{2k \ln \ln k}$ infinitely many times but crosses the boundary $(1+\varepsilon)\sigma\sqrt{2k \ln \ln k}$ finitely many times with probability 1. Similar results hold true for trajectories of Wiener processes $\{w(t)\}_{t\in[0,1]}$ and $\{w(t)\}_{t\in[1,\infty)}$.

In mathematical statistics a closely related to functional CLT result says that the so-called "empirical process" $\{\sqrt{n}(F_n^*(u) - F(u))\}_{u\in(-\infty,\infty)}$ converges in distribution to $\{w^0(F(u))\}_{u\in(-\infty,\infty)}$, where $w^0(t) := w(t) - tw(1)$ is the Brownian bridge process. This LT implies ►asymptotic normality of a great many estimators that can be represented as smooth functionals of the empirical distribution function $F_n^*(u)$.

There are many other areas in Probability Theory and its applications where various LTs appear and are extensively used. For instance, convergence theorems for ►martingales, asymptotics of extinction probability of a branching processes and conditional (under non-extinction condition) LTs on a number of particles etc.

Linear Mixed Models

Geert Molenberghs
Professor
Universiteit Hasselt & Katholieke Universiteit Leuven, Leuven, Belgium

In observational studies, repeated measurements may be taken at almost arbitrary time points, resulting in an extremely large number of time points at which only one

or only a few measurements have been taken. Many of the parametric covariance models described so far may then contain too many parameters to make them useful in practice, while other, more parsimonious, models may be based on assumptions which are too simplistic to be realistic. A general, and very flexible, class of parametric models for continuous longitudinal data is formulated as follows:

$$\boldsymbol{y_i}|\boldsymbol{b_i} \sim N(X_i\boldsymbol{\beta} + Z_i\boldsymbol{b_i}, \Sigma_i), \quad (1)$$

$$\boldsymbol{b_i} \sim N(\mathbf{0}, D), \quad (2)$$

where X_i and Z_i are $(n_i \times p)$ and $(n_i \times q)$ dimensional matrices of known covariates, $\boldsymbol{\beta}$ is a p-dimensional vector of regression parameters, called the fixed effects, D is a general $(q \times q)$ covariance matrix, and Σ_i is a $(n_i \times n_i)$ covariance matrix which depends on i only through its dimension n_i, i.e., the set of unknown parameters in Σ_i will not depend upon i. Finally, $\boldsymbol{b_i}$ is a vector of subject-specific or random effects.

The above model can be interpreted as a linear regression model (see ►Linear Regression Models) for the vector $\boldsymbol{y_i}$ of repeated measurements for each unit separately, where some of the regression parameters are specific (random effects, $\boldsymbol{b_i}$), while others are not (fixed effects, $\boldsymbol{\beta}$). The distributional assumptions in (2) with respect to the random effects can be motivated as follows. First, $\mathrm{E}(\boldsymbol{b_i}) = \mathbf{0}$ implies that the mean of $\boldsymbol{y_i}$ still equals $X_i\boldsymbol{\beta}$, such that the fixed effects in the random-effects model (1) can also be interpreted marginally. Not only do they reflect the effect of changing covariates within specific units, they also measure the marginal effect in the population of changing the same covariates. Second, the normality assumption immediately implies that, marginally, $\boldsymbol{y_i}$ also follows a normal distribution with mean vector $X_i\boldsymbol{\beta}$ and with covariance matrix $V_i = Z_iDZ_i' + \Sigma_i$.

Note that the random effects in (1) implicitly imply the marginal covariance matrix V_i of $\boldsymbol{y_i}$ to be of the very specific form $V_i = Z_iDZ_i' + \Sigma_i$. Let us consider two examples under the assumption of conditional independence, i.e., assuming $\Sigma_i = \sigma^2 I_{n_i}$. First, consider the case where the random effects are univariate and represent unit-specific intercepts. This corresponds to covariates Z_i which are n_i-dimensional vectors containing only ones.

The marginal model implied by expressions (1) and (2) is

$$\boldsymbol{y_i} \sim N(X_i\boldsymbol{\beta}, V_i), \quad V_i = Z_iDZ_i' + \Sigma_i$$

which can be viewed as a multivariate linear regression model, with a very particular parameterization of the covariance matrix V_i.

With respect to the estimation of unit-specific parameters $\boldsymbol{b_i}$, the posterior distribution of $\boldsymbol{b_i}$ given the observed data $\boldsymbol{y_i}$ can be shown to be (multivariate) normal with mean vector equal to $DZ_i'V_i^{-1}(\boldsymbol{\alpha})(\boldsymbol{y_i} - X_i\boldsymbol{\beta})$. Replacing $\boldsymbol{\beta}$ and $\boldsymbol{\alpha}$ by their maximum likelihood estimates, we obtain the so-called empirical Bayes estimates $\widehat{\boldsymbol{b_i}}$ for the $\boldsymbol{b_i}$. A key property of these EB estimates is shrinkage, which is best illustrated by considering the prediction $\widehat{\boldsymbol{y_i}} \equiv X_i\widehat{\boldsymbol{\beta}} + Z_i\widehat{\boldsymbol{b_i}}$ of the ith profile. It can easily be shown that

$$\widehat{\boldsymbol{y_i}} = \Sigma_i V_i^{-1} X_i\widehat{\boldsymbol{\beta}} + \left(I_{n_i} - \Sigma_i V_i^{-1}\right)\boldsymbol{y_i},$$

which can be interpreted as a weighted average of the population-averaged profile $X_i\widehat{\boldsymbol{\beta}}$ and the observed data $\boldsymbol{y_i}$, with weights $\Sigma_i V_i^{-1}$ and $I_{n_i} - \Sigma_i V_i^{-1}$, respectively. Note that the "numerator" of $\Sigma_i V_i^{-1}$ represents within-unit variability and the "denominator" is the overall covariance matrix V_i. Hence, much weight will be given to the overall average profile if the within-unit variability is large in comparison to the between-unit variability (modeled by the random effects), whereas much weight will be given to the observed data if the opposite is true. This phenomenon is referred to as shrinkage toward the average profile $X_i\widehat{\boldsymbol{\beta}}$. An immediate consequence of shrinkage is that the EB estimates show less variability than actually present in the random-effects distribution, i.e., for any linear combination $\boldsymbol{\lambda}$ of the random effects,

$$\mathrm{var}(\lambda'\widehat{\boldsymbol{b_i}}) \leq \mathrm{var}(\lambda'\boldsymbol{b_i}) = \lambda' D\lambda.$$

Linear Regression Models

Raoul LePage
Professor
Michigan State University, East Lansing, MI, USA

► I did not want proof, because the theoretical exigencies of the problem would afford that. What I wanted was to be started in the right direction.

(F. Galton)

The *linear regression model* of statistics is any functional relationship $y = f(x, \beta, \varepsilon)$ involving a *dependent* real-valued variable y, *independent* variables x, *model parameters* β and *random variables* ε, such that a measure of central tendency for y in relation to x termed the *regression function* is linear in β. Possible regression functions include the conditional mean $E(y|x, \beta)$ (as when β is itself random as in Bayesian approaches), conditional medians, quantiles or other forms. Perhaps y is corn yield from a given plot of earth and variables x include levels of water, sunlight, fertilization, discrete variables identifying the genetic variety of seed, and combinations of these intended to model interactive effects they may have on y. The form of this linkage is specified by a function f known to the experimenter, one that depends upon parameters β whose values are not known, and also upon unseen random errors ε about which statistical assumptions are made. These models prove surprisingly flexible, as when localized linear regression models are knit together to estimate a regression function nonlinear in β. Draper and Smith (1981) is a plainly written elementary introduction to linear regression models, Rao (1965) is one of many established general references at the calculus level.

Aspects of Data, Model and Notation

Suppose a time varying sound signal is the superposition of sine waves of unknown amplitudes at two fixed known frequencies embedded in white noise background $y[t] = \beta_1 + \beta_2 \sin[.2t] + \beta_3 \sin[.35t] + \varepsilon$. We write $\beta_1 + \beta_2 x_2 + \beta_3 x_3 + \varepsilon$ for $\beta = (\beta_1, \beta_2, \beta_3), x = (x_1, x_2, x_3), x_1 \equiv 1, x_2(t) = \sin[.2t], x_3(t) = \sin[.35t], t \geq 0$. A natural choice of regression function is $m(x, \beta) = E(y|x, \beta) = \beta_1 + \beta_2 x_2 + \beta_3 x_3$ provided $E\varepsilon \equiv 0$. In the *classical linear regression model* one assumes for different instances "i" of observation that random errors satisfy $E\varepsilon_i \equiv 0$, $E\varepsilon_i \varepsilon_k \equiv \sigma^2 > 0$, $i = k \leq n$, $E\varepsilon_i \varepsilon_k \equiv 0$ otherwise. Errors in linear regression models typically depend upon instances i at which we select observations and may in some formulations depend also on the values of x associated with instance i (perhaps the

errors are correlated and that correlation depends upon the x values). What we observe are y_i and associated values of the independent variables x. That is, we observe $(y_i, 1, \sin[.2t_i], \sin[.35t_i]), i \le n$. The linear model on data may be expressed $y = x\beta + \varepsilon$ with y = column vector $\{y_i,\ i \le n\}$, likewise for ε, and matrix x (the *design matrix*) whose $3n$ entries are $x_{ik} = x_k[t_i]$.

Terminology

Independent variables, as employed in this context, is misleading. It derives from language used in connection with mathematical equations and does not refer to statistically independent random variables. Independent variables may be of any dimension, in some applications functions or surfaces. If y is not scalar-valued the model is instead a *multivariate linear regression*. In some versions either x, β or both may also be random and subject to statistical models. Do not confuse multivariate linear regression with *multiple linear regression* which refers to a model having more than one non-constant independent variable.

General Remarks on Fitting Linear Regression Models to Data

Early work (the classical linear model) emphasized independent identically distributed (i.i.d.) additive *normal* errors in linear regression where ▶*least squares* has particular advantages (connections with ▶multivariate normal distributions are discussed below). In that setup least squares would arguably be a principle method of fitting linear regression models to data, perhaps with modifications such as Lasso or other constrained optimizations that achieve reduced sampling variations of coefficient estimators while introducing bias (Efron et al. 2004). Absent a breakthrough enlarging the applicability of the classical linear model other methods gain traction such as Bayesian methods (▶Markov Chain Monte Carlo having enabled their calculation); Non-parametric methods (good performance relative to more relaxed assumptions about errors); Iteratively Reweighted least squares (having under some conditions behavior like maximum likelihood estimators without knowing the precise form of the likelihood). The Dantzig selector is good news for dealing with far fewer observations than independent variables when a relatively small fraction of them matter (Candès and Tao 2007).

Background

C.F. Gauss may have used least squares as early as 1795. In 1801 he was able to predict the apparent position at which asteroid Ceres would re-appear from behind the sun after it had been lost to view following discovery only 40 days before. Gauss' prediction was well removed from all others and he soon followed up with numerous other high-caliber successes, each achieved by fitting relatively simple models motivated by Keppler's Laws, work at which he was very adept and quick. These were fits to imperfect, sometimes limited, yet fairly precise data. Legendre (1805) published a substantive account of least squares following which the method became widely adopted in astronomy and other fields. See Stigler (1986).

By contrast Galton (1877), working with what might today be described as "low correlation" data, discovered deep truths not already known by fitting a straight line. No theoretical model previously available had prepared Galton for these discoveries which were made in a study of his own data w = standard score of weight of parental sweet pea seed(s), y = standard score of seed weights(s) of their immediate issue. Each sweet pea seed has but one parent and the distributions of x and y the same. Working at a time when correlation and its role in regression were yet unknown, Galton found to his astonishment a nearly perfect straight line tracking points (parental seed weight w, median filial seed weight $m(w)$). Since for this data $s_y \sim s_w$ this was the least squares line (also the regression line since the data was bivariate normal) and its slope was $rs_y/s_w = r$ (the correlation). Medians $m(w)$ being essentially equal to means of y for each w greatly facilitated calculations owing to his choice to select equal numbers of parent seeds at weights $0, \pm1, \pm2, \pm3$ standard deviations from the mean of w. Galton gave the name co-relation (later correlation) to the slope $\sim$ 0.33 of this line and for a brief time thought it might be a universal constant. Although the correlation was small, this slope nonetheless gave measure to the previously vague principle of reversion (later regression, as when larger parental examples beget offspring typically not quite so large). Galton deduced the general principle that if $0 < r < 1$ then for a value $w > Ew$ the relation $Ew < m(w) < w$ follows. Having sensibly selected equal numbers of parental seeds at intervals may have helped him observe that points (w, y) departed on each vertical from the regression line by statistically independent $N(0, \theta^2)$ random residuals whose variance $\theta^2 > 0$ was the same for all w. Of course this likewise amazed him and by 1886 he had identified all these properties as a consequence of bivariate normal observations (w, y), (Galton 1886).

Echoes of those long ago events reverberate today in our many statistical models "driven," as we now proclaim, by random errors subject to ever broadening statistical modeling. In the beginning it was very close to truth.

Aspects of Linear Regression Models

Data of the real world seldom conform exactly to any deterministic mathematical model $y = f(x, \beta)$ and through the device of incorporating random errors we have now an established paradigm for fitting models to data (x, y) by statistically estimating model parameters. In consequence we obtain methods for such purposes as predicting what will be the average response y to particular given inputs x; providing *margins of error* (and *prediction error*) for various quantities being estimated or predicted, tests of hypotheses and the like. It is important to note in all this that more than one statistical model may apply to a given problem, the function f and the other model components differing among them. Two statistical models may disagree substantially in structure and yet neither, either or both may produce useful results. In this respect statistical modeling is more a matter of how much we gain from using a statistical model and whether we trust and can agree upon the assumptions placed on the model, at least as a practical expedient. In some cases the regression function conforms precisely to underlying mathematical relationships but that does not reflect the majority of statistical practice. It may be that a given statistical model, although far from being an underlying truth, confers advantage by capturing some portion of the variation of y vis-a-vis x. The method *principle components,* which seeks to find relatively small numbers of linear combinations of the independent variables that together account for most of the variation of y, illustrates this point well. In one application electromagnetic theory was used to generate by computer an elaborate database of theoretical responses of an induced electromagnetic field near a metal surface to various combinations of flaws in the metal. The role of principle components and linear modeling was to establish a simple model reflecting those findings so that a portable device could be devised to make detections in real time based on the model.

If there is any weakness to the statistical approach it lies in the fact that margins of error, statistical tests and the like can be seriously incorrect even if the predictions afforded by a model have apparent value. Refer to Hinkelmann and Kempthorne (2008), Berk (2004), Freedman (2005), Freedman (1991).

Classical Linear Regression Model and Least Squares

The classical linear regression model may be expressed $y = x\beta + \varepsilon$, an abbreviated matrix formulation of the system of equations in which random errors ε are assumed to satisfy $E\varepsilon_I \equiv 0, E\varepsilon_i^2 \equiv \sigma^2 > 0, i \le n$:

$$y_i = x_{i1}\beta_1 + \cdots + x_{ip}\beta_p + \varepsilon_i,\ i \le n. \tag{1}$$

The interpretation is that response y_i is observed for the ith sample in conjunction with numerical values $(x_{i1}, \ldots, x_{ip})$ of the independent variables. If these errors $\{\varepsilon_I\}$ are jointly normally distributed (and therefore statistically independent having been assumed to be uncorrelated) and if the matrix $x^{\mathrm{tr}}x$ is non-singular then the maximum likelihood (ML) estimates of the model coefficients $\{\beta_k, k \le p\}$ are produced by ordinary least squares (LS) as follows:

$$\beta_{ML} = \beta_{LS} = (x^{\mathrm{tr}}x)^{-1}x^{\mathrm{tr}}y = \beta + M\varepsilon \tag{2}$$

for $M = (x^{\mathrm{tr}}x)^{-1}x^{\mathrm{tr}}$ with x^{tr} denoting matrix transpose of x and $(x^{\mathrm{tr}}x)^{-1}$ the matrix inverse. These coefficient estimates β_{LS} are linear functions in y and satisfy the Gauss–Markov properties (3)(4):

$$E(\beta_{LS})_k = \beta_k, k \le p. \tag{3}$$

and, among all unbiased estimators β_k^* (of β_k) that are linear in y,

$$E((\beta_{LS})_k - \beta_k)^2 \le E\left(\beta_k^* - \beta_k\right)^2, \text{ for every } k \le p. \tag{4}$$

Least squares estimator (2) is frequently employed without the assumption of normality owing to the fact that properties (3)(4) must hold in that case as well. Many statistical distributions F, t, *chi-square* have important roles in connection with model (1) either as exact distributions for quantities of interest (normality assumed) or more generally as limit distributions when data are suitably enriched.

Algebraic Properties of Least Squares

Setting all randomness assumptions aside we may examine the algebraic properties of least squares. If $y = x\beta + \varepsilon$ then $\beta_{LS} = My = M(x\beta + \varepsilon) = \beta + M\varepsilon$ as in (2). That is, the least squares estimate of model coefficients acts on $x\beta + \varepsilon$ returning β plus the result of applying least squares to ε. This has nothing to do with the model being correct or ε being error but is purely algebraic. If ε itself has the form $xb + e$ then $M\varepsilon = b + Me$. Another useful observation is that if x has first column identically one, as would typically be the case for a model with constant term, then each row $M_k, k > 1$, of M satisfies $1.M_k = 0$ (i.e., M_k is a *contrast*) so $(\beta_{LS})_k = \beta_k + M_k.\varepsilon$ and $M_k.(\varepsilon + c) = M_k.\varepsilon$ so ε may as well be assumed to be centered for $k > 1$. There are many of these interesting algebraic properties such as $s^2(y - x\beta_{LS}) = (1 - R^2)s^2(y)$ where $s(.)$ denotes the sample standard deviation and R is the *multiple correlation* defined as the correlation between y and the *fitted values* $x\beta_{LS}$. Yet another algebraic identity, this one involving

an interplay of permutations with projections, is exploited to help establish for *exchangeable* errors ε, and contrasts v, a permutation bootstrap of least squares residuals that consistently estimates the *conditional sampling distribution* of $v.(\beta_{LS} - \beta)$ conditional on the ▶order statistics of ε. (See LePage and Podgorski 1996). Freedman and Lane in 1983 advocated tests based on permutation bootstrap of residuals as a descriptive method.

Generalized Least Squares

If errors ε are $N(0, \Sigma)$ distributed for a covariance matrix Σ known up to a constant multiple then the maximum likelihood estimates of coefficients β are produced by a *generalized* least squares solution retaining properties (3)(4) (any positive multiple of Σ will produce the same result) given by:

$$\beta_{ML} = (x^{\mathrm{tr}}\Sigma^{-1}x)^{-1}x^{\mathrm{tr}}\Sigma^{-1}y = \beta + (x^{\mathrm{tr}}\Sigma^{-1}x)^{-1}x^{\mathrm{tr}}\Sigma^{-1}\varepsilon. \quad (5)$$

Generalized least squares solution (5) retains properties (3)(4) even if normality is not assumed. It must not be confused with ▶*generalized linear models* which refers to models equating moments of y to nonlinear functions of $x\beta$.

A very large body of work has been devoted to linear regression models and the closely related subject areas of experimental design, ▶analysis of variance, principle component analysis and their consequent distribution theory.

Reproducing Kernel Generalized Linear Regression Model

Parzen (1961, Sect. 6) developed the reproducing kernel framework extending generalized least squares to spaces of arbitrary finite or infinite dimension when the random error function $\varepsilon = \{\varepsilon(t), t \in T\}$ has zero means $E\varepsilon(t) \equiv 0$ and a covariance function $K(s,t) = E\varepsilon(s)\varepsilon(t)$ that is assumed known up to some positive constant multiple. In this formulation:

$$y(t) = m(t) + \varepsilon(t),\ t \in T,$$
$$m(t) = Ey(t) = \Sigma_i \beta_i w_i(t),\ t \in T,$$

where $w_i(.)$ are *known* linearly independent functions in *the reproducing kernel Hilbert* (*RKHS*) *space* $H(K)$ of the kernel K. For reasons having to do with singularity of Gaussian measures it is assumed that the series defining m is convergent in H(K). Parzen extends to that context and solves the problem of best linear unbiased estimation of the model coefficients β and more generally of *estimable* linear functions of them, developing confidence regions, prediction intervals, exact or approximate distributions, tests and other matters of interest, and establishing the Gauss–Markov properties (3)(4). The *RKHS* setup has been examined from an on-line learning perspective (Vovk 2008).

Joint Normal Distributed (*x*, *y*) as Motivation for the Linear Regression Model and Least Squares

For the moment, think of (x, y) as following a multivariate normal distribution, as might be the case under process control or in natural systems. The (regular) conditional expectation of y relative to x is then, for some β:

$$E(y|x) = Ey + E((y - Ey)|x) = Ey + x.\beta \text{ for every } x$$

and the discrepancies $y - E(y|x)$ are for each x distributed $N(0, \sigma^2)$ for a fixed σ^2, independent for different x.

Comparing Two Basic Linear Regression Models

Freedman (1981) compares the analysis of two superficially similar but differing models:

Errors model: Model (1) above.

Sampling model: Data $(x_{i1}, \ldots, x_{ip}, y_i), i \le n$ represent a *random sample* from a finite population (e.g., an actual physical population).

In the sampling model, $\{\varepsilon_i\}$ are simply the *residual discrepancies* y-$x\beta_{LS}$ of a least squares fit of linear model $x\beta$ *to the population*. Galton's seed study is an example of this if we regard his data (w, y) as resulting from equal probability without-replacement random sampling of a population of pairs (w, y) with w restricted to be at $0, \pm1, \pm2, \pm3$ standard deviations from the mean. Both with and without-replacement equal-probability sampling are considered by Freedman. Unlike the errors model there is no assumption in the sampling model that the population linear regression model is in any way correct, although least squares may not be recommended if the population residuals depart significantly from i.i.d. normal. Our only purpose is to estimate the coefficients of the population *LS* fit of the model using *LS* fit of the model to our sample, give estimates of the likely proximity of our sample least squares fit to the population fit and estimate the quality of the population fit (e.g., multiple correlation).

Freedman (1981) established the applicability of Efron's Bootstrap to each of the two models above but under different assumptions. His results for the sampling model are a textbook application of Bootstrap since a description of the sampling theory of least squares estimates for the sampling model has complexities largely, as had been said, out of the way when the Bootstrap approach is used. It would be an interesting exercise to examine data, such as Galton's

seed data, analyzing it by the two different models, obtaining confidence intervals for the estimated coefficients of a straight line fit in each case to see how closely they agree.

Balancing Good Fit Against Reproducibility

A balance in the linear regression model is necessary. Including too many independent variables in order to assure a close fit of the model to the data is called overfitting. Models over-fit in this manner tend not to work with fresh data, for example to predict y from a fresh choice of the values of the independent variables. Galton's regression line, although it did not afford very accurate predictions of y from w, owing to the modest correlation ~ 0.33, was arguably best for his bi-variate normal data (w, y). Tossing in another independent variable such as w^2 for a parabolic fit would have over-fit the data, possibly spoiling discovery of the principle of regression to mediocrity.

A model might well be used even when it is understood that incorporating additional independent variables will yield a better fit to data and a model closer to truth. How could this be? If the more parsimonious choice of x accounts for enough of the variation of y in relation to the variables of interest to be useful and if its fewer coefficients β are estimated more reliably perhaps. Intentional use of a simpler model might do a reasonably good job of giving us the estimates we need but at the same time violate assumptions about the errors thereby invalidating confidence intervals and tests. Gauss needed to come close to identifying the location at which Ceres would appear. Going for too much accuracy by complicating the model risked overfitting owing to the limited number of observations available.

One possible resolution to this tradeoff between reliable estimation of a few model coefficients, versus the risk that by doing so too much model related material is left in the error term, is to include all of several hierarchically ordered layers of independent variables, more than may be needed, then remove those that the data suggests are not required to explain the greater share of the variation of y (Raudenbush and Bryk 2001). New results on data compression (Candès and Tao 2007) may offer fresh ideas for reliably removing, in some cases, less relevant independent variables without first arranging them in a hierarchy.

Regression to Mediocrity Versus Reversion to Mediocrity or Beyond

Regression (when applicable) is often used to prove that a high performing group on some scoring, i.e., $X > c > EX$, will not average so highly on another scoring Y, as they do on X, i.e., $E(Y|X > c) < E(X|X > c)$. Termed reversion to mediocrity or beyond by Samuels (1991) this property is easily come by when X, Y have the same distribution. The following result and brief proof are Samuels' except for clarifications made here (***italics***). These comments are addressed only to the *formal mathematical proof* of the paper.

Proposition Let random variables X, Y be *identically distributed* with finite mean EX and fix any $c > \max(0, EX)$. If $P(X > c \text{ and } Y > c) < P(Y > c)$ then there is reversion to mediocrity or beyond for that c.

Proof For any given $c > \max(0, EX)$ define the difference J of indicator random variables $J = (X > c) - (Y > c)$. J is zero unless one indicator is 1 and the other 0. YJ is less *or equal* $cJ = c$ on $J = 1$ (i.e., on $X > c, Y \le c$) and YJ is *strictly less* than $cJ = -c$ on $J = -1$ (i.e., on $X \le c, Y > c$). *Since the event* $J = -1$ *has positive probability by assumption*, the previous implies $E\,YJ < c\,EJ$ and so

$$EY(X > c) = E(Y(Y > c) + YJ) = EX(X > c) + E\,YJ < EX(X > c) + cEJ = EX(X > c),$$

yielding $E(Y|X > c) < E(X|X > c)$. □

Local Asymptotic Mixed Normal Family

Ishwar V. Basawa
Professor
University of Georgia, Athens, GA, USA

Suppose $x(n) = (x_1, \ldots, x_n)$ is a sample from a stochastic process $x = \{x_1, x_2, \ldots\}$. Let $p_n(x(n);\theta)$ denote the joint density function of $x(n)$, where $\theta \epsilon \Omega \subset \mathcal{R}^k$ is a parameter. Define the log-likelihood ratio $\Lambda_n = \left[\frac{p_n(x(n);\theta_n)}{p_n(x(n);\theta)}\right]$, where $\theta_n = \theta + n^{-\frac{1}{2}}h$, and h is a $(k \times 1)$ vector. The joint density $p_n(x(n);\theta)$ belongs to a local asymptotic normal (LAN) family if Λ_n satisfies

$$\Lambda_n = n^{-\frac{1}{2}} h^t S_n(\theta) - n^{-1}\left(\frac{1}{2} h^t J_n(\theta) h\right) + o_p(1) \qquad (1)$$

where $S_n(\theta) = \frac{dlnp_n(x(n);\theta)}{d\theta}$, $J_n(\theta) = -\frac{d^2 lnp_n(x(n);\theta)}{d\theta d\theta^t}$, and

$$(i) n^{-\frac{1}{2}} S_n(\theta) \xrightarrow{d} N_k(0, F(\theta)), (ii) n^{-1} J_n(\theta) \xrightarrow{p} F(\theta), \qquad (2)$$

$F(\theta)$ being the limiting Fisher information matrix. Here, $F(\theta)$ ia assumed to be non-random. See LaCam and Yang (1990) for a review of the LAN family.

For the LAN family defined by (1) and (2), it is well known that, under some regularity conditions, the maximum likelihood (ML) estimator $\widehat{\theta}_n$ is consistent asymptotically normal and efficient estimator of θ with

$$\sqrt{n}(\widehat{\theta}_n - \theta) \xrightarrow{d} N_k(0, F^{-1}(\theta)). \qquad (3)$$

A large class of models involving the classical *i.i.d.* (independent and identically distributed) observations are covered by the LAN framework. Many time series models and ►Markov processes also are included in the LAN family.

If the limiting Fisher information matrix $F(\theta)$ is non-degenerate random, we obtain a generalization of the LAN family for which the limit distribution of the ML estimator in (3) will be a mixture of normals (and hence non-normal). If Λ_n satisfies (1) and (2) with $F(\theta)$ random, the density $p_n(x(n);\theta)$ belongs to a local asymptotic mixed normal (LAMN) family. See Basawa and Scott (1983) for a discussion of the LAMN family and related asymptotic inference questions for this family.

For the LAMN family, one can replace the norm $\sqrt{n}$ by a random norm $J_n^{\frac{1}{2}}(\theta)$ to get the limiting normal distribution, viz.,

$$J_n^{\frac{1}{2}}(\theta)(\widehat{\theta}_n - \theta) \xrightarrow{d} N(0, I), \qquad (4)$$

where I is the identity matrix.

Two examples belonging to the LAMN family are given below:

Example 1 Variance mixture of normals

Suppose, conditionally on $\mathcal{V} = v$, $(x_1, x_2, \ldots, x_n)$ are *i.i.d.* $N(\theta, v^{-1})$ random variables, and $\mathcal{V}$ is an exponential random variable with mean 1. The marginal joint density of $x(n)$ is then given by $p_n(x(n);\theta) \propto \left[1 + \frac{1}{2}\sum_1^n (x_i - \theta)^2\right]^{-\left(\frac{n}{2}+1\right)}$. It can be verified that $F(\theta)$ is an exponential random variable with mean 1. The ML estimator $\widehat{\theta}_n = \bar{x}$ and $\sqrt{n}(\bar{x} - \theta) \xrightarrow{d} t(2)$. It is interesting to note that the variance of the limit distribution of $\bar{x}$ is ∞!

Example 2 Autoregressive process

Consider a first-order autoregressive process $\{x_t\}$ defined by $x_t = \theta x_{t-1} + e_t, t = 1, 2, \ldots,$ with $x_0 = 0$, where $\{e_t\}$ are assumed to be *i.i.d.* $N(0,1)$ random variables.

We then have $p_n(x(n);\theta) \propto exp\left[-\frac{1}{2}\sum_1^n (x_t - \theta x_{t-1})^2\right]$. For the stationary case, $|\theta| < 1$, this model belongs to the LAN family. However, for $|\theta| > 1$, the model belongs to the LAMN family. For any θ, the ML estimator $\widehat{\theta}_n = \left(\sum_1^n x_i x_{i-1}\right)\left(\sum_1^n x_{i-1}^2\right)^{-1}$. One can verify that $\sqrt{n}(\widehat{\theta}_n - \theta) \xrightarrow{d} N(0,(1-\theta^2)^{-1})$, for $|\theta| < 1$, and $(\theta^2-1)^{-1}\theta^n(\widehat{\theta}_n - \theta) \xrightarrow{d}$ Cauchy, for $|\theta| > 1$.

About the Author

Dr. Ishwar Basawa is a Professor of Statistics at the University of Georgia, USA. He has served as interim head of the department (2000–2003), Executive Editor of the *Journal of Statistical Planning and Inference* (1995–1997), on the editorial board of *Communications in Statistics*, and currently the online *Journal of Probability and Statistics*. Professor Basawa is a Fellow of the Institute of Mathematical Statistics and he was an Elected member of the International Statistical Institute. He has co-authored two books and co-edited eight Proceedings/Monographs/Special Issues of journals. He has authored more than 125 publications. His areas of research include inference for stochastic processes, time series, and asymptotic statistics.

Location-Scale Distributions

Horst Rinne
Professor Emeritus for Statistics and Econometrics
Justus–Liebig–University Giessen, Giessen, Germany

A random variable X with realization x belongs to the location-scale family when its cumulative distribution is a function only of $(x-a)/b$:

$$F_X(x\,|\,a,b) = \Pr(X \le x|a,b) = F\left(\frac{x-a}{b}\right);\ a \in \mathbb{R},\ b > 0;$$

where $F(\cdot)$ is a distribution having no other parameters. Different $F(\cdot)$'s correspond to different members of the family. (a,b) is called the location–scale parameter, a being the location parameter and b being the scale parameter. For fixed $b = 1$ we have a subfamily which is a location family with parameter a, and for fixed $a = 0$ we have a scale family with parameter b. The variable

$$Y = \frac{X-a}{b}$$

is called the reduced or standardized variable. It has $a = 0$ and $b = 1$. If the distribution of X is absolutely continuous with density function

$$f_X(x\,|\,a,b) = \frac{\mathrm{d}F_X(x\,|\,a,b)}{\mathrm{d}\,x}$$

then (a,b) is a location scale-parameter for the distribution of X if (and only if)

$$f_X(x\,|\,a,b) = \frac{1}{b} f\left(\frac{x-a}{b}\right)$$

for some density $f(\cdot)$, called the reduced density. All distributions in a given family have the same shape, i.e., the same skewness and the same kurtosis. When Y has mean μ_Y and standard deviation σ_Y then, the mean of X is $\mathrm{E}(X) = a + b\,\mu_Y$ and the standard deviation of X is $\sqrt{\mathrm{Var}(X)} = b\,\sigma_Y$.

The location parameter a, $a \in \mathbb{R}$ is responsible for the distribution's position on the abscissa. An enlargement (reduction) of a causes a movement of the distribution to the right (left). The location parameter is either a measure of central tendency e.g., the mean, median and mode or it is an upper or lower threshold parameter. The scale parameter b, $b > 0$, is responsible for the dispersion or variation of the variate X. Increasing (decreasing) b results in an enlargement (reduction) of the spread and a corresponding reduction (enlargement) of the density. b may be the standard deviation, the full or half length of the support, or the length of a central $(1-\alpha)$–interval.

The location-scale family has a great number of members:

- Arc-sine distribution
- Special cases of the beta distribution like the rectangular, the asymmetric triangular, the U–shaped or the power–function distributions
- Cauchy and half–Cauchy distributions
- Special cases of the χ–distribution like the half–normal, the Rayleigh and the Maxwell–Boltzmann distributions
- Ordinary and raised cosine distributions
- Exponential and reflected exponential distributions
- Extreme value distribution of the maximum and the minimum, each of type I
- Hyperbolic secant distribution

- Laplace distribution
- Logistic and half–logistic distributions
- Normal and half–normal distributions
- Parabolic distributions
- Rectangular or uniform distribution
- Semi–elliptical distribution
- Symmetric triangular distribution
- Teissier distribution with reduced density $f(y) = \left[\exp(y) - 1\right] \exp\left[1 + y - \exp(y)\right], y \geq 0$
- V–shaped distribution

For each of the above mentioned distributions we can design a special probability paper. Conventionally, the abscissa is for the realization of the variate and the ordinate, called the probability axis, displays the values of the cumulative distribution function, but its underlying scaling is according to the percentile function. The ordinate value belonging to a given sample data on the abscissa is called plotting position; for its choice see Barnett (1975, 1976), Blom (1958), Kimball (1960). When the sample comes from the probability paper's distribution the plotted data will randomly scatter around a straight line, thus, we have a graphical goodness-fit-test. When we fit the straight line by eye we may read off estimates for a and b as the abscissa or difference on the abscissa for certain percentiles. A more objective method is to fit a least-squares line to the data, and the estimates of a and b will be the the parameters of this line.

The latter approach takes the order statistics $X_{i:n}$, $X_{1:n} \leq X_{2:n} \leq \ldots \leq X_{n:n}$ as regressand and the mean of the reduced order statistics $\alpha_{i:n} := \mathrm{E}\left(Y_{i:n}\right)$ as regressor, which under these circumstances acts as plotting position. The regression model reads:

$$X_{i:n} = a + b\,\alpha_{i:n} + \varepsilon_i,$$

where ε_i is a random variable expressing the difference between $X_{i:n}$ and its mean $\mathrm{E}\left(X_{i:n}\right) = a + b\,\alpha_{i:n}$. As the order statistics $X_{i:n}$ and – as a consequence – the disturbance terms ε_i are neither homoscedastic nor uncorrelated we have to use – according to Lloyd (1952) – the general-least-squares method to find best linear unbiased estimators of a and b. Introducing the following vectors and matrices:

$$\boldsymbol{x} := \begin{pmatrix} X_{1:n} \\ X_{2:n} \\ \vdots \\ X_{n:n} \end{pmatrix}, \mathbf{1} := \begin{pmatrix} 1 \\ 1 \\ \vdots \\ 1 \end{pmatrix}, \boldsymbol{\alpha} := \begin{pmatrix} \alpha_{1:n} \\ \alpha_{2:n} \\ \vdots \\ \alpha_{n:n} \end{pmatrix}, \boldsymbol{\varepsilon} := \begin{pmatrix} \varepsilon_1 \\ \varepsilon_2 \\ \vdots \\ \varepsilon_n \end{pmatrix}, \boldsymbol{\theta} := \begin{pmatrix} a \\ b \end{pmatrix},$$

$$\boldsymbol{A} := \begin{pmatrix} \mathbf{1} & \boldsymbol{\alpha} \end{pmatrix}$$

the regression model now reads

$$\boldsymbol{x} = \boldsymbol{A}\,\boldsymbol{\theta} + \boldsymbol{\varepsilon}$$

with variance–covariance matrix

$$\mathrm{Var}(\boldsymbol{x}) = b^2\,\boldsymbol{B}.$$

The GLS estimator of $\boldsymbol{\theta}$ is

$$\widehat{\boldsymbol{\theta}} = \left(\boldsymbol{A}'\,\boldsymbol{\Omega}\,\boldsymbol{A}\right)^{-1} \boldsymbol{A}'\,\boldsymbol{\Omega}\,\boldsymbol{x}$$

and its variance–covariance matrix reads

$$\mathrm{Var}\left(\widehat{\boldsymbol{\theta}}\right) = b^2 \left(\boldsymbol{A}'\,\boldsymbol{\Omega}\,\boldsymbol{A}\right)^{-1}.$$

The vector $\boldsymbol{\alpha}$ and the matrix $\boldsymbol{B}$ are not always easy to find. For only a few location–scale distributions like the exponential, the reflected exponential, the extreme value, the logistic and the rectangular distributions we have closed-form expressions, in all other cases we have to evaluate the integrals defining $\mathrm{E}\left(Y_{i:n}\right)$ and $\mathrm{E}\left(Y_{i:n}\,Y_{j:n}\right)$. For more details on linear estimation and probability plotting for location-scale distributions and for distributions which can be transformed to location–scale type see Rinne (2010). Maximum likelihood estimation for location–scale distributions is treated by Mi (2006).

About the Author

Dr. Horst Rinne is Professor Emeritus (since 2005) of statistics and econometrics. In 1971 he was awarded the Venia legendi in statistics and econometrics by the Faculty of economics of Berlin Technical University. From 1965 to 1972 he worked as a part-time lecturer of statistics at Berlin Polytechnic and at the Technical University of Hannover. In 1969 he joined Volkswagen AG to do operations research. In 1972 he was appointed full professor of statistics and econometrics at the Justus-Liebig University in Giessen, where later on he was Dean of the faculty of economics and management science for three years. He got further appointments to the universities of Tübingen and Cologne and to Berlin Polytechnic. He was a member of the board of the German Statistical Society and in charge of editing its journal *Allgemeines Statistisches Archiv*, now *AStA – Advances in Statistical Analysis*, from 1981 to 1997. He is Co-founder of the Econometric Board of the German Society of Economics. Since 1985 he is Elected member of the International Statistical Institute. He is Associate editor for *Quality Technology and Quantitative Management*. His scientific interests are wide-spread, ranging from financial mathematics, business and economics statistics, technical statistics to econometrics. He has written numerous papers in these fields and is author of several textbooks and monographs in statistics, econometrics, time series analysis, multivariate statistics and statistical quality control including process capability. He is the author of the text *The Weibull Distribution: A Handbook* (Chapman and Hall/CRC, 2008).

Logistic Normal Distribution

John Hinde
Professor of Statistics
National University of Ireland, Galway, Ireland

The logistic-normal distribution arises by assuming that the *logit* (or logistic transformation) of a proportion has a normal distribution, with an obvious extension to a vector of proportions through taking a logistic transformation of a multivariate normal distribution, see Aitchison and Shen (1980). In the univariate case, this provides a family of distributions on $(0,1)$ that is distinct from the ►*beta distribution*, while the multivariate version is an alternative to the *Dirichlet distribution*. Note that in the multivariate case there is no unique way to define the set of logits for the multinomial proportions (just as in multinomial logit models, see Agresti 2002) and different formulations may be appropriate in particular applications (Aitchison 1982). The univariate distribution has been used, often implicitly, in random effects models for binary data and the multivariate version was pioneered by Aitchison for statistical diagnosis/discrimination (Aitchison and Begg 1976), the Bayesian analysis of contingency tables and the analysis of compositional data (Aitchison 1982, 1986).

The use of the logistic-normal distribution is most easily seen in the analysis of binary data where the logit model (based on a logistic tolerance distribution) is extended to the *logit-normal* model. For grouped binary data with responses r_i out of m_i trials ($i = 1,\ldots,n$), the response probabilities, P_i, are assumed to have a logistic-normal distribution with $\text{logit}(P_i) = \log(P_i/(1-P_i)) \sim N(\mu_i, \sigma^2)$, where μ_i is modelled as a linear function of explanatory variables, $x_1,\ldots,x_p$. The resulting model can be summarized as

$$\begin{aligned} R_i|P_i &\sim \text{Binomial}(m_i, P_i) \\ \text{logit}(P_i)|Z &= \eta_i + \sigma Z = \beta_0 + \beta_1 x_{i1} + \cdots + \beta_p x_{ip} + \sigma Z \\ Z &\sim N(0,1) \end{aligned}$$

This is a simple extension of the basic logit model with the inclusion of a single normally distributed random effect in the linear predictor, an example of a *generalized linear mixed model*, see McCulloch and Searle (2001). Maximum likelihood estimation for this model is complicated by the fact that the likelihood has no closed form and involves integration over the normal density, which requires numerical methods using Gaussian quadrature; routines now exist as part of generalized linear mixed model fitting in all major software packages, such as SAS, R, Stata and Genstat. Approximate moment-based estimation methods make use of the fact that if σ^2 is small then, as derived in Williams (1982),

$$\begin{aligned} E[R_i] &= m_i\pi_i \quad \text{and} \\ Var(R_i) &= m_i\pi_i(1-\pi_1)[1+\sigma^2(m_i-1)\pi_i(1-\pi_i)] \end{aligned}$$

where $\text{logit}(\pi_i) = \eta_i$. The form of the variance function shows that this model is *overdispersed* compared to the binomial, that is it exhibits greater variability; the random effect Z allows for unexplained variation across the grouped observations. However, note that for binary data ($m_i = 1$) it is not possible to have overdispersion arising in this way.

Logistic Regression

Joseph M. Hilbe
Emeritus Professor
University of Hawaii, Honolulu, HI, USA
Adjunct Professor of Statistics
Arizona State University, Tempe, AZ, USA
Solar System Ambassador
California Institute of Technology, Pasadena, CA, USA

Logistic regression is the most common method used to model binary response data. When the response is binary, it typically takes the form of 1/0, with 1 generally indicating a success and 0 a failure. However, the actual values that 1 and 0 can take vary widely, depending on the purpose of the study. For example, for a study of the odds of failure in a school setting, 1 may have the value of *fail*, and 0 of *not-fail*, or pass. The important point is that 1 indicates the foremost subject of interest for which a binary response study is designed. Modeling a binary response variable using normal linear regression introduces substantial bias into the parameter estimates. The standard linear model assumes that the response and error terms are normally or Gaussian distributed, that the variance, σ^2, is constant across observations, and that observations in the model are independent. When a binary variable is modeled using this method, the first two of the above assumptions are violated. Analogical to the normal regression model being based on the Gaussian probability distribution function (*pdf*), a binary response model is derived from a Bernoulli distribution, which is a subset of the binomial *pdf* with the binomial denominator taking the value of 1. The Bernoulli *pdf* may be expressed as:

$$f(y_i;\pi_i) = \pi_i^{y_i}(1-\pi_i)^{1-y_i}. \quad (1)$$

Binary logistic regression derives from the canonical form of the Bernoulli distribution. The Bernoulli *pdf* is a member of the exponential family of probability distributions, which has properties allowing for a much easier estimation of its parameters than traditional Newton–Raphson-based maximum likelihood estimation (*MLE*) methods.

In 1972 Nelder and Wedderbrun discovered that it was possible to construct a single algorithm for estimating models based on the exponential family of distributions. The algorithm was termed ▶Generalized linear models (*GLM*), and became a standard method to estimate binary response models such as logistic, probit, and complimentary-loglog regression, count response models such as Poisson and negative binomial regression, and continuous response models such as gamma and inverse Gaussian regression. The standard normal model, or Gaussian regression, is also a generalized linear model, and may be estimated under its algorithm. The form of the exponential distribution appropriate for generalized linear models may be expressed as

$$f(y_i;\theta_i,\phi) = \exp\{(y_i\theta_i - b(\theta_i))/\alpha(\phi) + c(y_i;\phi)\}, \quad (2)$$

with θ representing the link function, $\alpha(\phi)$ the scale parameter, $b(\theta)$ the cumulant, and $c(y;\phi)$ the normalization term, which guarantees that the probability function sums to 1. The link, a monotonically increasing function, linearizes the relationship of the expected mean and explanatory predictors. The scale, for binary and count models, is constrained to a value of 1, and the cumulant is used to calculate the model mean and variance functions. The mean is given as the first derivative of the cumulant with respect to θ, $b'(\theta)$; the variance is given as the second derivative, $b''(\theta)$. Taken together, the above four terms define a specific *GLM* model.

We may structure the Bernoulli distribution (3) into exponential family form (2) as:

$$f(y_i;\pi_i) = \exp\{y_i \ln(\pi_i/(1-\pi_i)) + \ln(1-\pi_i)\}. \quad (3)$$

The link function is therefore $\ln(\pi/(1-\pi))$, and cumulant $-\ln(1-\pi)$ or $\ln(1/(1-\pi))$. For the Bernoulli, π is defined as the probability of success. The first derivative of the cumulant is π, the second derivative, $\pi(1-\pi)$. These two values are, respectively, the mean and variance functions of the Bernoulli *pdf*. Recalling that the logistic model is the canonical form of the distribution, meaning that it is the form that is directly derived from the *pdf*, the values expressed in (3), and the values we gave for the mean and variance, are the values for the logistic model.

Estimation of statistical models using the *GLM* algorithm, as well as *MLE*, are both based on the log-likelihood function. The likelihood is simply a re-parameterization of the *pdf* which seeks to estimate π, for example, rather than y. The log-likelihood is formed from the likelihood by taking the natural log of the function, allowing summation

across observations during the estimation process rather than multiplication.

The traditional *GLM* symbol for the mean, μ, is typically substituted for π, when *GLM* is used to estimate a logistic model. In that form, the log-likelihood function for the binary-logistic model is given as:

$$L(\mu_i; y_i) = \sum_{i=1}^{n} \{y_i \ln(\mu_i/(1-\mu_i)) + \ln(1-\mu_i)\}, \quad (4)$$

or

$$L(\mu_i; y_i) = \sum_{i=1}^{n} \{y_i \ln(\mu_i) + (1-y_i)\ln(1-\mu_i)\}. \quad (5)$$

The Bernoulli-logistic log-likelihood function is essential to logistic regression. When *GLM* is used to estimate logistic models, many software algorithms use the deviance rather than the log-likelihood function as the basis of convergence. The deviance, which can be used as a goodness-of-fit statistic, is defined as twice the difference of the saturated log-likelihood and model log-likelihood. For logistic model, the deviance is expressed as

$$D = 2\sum_{i=1}^{n} \{y_i \ln(y_i/\mu_i) + (1-y_i)\ln((1-y_i)/(1-\mu_i))\}. \quad (6)$$

Whether estimated using maximum likelihood techniques or as *GLM*, the value of μ for each observation in the model is calculated on the basis of the linear predictor, $x'\beta$. For the normal model, the predicted fit, $\hat{y}$, is identical to $x'\beta$, the right side of (7). However, for logistic models, the response is expressed in terms of the link function, $\ln(\mu_i/(1-\mu_i))$. We have, therefore,

$$x_i'\beta = \ln(\mu_i/(1-\mu_i)) = \beta_0 + \beta_1 x_1 + \beta_2 x_2 + \cdots + \beta_n x_n. \quad (7)$$

The value of μ_i, for each observation in the logistic model, is calculated as

$$\mu_i = 1/\left(1+\exp\left(-x_i'\beta\right)\right) = \exp\left(x_i'\beta\right)/\left(1+\exp\left(x_i'\beta\right)\right). \quad (8)$$

The functions to the right of μ are commonly used ways of expressing the logistic inverse link function, which converts the linear predictor to the fitted value. For the logistic model, μ is a probability.

When logistic regression is estimated using a Newton-Raphson type of *MLE* algorithm, the log-likelihood function as parameterized to $x'\beta$ rather than μ. The estimated fit is then determined by taking the first derivative of the log-likelihood function with respect to β, setting it to zero, and solving. The first derivative of the log-likelihood function is commonly referred to as the gradient, or score function. The second derivative of the log-likelihood with respect to β produces the Hessian matrix, from which the standard errors of the predictor parameter estimates are derived. The logistic gradient and hessian functions are given as

$$\frac{\partial L(\beta)}{\partial \beta} = \sum_{i=1}^{n} (y_i - \mu_i) x_i \quad (9)$$

$$\frac{\partial^2 L(\beta)}{\partial \beta \partial \beta'} = -\sum_{i=1}^{n} \left\{x_i x_i' \mu_i (1-\mu_i)\right\} \quad (10)$$

One of the primary values of using the logistic regression model is the ability to interpret the exponentiated parameter estimates as odds ratios. Note that the link function is the log of the odds of μ, $\ln(\mu/(1-\mu))$, where the odds are understood as the success of μ over its failure, $1-\mu$. The log-odds is commonly referred to as the *logit* function. An example will help clarify the relationship, as well as the interpretation of the odds ratio.

We use data from the 1912 Titanic accident, comparing the odds of survival for adult passengers to children. A tabulation of the data is given as:

Survived	Age (Child vs Adult)		Total
	child	adults	
no	52	765	817
yes	57	442	499
Total	109	1,207	1,316

The odds of survival for adult passengers is 442/765, or 0.578. The odds of survival for children is 57/52, or 1.096. The ratio of the odds of survival for adults to the odds of survival for children is (442/765)/(57/52), or 0.52709552. This value is referred to as the *odds ratio*, or ratio of the two component odds relationships. Using a logistic regression procedure to estimate the odds ratio of age produces the following results

survived	Odds Ratio	Std. Err.	z	P>|z|	[95% Conf. Interval]	
age	.5270955	.1058718	−3.19	0.001	.3555642	.7813771

With 1 = *adult* and 0 = *child*, the estimated odds ratio may be interpreted as:

- *The odds of an adult surviving were about half the odds of a child surviving.*

By inverting the estimated odds ratio above, we may conclude that children had [1/.527 ~ 1.9] some 90% – or

nearly two times – greater odds of surviving than did adults.

For continuous predictors, a one-unit increase in a predictor value indicates the change in odds expressed by the displayed odds ratio. For example, if age was recorded as a continuous predictor in the Titanic data, and the odds ratio was calculated as 1.015, we would interpret the relationship as:

- *The odds of surviving is one and a half percent greater for each increasing year of age.*

Non-exponentiated logistic regression parameter estimates are interpreted as log-odds relationships, which carry little meaning in ordinary discourse. Logistic models are typically interpreted in terms of odds ratios, unless a researcher is interested in estimating predicted probabilities for given patterns of model covariates; i.e., in estimating μ.

Logistic regression may also be used for grouped or proportional data. For these models the response consists of a numerator, indicating the number of successes (1s) for a specific covariate pattern, and the denominator (m), the number of observations having the specific covariate pattern. The response y/m is binomially distributed as:

$$f(y_i;\pi_i,m_i) = \binom{m_i}{y_i}\pi_i^{y_i}(1-\pi_i)^{m_i-y_i}, \qquad (11)$$

with a corresponding log-likelihood function expressed as

$$L(\mu_i;y_i,m_i) = \sum_{i=1}^{n}\left\{y_i\ln(\mu_i/(1-\mu_i)) + m_i\ln(1-\mu_i) + \binom{m_i}{y_i}\right\}. \qquad (12)$$

Taking derivatives of the cumulant, $-m_i\ln(1-\mu_i)$, as we did for the binary response model, produces a mean of $\mu_i = m_i\pi_i$ and variance, $\mu_i(1-\mu_i/m_i)$.

Consider the data below:

y	cases	x_1	x_2	x_3
1	3	1	0	1
1	1	1	1	1
2	2	0	0	1
0	1	0	1	1
2	2	1	0	0
0	1	0	1	0

y indicates the number of times a specific pattern of covariates is successful. *Cases* is the number of observations having the specific covariate pattern. The first observation in the table informs us that there are three cases having predictor values of $x_1 = 1, x_2 = 0$, and $x_3 = 1$. Of those three cases, one has a value of y equal to 1, the other two have values of 0. All current commercial software applications estimate this type of logistic model using *GLM* methodology.

y	Odds ratio	OIM std. err.	z	$P > \|z\|$	[95% conf.	interval]
x_1	1.186947	1.769584	0.11	0.908	0.0638853	22.05271
x_2	0.2024631	0.3241584	−1.00	0.318	0.0087803	4.668551
x_3	0.5770337	0.9126937	−0.35	0.728	0.025993	12.8099

The data in the above table may be restructured so that it is in individual observation format, rather than grouped. The new table would have ten observations, having the same logic as described. Modeling would result in identical parameter estimates. It is not uncommon to find an individual-based data set of, for example, 10,000 observations, being grouped into 10–15 rows or observations as above described. Data in tables is nearly always expressed in grouped format.

Logistic models are subject to a variety of fit tests. Some of the more popular tests include the Hosmer-Lemeshow goodness-of-fit test, *ROC* analysis, various information criteria tests, link tests, and residual analysis. The Hosmer–Lemeshow test, once well used, is now only used with caution. The test is heavily influenced by the manner in which tied data is classified. Comparing observed with expected probabilities across levels, it is now preferred to construct tables of risk having different numbers of levels. If there is consistency in results across tables, then the statistic is more trustworthy.

Information criteria tests, e.g., Akaike information Criteria (see ►Akaike's Information Criterion and ►Akaike's Information Criterion: Background, Derivation, Properties, and Refinements) (*AIC*) and Bayesian Information Criteria (*BIC*) are the most used of this type of test. Information tests are comparative, with lower values indicating the preferred model. Recent research indicates that *AIC* and *BIC* both are biased when data is correlated to any degree. Statisticians have attempted to develop enhancements of these two tests, but have not been entirely successful. The best advice is to use several different types of tests, aiming for consistency of results.

Several types of residual analyses are typically recommended for logistic models. The references below provide extensive discussion of these methods, together with

appropriate caveats. However, it appears well established that m-asymptotic residual analyses is most appropriate for logistic models having no continuous predictors. m-asymptotics is based on grouping observations with the same covariate pattern, in a similar manner to the grouped or binomial logistic regression discussed earlier. The Hilbe (2009) and Hosmer and Lemeshow (2000) references below provide guidance on how best to construct and interpret this type of residual.

Logistic models have been expanded to include categorical responses, e.g., proportional odds models and multinomial logistic regression. They have also been enhanced to include the modeling of panel and correlated data, e.g., generalized estimating equations, fixed and random effects, and mixed effects logistic models.

Finally, exact logistic regression models have recently been developed to allow the modeling of perfectly predicted data, as well as small and unbalanced datasets. In these cases, logistic models which are estimated using GLM or full maximum likelihood will not converge. Exact models employ entirely different methods of estimation, based on large numbers of permutations.

Logistic Distribution

John Hinde
Professor of Statistics
National University of Ireland, Galway, Ireland

The logistic distribution is a location-scale family distribution with a very similar shape to the normal (Gaussian) distribution but with somewhat heavier tails. The distribution has applications in reliability and survival analysis. The cumulative distribution function has been used for

modelling growth functions and as a tolerance distribution in the analysis of binary data, leading to the widely used *logit* model. For a detailed discussion of the properties of the logistic and related distributions, see Johnson et al. (1995).

The probability density function is

$$f(x) = \frac{1}{\tau}\frac{\exp\{-(x-\mu)/\tau\}}{[1+\exp\{-(x-\mu)/\tau\}]^2}, \quad -\infty < x < \infty \quad (1)$$

and the cumulative distribution function is

$$F(x) = \frac{1}{[1+\exp\{-(x-\mu)/\tau\}]}, \quad -\infty < x < \infty .$$

The distribution is symmetric about the mean μ and has variance $\tau^2\pi^2/3$, so that when comparing the standard logistic distribution ($\mu = 0$, $\tau = 1$) with the standard normal distribution, $N(0,1)$, it is important to allow for the different variances. The suitably scaled logistic distribution has a very similar shape to the normal, although the kurtosis is 4.2 which is somewhat larger than the value of 3 for the normal, indicating the heavier tails of the logistic distribution.

In survival analysis, one advantage of the logistic distribution, over the normal, is that both *right-* and *left-censoring* can be easily handled. The *survivor* and *hazard* functions are given by

$$S(x) = \frac{1}{[1+\exp\{(x-\mu)/\tau\}]}, \quad -\infty < x < \infty$$

$$h(x) = \frac{1}{\tau}\frac{1}{[1+\exp\{-(x-\mu)/\tau\}]}.$$

The hazard function has the same logistic form and is monotonically increasing, so the model is only appropriate for ageing systems with an increasing failure rate over time. In modelling the dependence of failure times on explanatory variables, if we use a linear regression model for μ, then the fitted model has an *accelerated failure time* interpretation for the effect of the variables. Fitting of this model to right- and left-censored data is described in Aitkin et al. (2009).

One obvious extension for modelling failure times, T, is to assume a logistic model for $\log T$, giving a *log-logistic* model for T analagous to the *lognormal model*. The resulting hazard function based on the logistic distribution in (1) is

$$h(t) = \frac{\alpha}{\theta}\frac{(t/\theta)^{\alpha-1}}{1+(t/\theta)^{\alpha}}, \quad t, \theta, \alpha > 0$$

where $\theta = e^{\mu}$ and $\alpha = 1/\tau$. For $\alpha \leq 1$ the hazard is monotone decreasing, and for $\alpha > 1$ it has a single maximum as for the lognormal distribution; hazards of this form may be appropriate in the analysis of data such as heart transplant survival – there may be an initial period of increasing hazard associated with rejection, followed by decreasing hazard as the patient survives the procedure and the transplanted organ is accepted.

For the standard logistic distribution ($\mu = 0$, $\tau = 1$), the probability density and the cumulative distribution functions are related through the very simple identity

$$f(x) = F(x)\,[1 - F(x)]$$

which in turn, by elementary calculus, implies that

$$\text{logit}(F(x)) := \log_e\left[\frac{F(x)}{1-F(x)}\right] = x \quad (2)$$

and uniquely characterizes the standard logistic distribution. Equation (2) provides a very simple way for simulating from the standard logistic distribution by setting $X = \log_e[U/(1-U)]$ where $U \sim U(0,1)$; for the general logistic distribution in (1) we take $\tau X + \mu$.

The logit transformation is now very familiar in modelling probabilities for binary responses. Its use goes back to Berkson (1944), who suggested the use of the logistic distribution to replace the normal distribution as the underlying tolerance distribution in quantal bio-assays, where various dose levels are given to groups of subjects (animals) and a simple binary response (e.g., cure, death, etc.) is recorded for each individual (giving r-out-of-n type response data for the groups). The use of the normal distribution in this context had been pioneered by Finney through his work on ▶probit analysis and the same methods mapped across to the logit analysis, see Finney (1978) for a historical treatment of this area. The probability of response, $P(d)$, at a particular dose level d is modelled by a linear logit model

$$\text{logit}(P(d)) = \log_e\left[\frac{P(d)}{1-P(d)}\right] = \beta_0 + \beta_1 d$$

which, by the identity (2), implies a logistic tolerance distribution with parameters $\mu = -\beta_0/\beta_1$ and $\tau = 1/|\beta_1|$. The logit transformation is computationally convenient and has the nice interpretation of modelling the *log-odds* of a response. This goes across to general logistic regression models for binary data where parameter effects are on the log-odds scale and for a two-level factor the fitted effect corresponds to a log-odds-ratio. Approximate methods for parameter estimation involve using the empirical logits of the observed proportions. However, maximum likelihood estimates are easily obtained with standard generalized linear model fitting software, using a binomial response distribution with a logit link function for the response probability; this uses the iteratively reweighted least-squares Fisher-scoring algorithm of

Nelder and Wedderburn (1972), although Newton-based algorithms for maximum likelihood estimation of the logit model appeared well before the unifying treatment of ►generalized linear models. A comprehensive treatment of ►logistic regression including models and applications is given in Agresti (2002) and Hilbe (2009).

Lorenz Curve

Johan Fellman
Professor Emeritus
Folkhälsan Institute of Genetics, Helsinki, Finland

Definition and Properties

It is a general rule that income distributions are skewed. Although various distribution models, such as the Lognormal and the Pareto have been proposed, they are usually applied in specific situations. For general studies, more wide-ranging tools have to be applied, the first and most common tool of which is the Lorenz curve. Lorenz (1905) developed it in order to analyze the distribution of income and wealth within populations, describing it in the following way:

► *Plot along one axis accumulated percentages of the population from poorest to richest, and along the other, wealth held by these percentages of the population.*

The Lorenz curve $L(p)$ is defined as a function of the proportion p of the population. $L(p)$ is a curve starting from the origin and ending at point $(1,1)$ with the following additional properties (I) $L(p)$ is monotone increasing, (II) $L(p) \leq p$, (III) $L(p)$ convex, (IV) $L(0) = 0$ and $L(1) = 1$. The Lorenz curve is convex because the income share of the poor is less than their proportion of the population (Fig. 1).

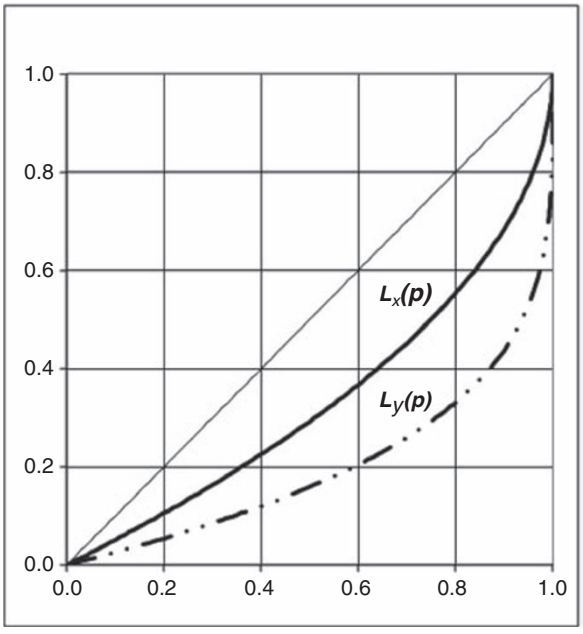
The Lorenz curve satisfies the general rules:

► *A unique Lorenz curve corresponds to every distribution. The contrary does not hold, but every Lorenz $L(p)$ is a common curve for a whole class of distributions $F(\theta x)$ where θ is an arbitrary constant.*

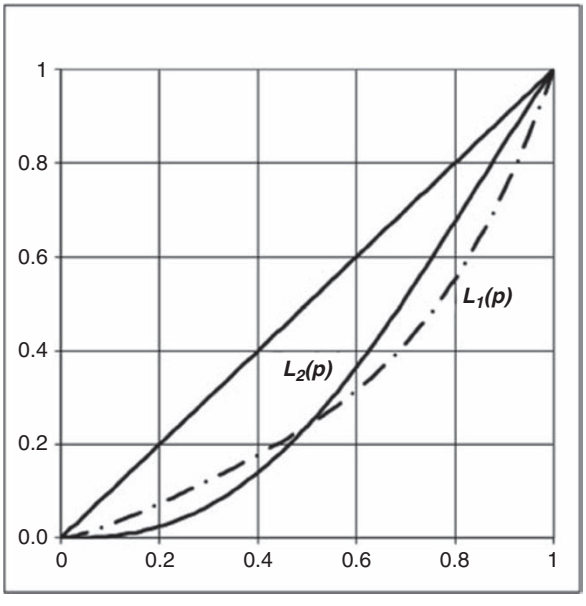
The higher the curve, the less inequality in the income distribution. If all individuals receive the same income, then the Lorenz curve coincides with the diagonal from $(0,0)$ to $(1,1)$. Increasing inequality lowers the Lorenz curve, which can converge towards the lower right corner of the square.

Consider two Lorenz curves $L_X(p)$ and $L_Y(p)$. If $L_X(p) \geq L_Y(p)$ for all p, then the distribution corresponding to $L_X(p)$ has lower inequality than the distribution corresponding to $L_Y(p)$ and is said to Lorenz dominate the other. Figure 1 shows an example of Lorenz curves.

The inequality can be of a different type, the corresponding Lorenz curves may intersect, and for these no Lorenz ordering holds. This case is seen in Fig. 2. Under such circumstances, alternative inequality measures have to be defined, the most frequently used being the Gini index, G, introduced by Gini (1912). This index is the ratio



Lorenz Curve. Fig. 1 Lorenz curves with Lorenz ordering; that is, $L_X(p) \geq L_Y(p)$



Lorenz Curve. Fig. 2 Two intersecting Lorenz curves. Using the Gini index $L_1(p)$ has greater inequality ($G_1 = 0.37$) than $L_2(p)$ ($G_2 = 0.33$)

between the area between the diagonal and the Lorenz curve and the whole area under the diagonal. This definition yields Gini indices satisfying the inequality $0 \leq G \leq 1$. The higher the G value, the greater the inequality in the income distribution.

Income Redistributions

It is a well-known fact that progressive taxation reduces inequality. Similar effects can be obtained by appropriate transfer policies, findings based on the following general theorem (Fellman 1976; Jakobsson 1976; Kakwani 1977):

Theorem *Let $u(x)$ be a continuous monotone increasing function and assume that $\mu_Y = E(u(X))$ exists. Then the Lorenz curve $L_Y(p)$ for $Y = u(X)$ exists and*

(I) $L_Y(p) \geq L_X(p)$ *if* $\frac{u(x)}{x}$ *is monotone decreasing*

(II) $L_Y(p) = L_X(p)$ *if* $\frac{u(x)}{x}$ *is constant*

(III) $L_Y(p) \leq L_X(p)$ *if* $\frac{u(x)}{x}$ *is monotone increasing.*

For progressive taxation rules, $\frac{u(x)}{x}$ measures the proportion of post-tax income to initial income and is a monotone-decreasing function satisfying condition (I), and the Gini index is reduced. Hemming and Keen (1993) gave an alternative condition for the Lorenz dominance, which is that $\frac{u(x)}{x}$ crosses the $\frac{\mu_Y}{\mu_X}$ level once from above. If the taxation rule is a flat tax, then (II) holds and the Lorenz curve and the Gini index remain. The third case in Theorem 1 indicates that the ratio $\frac{u(x)}{x}$ is increasing and the Gini index increases, but this case has only minor practical importance.

A crucial study concerning income distributions and redistributions is the monograph by Lambert (2001).

About the Author

Dr Johan Fellman is Professor Emeritus in statistics. He obtained Ph.D. in mathematics (University of Helsinki) in 1974 with the thesis On the Allocation of Linear Observations and in addition, he has published about 180 printed articles. He served as professor in statistics at Hanken School of Economics, (1977–1994) and has been a scientist at Folkhälsan Institute of Genetics since 1963. He is member of the Editorial Board of *Twin Research and Human Genetics* and of the Advisory Board of *Mathematica Slovaca* and Editor of *InterStat*. He has been awarded the Knight, First Class, of the Order of the White Rose of Finland and the Medal in Silver of Hanken School of Economics. He is Elected member of the Finnish Society of Sciences and Letters and of the International Statistical Institute.

Loss Function

Wolfgang Bischoff
Professor and Dean of the Faculty of Mathematics and Geography
Catholic University Eichstätt–Ingolstadt, Eichstätt, Germany

Loss functions occur at several places in statistics. Here we attach importance to decision theory (see ►Decision Theory: An Introduction, and ►Decision Theory: An Overview) and regression. For both fields the same loss functions can be used. But the interpretation is different.

Decision theory gives a general framework to define and understand statistics as a mathematical discipline. The loss function is the essential component in decision theory. The loss function judges a decision with respect to the truth by a real value greater or equal to zero. In case the decision coincides with the truth then there is no loss. Therefore the value of the loss function is zero then, otherwise the value gives the loss which is suffered by the decision unequal the truth. The larger the value the larger the loss which is suffered.

To describe this more exactly let Θ be the known set of all outcomes for the problem under consideration on which we have information by data. We assume that one of the values $\theta \in \Theta$ is the true value. Each $d \in \Theta$ is a possible decision. The decision d is chosen according to a rule, more exactly according to a function with values in Θ and defined on the set of all possible data. Since the true value θ is unknown the loss function L has to be defined on $\Theta \times \Theta$, i.e.,

$$L : \Theta \times \Theta \to [0, \infty).$$

The first variable describes the true value, say, and the second one the decision. Thus $L(\theta, a)$ is the loss which is suffered if θ is the true value and a is the decision. Therefore, each (up to technical conditions) function $L : \Theta \times \Theta \to [0, \infty)$ with the property

$$L(\theta, \theta) = 0 \text{ for all } \theta \in \Theta$$

is a possible loss function. The loss function has to be chosen by the statistician according to the problem under consideration.

Next, we describe examples for loss functions. First let us consider a test problem. Then Θ is divided in two disjoint subsets Θ_0 and Θ_1 describing the null hypothesis and the alternative set, $\Theta = \Theta_0 + \Theta_1$. Then the usual loss function is given by

$$L(\theta, \vartheta) = \begin{cases} 0 & \text{if} \quad \theta, \vartheta \in \Theta_0 \qquad \text{or} \quad \theta, \vartheta \in \Theta_1 \\ 1 & \text{if} \quad \theta \in \Theta_0, \vartheta \in \Theta_1 \quad \text{or} \quad \theta \in \Theta_1, \vartheta \in \Theta_0 \end{cases}.$$

For point estimation problems we assume that Θ is a normed linear space and let $|\cdot|$ be its norm. Such a space is typical for estimating a location parameter. Then the loss $L(\theta, \vartheta) = |\theta - \vartheta|$, $\theta, \vartheta \in \Theta$, can be used. Next, let us consider the specific case $\Theta = \mathrm{R}$. Then $L(\theta, \vartheta) = \ell(\theta - \vartheta)$ is a typical form for loss functions, where $\ell : IR \to [0, \infty)$ is nonincreasing on $(-\infty, 0]$ and nondecreasing on $[0, \infty)$ with $\ell(0) = 0$. ℓ is also called loss function. An important class of such functions is given by choosing $\ell(t) = |t|^p$, where $p > 0$ is a fixed constant. There are two prominent cases, for $p = 2$ we get the classical square loss and for $p = 1$ the robust L_1-loss. Another class of robust losses are the famous Huber losses

$$\ell(t) = t^2/2, \text{ if } |t| \le \gamma, \text{ and } \ell(t) = \gamma|t| - \gamma^2/2, \text{ if } |t| > \gamma,$$

where $\gamma > 0$ is a fixed constant. Up to now we have shown symmetrical losses, i.e., $L(\theta, \vartheta) = L(\vartheta, \theta)$. There are many problems in which underestimating of the true value θ has to be differently judged than overestimating. For such problems Varian (1975) introduced LinEx losses

$$\ell(t) = b(exp(at) - at - 1),$$

where $a, b > 0$ can be chosen suitably. Here underestimating is judged exponentially and overestimating linearly.

For other estimation problems corresponding losses are used. For instance, let us consider the estimation of a

scale parameter and let $\Theta = (0, \infty)$. Then it is usual to consider losses of the form $L(\theta, \vartheta) = \ell(\vartheta/\theta)$, where ℓ must be chosen suitably. It is, however, more convenient to write $\ell(\ln \vartheta - \ln \theta)$. Then ℓ can be chosen as above.

In theoretical works the assumed properties for loss functions can be quite different. Classically it was assumed that the loss is convex (see ►Rao–Blackwell Theorem). If the space Θ is not bounded, then it seems to be more convenient in practice to assume that the loss is bounded which is also assumed in some branches of statistics. In case the loss is not continuous then it must be carefully defined to get no counter intuitive results in practice, see Bischoff (1999).

In case a density of the underlying distribution of the data is known up to an unknown parameter the class of divergence losses can be defined. Specific cases of these losses are the Hellinger and the Kulback-Leibler loss.

In regression, however, the loss is used in a different way. Here it is assumed that the unknown location parameter is an element of a known class $\mathcal{F}$ of real valued functions. Given n observations (data) $y_1, \ldots, y_n$ observed at design points $t_1, \ldots, t_n$ of the experimental region a loss function is used to determine an estimation for the unknown regression function by the 'best approximation', i.e., the function in $\mathcal{F}$ that minimizes $\sum_{i=1}^{n} \ell\left(r_i^f\right), f \in \mathcal{F}$, where $r_i^f = y_i - f(t_i)$ is the residual in the ith design point. Here ℓ is also called loss function and can be chosen as described above. For instance, the least squares estimation is obtained if $\ell(t) = t^2$.

Margin of Error

Judith M. Tanur
Distinguished Teaching Professor Emerita
Stony Brook University, Stony Brook, NY, USA

Margin of error is a term that probably originated in the popular reporting of results of ▶public opinion polls but has made its way into more professional usage. It usually represents half of the length of a confidence interval (most usually a 95% confidence interval, though it could in theory be any confidence interval) for a proportion or percentage, calculated under the assumption of simple random sampling. The sample value of the proportion, $\hat{p}$, is used as an estimate of the population proportion π, and the standard error (se) is estimated as $\sqrt{\hat{p}(1-\hat{p})/n}$. Then a 95% confidence interval is given as $\hat{p} \pm 1.96\times$ se and the margin of error is $1.96\times$ se. For example, if an opinion poll gives a result of 40% of 900 respondents in favor of a proposition (a proportion of .40), then the estimated se of the proportion is $\sqrt{(0.4 \times 0.6)/900} = .016$ and that is expressed as 1.6 percentage points. Then the margin of error would be presented as $1.96 \times 1.6 = 3.2$ percentage points.

The fact that the margin of error is often reported in the popular press represents progress from a time when sample results were not qualified at all by notions of sample-to-sample variability. Such reporting, however, is frequently subject to misinterpretation, though reporters often caution against such misinterpretation. First, like the confidence interval, the margin of error does not represent anything about the probability that the results are close to truth. A 95% confidence interval merely says that, with the procedure as carried out repeatedly by drawing a sample from this population, 95% of the time the stated interval would cover the true population parameter. There is no information whether this current interval does or does not cover the population parameter and similarly the margin of error gives no information whether it covers the true population percentage. Second, the procedure assumes simple random sampling, but frequently the sampling for a survey is more complicated than that and hence the standard error calculated under the assumption of simple random sampling is an underestimate. Third, the margin of error is frequently calculated for the sample as a whole, but when interest centers on a subgroup of respondents (e.g., the percentage of females who prefer a particular candidate) the sample size is smaller and a fresh margin of error should be calculated for the subgroup, though it frequently is not. And finally, and perhaps most importantly, there is a tendency to assume that the margin of error takes into account all possible "errors" when in fact it deals only with sampling error. Nonsampling errors, such as noncoverage, nonresponse, or inaccurate responses are not taken into account via a confidence interval or the margin of error and may indeed be of much larger magnitude than the sampling error measured by the standard error.

Marginal Probability: Its Use in Bayesian Statistics as Model Evidence

Luis Raúl Pericchi
Professor
University of Puerto Rico, San Juan, Puerto Rico

Definition

Suppose that we have vectors of random variables $[\mathbf{v},\mathbf{w}] = [v_1, v_2, \ldots, v_I, w_1, \ldots, w_J]$ in $\Re^{(I+J)}$. Denote as the **joint** density function: $f_{\mathbf{v},\mathbf{w}}$, which obeys: $f_{\mathbf{v},\mathbf{w}}(v, w) \geq 0$ and

Miodrag Lovric (ed.), *International Encyclopedia of Statistical Science*, DOI 10.1007/978-3-642-04898-2,

$\int_{-\infty}^{\infty} \dots \int_{-\infty}^{\infty} f_{\mathbf{v},\mathbf{w}}(v,w)dv_1 \dots dv_I dw_1 \dots dw_I = 1$. Then the probability of the set $[A_v, B_w]$ is given by

$$P(A_v, B_w) = \int \dots \int_{A_v,B_w} f_{\mathbf{v},\mathbf{w}}(v,w)\mathbf{dvdw}.$$

The *marginal* density $f_{\mathbf{v}}$ is obtained as

$$f_{\mathbf{v}}(v) = \int_{-\infty}^{\infty} \dots \int_{-\infty}^{\infty} f_{\mathbf{v},\mathbf{w}}(v,w)dw_1 \dots dw_I.$$

The *marginal probability* of the set A_v is then obtained as,

$$P(A_v) = \int \dots \int_{A_v} f_{\mathbf{v}}(v)dv.$$

We have assumed that the random variables are continuous. When they are discrete, integrals are substituted by sums. We proceed to present an important application of marginal probabilities for measuring the probability of a model.

Measuring the Evidence in Favor of a Model

In Statistics, a parametric model, is denoted as $f(x_1, \dots, x_n|\theta_1, \dots, \theta_k)$, where $\mathbf{x} = (x_1, \dots, x_n)$ is the vector of n observations and $\theta = (\theta_1, \dots, \theta_k)$ is the vector of k parameters. For instance we may have $n = 15$ observations normally distributed and the vector of parameters is (θ_1, θ_2) the location and scale respectively, denoted by $f_{Normal}(\mathbf{x}|\theta) = \prod_{\mathbf{i=1}}^{\mathbf{n}} \frac{1}{\sqrt{2\pi}\theta_2} \exp\left(-\frac{1}{2\theta_2^2}(\mathbf{x}_i - \theta_1)^2\right)$.

Assume now that there is reason to suspect that the location is zero. As a second example, it may be suspected that the sampling model which usually has been assumed Normally distributed, is instead a Cauchy, $f_{Cauchy}(X|\theta) = \prod_1^n \frac{1}{\pi\theta_2} \frac{1}{\left(1+\left(\frac{x_i-\theta_1}{\theta_2}\right)^2\right)}$. The first problem is a *hypothesis test* denoted by

$$H_0 : \theta_1 = 0 \text{ VS } H_1 : \theta_1 \neq 0,$$

and the second problem is a *model selection* problem:

$$M_0 : f_{Normal} \text{ VS } M_1 : f_{Cauchy}.$$

How to measure the evidence in favor of H_0 or M_0? Instead of maximized likelihoods as it is done in traditional statistics, in ►Bayesian statistics the central concept is *the evidence* or *marginal probability density*

$$m_j(\mathbf{x}) = \int f_j(\mathbf{x}|\theta_j)\pi(\theta_j)\mathbf{d}\theta_j,$$

where j denotes either model or hypothesis j and $\pi(\theta)$ denotes the prior for the parameters under model or hypothesis j.

Marginal probabilities embodies the likelihood of a model or hypothesis in great generality and can be claimed it is the natural probabilistic quantity to compare models.

Marginal Probability of a Model

Once the marginal densities of the model j, for $j = 1, \dots, J$ models have been calculated and assuming the prior model probabilities $P(M_j), j = 1, \dots, J$ with $\sum_{j=1}^{J} P(M_j) = 1$ then, using Bayes Theorem, *the marginal probability of a model* $P(M_j|\mathbf{x})$ can be calculated as,

$$P(M_j|\mathbf{x}) = \frac{\mathbf{m_j}(\mathbf{x}) \cdot \mathbf{P}(\mathbf{M_j})}{\sum_{\mathbf{i=1}}^{\mathbf{n}} \mathbf{m_i}(\mathbf{x}) \cdot \mathbf{P}(\mathbf{M_i})}.$$

We have then the following formula for any two models or hypotheses:

$$\frac{P(M_j|\mathbf{x})}{P(M_i|\mathbf{x})} = \frac{P(M_j)}{P(M_i)} \times \frac{m_j(\mathbf{x})}{m_i(\mathbf{x})},$$

or in words: Posterior Odds equals Prior Odds times Bayes Factor, where the Bayes Factor of M_j over M_i is

$$B_{j,i} = \frac{m_j(\mathbf{x})}{m_i(\mathbf{x})},$$

Jeffreys (1961).

In contrast to ►*p-values*, which have interpretations heavily dependent on the sample size n, and its definition is not the same as the scientific question, the posterior probabilities and Bayes Factors address the scientific question: "how probable is model or hypothesis j as compared with model or hypothesis i?," and the interpretation is the same for any sample size, Berger and Pericchi (2001). Bayes Factors and Marginal Posterior Model Probabilities have several advantages, like for example large sample consistency, that is as the sample size grows the Posterior Model Probability of the sampling model tends to one. Furthermore, if the goal is to predict future observations y_f it is **not** necessary to select one model as *the* predicting model since we may predict by the so called Bayesian Model Averaging, which if quadratic loss is assumed, the optimal predictor takes the form,

$$E[Y_f|\mathbf{x}] = \sum_{\mathbf{j=1}}^{\mathbf{J}} \mathbf{E}[\mathbf{Y_f}|\mathbf{x}, \mathbf{M_j}] \times \mathbf{P}(\mathbf{M_j}|\mathbf{x}),$$

where $E[Y_f|\mathbf{x}, \mathbf{M_j}]$ is the expected value of a future observation under the model or hypothesis M_j.

Intrinsic Priors for Model Selection and Hypothesis Testing

Having said some of the advantages of the marginal probabilities of models, the question arises: how to assign the conditional priors $\pi(\theta_j)$? In the two examples above which priors are sensible to use? The problem is *not* a simple one since it is not possible to use the usual Uniform priors since then the Bayes Factors are undetermined. To solve this problem with some generality, Berger and Pericchi (1996)

introduced the concepts of Intrinsic Bayes Factors and Intrinsic Priors. Start by splitting the sample in two subsamples $\mathbf{x} = [\mathbf{x}(\mathbf{l}), \mathbf{x}(-\mathbf{l})]$ where the training sample $\mathbf{x}(\mathbf{l})$ is as small as possible such that for $j = 1, \ldots, J : 0 < m_j(\mathbf{x}(\mathbf{l})) < \infty$. Thus starting with an improper prior $\pi^N(\theta_j)$, which does not integrate to one (for example the Uniform), by using the minimal training sample $\mathbf{x}(\mathbf{l})$, all the conditional prior densities $\pi(\theta_j|\mathbf{x}(\mathbf{l}))$ *become* proper. So we may form the Bayes Factor using the training sample $\mathbf{x}(\mathbf{l})$ as

$$B_{ji}(\mathbf{x}(\mathbf{l})) = \frac{\mathbf{m_j}(\mathbf{x}(-\mathbf{l})|\mathbf{x}(\mathbf{l}))}{\mathbf{m_i}(\mathbf{x}(-\mathbf{l})|\mathbf{x}(\mathbf{l}))}.$$

This however depends on the particular training sample $\mathbf{x}(\mathbf{l})$. So some sort of average of Bayes Factor is necessary. In Berger and Pericchi (1996) it is shown that the average should be the arithmetic average. It is also found a theoretical prior that is an approximation to the procedure just described as the sample size grows. This is called an *Intrinsic Prior*. In the examples above: (i) in the normal case, assuming for simplicity that the variance is known and $\theta_2^2 = 1$ then it turns out that the Intrinsic Prior is Normal centered at the null hypothesis $\theta_1 = 0$ and with variance 2. On the other hand in the Normal versus Cauchy example, it turns out that the improper prior $\pi(\theta_1, \theta_2) = 1/\theta_2$ is the appropriate prior for comparing the models. For other examples of Intrinsic Priors see for instance, Berger and Pericchi (1996a,b, 2001), and Moreno et al. (1998).

Marine Research, Statistics in

Gunnar Stefansson
Professor, Director of the Statistical Center
University of Iceland, Reykjavik, Iceland

Marine science is a wide field of research, including hydrography, chemistry, biological oceanography and fishery science. One may consider that the longer-term aspects of global warming and issues with pollution monitoring are the most critical statistical modeling issues. Somewhat subjectively, the next in line are probably issues which relate to the sustainable use of marine resources, commonly called fishery science. Statistics enters all of the above subfields but the most elaborate models have been developed for fishery science and aspects of these will mainly be described here. Within marine research it was quite common up through about 1980 to use models of the biological processes set up using differential equations, but had no error component and basically transformed observed data through an arbitrary computational mechanism into desired measures of population size, growth, yield potential and so forth (Baranov 1918; Beverton and Holt 1957; Gulland 1965).

Data in fishery science are quite noisy for several reasons. One source of variation is measurement error and one should expect considerable variability in data which

are almost always collected indirectly. Thus one cannot observe the marine community through simple population measurements but only with surveys (bottom trawl, divers etc) or sampling of catch, both of which will provide measures which only relate indirectly to the corresponding stock parameters, are often biased and always quite variable. The second source of variation is due to the biological processes themselves, all of which have natural variation. A typical such process is the recruitment process, i.e., the production of a new yearclass by the mature component of the stock in question. Even for biology, this process is incredibly variable and it is quite hard to extract meaningful signals out of the noise. Unfortunately this process is the single most important process with regard to sustainable utilization (Beverton and Holt 1957, 1993).

As is to be expected, noisy input data will lead to variation in estimates of stock sizes, productivity and predictions (Patterson et al. 2001). As is well-known to statisticians, it is therefore important not only to obtain point estimates but also estimates of variability. In addition to the general noise issue, fisheries data are almost never i.i.d. and examples show how ignoring this can easily lead to incorrect estimates of stock size, state of utilization and predictions (Myers and Cadigan 1995).

Bayesian approaches have been used to estimate stock sizes (Patterson 1999). A particular virtue of Bayesian analysis in this context is the potential to treat natural mortality more sensibly than in other models. The natural mortality rate, M, is traditionally treated as a constant in parametric models and it turns out that this is very hard to estimate unless data are quite exceptional. Thus, M is commonly assumed to be a known constant and different values are tested to evaluate the effect of different assumptions. The Bayesian approach simply sets a prior on the natural mortality like all other parameters and the resulting computations extend all the way into predictions. Other methods typically encounter problems in the prediction phase where it is difficult to encompass the uncertainty in M in the estimate of prediction uncertainty.

One approach to extracting general information on difficult biological parameters is to consider several stocks and even several species. For the stock-recruit question it is clear when many stocks are considered that the typical behavior is such that the stock tend to produce less at low stock sizes, but this signal can rarely be seen for individual stocks. Formalizing such analyses needs to include parameters (as random effects) for each stock and combining them reduces the noise enough to provide patterns which otherwise could not be seen (see e.g., Myers et al. 1999).

In addition to the overall view of sustainable use of resources, many smaller statistical models are commonly considered. For example, one can model growth alone, typically using a nonlinear model, sometimes incorporating environmental effects and/or random effects (Miller 1992; Taylor and Stefansson 1999; Brandão et al. 2004; Gudmundsson 2005).

Special efforts have been undertaken to make the use of nonlinear and/or random effects models easier for the user (Skaug 2002; Skaug and Fournier 2006). Although developed for fishery science, these are generic C++-based model-building languages which undertake automatic differentiation transparently to the user (Fournier 1996).

Most of the above models have been developed for "data-rich" scenarios but models designed for less informative data sets abound. Traditionally these include simple models which were non-statistical and were simply a static model of equilibrium catch but a more time-series orientated approach was set up by Collie and Sissenwine (1983). In some cases these simple population models have been extended to formal random effects models (Conser 1991; Trenkel 2008).

At the other extreme of the complexity scale, several multispecies models have been developed, some of which are formal statistical models (Taylor et al. 2007), though most are somewhat ad-hoc and do not take a statistical approach (Helgason and Gislason 1979; Fulton et al. 2005; Pauly et al. 2000). Simple mathematical descriptions of species interactions are not sufficient here since it is almost always essential to take into account spatial variation in species overlap, different nursery and spawning areas and so forth. For these reasons a useful multispecies model needs to take into account multiple areas, migration and maturation along with several other processes (Stefansson and Palsson 1998). To become statistical models, these need to be set up in the usual statistical manner with likelihood functions, parameters to be formally estimated, methods to estimate uncertainty and take into account the large number of different data sources available through appropriate weighting or comparisons (Richards 1991; Stefansson 1998, 2003).

In the year 2010, the single most promising venue of further research concerns the use of random effects in nonlinear fisheries models. Several of these have been described by Venables and Dichmont (2004) and some examples go a few decades back in time as seen above, often in debated implementations (de Valpine and Hilborn 2005). How this can be implemented in the context of complex multispecies models remains to be seen.

Markov Chain Monte Carlo

Siddhartha Chib

Introduction

Suppose that π is a probability measure on the probability space $(S, \mathcal{A})$, h is a measurable function from $S \to \mathrm{R}$, and one is interested in the calculation of the expectation

$$\bar{h} = \int h d\pi$$

assuming that the integral exists. In many problems, especially when the sample space S is multivariate or when the normalizing constant of π is not easily calculable, finding the value of this integral is not feasible either by numerial methods of integration (such as the method of quadrature) or by classical Monte Carlo methods (such as the method of rejection sampling). In such instances, it is usually possible to find $\bar{h}$ by Markov chain Monte Carlo, or MCMC for short, a method that stems from Metropolis et al. (1953)

in connection with work related to the hydrogen bomb project. It found early and wide use in computational statistical mechanics and quantum field theory where it was used to sample the coordinates of a point in phase space. Applications and developments of this method in statistics, in particular for problems arising in ►Bayesian statistics, can be traced to Hastings (1970), Geman and Geman (1984), Tanner and Wong (1987) and Gelfand and Smith (1990).

The idea behind MCMC is to generate a sequence of draws $\{\boldsymbol{\psi}^{(g)}, g \geq 0\}$ that follow a Markov chain (see ►Markov Chains) with the property that the unique invariant distribution of this Markov chain is the target distribution π. Then, after ignoring the first n_0 draws to remove the effect of the initial value $\boldsymbol{\psi}^{(0)}$, the sample

$$\{\boldsymbol{\psi}^{(n_0+1)}, ..., \boldsymbol{\psi}^{(n_0+M)}\}$$

for M large, is taken as an approximate sample from π and $\bar{h}$ estimated by the sample average

$$M^{-1}\sum_{g=1}^{M} h(\boldsymbol{\psi}^{(n_0+g)})$$

Laws of large numbers for Markov chains show that

$$M^{-1}\sum_{g=1}^{M} h(\boldsymbol{\psi}^{(n_0+g)}) \rightarrow \int h d\pi$$

as the simulation sample size M goes to infinity (Tierney 1994; Chib and Greenberg 1995; Chen et al. 2000; Liu 2001; Robert and Casella 2004).

A key reason for the interest in MCMC methods is that, somewhat surprisingly, it is straightforward to construct one or more Markov chains whose limiting invariant distribution is the desired target distribution. A leading method is the Metropolis–Hasting (M-H) method.

Metropolis–Hastings method

In the Metropolis–Hastings method, as the Hastings (1970) extension of the Metropolis et al. (1953) method is called, the Markov chain simulation is constructed by a recursive two step process.

Let $\pi(\boldsymbol{\psi})$ be a probabiliy measure that is dominated by a sigma-finite measure μ. Let the density of π with respect to μ be denoted by $p(\cdot)$. Let $q(\boldsymbol{\psi}, \boldsymbol{\psi}^{\dagger})$ denote a conditional density for $\boldsymbol{\psi}^{\dagger}$ given $\boldsymbol{\psi}$ with respect to μ. This density $q(\boldsymbol{\psi}, \cdot)$ is referred to as the proposal or candidate generating density. Then, the Markov chain in the M-H algorithm is constructed in two steps as follows.

Step 1 Sample a proposal value $\boldsymbol{\psi}^{\dagger}$ from $q(\boldsymbol{\psi}^{(g)}, \boldsymbol{\psi})$ and calculate the quantity (the *acceptance probability* or the *probability of move*)

$$\alpha(\boldsymbol{\psi}, \boldsymbol{\psi}^{\dagger}) = \begin{cases} \min\left[\frac{p(\boldsymbol{\psi}^{\dagger})q(\boldsymbol{\psi}^{\dagger}, \boldsymbol{\psi})}{p(\boldsymbol{\psi})q(\boldsymbol{\psi}, \boldsymbol{\psi}^{\dagger})}, 1\right] & \text{if } p(\boldsymbol{\psi})q(\boldsymbol{\psi}, \boldsymbol{\psi}^{\dagger}) > 0; \\ 1 & \text{otherwise}. \end{cases}$$

Step 2 Set

$$\boldsymbol{\psi}^{(g+1)} = \begin{cases} \boldsymbol{\psi}^{\dagger} & \text{with prob } \alpha(\boldsymbol{\psi}^{(g)}, \boldsymbol{\psi}^{\dagger}) \\ \boldsymbol{\psi}^{(g)} & \text{with prob } 1 - \alpha(\boldsymbol{\psi}^{(g)}, \boldsymbol{\psi}^{\dagger}) \end{cases}$$

If the proposal value is rejected then the next sampled value is taken to be the current value which means that when a rejection occurs the current value is repeated and the chain stays at the current value. Given the new value, the same two step process is repeated and the whole process iterated a large number of times.

Given the form of the acceptance probability $\alpha(\boldsymbol{\psi}, \boldsymbol{\psi}')$ it is clear that the M-H algorithm does not require knowledge of the normalizing constant of $p(\cdot)$. Furthermore, if the proposal density satisfies the symmetry condition $q(\boldsymbol{\psi}, \boldsymbol{\psi}') = q(\boldsymbol{\psi}', \boldsymbol{\psi})$, the acceptance probability reduces to $p(\boldsymbol{\psi}')/p(\boldsymbol{\psi})$; hence, if $p(\boldsymbol{\psi}') \geq p(\boldsymbol{\psi})$, the chain moves to $\boldsymbol{\psi}'$, otherwise it moves to $\boldsymbol{\psi}'$ with probability given by $p(\boldsymbol{\psi}')/p(\boldsymbol{\psi})$. The latter is the algorithm originally proposed by Metropolis et al. (1953).

A full expository discussion of this algorithm, along with a derivation of the method from the logic of reversibility, is provided by Chib and Greenberg (1995).

The M-H method delivers variates from π under quite general conditions. A weak requirement for a law of large numbers for sample averages based on the M-H output involve positivity and continuity of $q(\boldsymbol{\psi}, \boldsymbol{\psi}')$ for $(\boldsymbol{\psi}, \boldsymbol{\psi}')$ and connectedness of the support of the target distribution. In addition, if π is bounded then conditions for ergodicity, required to establish the central limit theorem (see ►Central Limit Theorems), are satisfied (Tierney 1994).

It is important that the proposal density be chosen to ensure that the chain makes large moves through the support of the invariant distribution without staying at one place for many iterations. Generally, the empirical behavior of the M-H output is monitored by the autocorrelation time of each component of $\boldsymbol{\psi}$ defined as

$$\left\{1 + 2\sum_{s=1}^{M} \rho_{ks}\right\},$$

where ρ_{ks} is the sample autocorrelation at lag s for the kth component of $\boldsymbol{\psi}$, and by the acceptance rate which is the proportion of times a move is made as the sampling proceeds. Because independence sampling produces an autocorrelation time that is theoretically equal to one, one tries to tune the M-H algorithm to get values close to one, if possible.

Different proposal densities give rise to specific versions of the M-H algorithm, each with the correct invariant distribution π. One family of candidate-generating densities is given by $q(\psi, \psi') = q(\psi' - \psi)$. The candidate ψ' is thus drawn according to the process $\psi' = \psi + z$, where z follows the distribution q, and is referred to as the random walk M-H chain. The random walk M-H chain is perhaps the simplest version of the M-H algorithm and is quite popular in applications. One has to be careful, however, in setting the variance of z because if it is too large it is possible that the chain may remain stuck at a particular value for many iterations while if it is too small the chain will tend to make small moves and move inefficiently through the support of the target distribution. Hastings (1970) considers a second family of candidate-generating densities that are given by the form $q(\psi, \psi') = q(\psi')$. Proposal values are thus drawn independently of the current location ψ.

Multiple-Block M-H

In applications when the dimension of ψ is large it is usually necessary to construct the Markov chain simulation by first grouping the variables ψ into smaller blocks. Suppose that two blocks are adequate and that ψ is written as (ψ_1, ψ_2), with $\psi_k \in \Omega_k \subseteq \Re^{d_k}$. In that case the M-H algorithm requires the specification of two proposal densities,

$$q_1\left(\psi_1, \psi_1^{\dagger} | \psi_2\right) \; ; \; q_2\left(\psi_2, \psi_2^{\dagger} | \psi_1\right),$$

one for each block ψ_k, where the proposal density q_k may depend on the current value of the remaining block. Also, define

$$\alpha\left(\psi_1, \psi_1^{\dagger} | \psi_2\right) = \min\left\{\frac{p\left(\psi_1^{\dagger}, \psi_2\right) q_1\left(\psi_1^{\dagger}, \psi_1 | \psi_2\right)}{p(\psi_1, \psi_2) q_1\left(\psi_1, \psi_1^{\dagger} | \psi_2\right)}, 1\right\}$$

and

$$\alpha\left(\psi_2, \psi_2^{\dagger} | \psi_1\right) = \min\left\{\frac{p\left(\psi_1, \psi_2^{\dagger}\right) q_2\left(\psi_2^{\dagger}, \psi_2 | \psi_1\right)}{p(\psi_1, \psi_2) q_2\left(\psi_2, \psi_2^{\dagger} | \psi_1\right)}, 1\right\},$$

as the probability of move for block ψ_k conditioned on the other block. Then, one cycle of the algorithm is completed by updating each block using a M-H step with the above probability of move, given the most current value of the other block.

Gibbs Sampling

A special case of the multiple-block M-H method is the Gibbs sampling method which was introduced by Geman and Geman (1984) in the context of image-processing and broadened for use in Bayesian problems by Gelfand and Smith (1990). To describe this algorithm, suppose that the parameters are grouped into two blocks (ψ_1, ψ_2) and each block is sampled according to the full conditional distribution of block ψ_k,

$$p(\psi_1 | \psi_2) \; ; \; p(\psi_2 | \psi_1)$$

defined as the conditional distribution under π of ψ_k given the other block. In parallel with the multiple-block M-H algorithm, the most current value of the other block is used in sampling the full conditional distribution. Derivation of these full conditional distributions is usually quite simple since, by ▶Bayes' theorem, each full conditional is proportional to $p(\psi_1, \psi_2)$, the joint distribution of the two blocks. In addition, the introduction of latent or auxiliary variables can sometimes simplify the calculation and sampling of the full conditional distributions. Albert and Chib (1993) develop such an approach for the Bayesian analysis of categorical response data.

Concluding Remarks

Some of the recent theoretical work on MCMC methods is related to the question of the rates of convergence (Cai 2000; Fort et al. 2003; Jarner and Tweedie 2003; Douc et al. 2007) and in the development of adaptive MCMC methods (Atchade and Rosenthal; Andrieu and Moulines 2005; 2006).

The importance of MCMC methods in statistics and in particular Bayesian statistics cannot be overstated. The remarkable growth of Bayesian thinking over the last 20 years was made possible largely by the innovative use of MCMC methods. Software programs such as WINBUGS and the various MCMC packages in R have contributed to the use of MCMC methods in applications across the sciences and social sciences (Congdon 2006) and these applications are likely to continue unabated.

About the Author

Siddhartha Chib is the Harry Hartkopf Professor of Econometrics and Statistics at the Olin Business School, Washington University in St. Louis. He is a Fellow of the American Statistical Association and the Director of the NBER-NSF Seminar in Bayesian Inference in Econometrics and Statistics. Professor Chib has made several contributions in the areas of binary, categorical and censored response models, the Metropolis-Hastings algorithm and MCMC methods, the estimation of the marginal likelihood and Bayes factors, and in the treatment of hidden Markov and change-point models, and stochastic volatility and diffusion models. He has served as an Associate Editor

of the *Journal of the American Statistical Association* (Theory and Methods), *Journal of Econometrics*, the *Journal of Business and Economics Statistics*, and others. Currently he is an Associate Editor of the *Journal of Computational and Graphical Statistics*, and *Statistics and Computing*.

Introduction

Markov chains, which comprise Markov chains and ►Markov processes, have been successfully applied in areas as divers as biology, finance, manufacturing, telecommunications, physics and transport planning, and even for experts it is impossible to have an overview on the full richness of Markovian theory. Roughly speaking, Markov chains are used for modeling how a system moves from one state to another at each time point. Transitions are random and governed by a conditional probability distribution which assigns a probability to the move into a new state, given the current state of the system. This dependence represents the memory of the system. A basic example of a Markov chain is the so-called random walk defined as follows. Let $X_t \in N$, for $t \in \mathbb{N}$, be a sequence of random variables with initial value $X_0 = 0$. Furthermore assume that $P(X_{t+1} = X_t + 1 | X_t \geq 1) = p = 1 - P(X_{t+1} = X_t - 1 | X_t \geq 1)$. The sequence $X = \{X_t : t \in \mathbb{N}\}$ is an example of a Markov chain (for a detailed definition see below) and the aspects of X one is usually interested in in Markov chain theory is (i) whether X returns to 0 in a finite number of steps (this holds for $0 \leq p \leq 1/2$), (ii) the expected number of steps until the chain returns to 0 (which is finite for $0 \leq p < 1/2$), and (iii) the limiting behavior of X_t.

In the following we present some realistic examples. A useful model in modeling infectious diseases assumes that there are four possible states: Susceptible (S), Infected (I), Immune (A), Dead (R). Possible transitions are from S to I, S or R; from I to A or R; from A to A or R; from R to R only. The transitions probabilities, from S to I, S to R

and the loop S to S, must sum to one and can depend on characteristics of the individuals modeled, like age, gender, life style, etc. All individuals start in S, and move at each time unit (say a day). Given observations of the sequence of visited states (called trajectory) for a sample of individuals, with their personal characteristics, one can estimate the transition probabilities, by ►logistic regression, for example. This model assumes that the transition probability at time t from one state A to state B, only depends on the state A, and not on the trajectory that lead to A. This might not be realistic, as for example a perdurance in the diseased state I over many days, could increase the probability of transition to R. It is possible to model a system with longer memory, and thus leave the simplest setting of a Markov Chain (though one can formulate such a model still as a Markov Chain over a more complex state space which includes the length of stay in the current state). A second example refers to finance. Here we follow the daily value in Euro of a stock. The state space is continuous, and one can model the transitions from state x Euro to y Euro with an appropriate Normal density with mean $x - y$. The time series of the value of the stock might well show a longer memory, which one would typically model with some autoregressive terms, leading to more complex process again. As a further example, consider the set of all web pages on the Internet as the state space of a giant Markov chain, where the user clicks from one page to the next, according to a transition probability. A Markov Chain has been used to model such a process. The transitions from the current web page to the next web page can be modeled as a mixture of two terms: with probability λ the user follows one of the links present in the current web page and among these uniformly; with probability $1 - \lambda$ the user chooses another web page at random among all other ones. Typically $\lambda = 0.85$. Again, one could discuss how correct the assumption is, that only the current web page determines the transition probability to the next one. The modeler has to critically validate such hypothesis before trusting results based on the Markov Chain model, or chains with higher order of memory. In general a stochastic process has the Markov property if the probability to enter a state in the future is independent of the states visited in the past given the current state. Finally, Markov Chain Monte Carlo (MCMC) algorithms (see ►Markov Chain Monte Carlo) are Markov chains, where at each iteration, a new state is visited according to a transition probability that depends on the current state. These stochastic algorithm are used to sample from a distribution on the state space, which is the marginal distribution of the chain in the limit, when enough iterations have been performed.

In the literature the term Markov processes is used for Markov chains for both discrete- and continuous time cases, which is the setting of this paper. Standard textbooks on Markov chains are Kijima (1997), Meyn and Tweedie (1993), Nummelin (1984), Revuz (1984). In this paper we follow (Iosifescu 1980) and use the term 'Markov chain' for the discrete time case and the term 'Markov process' for the continuous time case. General references on Markov chains are Feller (1968), Gilks et al. (1995), Haeggstroem (2002), Kemeny and Snell (1960), Seneta (1973).

Discrete Time Markov Chains

Consider a sequence of random variables $X = \{X_t : t \in \mathbb{N}\}$ defined on a common underlying probability space $(\Omega, \mathcal{F}, \mathbb{P})$ with state discrete space $(S, \mathcal{S})$, i.e., X_t is $\mathcal{F} - \mathcal{S}$-measurable for $t \in \mathbb{N}$. The defining property of a Markov chain is that the distribution of X_{t+1} depends on the past only through the immediate predecessor X_t, i.e., given $X_0, X_1, \ldots, X_t$ it holds that

$$\mathbb{P}(X_{t+1} = x | X_0 = x_0, X_1 = x_1, \ldots X_{t-1} = x_{t-1}, X_t = y) = \mathbb{P}(X_{t+1} = x | X_t = y),$$

where x, y and all other x_i are element of the given state space S. If $\mathbb{P}(X_{t+1} = x | X_t = y)$ does not depend on t, the chain is called *homogenous* and it is called inhomogeneous otherwise. Provided that S is at most countable, the transition probabilities of a homogeneous Markov Chain are given by $P = (p_{x,y})_{S \times S}$, where $p_{x,y} = \mathbb{P}(X_{t+1} = y | X_t = x)$ is the probability of a transition from x to y. The matrix P is called the *one-step transition probability matrix* of the Markov chain. For the introductory ►random walk example the transition matrix is given by $p_{i,i+1} = p$, $p_{i,i-1} = p - 1$, for $i \geq 1, p_{o,1} = 1$ and otherwise zero, for $i \in \mathbb{Z}$. The row sums are one and the k-th power of the transition matrix represent the probability to move between states in k time units.

In order to fully define a Markov Chain it is necessary to assign an initial distribution $\mu = (\mathbb{P}(X_0 = s) : s \in S)$. The marginal distribution at time t can then be computed, for example, as

$$\mathbb{P}(X_t = x) = \sum_{s \in S} p_{s,x}^{(t)} \mathbb{P}(X_0 = s),$$

where $p_{s,x}^{(t)}$ denotes the s, x element of the t-th power of the transition matrix. Note that given an initial distribution μ and a transition matrix P, the distribution of the Markov chain X is uniquely defined.

A Markov chain is said to be *aperiodic* if for each pair of states i, j the greatest common divisor of the set of all t such that $p_{ij}^{(t)} > 0$ is one. Note that the random walk in

our introductory example fails to be aperiodic as any path from starting in 0 and returning there has a length that is a multiple of 2.

A distribution $(\pi_i : i \in S)$ is called a *stationary distribution* of P if

$$\pi P = \pi.$$

A key topic in Markov chain theory is the study of the limiting behavior of X. Again, with initial distribution μ, X has limiting distribution ν for initial distribution μ if

$$\lim_{t\to\infty} \mu P^t = \nu. \tag{1}$$

Note that any limiting distribution is a stationary distribution. A case of particular interest is that when X has a unique stationary distribution, which is then also the unique limiting distribution and thus describes the limit behavior of the Markov chain. If P fails to be aperiodic, then the limit in (1) may not exists and should be replaced by the Cesaro limit

$$\lim_{t\to\infty} \frac{1}{t}\sum_{k=1}^{t} \mu P^k = \nu,$$

which always exists for finite Markov chains.

A Markov chain is called *ergodic* if the limit in (1) is independent of the initial distribution. Consequently, an ergodic Markov chain has a unique limiting distribution and this limiting distribution is also a stationary distribution, and since any stationary distribution is a limiting distribution it is also unique.

A Markov chain is called *irreducible* if for any pair of states $i, j \in S$, there exists a path from i to j that X will follow with positive probability. In words, any state can be reached from any other state with positive probability. An irreducible Markov chain is called *recurrent* if the number of steps from a state i to the first visit of a state j, denoted by $\tau_{i,j}$, is almost surely finite for all $i, j \in S$, and it is called *positive recurrent* if $\mathbb{E}[\tau_{i,i}] < \infty$ for at least one $i \in S$. Note that for $p = 1/2$ the random walk is recurrent and for $p < 1/2$ it is positive recurrent.

The terminology developed so far allows to present the main result of Markov chain theory: Any aperiodic, irreducible and positive recurrent Markov chain P possesses a unique stationary distribution π which is the unique probability vector solving $\pi P = \pi$ (and which is also the unique limiting distribution). This ▶ergodic theorem is one of the central results and it has been established in many variations and extensions, see the references. Also, efficient algorithms for computing π have been a focus of research as for Markov chains on large state-spaces computing π is a non-trivial task.

An important topic of the statistics of Markov chains is to estimate the (one-step) transition probabilities. Consider a discrete time, homogeneous Markov chain with finite state space $S = \{1, 2, \ldots, m\}$, observed at time points $0, 1, 2, \ldots, T$ on the trajectory $s_0, s_2, s_2, \ldots, s_T$. We wish to estimate the transition probabilities $p_{i,j}$ by maximum likelihood. The likelihood is

$$\begin{aligned}\mathbb{P}(X_0 = s_0) \prod_{t=0}^{'T-1} \mathbb{P}(X_t = s_{t+1} | X_y = s_t) \\ = \mathbb{P}(X_0 = s_0) \prod_{i=1}^{m}\prod_{j=1}^{m} p_{i,j}^{k(i,j)}\end{aligned}$$

where $k(i, j)$ is the number of transitions from i to j in the observed trajectory. Ignoring the initial factor, the maximum likelihood estimator of $p_{i,j}$ is found to be equal to $\hat{p}_{i,j} = \frac{k(i,j)}{k(i,\cdot)}$, where $k(i, \cdot)$ is the number of transitions out from state i. Standard likelihood asymptotic applies, despite the data are dependent, as $k(i, \cdot) \to \infty$, which will happen if the chain is ergodic. The asymptotic variance of the maximum likelihood estimates can be approximated as $\mathrm{var}(\hat{p}_{i,j}) \sim \hat{p}_{i,j}(1 - \hat{p}_{i,j})/k(i, \cdot)$. The covariances are zero, except $\mathrm{cov}(\hat{p}_{i,j}, \hat{p}_{i,j'}) \sim -\hat{p}_{i,j}\hat{p}_{i,j'}/k(i, \cdot)$ for $j \neq j'$. If the trajectory is short, the initial distribution should be considered. A possible model is to use the stationary distribution $\pi(s_0)$, which depend on the unknown transition probabilities. Hence numerical maximization is needed to obtain the maximum likelihood estimates. In certain medical applications, an alternative asymptotic regime can be of interest, when many (k) short trajectories are observed, and $k \to \infty$. In this case the initial distribution cannot be neglected.

Markov Chains and Markov Processes

Let $\{X_t : t \geq 0\}$ denote the (continuous time) Markov process on state space $(S, \mathcal{S})$ with transition matrix $P(t)$, i.e.,

$$(P(t))_{ij} = \mathbb{P}(X_{t+s} = j | X_s = i), \quad s \geq 0, \quad i, j \in S.$$

Under some mild regularity conditions is holds that the *generator matrix* Q, defined as

$$\left.\frac{d}{dt}\right|_{t=0} P(t) = Q,$$

exists for $P(t)$. The stationary distribution of a Markov process can be found as the unique probability π that solves $\pi Q = 0$, see Anderson (1991). A generator matrix Q is called uniformizable with rate μ if $\mu = \sup_j |q_{jj}| < \infty$. While any finite dimensional generator matrix is uniformizable a classical example of a Markov process on denumerable state space that fails to have this property is the M/M/∞

queue. Note that if Q is uniformizable with rate μ, then Q is uniformizable with rate η for any $\eta > \mu$. Let Q be uniformizable with rate μ and introduce the Markov chain P_μ as follows

$$[P_\mu]_{ij} = \begin{cases} q_{ij}/\mu & i \neq j \\ 1 + q_{ii}/\mu & i = j, \end{cases} \tag{2}$$

for $i, j \in S$, or, in shorthand notation,

$$P_\mu = I + \frac{1}{\mu} Q,$$

then it holds that

$$P(t) = e^{-\mu t} \sum_{n=0}^{\infty} \frac{(\mu t)^n}{n!} (P_\mu)^n, \quad t \geq 0. \tag{3}$$

Moreover, the stationary distribution of P_μ and $P(t)$ coincide. The Markov chain $\mathcal{X}_\mu = \{X_n^\mu : n \geq 0\}$ with transition probability matrix P_μ is called the *sampled chain*. The relationship between $\mathcal{X}$ and $\mathcal{X}_\mu$ can be expressed as follows. Let $N_\mu(t)$ denote a Poisson process (see ►Poisson Processes) with rate μ, then $X^\mu_{N_\mu(t)}$ and X_t are equal in distribution for all $t \geq 0$. From the above it becomes clear that the analysis of the stationary behavior of a (uniformizable) continuous time Markov chain reduces to that of a discrete time Markov chain.

About the Authors

Arnoldo Frigessi is Professor in statistics, University of Oslo. He is director of the center for research based innovation Statistics for Innovation (sfi)2 and holds a position at the Norwegian Computing Center. Previously he hold positions at the University of Roma Tre and University of Venice. He is an Elected member of the Royal Norwegian Academy of Science and Letters. He is past scientific secretary of the Bernoulli Society for Mathematical Statistics and Probability. His research is mainly in the area of Bayesian statistics and MCMC, both methodological and applied.

Dr Bernd Heidergott is Associate Professor at the Department of Econometrics, Vrije Universiteit Amsterdam, the Netherlands. He is also research fellow at the Tinbergen Institute and at EURANDOM, both situated in the Netherlands. He has authored and co-authored more than 30 papers and two books, *Max-Plus linear Systems and Perturbation Analysis* (Springer, 2007), and *Max Plus at Work* (with Jacob van der Woude and Geert Jan Olsder, Princeton, 2006.)

Markov Processes

Zoran R. Pop-Stojanović
Professor Emeritus
University of Florida, Gainesville, FL, USA

The class of Markov Processes is characterized by a special stochastic dependence known as the *Markov Dependence* that was introduced in 1907 by A.A. Markov while extending in a natural way the concept of stochastic independence that will preserve, for example, the asymptotic properties of sums of random variables such as the law of large numbers. One of his first applications of this dependence was in investigation of the way the vowels and consonants alternate in literary works in the Russian literature. This dependence that Markov introduced, dealt with what we

call today *a discrete-parameter Markov Chain with a finite number of states,* and it can be stated as follows: a sequence $\{X_n;\ n = 1, 2, \dots\}$ of real-valued random variables given on a probability space $(\Omega, \mathcal{F}, \mathrm{P})$, each taking on a finite number of values, satisfies

$$\mathrm{P}[X_{n+1} = x_{n+1} | X_1, X_2, \dots, X_n] = \mathrm{P}[X_{n+1} = x_{n+1} | X_n]. \quad (1)$$

Roughly speaking, (1) states that *any prediction of* X_{n+1} *knowing*

$$X_1, X_2, \dots, X_n,$$

can be achieved by using X_n *alone.*

This concept was further extended (as shown in what follows), for the *continuous-parameter Markov processes* by A.N. Kolmogorov in 1931. Further essential developments in the theory of continuous-parameter Markov Processes were due to W. Feller, J.L. Doob, G.A. Hunt, and E.B. Dynkin.

In order to introduce a continuous-parameter Markov Process, one needs the following setting. Let $\mathbf{T} \equiv [0, +\infty) \subset \mathbb{R}$ be the parameter set of the process, referred to in the sequel as *time*, where $\mathbb{R}$ denotes the one-dimensional Euclidean space; let $X = \{X_t,\ \mathcal{F}_t,\ t \in \mathbf{T}\}$ be the process given on the probability space $(\Omega, \mathcal{F}, \mathrm{P})$ that takes values in a topological space $(\mathcal{S}, \mathcal{E})$, where $\mathcal{E}$ is a Borel field of $\mathcal{S}$, that is, a σ-field generated by open sets in $\mathcal{S}$. The process X is adapted to the increasing family $\{\mathcal{F}_t,\ t \in \mathbf{T}\}$ of σ-fields of $\mathcal{F}$, where $\mathcal{F}_0$ contains all P-null sets. All X_t's are $\mathcal{E}$-measurable. Here, X_t *is adapted to* $\mathcal{F}_t$ *means that all random events related to* X_t *are contained in* $\mathcal{F}_t$ *for every value* t *of the parameter of the process, that is,* X_t *is* $\mathcal{F}_t$*-measurable in addition of being* $\mathcal{E}$*-measurable.* In order to describe the Markov dependence for the process X, the following two σ-fields are needed: $\forall t,\ t \in \mathbf{T},\ \mathcal{F}_t^{past} = \sigma(\{X_s,\ s \in [0, t]\})$ and $\mathcal{F}_t^{future} = \sigma(\{X_s,\ s \in [t, +\infty)\})$. Here, the *past* and the *future* are relative to the instant t that is considered as the *present.* Now the process $X = \{X_t, \mathcal{F}_t,\ t \in \mathbf{T}\}$ is called a *Markov Process* if and only if one of the following equivalent conditions is satisfied:

$$\begin{aligned}
&(i)\ \forall t,\ t \in \mathbf{T},\ A \in \mathcal{F}_t,\ B \in \mathcal{F}_t^{future}:\\
&\quad \mathrm{P}(A \cap B | X_t) = \mathrm{P}(A | X_t)\mathrm{P}(B | X_t).\\
&(ii)\ \forall t,\ t \in \mathbf{T},\ B \in \mathcal{F}_t^{future}:\\
&\quad \mathrm{P}(B | \mathcal{F}_t) = \mathrm{P}(B | X_t).\\
&(iii)\ \forall t,\ t \in \mathbf{T},\ A \in \mathcal{F}_t:\\
&\quad \mathrm{P}\left(A | \mathcal{F}_t^{future}\right) = \mathrm{P}(A | X_t).
\end{aligned} \quad (2)$$

Observe that (ii) in (2) is the analog of (1) stating that *the probability of an event in the future of the Markov process* X *depends only on the probability of the present state of the process and it is independent of the past history of the process.* There are numerous phenomena occurring in physical sciences, social sciences, econometrics, the world of finance, to name just a few, that can all be modelled by Markov processes. Among Markov processes there is a very important subclass of the so-called *strong Markov processes.* This proper subclass of Markov processes is obtained by *randomizing* the parameter of the process. This randomization of the parameter leads to the so-called *optional times of the process* and the Markov property (2) is replaced by the *strong Markov property*, where in (2) deterministic time t is replaced by an *optional time* of the process. The most important example of a strong Markov process is the *Brownian Motion Process* (see ►Brownian Motion and Diffusions) that models the physical phenomenon known as the *Brownian Movement of particles.* Another important class of processes – *Diffusion processes,* are *strong Markov Processes with continuous paths.*

One of the most important properties of Markov processes is *that times between transitions from one state to another, are random variables that are conditionally independent of each other given the successive states being visited, and each such sojourn time has an exponential distribution with the parameter dependent on the state being visited.* This property coupled with the property that successive states visited by the process form a Markov chain (see ►Markov Chains), clearly describe the structure of a Markov process. Other important examples of Markov processes are ►Poisson processes, Compound Poisson processes, The ►Random Walk, Birth and Death processes, to mention just a few. The last mentioned class of Markov processes has many applications in biology, ►demography, and ►queueing theory.

For further details and proofs of all facts mentioned here, a reader may consult the enclosed list of references.

Martingale Central Limit Theorem

Petra Posedel
Faculty of Economics and Business
University of Zagreb, Zagreb, Croatia

The martingale central limit theorem (MCLT) links the notions of martingales and the Lindeberg–Feller classical central limit theorem (CLT, see ▶Central Limit Theorems) for independent summands.

Perhaps the greatest achievement of modern probability is the unified theory of limit results for sums of independent random variables, such as the law of large numbers, the central limit theorem, and the law of the iterated logarithm. In comparison to the classical strong law of large numbers, the classical CLT says something also about the rate of this convergence. We recall the CLT for the case of independent, but not necessarily identically distributed random variables. Suppose that $\{X_i,\ i \geq 1\}$ is a sequence of zero-mean independent random variables such that $Var[X_n] = \sigma_n^2 < \infty,\ n \geq 1$. Let $S_n = \sum_{i=1}^n X_i,\ n \geq 1$ and set $Var[S_n] = s_n^2$. If the Lindeberg condition holds, i.e., $\frac{\sum_{i=1}^n E\left[X_i \mathbb{1}_{\{|X_i| \geq \epsilon s_n\}}\right]}{s_n^2} \longrightarrow 0$ as $n \to \infty$, for all $\epsilon > 0$, and $\mathbb{1}_{\{.\}}$ denoting the indicator function, then $\frac{S_n}{s_n} \xrightarrow{\mathcal{D}} N(0,1)$, where $N(0,1)$ denotes the standard normal random variable.

Limit theorems have applicability far beyond the corresponding results for sums of independent random variables. Namely, since sums of independent random variables centered at their expectations have a specific dependence structure (i.e., are martingales), there is interest in extending the results to sums of dependent random variables.

In order to define martingales and state the MCLT attributed to Brown (1971), one needs the following setting. Let $(\Omega,\ \mathcal{F},\ \mathbb{P})$ be a probability space and let $\{\mathcal{F}_n,\ n \geq 0\}$ be an increasing sequence of σ-fields of $\mathcal{F}$ sets.

Definition 1 *A sequence $\{Y_n,\ n \geq 0\}$ of random variables on Ω is said to be a martingale with respect to $\{\mathcal{F}_n,\ n \geq 0\}$ if (1) Y_n is measurable with respect to $\mathcal{F}_n$, (2) $E|Y_n| < \infty$, and (3) $E[Y_n|\mathcal{F}_m] = Y_m$ a.s. for all $m < n,\ m,\ n \geq 0$.*

In order to highlight the dependence structure of the underlying random variables, one should note that condition (3) is weaker than independence since it cannot be deduced which structure conditional higher-order moments may have given the past. The mathematical theory of martingales may be regarded as an extension of the independence theory, and it too has its origins in limit results, beginning with Bernstein (1927) and Lévy's (1935) early central limit theorems. These authors introduced the martingale in the form of consecutive sums with a view to generalizing limit results for sums of independent random variables. However, it was the subsequent work of Doob, including the proof of the celebrated martingale convergence theorem, that completely changed the direction of the subject, and his book (Doob 1953), popularly called in academia the *Holy Bible for stochastic processes*, has remained a major influence for nearly three decades.

The main result that follows applies the CLT to sequences of random variables that are martingales. If $\{S_n,\ \mathcal{F}_n\}$ is a martingale, it seems natural to replace $Var[S_n]$ in the CLT by the sum of conditional variances. Secondly, the norming by $1/n$ is very restrictive. For a sequence of independent, but not identically distributed random variables, it seems appropriate to norm by a different constant, and for a sequence of dependent random variables norming by another random variable should be considered. The limit theory for martingales essentially covers that for the categories of processes with independent increments and ▶Markov processes. Using stochastic processes that are martingales for analyzing limit results, one has at their disposal all the machinery from martingale theory. This reason makes martingales considerably attractive for inference purposes. A standard reference on martingales is Williams (1991).

Theorem 1 *Let $\{S_n,\ \mathcal{F}_n,\ n \geq 1\}$ be a zero-mean martingale with $S_0 = 0$, whose increments have finite variance. Write*

$$S_n = \sum_{i=1}^n X_i, \quad V_n^2 = \sum_{i=1}^n E\left[X_i^2 | \mathcal{F}_{i-1}\right], \quad \text{and}$$
$$s_n^2 = E\left[V_n^2\right] = E\left[S_n^2\right]. \tag{1}$$

If

$$\frac{V_n^2}{s_n^2} \xrightarrow{\mathbb{P}} 1 \quad \textit{and} \quad \frac{\sum_{i=1}^{n} E\left[X_i^2 \mathbb{1}_{\{|X_i| \geq \epsilon s_n\}}\right]}{s_n^2} \xrightarrow{\mathbb{P}} 0 \qquad (2)$$

as $n \to \infty$, *for all* $\epsilon > 0$, *and* $\mathbb{1}_{\{.\}}$ *denoting the indicator function, then*

$$\frac{S_n}{s_n} \xrightarrow{\mathcal{D}} N(0,1), \qquad (3)$$

where $N(0,1)$ *denotes the standard normal random variable.*

Roughly speaking, (3) says that the sum of martingale differences, when scaled appropriately, is approximately normally distributed provided the conditional variances are sufficiently well behaved. The theorem seems relevant in any context in which conditional expectations, given the past, have a simple and possibly explicit form. Various results on sums of independent random variables in fact require only orthogonality of the increments, i.e., $E[X_i X_j] = 0$, $i \neq j$, and this property holds for martingales whose increments have finite variance. The MCLT reduces to the sufficiency part of the standard Lindeberg–Feller result in the case of independent random variables.

The interpretation of V_n^2 is highlighted and particularly interesting for inference purposes. Let $X_1, X_2, \ldots$ be a sequence of observations of a stochastic process whose distribution depends on a (single) parameter θ, and let $L_n(\theta)$ be the likelihood function associated with $X_1, X_2, \ldots$. Under very mild conditions, score functions $S_n = \partial \log L_n(\theta)/\partial\theta$ form a martingale whose conditional variance $V_n^2 = I_n(\theta)$ is a generalized form of the standard Fisher information, as shown in Hall and Heyde (1980). Namely, suppose that the likelihood function $L(\theta)$ is differentiable with respect to θ and that $E_\theta[\partial \log L(\theta)/\partial\theta]^2 < \infty$.
Let θ be a true parameter vector. We have

$$S_n = \frac{\partial \log L_n(\theta)}{\partial\theta} = \sum_{i=1}^{n} x_i(\theta),$$

$$x_i(\theta) = \frac{\partial}{\partial\theta}[\log L_i(\theta) - \log L_{i-1}(\theta)],$$

and thus $E_\theta[x_i(\theta)|\mathcal{F}_{i-1}] = 0$ a.s., so that $\{S_n, \mathcal{F}_n, n \geq 1\}$ is a square-integrable martingale. Set $V_n^2 = \sum_{i=1}^{n} E_\theta\left[x_i^2(\theta)\middle|\mathcal{F}_{i-1}\right]$. The quantity V_n^2 reduces to the standard Fisher information $I_n(\theta)$ in the case where the observations $\{X_i, i \geq 1\}$ are independent random variables. If the behavior of V_n^2 is very erratic, then so is that of S_n, and it may not be possible to obtain a CLT.

So, if we have a reasonably large sample, we can assume that estimators obtained from estimating functions that are martingales, have an approximately normal distribution, which can be used for testing and constructing confidence intervals. A standard reference for the more general theory of martingale estimating functions is Sørensen (1999).

Billingsley (1961), and independently Ibragimov (1963), proved the central limit theorem for martingales with stationary and ergodic differences. For such martingales the conditional variance V_n^2 is asymptotically constant, i.e., $\frac{V_n^2}{s_n^2} \xrightarrow{P} 1$. Brown (1971) showed that the first part of condition (2) and not stationarity or ergodicity is crucial for such a result to hold. Further extensions in view of other central limit theorems for double arrays are based on Dvoretzky (1970) and McLeish (1974), where limit results employ a double sequence schema $\{X_{n,j}, 1 \leq j \leq k_n < \infty, n \geq 1\}$ and furnish conditions for the row sums $S_n = \sum_{j=1}^{k_n} X_{n,j}$ to converge in distributions to a mixture of normal distributions with means zero. A large variety of negligibility assumptions have been made about differences $X_{n,j}$ during the formulation of martingale central limit theorems. The classic condition of negligibility in the theory of sums of independent random variables asks the $X_{n,j}$ to be uniformly asymptotically negligible.

A comprehensive review on mainly one-dimensional martingales can be found in Helland (1982). Multivariate versions of the central limit theorem for martingales satisfying different conditions or applicable to different frameworks, can be found in Hutton and Nelson (1984), Sørensen (1991), Küchler and Sørensen (1999), Crimaldi and Pratelli (2005), and Hubalek and Posedel (2007).

Martingales

Rüdiger Kiesel
Professor, Chair for energy trading and financial services
Universität Duisburg-Essen, Duisburg, Germany

The fundamental theorem of asset pricing (The term *fundamental theorem of asset pricing* was introduced in Dybvig and Ross [1987]. It is used for theorems establishing the equivalence of an economic modeling condition such as no-arbitrage to the existence of the mathematical modeling condition existence of equivalent martingale measures.) links the martingale property of (discounted) asset price processes under a particular class of probability measures to the 'fairness' (in this context no arbitrage condition) of financial markets. In elementary models one such result is *In an arbitrage-free complete financial market model, there exists a unique equivalent martingale measure*, see e.g., Bingham and Kiesel (2004).

So despite martingales have been around for more than three and a half centuries they are still at the forefront of applied mathematics and have not lost their original motivation of describing the notion of fairness in games of chance. The *Oxford English Dictionary* lists under the word *martingale* (we refer to Mansuy [2009] for a interesting account of the etymology of the word): A system of gambling which consists in doubling the stake when losing in order to recoup oneself (1815).

Indeed, the archetype of a martingale is the capital of a player during a fair gambling game, where the capital stays "constant on average"; a supermartingale is "decreasing on average," and models an unfavourable game; a submartingale is "increasing on average," and models a favorable game.

Gambling games have been studied since time immemorial – indeed, the Pascal–Fermat correspondence of 1654 which started the subject was on a problem (de Méré's problem) related to gambling. The doubling strategy above has been known at least since 1815. The term "martingale" in our sense is due to J. Ville (1910–1989) in his thesis in 1939. Martingales were studied by Paul Lévy (1886–1971) from 1934 on (see obituary Loève (1973)) and by J.L. Doob (1910–2004) from 1940 on. The first systematic exposition was Doob (1953). Nowadays many very readable accounts exist, see Neveu (1975), Williams (1991) and Williams (2001).

Martingales are of central importance in any modelling framework which uses ▶stochastic processes, be it in discrete or continuous time. The concept has been central to the theory of stochastic processes, stochastic analysis, in mathematical statistics, information theory, and in parts of mathematical physics, see Kallenberg (1997) and Meyer (2009) for further details. The Martingale gambling insight 'You can't beat the system' establishes properties of martingale transforms and lays the foundation of stochastic integrals, Øksendal (1998). Martingale stopping results establish optimality criteria which help develop optimal strategies for decision problems (and exercising financial options), see Chow (1971) and Shiryaev (2007).

We can here only give a few fundamental definitions and results and point to the vast literature for many more exiting results.

For the definition, let I be a suitable (discrete or continuous) index set and assume that an index t is always taken from I. Given a stochastic basis $(\Omega, \mathcal{F}, I\!P, I\!F = \{\mathcal{F}_t\})$ (where the filtration $I\!F$ models the flow of information) we call a process $X = (X_t)$ a *martingale* relative to $(\{\mathcal{F}_t\}, I\!P)$ if

(i) X is adapted (to $\{\mathcal{F}_t\}$).
(ii) $I\!E|X_t| < \infty$ for all t.
(iii) For $s \le t$ we have $I\!E[X_t|\mathcal{F}_s] = X_s \quad I\!P - a.s.$.

X is a *supermartingale* if in place of (ii)

$$\mathbb{E}[X_t|\mathcal{F}_s] \le X_s \quad \mathbb{P}-a.s.;$$

X is a *submartingale* if in place of (iii)

$$\mathbb{E}[X_t|\mathcal{F}_s] \ge X_s \quad \mathbb{P}-a.s..$$

Basic examples are the mean-zero ►random walk: $S_n = \sum X_i$, with X_i independent, where for $\mathbb{E}(X_i) = 0$ S_n is a martingale (submartingales: positive mean; supermartingale: negative mean) and stock prices: $S_n = S_0\zeta_1\cdots\zeta_n$ with ζ_i independent positive r.vs with existing first moment. (See Williams (1991) and Williams (2001) for many more examples). In continuous time the central example is that of Brownian motion, see Revuz and Yor (1991), Karatzas and Shreve (1991), which of course is a central process for many branches of probability (see also ►Brownian Motion and Diffusions).

Now think of a gambling game, or series of speculative investments, in discrete time. There is no play at time 0; there are plays at times $n = 1, 2, \ldots$, and

$$\Delta X_n := X_n - X_{n-1}$$

represents our net winnings per unit stake at play n. Thus if X_n is a martingale, the game is "fair on average."

Call a process $C = (C_n)_{n=1}^{\infty}$ *predictable* if C_n is $\mathcal{F}_{n-1}$-measurable for all $n \ge 1$. Think of C_n as your stake on play n (C_0 is not defined, as there is no play at time 0). Predictability says that you have to decide how much to stake on play n based on the history *before* time n (i.e., up to and including play $n-1$). Your winnings on game n are $C_n\Delta X_n = C_n(X_n - X_{n-1})$. Your total (net) winnings up to time n are

$$Y_n = \sum_{k=1}^{n} C_k\Delta X_k = \sum_{k=1}^{n} C_k(X_k - X_{k-1}).$$

This constitutes the *Martingale transform* of X by C.

The central theorem for betting and applications in finance says that "You can't beat the system!," i.e., if X is a martingale then the martingale transform is a martingale (under some mild regularity conditions on C). So in the martingale case, predictability of C means we can't foresee the future (which is realistic and fair). So we expect to gain nothing – as we should, see e.g., Neveu (1975). Likewise one can analyze different strategies to stop the game, then Doob's stopping time principle reassures that it is not possible to beat the system, see e.g., Williams (2001).

Martingale transforms were introduced and studied by Burkholder (1966). They are the discrete analogs of stochastic integrals and dominate the mathematical theory of finance in discrete time, see Shreve (2004), just as stochastic integrals dominate the theory in continuous time, see Harrison and Pliska (1981). The various links between mathematical finance and martingale theory are discussed in Musiela and Rutkowski (2004) and Karatzas and Shreve (1998).

Martingale-convergence results are among the most important results in probability (arguably in mathematics). Hall and Heyde (1980) and Chow (1988) are excellent sources, but Doob (1953) lays the foundations. Martingale techniques play a central role in many parts of probability, consult Rogers (1994), Revuz and Yor (1991), Karatzas and Shreve (1991) or Kallenberg (1997) for excellent accounts. Martingales appear in time series theory and sequential analysis, see Lai (2009) and Hamilton (1994).

About the Author

Rüdiger Kiesel holds the chair of energy trading and financial services (sponsored by the Stifterverband für die Deutsche Wissenschaft and RWE Supply & Trading; the first such chair in Europe). Previously, he was Professor and Head of the Institute of Financial Mathematics at Ulm University. Kiesel also holds guest professorships at the London School of Economics and the Centre of Mathematical Applications at the University of Oslo. His main research areas are currently risk management for power utility companies, design and analysis of credit risk models, valuation and hedging of derivatives (interest-rate, credit- and energy-related), methods of risk transfer and structuring of risk (securitization), and the stochastic modelling of financial markets using Lévy-type processes. He is on the editorial board of the *Journal of Energy Markets* and co-author (with Nicholas H. Bingham) of the Springer Finance monograph *Risk-Neutral Valuation: Pricing and Hedging of Financial Derivatives* (2nd edition, 2004).

Mathematical and Statistical Modeling of Global Warming

Chris P. Tsokos
Distinguished University Professor
University of South Florida, Tampa, FL, USA

Introduction

Do we scientifically understand the concept of "Global Warming"? A very basic definition of "Global Warming" is an increase in temperature at the surface of the earth supposedly caused by the greenhouse effect, carbon dioxide, CO_2 (greenhouse gas). The online encyclopedia, Wikipedia, defines the phenomenon of "GLOBAL WARMING" as the increase in the average temperature of the earth's near surface air and oceans in the recent decades and its projected continuation.

For the past 3 years this has been a media chaos: pro and concerned skeptics. The Intergovernmental Panel of the United States on Climate Change (IPCC) – "Climate Change 2007" claimed that the following are some of the causes of Global Warming:

- Increase in temperature – Increase in sea level
- Unpredictable pattern in rainfall
- Increase in extreme weather events
- Increase in river flows
- Etc.

Furthermore, the award winning documentary narrated by Vice President Gore strongly supports the IPCC findings. However, the ABC news program 20/20 "Give Me a Break," raises several questions and disputes the process by which IPCC stated their findings. A number of professional organizations, the American Meteorological Society, American Geographical Union, AAAS, supported the subject matter. The U.S. National Academics blame global warming on human activities.

The concerned skeptics raise several points of interest concerning Global Warming. Great Britain's Channel 4 Documentary entitled "*The Great Global Warming Swindle*" disputes several of the aspects of Vice President former documentary. NASA scientists reveal through their scientific experiments and studies that the increase in atmospheric temperature is due to the fact that sea spots are hotter than previously thought. Their findings are also reported by the *Danish National Space Center*, DNSC, on similar investigations conducted by NASA. DNSC stated that there is absolutely nothing we can do to correct this situation. *Times Washington Bureau Chief*, Bill Adair, states that "Global Warming has been called the most dire issue facing the planet and yet, if you are not a scientist, it can be difficult to sort out the truth." The Wall Street Journal in a leading article "Global Warming is 300-year-old News," stated that "the various kind of evidence examined by the *National Research Council*, NRC, led it to conclude that the observed disparity between the surface and atmospheric temperature trends during the 20-year period is probably at least partially real." It further stated that "uncertainties in all aspects exist- cannot draw any conclusion concerning *Global Warming*." However, the NRC study concluded with an important statement that "major advances in scientific

methods will be necessary before these questions on *Global Warming* can be resolved."

Furthermore, the temperature increase that we are experiencing are infinitesimal, during the past 100 years – the mean global surface air temperature increased by approximately $1.3^{\circ}F$ $(0.32^{\circ}F)$. Dr. Thomas G. Moore, Senior Fellow at the Hoover Institute at Stanford University, in his article entitled "Climate of Fear: Why We Shouldn't Worry About Global Warming" is not concerned with such small changes in temperatures. Furthermore, in his interview with *Newsweek*, he said more people die from cold than from warmth and an increase of a few degrees could prevent thousands of deaths.

It is well known that carbon dioxide, CO_2, and surface/atmospheric temperatures are the primary cause of "GLOBAL WARMING." Jim Verhult, Perspective Editor, *St. Petersburg Times*, writes, "carbon dioxide is invisible – no color, no odor, no taste. It puts out fires, puts the fizz in seltzer and it is to plants what oxygen is to us. It's hard to think of it as a poison." The U.S.A. is emitting approximately 5.91221 billion metric tons of CO_2 in the atmosphere, which makes us the world leader; however, by the end of 2007, the Republic of China became the new leader. Temperatures and CO_2 are related in that as CO_2 emissions increase, the gasses start to absorb too much sunlight and this interaction warms up the globe. Thus, the rise in temperature and the debate of "GLOBAL WARMING."

While working on the subject matter, an article appeared on the front page of the *St. Petersburg Times* on January 23, 2007. This article, entitled "Global Warming: Meet your New Adversary," was written by David Adams. The highlight of this article was a section called "By the Numbers," which stated some information concerning the continental United States: 2006 hottest year; U.S. top global warming polluter; 20% increase of CO_2 since 1990; 15% of CO_2 emissions by 2020; 78 number of days U.S. fire season has increased; and 200 million people that will be displaced due to global warming. Our data for the continental U.S. does not support the first four statistics, we have no data for the fifth, and the sixth is quite hypothetical. The final assertion, with "0" representing the number of federal bills passed by the Congress to cap America's global warming pollution. Thus, it is very important that we perform sophisticated statistical analysis and modeling to fully understand the subject matter. Also, very recently, the Supreme Court of the U.S., in one of its most important environmental decisions, ruled that the Environmental Protection Agency (EPA) has the authority to regulate the greenhouse gases that contribute to global climate changes unless it can provide a scientific basis for its refusal.

We believe that a contributing factor in creating these controversies among scientists (and this is passed onto the policymakers and the media) is a lack of precise and accurate statistical analysis and modeling of historical data with an appropriate degree of confidence. The problem of "GLOBAL WARMING" is very complex with a very large number of contributing entities with significant interactions. The complexity of the subject matter can be seen in the attached diagram "A Schematic View" (Fig. 1). We believe that statisticians/mathematicians can help to create a better understanding of the subject problem that hopefully will lead to the formulation of legislative policies.

Thus, to scientifically make an effort to understand "Global Warming," we must study the marriage of CO_2 and atmosphere temperature, individually and together, using available historical data. Here we shall briefly present some parametric statistical analysis, forecasting models for CO_2 and atmospheric temperature, T_a along with a differential equation, that give the rate of change of CO_2 as a function of time. Scientists can utilize these preliminary analysis and models to further the study of Global Warming. Additional information can be found in Tsokos (2007a, b), and Tsokos 2008b.

Atmospheric Temperature, T_a

Here we shall utilize historical temperature data recorded in the Continental United States from 1895 to 2007, to parametrically identify the probability density of the subject data and to develop a forecasting model to predict short and long term values of T_a.

The probability density function, pdf, of T_a is the three-parameter lognormal pdf. It is given by

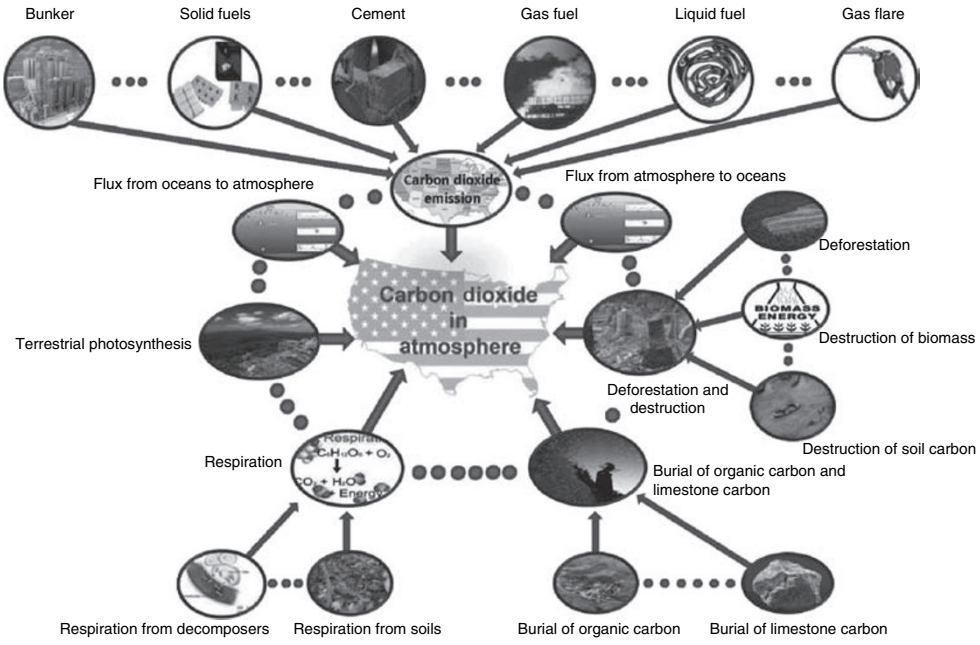
$$f(t;\mu,\theta,\sigma) = \frac{\exp\left\{-\frac{1}{2}\left[\ln(t-\theta)-\mu\right]^2\right\}}{(t-\theta)\sigma\sqrt{2\pi}},\quad t \geq \theta, \sigma, \mu > 0, \tag{1}$$

where μ, σ and θ, are the scale, shape and location parameters, respectively.

For the given T_a data the maximum likelihood estimation of population parameter, μ, σ and θ are $\hat{\mu} = 3.59, \hat{\sigma} = 0.019$ and $\hat{\theta} = 0.195$. Thus, the actual pdf that we will be working with is given by

$$f(t;\hat{\mu},\hat{\theta},\hat{\sigma}) = \frac{\exp\left\{-\frac{1}{2}\left[\ln(t-0.195)-2.59\right]^2\right\}}{(t-0.195)\cdot 0.019\sqrt{2\pi}},\quad t \geq 0.195. \tag{2}$$

Having identified the pdf that probabilistically characterizes the behavior of the atmospheric T_a, we can obtain the expected value of T_a, all the useful basic statistics along with being able to obtain confidence limits on the true T_a.



Mathematical and Statistical Modeling of Global Warming. Fig. 1 Carbon dioxide (CO_2) in the atmosphere in USA "A Schematic View"

Such a pdf should be applicable in other countries around the world.

The subject data, T_a, is actually a stochastic realization and is given as nonstationary time series. The development of the multiplicative seasonal autoregressive integrated moving average, ARIMA model is defined by

$$\Phi_p(B^s)\phi(1-B)^d(1-B^s)^D x_t = \theta_q(B)\Gamma_Q(B^s)\varepsilon_t, \qquad (3)$$

where p is the order of the autoregressive process; d is the order of regular differencing; q is the order of the moving average process; P is the order of the seasonal autoregressive process; D is the order of the seasonal differencing; Q is the order of the seasonably moving average process; and s refers to the seasonal period, and

$$\begin{aligned}
\phi_p(B) &= (1-\phi_1 B-\phi_2 B^2-\cdots-\phi_p B^p)\\
\theta_q(B) &= (1-\theta_1 B-\theta_2 B^2-\cdots-\theta_q B^q)\\
\Phi_P(B^s) &= 1-\Phi_1 B^s-\Phi_2 B^{2s}-\cdots-\Phi_P B^{Ps}\\
\Gamma_Q(B^s) &= 1-\Gamma_1 B^s-\Gamma_2 B^{2s}-\cdots-\Gamma_Q B^{Qs}.
\end{aligned}$$

The developing process of (3) using the actual data is complicated and here we present the final useful form of the model. The reader is referred to Shih and Tsokos (2007, 2009) for details.

The estimated forecasting model for the atmospheric data is given by

$$\begin{aligned}
\hat{x}_t = {} & 1.0941x_{t-1} - 0.057x_{t-2} - 0.0371x_{t-3} + 0.9954x_{t-12}\\
& - 1.0891x_{t-13} + 0.0567x_{t-14} + 0.0369x_{t-15}\\
& + 0.0046x_{t-24} + 0.0895x_{t-25} - 0.0004x_{t-26}\\
& + 0.0017x_{t-27} - 0.9861\varepsilon_{t-1} - 0.9742\Gamma_1\varepsilon_{t-12}\\
& + 0.9607\varepsilon_{t-13}. \qquad (4)
\end{aligned}$$

The mean of the residuals, $\bar{r}$, the variance, S_r^2, the standard deviation, S_r, standard error, SE, and the mean square error, MSE, are presented below for one unit of time ahead forecasting.

$\bar{r}$	S_r^2	S_r	SE	MSE
−0.008512476	4.331902	2.081322	0.05673052	4.328756

These numerical results give an indication of the quality of the developed model.

Carbon Dioxide, CO_2

Parametric Analysis

The other most important entity in Global Warming is CO_2. The complexity of CO_2 in the atmosphere is illustrated by the schematic diagram that was introduced. To

better understand CO_2, we need to probabilistically determine the best probability distribution, pdf, that characterizes its behavior. Presently, scientists working on the subject matter make the assumption that CO_2 in the atmosphere follows the classical Gaussian pdf and that is not the best possible fit of the actual data and could lead to misleading decisions. The actual data that we are using was collected in the Island of Hawaii/Mauna Loa from 1990 to 2004. Through goodness-of-fit statistical testing, the best fit of the CO_2 data that we can study its behavior probabilistically is the three-parameter Weibull pdf. The cumulative three-parameter Weibull probability distribution is given by

$$F(x) = 1 - \exp\left\{-\left(\frac{x-\gamma}{\beta}\right)^{\alpha}\right\},\ \gamma \le x < \infty, \delta > 0, \beta > 0 \quad (5)$$

where α, β, and γ are the shape, scale, and location parameter. The nth moment, mean and variance are given by

$$m_n = \beta^n \Gamma\left(1+\frac{n}{\alpha}\right),\ \mu = \beta\Gamma\left(1+\frac{1}{\alpha}\right) \text{ and } \sigma^2 = \beta^2\Gamma\left(1+\frac{2}{\alpha}\right) - \mu,$$

respectively, where Γ is the gamma function. The approximate maximum likelihood estimates of the true parameters, α, β and γ for the Hawaii data are given by

$$\hat{\alpha} = 2.108,\ \hat{\beta} = 17.092,\ \text{and } \hat{\gamma} = 349.6.$$

Thus, the cumulative pdf that we can use to probabilistically characterize the CO_2 behavior and answer related questions is given by:

$$F(x) = 1 - \exp\left\{-\left(\frac{x-349.6}{17.092}\right)^{2.108}\right\}. \quad (6)$$

For additional details of the subject area see Shih and Tsokos (2009).

Forecasting Model of CO_2

Here we present a forecasting model of CO_2 in the atmosphere. Having such a model will allow us to accurately predict the amount of CO_2 in the atmosphere, and make appropriate decisions as needed. The actual CO_2 data as a function of time results in a nonstationary time series. For details in the development of this model, see Shih and Tsokos (2009). The best forecasting model that we developed is an ARIMA model with second order autoregressive process, with a first order moving average process and a 12-month seasonal effect. Its final form is given by

$$\begin{aligned}\hat{CO}_{2_A} &= 0.6887x_{t-1} + 0.1989x_{t-2} + 0.1124x_{t-3} + 1.0759x_{t-12} \\ &\quad - 0.74097x_{t-13} - 0.213997x_{t-14} - 0.12093x_{t-15} \\ &\quad - 0.0683x_{t-24} + 0.047038x_{t-25} + 0.013585x_{t-26} \\ &\quad + 0.00768x_{t-27} - 0.00076x_{t-36} + 0.005234x_{t-37} \\ &\quad + 0.0015116x_{t-38} + 0.00085x_{t-39} - 0.8787\varepsilon_{t-12}.\end{aligned}$$

A similar statistical model can be developed for CO_2 emission, Shih and Tsokos (2009).

A Differential Equation of CO_2 in the Atmosphere

The main attributable variables in CO_2 in the atmosphere are:

E: CO_2 emission (fossil fuel combination)
D: Deforestation and destruction
R: Terrestrial plant respiration
S: Respiration
O: the flux from oceans to atmosphere
P: terrestrial photosynthesis
A: the flux from atmosphere to oceans
B: Burial of organic carbon and limestone carbon

One important question that we would like to know is the rate of change of CO_2 as a function of time. The general form of the differential equation of the subject matter is of the form:

$$\frac{d(CO_2)}{dt} = f(E, D, R, S, O, P, A, B)$$

or

$$CO_{2_A} = \int (E + D + R + S + (O - A) - P - B)dt.$$

Here, B, P and R are constants, thus

$$\begin{aligned}CO_{2_A} = \int &(k_E E + k_D D + k_R R + k_S S + k_{O-A}(O - A) \\ &+ k_P P - k_B B)dt.\end{aligned}$$

Using the available data we can estimate the functional analytical form of all the attributable variables that appear

in the integrand. Thus, the final working form of CO_2 in the atmosphere is given by

$$CO_2 = \begin{cases} k_E\{-593503t + 2.4755 \times 10^9 e^{-\frac{1}{1200}}\} \\ +k_D(10730.5t + 0.01625t^2) \\ +k_S\{-0.132(1995 + \frac{t}{12})^4 + 1054.4(1995 + \frac{t}{12})^3 \\ -315462(1995 + \frac{t}{12})^2 + 3 \times 10^8 t\} \\ +K_{A-O}\{42.814t - 4.2665t^2 \\ +0.0967t^3\} - k_P \int Pdt - k_B \int Bdt \end{cases}.$$

Having a workable form of the differential equation, we can develop the necessary algorithm to track the influence the attributable variables will have in estimating the change of rate of CO_2 as a function of time.

Conclusion

Finally, is the "Global Warming" phenomenon real? Yes. However, it is not as urgent as some environmentalists claim. For example, our statistical analytical models predict that in the next 10 years, 2019, we will have an increase of carbon dioxide in the atmosphere in the continental U.S. of approximately 7%. In developing a strategic legislative plan, we must address the economic impact it will have in our society. In our present global economic crisis, introducing legislation to address Global Warming issues will present additional critical economic problems. In a global context we must consider about 155 economic developing countries that have minimal to no strategic plans in effect that collect the necessary information that addresses the subject matter in their country. Furthermore, we have approximately 50 undeveloped countries that have minimum understanding about the concept of global warming. Thus, talking about developing global strategies and policies about "Global Warming" is quite premature.

Maximum Entropy Method for Estimation of Missing Data

D. S. Hooda
Professor and Dean (Research)
Jaypee University of Engineering and Technology, Guna, India

In field experiments we design the field plots. In case we find one or more observations missing due to natural calamity or destroyed by a pest or eaten by animals, it is cumbersome to estimate the missing value or values as in field trials it is practically impossible to repeat the experiment under identical conditions. So we have no option except to make best use of the data available. Yates (1933) suggested a method: "Substitute x for the missing value and then choose x so as to minimize the error sum of squares."

Actually, the substituted value does not recover the best information, however, it gives the best estimate according to a criterion based on the least square method. For the randomized block experiment

$$x = \frac{pP + qQ - T}{(p-1)(q-1)}, \tag{1}$$

where

p = number of treatments;
q = number of blocks;
P = total of all plots receiving the same treatment as the missing plot;
Q = total of all plots in the same block as the missing plot; and
T = total of all plots.

For the Latin Square Design, the corresponding formula is

$$x = \frac{p(P_r + P_c + P_t) - 2T}{(p-1)(q-1)}, \tag{2}$$

where

p = number of rows or columns of treatments;
P_r = total of row containing the missing plot;
P_c = total of column containing the missing plot;
P_t = total of treatment contained in the missing plot; and
T = grand total.

In case more than one plot yields are missing, we substitute the average yield of available plots in all except one of these and substitute x in this plot. We estimate x by Yate's method and use this value to estimate the yields of other plots one by one.

Next we discuss the maximum entropy method. If $x_1, x_2, \ldots, x_n$ are known yields and x is the missing yield. We obtain the maximum entropy estimate refer to Kapur and Kesavan (1992) for x by maximizing:

$$-\sum_{i=0}^{n} \frac{x_i}{T+x} \log \frac{x_i}{T+x} - \frac{x}{T+x} \log \frac{x}{T+x}. \tag{3}$$

Thus we get

$$\hat{x} = \left[x_1^{x_1} x_2^{x_2} \ldots x_n^{x_n}\right]^{\frac{1}{T}}, \tag{4}$$

where $T = \sum_{i=1}^{n} x_i$.

The value given by (4) is called maximum entropy mean of $x_1, x_2, \ldots, x_n$.

Similarly, if two values x and y are missing, x and y are determined from

$$\hat{x} = \left[x_1^{x_1} x_2^{x_2} \ldots x_n^{x_n}\right]^{\frac{1}{T+y}}, \tag{5}$$

$$\hat{y} = \left[x_1^{x_1} x_2^{x_2} \ldots x_n^{x_n}\right]^{\frac{1}{T+x}}. \tag{6}$$

The solution of (5) and (6) is

$$\hat{x} = \hat{y} = \left[x_1^{x_1} x_2^{x_2} \ldots x_n^{x_n}\right]^{\frac{1}{T}}. \tag{7}$$

Hence all the missing values have the same estimate and this does not change if the missing values are estimated one by one.

There are three following drawbacks of the estimate given by (4)

(1) $\hat{x}$ is rather unnatural. In fact $\hat{x}$ is always greater than arithmetic mean of $x_1, x_2, \ldots, x_n$.
(2) If two values are missing, the maximum entropy estimated for each is the same as given by (7).
(3) This is not very useful for estimating missing values in design of experiments.

The first drawback can be overcome by using generalized measure of entropy instead of Shannon entropy. If we use Burg's measure given by

$$B(P) = \sum_{i=1}^{n} \log p_i. \tag{8}$$

Then we get the estimate

$$\hat{x} = \frac{x_1 + x_2 + \ldots + x_n}{n} = \overline{x}. \tag{9}$$

In fact we choose a value $\hat{x}$, which is as equal to $x_1, x_2, \ldots, x_n$ as possible and so we maximize a measure of equality. Since there are many measures of equality, therefore our estimate will also depend on the measure of equality we choose.

The second drawback can be understood by considering the fact that the information theoretic estimate for a missing value depends on:

(a) The information available to us
(b) The purpose for which missing value is to be used.

As for the third drawback, according to the principle of maximum entropy, we should use all the information given to us and avoid scrupulously using any information not given to us. In design of experiments, we are given information about the structure of the design, which we are not using this knowledge in estimating the missing values. Consequently, the estimate is not accurate; however, information theoretic model defined and studied by Hooda and Kumar (2005) can be applied to estimate the missing value x_{ij} in contingency tables. Accordingly, the value x_{ij} is to be chosen to minimize the measure of dependence D.

About the Author

Professor D. S. Hooda is Vice President of the International Forum of Interdisciplinary Mathematics. He is General Secretary of Indian Society of Information Theory and Applications. He is an Elected member of the International Statistical Institute. American Biographical Institute, USA, chose him in 2004 for his outstanding research and conferred with honorary appointment to Research Board of Advisors of the institute. Indian Society of Information Theory has bestowed on him a prestigious award in 2005 for his outstanding contribution and research in information theory. He was Pro-Vice-Chancellor of Kurukshetra University. He has published about 80 papers in various journals and four books in mathematics and statistics. Presently, Professor Hooda is Dean (Research) Jaypee Institute of Engineering and Technology, Raghogarh, Guna.

Mean, Median and Mode

Czesław Stępniak
Professor
Maria Curie-Skłodowska University, Lublin, Poland
University of Rzeszów, Rzeszów, Poland

Mean, median and mode indicate central point of distribution or data set. Let P_X denotes distribution of a random variable X. Any reasonable rule $\mathcal{O} = \mathcal{O}(P_X)$ indicating a point $\mathcal{O}$ to be the center of P_X should satisfy the following postulates:

A1 If $P(a \le X \le b) = 1$ then $a \le \mathcal{O}(P_X) \le b$
A2 $\mathcal{O}(P_{X+c}) = \mathcal{O}(P_X) + c$ for any constant c [transitivity]
A3 $\mathcal{O}(P_{cX}) = c\mathcal{O}(P_X)$ for any constant c [homogeneity]

The *mean* is a synonym of the first moment, i.e. the expected value EX. For a continuous random variable X it may be expressed in terms of density function $f(x)$, as the integral $EX = \int_{-\infty}^{+\infty} xf(x)dx$. In discrete case it is defined as the sum of type $EX = \sum_i x_i p_i$, where x_i is a possible value of X, $i \in I$, while $p_i = P(X = x_i)$ is its probability. The mean fulfils all the above postulates and, moreover, an extra condition

AM $E(X-EX)^2 \le E(X-c)^2$ for any $c \in R$

It is worth to add that mean may not exist.

The *median* $Me = Me(X)$ is a scalar α defined by conditions $P_X(X \le \alpha) \ge \frac{1}{2}$ and $P_X(X \ge \alpha) \ge \frac{1}{2}$. In terms of the cumulative distribution function $F = F_X$ it means that $F(\alpha) \ge \frac{1}{2}$ and $\lim_{x \uparrow \alpha} F(\alpha) \le \frac{1}{2}$. In particular, if X is continuous with density f, then the desired conditions reduces to $\int_{-\infty}^{\alpha} f(x)dx \ge \frac{1}{2}$ and $\int_{\alpha}^{\infty} f(x)dx \ge \frac{1}{2}$. In discrete case it can be expressed in the form $\sum_{\{i:x_i \le \alpha\}} p_i \ge \frac{1}{2}$ and $\sum_{\{i:x_i \ge \alpha\}} p_i \ge \frac{1}{2}$. The median also satisfies the conditions $A1 - A3$ and, moreover

AMe $E|X - MeX| \le E|X - c|$ for any $c \in R$.

The mode $Mo = Mo(X)$ of a random variable X is defined in terms of its density function f (continuos case) or its probability mass function $p_i = P(X = x_i)$ (discrete case). Namely, $Me(X) = \arg\max f(x)$, or is an element x in the set of possible values $\{x_i : i \in I\}$ that $P(X = x) = \max\{p_i : i \in I\}$. The mode also satisfies the conditions $A1 - A3$. It is worth to add that mode may not be unique. There exist bimodal and multimodal distributions. Moreover the set of possible modes may be interval.

In the context of data set, represented by a sequence $x = (x_1, \ldots, x_n)$ of observations, the postulates $A1 - A3$ may be reformulated as follows:

S1 $\mathcal{O}(x_{i_1}, \ldots, x_{i_n}) = \mathcal{O}(x_1, \ldots, x_n)$ for any permutation $i_1, .., i_n$ of the indices $1, \ldots, n$
S2 $\min\{x_1, \ldots, x_n\} \le \mathcal{O}(x_1, \ldots, x_n) \le \max\{x_1, \ldots, x_n\}$
S3 $\mathcal{O}(x_1 + c, \ldots, x_n + c) = \mathcal{O}(x_1, \ldots, x_n) + c$
S4 $\mathcal{O}(cx_1, \ldots, cx_n) = c\mathcal{O}(x_1, \ldots, x_n)$.

In this case the mean, median and mode are defined as follows.

The mean of the data $x = (x_1, \ldots, x_n)$, denoted usually by $\overline{x}$, is the usual arithmetic average $\overline{x} = \frac{1}{n}\sum x_i$. The mean not only satisfies all conditions $S1 - S4$ but also possesses the property

SM $\sum_{i=1}^n (x_i - \overline{x})^2 \le \sum_{i=1}^n (x_i - c)^2$ for all $c \in R$.

Now let us arrange the elements of the sequence $x = (x_1, \ldots, x_n)$ in the not decreasing order $x_{[1]} \le x_{[2]} \le \ldots \le x_{[n]}$. The median of the data set $x = (x_1, \ldots, x_n)$ is defined by the formula

$$Me(x) = \begin{cases} x_{[\frac{n+1}{2}]}, & \text{if } n \text{ is odd} \\ \frac{1}{2}\left(x_{[\frac{n}{2}]} + x_{[\frac{n}{2}+1]}\right) & \text{if } n \text{ is even.} \end{cases}$$

The median satisfies the conditions $S1 - S4$ and, moreover,

SMe $\sum_{i=1}^n |x_i - Me(x)| \le \sum_{i=1}^n |x_i - c|$ for all $c \in R$.

The mode of the data $x = (x_1, \ldots, x_n)$, denoted by $Mo(x)$, is the value in the set that occurs most often. For instance if $x = (7, 3, 18, 24, 9, 3, 18)$ then $x \uparrow = (3, 7, 9, 13, 18, 18, 24)$. For such data $Me(x) = x_{[4]} = 13$ and $Mo(x) = 18$.

It is worth to add that the mean is very sensitive for outlying observations.

Mean, Median, Mode: An Introduction

S. N. Gupta
University of South Pacific, Suva, Fiji

Introduction

Mean, median and mode are three statistical measures commonly used to summarize data sets. They are known by the common name *average*. In its broadest sense, an *average* is simply any single value that is representative of

many numbers. Averages are also called *measures of central tendency* because an average is usually located near the center of the data set. Some examples: average age of the players of a cricket team, average reaction time of a particular chemical, average amount spent by a customer in a shopping mall, etc.

The Mean

The *mean*, also known as *arithmetic mean*, is the most widely used average and is defined as the sum of the observations divided by the number of observations. The formula for computing mean is: $\bar{x} = (\sum x)/n$, where $\bar{x}$ is the symbol for mean (pronounced "x-bar"), x is the *symbol* for variable, $\sum x$ is the *sum* of observations (i.e., the sum of the values of the variable x) and n is the *number* of observations.

Although, there are also other kinds of means (such as the ▶harmonic mean and the ▶geometric mean), the arithmetic mean is by far the most popular. For this reason, the word arithmetic is rarely used in practice and we simply refer to the "mean."

Example 1 The ages (in weeks) of five babies are 5, 9, 8, 6 and 10. Find the mean.

Solution: The mean of the set is given by $\bar{x} = \frac{1}{n}\sum x = \frac{5+9+8+6+10}{5} = \frac{38}{5} = 7.6$ weeks.

Calculation of Mean for Discrete Frequency Distribution

Sometimes, it is convenient to represent the data in form of a frequency distribution. In such cases the formula for mean is: $\bar{x} = \frac{\sum fx}{\sum f}$, where f is the frequency, $\sum f$ is the sum of the frequencies, $\sum fx$ is the sum of each observation multiplied by its frequency.

Example 2 Data for numbers of children in 35 families are given below. Find the mean.

No. of children (x):	0	1	2	3	4
Frequency (f):	2	9	11	8	5

Solution:

x	0	1	2	3	4	
f	2	9	11	8	5	$\sum f = 35$
fx	0	9	22	24	20	$\sum fx = 75$

The mean $\bar{x} = \frac{\sum fx}{\sum f} = \frac{75}{35} = 2.1$ children per family.

Calculation of Mean for Grouped Frequency Distribution

It is not possible to calculate exact mean in grouped frequency distribution, because some information is lost when the data are grouped. So, only an approximate value of mean is obtained based on the assumption that all observations in a class interval occur at the *midpoint* (x_m) of that interval. Thus, the formula of Example 2 can be used after replacing x by x_m.

Example 3 The following is the distribution of the number of fish caught by 50 fishermen in a village. Find the mean number of fish caught by a fisherman.

No. of fish caught:	11–15	16–20	21–25	26–30
No. of fishermen:	12	14	13	11

Solution:

No. of fish caught	Midpoint (x_m)	f	fx_m
11–15	13	12	156
16–20	18	14	252
21–25	23	13	299
26–30	28	11	308
		$\sum f = 50$	$\sum fx_m = 1015$

Therefore, the mean is $\bar{x} = \frac{\sum fx_m}{\sum f} = \frac{1015}{50} = 20.3$ fish per fisherman.

Weighted Mean

When *weights* (measures of relative importance) are assigned to observations, weighted means are used. If an observation x is assigned a weight w, the weighted mean is given by $\bar{x} = \sum wx / \sum w$.

The Median

The *median* is another kind of average. It is defined as the centre value when the data are arranged in order of magnitude. Thus, the median is a value such that 50% of the data are below median and 50% are above median.

Calculation of Median for Raw Data

The observations are first arranged in ascending order of magnitude. If there are n observations, the median is

1. The value of the $[(n+1)/2]$th observation, *when n is odd.*
2. The mean of the $[n/2]$th and $[(n/2)+1]$th observations, *when n is even.*

Example 4 Find the median for the following data set:

16, 32, 20, 13, 13, 24, 10.

Solution: Arranging the data in ascending order we have

10, 13, 13, 16, 20, 24, 32.

Here, $n = 7$, which is odd. Therefore, median = $\frac{n+1}{2}$ th score=$\frac{7+1}{2}$th score=4th score=16.

Example 5 Find the median for the data:

17, 18, 26, 30, 19, 24, 20, 22, 29, 25.

Solution: Here, n = 10, which is even. Arranging the data in ascending order we have

17, 18, 19, 20, 22, 24, 25, 26, 29, 30.

$$\text{Therefore, median} = \frac{1}{2}\left[\frac{n}{2}\text{th score} + \left(\frac{n}{2}+1\right)\text{th score}\right]$$
$$= \frac{1}{2}\left[\frac{10}{2}\text{th score} + \left(\frac{10}{2}+1\right)\text{th score}\right]$$
$$= \frac{1}{2}[5\text{th score} + 6\text{th score}]$$
$$= \frac{1}{2}[22 + 24] = 23.$$

Calculation of Median for Discrete Frequency Distribution
The same basic formulae as used for raw data are used, but cumulative frequencies are calculated for convenience of locating the observations at specific numbers.

Example 6 Data for the number of books purchased by 28 customers are given below. Find the median.

No. of books (x):	1	2	3	4
No. of customers (f) :	5	9	8	6

Solution:

No. of books (x)	1	2	3	4
No. of customers (f)	5	9	8	6
Cumulative frequency ($c.f.$)	5	14	22	28

Here $n = \sum f = 28$ (even). Therefore,

$$\textit{median} = \frac{1}{2}\left[\frac{28}{2}\textit{th score} + \left(\frac{28}{2}+1\right)\text{th score}\right]$$
$$= \frac{1}{2}[14\text{th score} + 15\text{th score}] = \frac{1}{2}[2+3] = 2.5$$

Calculation of Median for Grouped Frequency Distribution
In a grouped distribution, exact median cannot be obtained because some information is lost in grouping. Here, we first locate the *median class* and then obtain an estimate of the *median* by the formula:

$$\textit{median} = l_1 + \frac{\left(\frac{n}{2} - c\right)}{f}(l_2 - l_1)$$

where, l_1, l_2 are the lower and upper boundaries of the median class, f is the frequency of the median class, n is the sum of all frequencies and c is the cumulative frequency of the class immediately preceding the median class.

Example 7 Find the median for the data of Example 3 above.

Solution: Construct a table for class boundaries and cumulative frequencies:

Class	Class boundaries	f	$c.f.$
11–15	10.5–15.5	12	12
16–20	15.5–20.5	14	26
21–25	20.5–25.5	13	39
26–30	25.5–30.5	11	50
		n = 50	

Here, $n/2$ = 25. The median will lie in the class having cumulative frequency ($c.f.$) just larger than 25. The median class is 16–20. Thus, l_1 = 15.5, l_2 = 20.5, c = 12, f = 14.

Hence, *median* = $15.5 + \left(\frac{25-12}{14}\right) \times 5 = 15.5 + 4.64 =$ 20.14.

The Mode

The *mode* is the most *frequent* value i.e., the value that has the largest frequency. A major drawback of mode is that a data set may have more than one mode or no mode at all. Also the mode may not always be a central value as in the Example 8(a) below.

Example 8 Find mode in the following data sets:

(a) 5, 5, 6, 7, 7, 8, 8, 9, 9, 9, 9.

(b) 12, 14, 15, 15, 15, 19, 19, 19, 20, 20.

(c) 11, 15, 16, 19, 21, 23, 26, 27, 29, 30.

Solution

(a) One mode at 9, (b) Two modes at 15 and 19, (c) No mode as each value occurs only once. For grouped frequency distribution, the mode can be estimated by taking the mid-point of the *modal class* corresponding to the

largest frequency. One advantage of mode is that it can be calculated for both kinds of data, qualitative and quantitative, whereas mean and median can be calculated for only quantitative data. E.g., A group consists of five Hindus, six Muslims and nine Christians. Here, Christianity is most frequent and so it is the mode of this data set.

Remarks If a distribution is symmetrical then mean = median = mode. For skewed distributions a thumb rule (though not without exceptions) is that if the distribution is skewed to the right then mean > median > mode and the inequalities are reversed if the distribution is skewed to the left.

To sum up, there is no general rule to determine which average is most appropriate for a given situation. Each of them may be better under different situations. Mean is the most widely used average followed by median. The median is better when the data set includes ▶outliers or is open ended. Mode is simple to locate and is preferred for finding the most popular item e.g. most popular drink or the most common size of shoes etc.

Mean Residual Life

Jonathan C. Steele[1], Frank M. Guess[2], Timothy M. Young[2], David J. Edwards[3]
[1]Minitab, Inc., State College, PA, USA
[2]Professor
University of Tennessee, Knoxville, TN, USA
[3]Assistant Professor
Virginia Commonwealth University, Richmond, VA, USA

Theories and applications that use Mean Residual Life (MRL) extend across a myriad of helpful fields, while the methods differ considerably from one application to the next. Accelerated stress testing, fuzzy set engineering modeling, mixtures, insurance assessment of human life expectancy, maintenance and replacement of bridges, replacement of safety significant components in power plants, and evaluation of degradation signals in systems are just a few examples of applications of MRL function analysis. Note that MRL is also called "expected remaining life," plus other phrase variations. For a random lifetime X, the MRL is the conditional expectation $E(X - t|X > t)$, where $t \geq 0$. The MRL function can be simply represented with the reliability function $R(t) = P(X > t) = 1 - F(t)$ as:

$$e(t) = E(X - t|X > t) = \frac{\int_t^\infty R(x)dx}{R(t)}$$

where $R(t) > 0$ for $e(t)$ to be well defined. When $R(0) = 1$ and $t = 0$, the MRL equals the average lifetime. When $R(t) = 0$, then $e(t)$ is defined to be 0. The empirical MRL is calculated by substituting either the standard empirical estimate of $R(t)$ or, when censoring occurs, by substituting the Kaplan-Meier estimate of $R(t)$ (see ▶Kaplan-Meier Estimator). To use the Kaplan-Meier estimate when the final observation is censored requires a modification to define the empirical reliability function as eventually 0.

The reliability function can also be represented as a function of the MRL as:

$$R(t) = \left(\frac{e(0)}{e(t)}\right) \exp^{-\int_0^t \left[\frac{1}{e(x)}\right]dx}.$$

Note that the MRL function can exist, while the hazard rate function might not exist, or vice versa, the hazard rate function can exist while the MRL function might not. Compare Guess and Proschan (1988) plus Hall and Wellner (1981) for comments. When both functions exist, and the MRL function is differentiable, the hazard rate function is a function of the MRL:

$$h(t) = \frac{1 + e'(t)}{e(t)}$$

where $e'(t)$ is the first derivative of the MRL function.

The breadth of applications for the MRL function is astounding. As examples, Chiang (1968) and Deevey (1947) cite the use of the MRL for annuities via expected life tables (see ▶Life Table) in ancient Roman culture. Bhattacharjee (1982) suggests how to use the MRL to decide when to sell an item that has maintenance costs, which has copious natural applications, such as to real estate. Steele (2006) and Guess et al. (2006) illustrate a confidence interval for the range of values where one MRL function dominates

another and use it to reveal an opportunity to increase the profitability of a process that manufactures engineered medium density fiberboard. See also the insightful results on MRL functions of mixtures, ►order statistics, and coherent systems from Navarro and Hernandez (2008). Another topic of extensive research over the years is testing classes of MRL functions. For more on those tests, see references in Hollander and Proschan (1984), Hollander and Wolfe (1999) or Anis et al. (2004), for example. A brief list of other MRL papers, among many wide-ranging papers available, includes Peiravi and Dehqanmongabadi (2008), Zhao and Elsayed (2005), Bradley and Gupta (2003), Asadi and Ebrahimi (2000), Oakes and Dasu (1990), Berger et al. (1988), Guess and Park (1988), and Guess et al. (1986). We would recommend many other useful papers, but space severely limits our list.

While we do not give a complete inventory, note that R packages like *evd*, *ismev*, and *locfit* possess capabilities such as MRL plotting and/or computing the MRL for censored data; compare Shaffer et al. (2008). Another freeware, Dataplot, the software for the NIST website, does a MRL plot, but calls it a "conditional mean exceedance" plot, see Heckert and Filliben (2003). For-profit statistical software, such as JMP, MINITAB, PASW (formerly SPSS), SAS, etc., can be appropriately utilized for computing the MRL, using the basic formulas above (PASW and others use the phrase "life tables," which often contain a column for MRL). Pathak et al. (2009) illustrate the use of MATLAB for computing several different lifetime data functions including the MRL. Steele (2006) computes MRL via Maple.

Measure Theory in Probability

Milan Merkle
Professor, Faculty of Electrical Engineering
University of Belgrade, Belgrade, Serbia

Foundations of Probability: Fields and Sigma-Fields

Since Kolmogorov's axioms, Probability theory is a legitimate part of Mathematics, with foundations that belong to Measure theory. Although a traditional probabilist works solely with countably additive measures on sigma fields, the concepts of countable additivity and infinite models are by no means natural. As Kolmogorov [1956 p. 15] points out, "... in describing any observable random process we can obtain only finite fields of probability. Infinite fields of probability occur only as idealized models of real random processes."

To build a probability model, we need first to have a non-empty set Ω which is interpreted as a set of all possible outcomes of a statistical experiment. Then we define which subsets of Ω will be assigned a probability. The family $\mathcal{F}$ of all such subsets has to satisfy

(1) $\Omega \in \mathcal{F}$,
(2) $B \in \mathcal{F} \implies B' \in \mathcal{F}$,
(3) $B_1, B_2 \in \mathcal{F} \implies B_1 \cup B_2 \in \mathcal{F}$,

and then we say that $\mathcal{F}$ is a field. If (3) is replaced by stronger requirement

(3') $B_1, B_2, \ldots \in \mathcal{F} \implies \bigcup_{i=1}^{\infty} B_i \in \mathcal{F}$

then we say that $\mathcal{F}$ is a sigma field.

The family $\mathcal{P}(\Omega)$ of all subsets of Ω is a field, and it is the largest field that can be made of subsets of Ω – it clearly contains all other possible fields. The smallest such field is $\mathcal{F}_0 = \{\emptyset, \Omega\}$; it is a subset of any other field.

The intersection of any family of fields is again a field. The union of a family of fields need not be a field. Both statements hold for sigma-fields, too.

Given a collection $\mathcal{A}$ of subsets of Ω, the intersection of all fields (sigma-fields) that contain $\mathcal{A}$ is called a field (sigma-field) *generated by* $\mathcal{A}$.

Having a non-empty set Ω and a field $\mathcal{F}$ of its subsets, a finitely additive probability measure is a function $P: \mathcal{F} \to \mathbb{R}_+$ such that

(a) $P(\Omega) = 1$.
(b) $P(A) \geq 0$ for every $A \in \mathcal{F}$.
(c) $P(A \cup B) = P(A) + P(B)$ whenever $A, B \in \mathcal{F}$ and $A \cap B = \emptyset$ (*finite additivity*).

If (c) is replaced by the condition of *countable additivity*

(c') For any countable collection $A_1, A_2, \ldots$ of sets in $\mathcal{F}$, such that $A_i \cap A_j = \emptyset$ for any $A_i \neq A_j$ and such that $A_1 \cup A_2 \cup \cdots \in \mathcal{F}$ (the latter condition is needless if $\mathcal{F}$ is a sigma-field):

$$P\left(\bigcup_{i=1}^{+\infty} A_i\right) = \sum_{i=1}^{+\infty} P(A_i)$$

then P is called (a countably additive) *probability measure*, or just *probability*. The triplet $(\Omega, \mathcal{F}, P)$ is called a *probability space*. By Carathéodory extension theorem, any countably additive probability measure P defined on a field $\mathcal{F}$ extends uniquely to a countably additive probability measure on the sigma field generated by $\mathcal{F}$; hence, if P is countably additive, we may always assume that $\mathcal{F}$ is a sigma-field.

A set $B \subset \Omega$ is called a *null set* if $B \subset A$ for some $A \in \mathcal{F}$ with $P(A) = 0$. Let $\mathcal{N}$ be a collection of all null sets in $(\Omega, \mathcal{F}, P)$. If $\mathcal{N} \subset \mathcal{F}$, the sigma-field $\mathcal{F}$ is called *complete*. For any sigma-field $\mathcal{F}$ there exists a complete sigma-field $\bar{\mathcal{F}}$, called a *completion* of $\mathcal{F}$, and defined as the sigma field generated by $\mathcal{F} \cup \mathcal{N}$.

A general positive measure μ is a set function defined on $(\Omega, \mathcal{F})$ with values in $\mathbb{R}_+ \cup \{+\infty\}$, which satisfies (b), (c) or (c'), and $\mu(\emptyset) = 0$. If $\mu(\Omega) < +\infty$, the measure is called *finite* and can be normalized to a probability measure by $P(A) = \mu(A)/\mu(\Omega)$ for all $A \in \mathcal{F}$. If Ω can be represented as a countable union of measurable sets of finite measure, then a measure is called *sigma-finite*. The most commonly used measure in Mathematics is the Lebesgue measure λ on $\mathbb{R}$, with the property that $\lambda([a, b]) = b - a$ for any $a < b$. This measure is not finite, as $\lambda(\mathbb{R}) = +\infty$, but it is sigma-finite.

If there exists a countable set $S \subset \Omega$ such that $\mu(S') = 0$, the measure μ is called *discrete*. Unless the measure is discrete, the sigma-field $\mathcal{F}$ is usually taken to be strictly smaller than $\mathcal{P}(\Omega)$, to ensure that it will be possible to assign some value of the measure to each set in $\mathcal{F}$. This is motivated by existence of non-measurable sets in $\mathbb{R}$ (sets that cannot be assigned any value of Lebesgue measure). Non-measurable sets cannot be effectively constructed and their existence is a consequence of Axiom of Choice [see Solovay (1970)]. The described construction of a probability space ensures that a probability can be assigned to all sets of interest.

The countable (vs. finite) additivity has a role to exclude from consideration measures that are too complicated, and also to enable applicability of fundamental theorems (for details on finitely additive measures see Yosida and Hewitt (1952)). Within axioms (a)-(b)-(c), the countable additivity is equivalent to *continuity of probability*, a property that can be described in two dual (equivalent) forms:

1. If $A_1 \subset A_2 \subset \cdots \subset \ldots$, then $P\left(\bigcup_{n=1}^{+\infty} A_n\right) = \lim_{n\to+\infty} P(A_n)$;
2. If $A_1 \supset A_2 \supset \cdots \supset \ldots$, then $P\left(\bigcap_{n=1}^{+\infty} A_n\right) = \lim_{n\to+\infty} P(A_n)$;

Random Variables and Their Distributions

Let $(\Omega, \mathcal{F}, P)$ be a probability space (usually called *abstract probability space*). Let X be a mapping from Ω to some other space S. A purpose of introducing such mappings can be twofold. First, in some simple models like tossing a coin, we prefer to have a numerical model that can also serve as a model for any experiment with two outcomes. Hence, instead of $\Omega = \{H, T\}$, we can think of $S = \{0,1\}$ as a set of possible outcomes, which are in fact labels for any two outcomes in a real world experiment. Second, in large scale models, we think of Ω as being a set of possible states of a system, but to study the whole system can be too difficult task, so by mapping we wish to isolate one or several characteristics of Ω.

While Ω can be a set without any mathematical structure, S is usually a set of real numbers, a set in $\mathbb{R}^d$, or a set of functions. To be able to assign probabilities to events of the form $\{\omega \in \Omega \mid X(\omega) \in B\} = X^{-1}(B)$, we have to define a sigma-field $\mathcal{B}$ on S, that will accommodate all sets B of interest. If S is a topological space, usual choices are for $\mathcal{B}$ to be generated by open sets in S (Borel sigma-field), or to be generated by all sets of the form $f^{-1}(U)$, where $U \subset S$ is an open set and f is a continuous function $S \mapsto \mathbb{R}$ (Baire sigma-field). Since for any continuous f and open U, the set $f^{-1}(U)$ is open, the Baire field is a subset of corresponding Borel field. In metric spaces (and, in particular, in $\mathbb{R}^d$, $d \geq 1$) the two sigma fields coincide.

A mapping $X : \Omega \mapsto S$ is called $(\Omega, \mathcal{F}) - (S, \mathcal{B})$ – measurable if $X^{-1}(B) \in \mathcal{F}$ for any $B \in \mathcal{B}$. The term *random variable* is reserved for such a mapping in the case when S is a subset of $\mathbb{R}$. Otherwise, X can have values in $\mathbb{R}^d$, when it is called a *random vector*, or in some functional space, when it is called a *random process*, where trajectories $X(\omega) = f(\omega, \cdot)$ depend on a numerical argument usually interpreted as time, or a *random field* if trajectories are functions of arguments that are not numbers. In general, X can be called *a random element*.

The central issue in a study of random elements is the probability measure $\mu = \mu_X$ induced by X on the space $(S, \mathcal{B})$ by $\mu_X(B) = P(X^{-1}(B))$, $B \in \mathcal{B}$, which is called the *probability distribution of* X. In fact, X is considered to be defined by its distribution; the mapping by itself is not of interest in Probability. In this way, each random element X is associated with two probability triplets: $(\Omega, \mathcal{F}, P)$ and $(S, \mathcal{B}, \mu)$. If a model considers only random variables that map Ω into S, then the first triplet can be discarded, or more formally, $(\Omega, \mathcal{F}, P)$ can be identified with $(S, \mathcal{B}, \mu)$.

The collection of sets $\{X^{-1}(B)\}_{B\in\mathcal{B}}$ is a sigma-field contained in $\mathcal{F}$, which is called a *sigma-field generated by* X, in notation $\sigma(X)$. It is considered in applications as a complete information about X, as it contains all relevant events in Ω from whose realizations we may deduce whether or not $X \in B$, for any $B \in \mathcal{B}$. In particular, if $\mathcal{B}$ contains all singletons $\{x\}$, then we know the value of X.

If there is another sigma-field $\mathcal{G}$ such that $\sigma(X) \subset \mathcal{G} \subset \mathcal{F}$, then we say that X is $\mathcal{G}$-measurable. In particular, if X is $\sigma(U)$-measurable, where U is another random element and if $\sigma(X)$ contains all sets of the form $X^{-1}(\{s\})$, $s \in S$, then X is a function of U.

The definition of a sigma-field does not provide any practical algorithm that can be used to decide whether or not a particular set belongs to a sigma field. For example, suppose that we have a Borel sigma-filed $\mathcal{B}$ on some topological space S, and we need to know whether or not $B \in \mathcal{B}$, for a given $B \subset S$. Then we need to either produce a formula that shows how to get B as a result of *countably many* unions, intersections and complements starting with open and closed sets, or to prove that such a formula does not exist. This is rarely obvious or straightforward, and sometimes it can require a considerable work. In cases when we want to show that a certain family of sets belongs to a given sigma-fields, the Dynkin's so-called "$\pi - \lambda$ theorem" is very useful. A collection $\mathcal{C}$ of subsets of a set S is called a π-system if $A \in \mathcal{C}, B \in \mathcal{C} \implies A \cap B \in \mathcal{C}$. It is called a λ-system if it has the following three properties: (1) $S \in \mathcal{C}$; (2) $A, B \in \mathcal{C}$ and $B \subset A \implies A \backslash B \in \mathcal{C}$; (3) For any sequence of sets $A_n \in \mathcal{C}$ with $A_n \subset A_{n+1}$ (increasing sets), it holds that $\sum_{i=1}^{+\infty} A_n \in \mathcal{C}$. Then we have the following.

Dynkin's $\pi - \lambda$ Theorem Let $\mathcal{A}$ be a π-system, $\mathcal{B}$ a λ-system and $\mathcal{A} \subset \mathcal{B}$. Then $\sigma(\mathcal{A}) \subset \mathcal{B}$.

Integration

Let X be a random variable that maps $(\Omega, \mathcal{F}, P)$ into $(\mathbb{R}, \mathcal{B}, \mu)$, where $\mathbb{R}$ is the set of reals, $\mathcal{B}$ is a Borel

sigma-algebra and μ is the distribution of X. The expectation of X is defined as

$$E\,X = \int_\Omega X(\omega)\mathrm{d}P(\omega) = \int_{\mathbb{R}} x\mathrm{d}\mu(x),$$

provided the integrals exist in the Lebesgue sense. By the construction of Lebesgue integral, E X exists if and only if E $|X|$ exists; in that case we say that X is integrable. To emphasize that the expectation is with respect to measure P, the notation $\mathrm{E}_P X$ can be used.

Let f be a measurable function $\mathbb{R} \to \mathbb{R}$ (in $\mathbb{R}$ we assume the Borel sigma-field if not specified otherwise). Then $f(X)$ is again a random variable, that is, the mapping $\omega \mapsto f(X(\omega))$ is $(\Omega, \mathcal{F}) - (\mathbb{R}, \mathcal{B})$ -measurable, and

$$Ef(X) = \int_\Omega f(X(\omega))\mathrm{d}P(\omega) = \int_{\mathbb{R}} f(x)\mathrm{d}\mu(x),$$

if the integral on the right hand side exists, and then we say that f is integrable. Expectations can be defined in the same way in more general spaces of values of f or X, for instance in $\mathbb{R}^d, d > 1$ or in any normed vector space.

Radon-Nikodym Theorem Suppose that P and Q are positive countably additive and sigma-finite measures (not necessarily probabilities) on the same space $(\Omega, \mathcal{F})$. We say that P is absolutely continuous with respect to Q (in notation $P \ll Q$) if $P(B) = 0$ for all $B \in \mathcal{F}$ with $Q(B) = 0$.

If $P \ll Q$, then there exists a non-negative measurable function f such that

$$P(A) = \int_\Omega I_A(\omega) f(\omega)\mathrm{d}Q(\omega), \quad \text{and}$$
$$\int_\Omega g(\omega)\mathrm{d}P(\omega) = \int_\Omega g(\omega) f(\omega)\mathrm{d}Q(\omega),$$

for any measurable g. The function f is called a *Radon-Nikodym derivative*, in notation $f = \frac{\mathrm{d}P}{\mathrm{d}Q}$, and it is Q-almost surely unique.

If Q is the Lebesgue measure and P a probability measure on $\mathbb{R}$, then the function f is called a *density* of P or of a corresponding random variable with the distribution P; distributions P on $\mathbb{R}$ that are absolutely continuous with respect to Lebesgue measure are called *continuous distributions*.

If both P and Q are probabilities and $P \ll Q$, then the ►Radon-Nikodym theorem yields that there exists a random variable $\Lambda \geq 0$ with $\mathrm{E}_Q \Lambda = 1$ such that

$$P(A) = \mathrm{E}_Q I_A \Lambda \qquad \text{and} \qquad \mathrm{E}_P X = \mathrm{E}_Q X\Lambda$$

for any random variable X.

Measurement Error Models

Alexander Kukush
Professor
National Taras Shevchenko University of Kyiv,
Kyiv, Ukraine

A (nonlinear) measurement error model (MEM) consists of three parts: (1) a *regression model* relating an observable regressor variable z and an unobservable regressor variable ξ (the variables are independent and generally vector valued) to a response variable y, which is considered here to be observable without measurement errors; (2) a *measurement model* relating the unobservable ξ to an observable surrogate variable x; and (3) a *distributional model* for ξ.

Parts of MEM

The *regression model* can be described by a conditional distribution of y given (z, ξ) and given an unknown parameter vector θ. As usual this distribution is represented by a probability density function $f(y|z, \xi; \theta)$ with respect to some underlying measure on the Borel σ-field of $\boldsymbol{R}$. We restrict our attention to distributions that belong to the exponential family, i.e., we assume f to be of the form

$$f(y|z, \xi; \beta, \varphi) = \exp\left(\frac{y\eta - c(\eta)}{\varphi} + a(y, \varphi)\right) \qquad (1)$$

with

$$\eta = \eta(z, \xi; \beta). \qquad (2)$$

Here β is the regression parameter vector, φ a scalar dispersion parameter such that $\theta = (\beta^T, \varphi)^T$, and a, c, and η are known functions. This class comprises the class of generalized linear models, where $\eta = \eta(\beta_0 + z^T\beta_z + \xi^T\beta_\xi)$, $\beta = (\beta_0, \beta_x^T, \beta_\xi^T)^T$.

The *classical measurement model* assumes that the observed variable x differs from the latent ξ by a measurement error variable δ that is independent of z, ξ, and y:

$$x = \xi + \delta \tag{3}$$

with $\mathbf{E}\delta = 0$. Here we assume that $\delta \sim N(0,\ \Sigma_\delta)$ with Σ_δ known. The observable data are independent realizations of the model $(x_i, y_i),\ \ i = 1, \ldots, n$.

Under the *Berkson measurement model*, the latent variable ξ differs from the observed x by a centered measurement error δ that is independent of z, x, and y:

$$\xi = x + \delta. \tag{4}$$

Thus, the values of x are fixed in advance, whereas the unknown true values, ξ, are fluctuating.

The *distributional model* for ξ either states that the ξ are unknown constants (*functional case*) or that ξ is a random variable (*structural case*) with a distribution given by a density $h(\xi; \gamma)$, where γ is a vector of nuisance parameters describing the distribution of ξ. In the structural case, we typically assume that

$$\xi \sim N(\mu_\xi,\ \Sigma_\xi), \tag{5}$$

although sometimes it is assumed that ξ follows a mixture of normal distributions. In the sequel, for the structural case we assume γ to be known. If not, it can often be estimated in advance (i.e., pre-estimated) without considering the regression model and the data y_i. For example, if ξ is normal, then μ_ξ and Σ_ξ can be estimated by $\overline{x}$ and $S_x - \Sigma_\delta$, respectively, where $\overline{x}$ and S_x are the empirical mean vector and the empirical covariance matrix of the data x_i, respectively.

The goal of measurement error modeling is to obtain nearly unbiased estimates of the regression parameter β by fitting a model for y in terms of (z, x). Attainment of this goal requires careful analysis. Substituting x for ξ in the model (1) – (2), but making no adjustments in the usual fitting methods for this substitution, leads to estimates that are biased, sometimes seriously.

In the structural case, the *regression calibration* (RC) estimator can be constructed by substituting $\mathbf{E}(\xi|x)$ for unobservable ξ. In both functional and structural cases, another, the simulation-extrapolation (*SIMEX*) estimator, becomes very popular. These estimators are not consistent in general, although they often reduce the bias significantly; see Carroll et al. (2006).

Polynomial and Poisson Model

We mention two important examples of the classical MEM (1) – (3) where for simplicity the latent variable is scalar and the observable regressor z is absent. The *polynomial model* is given by

$$y = \beta_0 + \beta_1 \xi + \ldots + \beta_k \xi^k + \varepsilon,$$

where $\varepsilon \sim N\left(0, \sigma_\varepsilon^2\right)$ and ε is independent of ξ. Here

$$\eta = \sum_{r=0}^{k} \beta_r \xi^r,\ \ c(\eta) = \frac{1}{2}\eta^2,$$

and $\varphi = \sigma_\varepsilon^2$. Both cases are possible: (a) the measurement error variance σ_δ^2 is known and (b) the ratio $\sigma_\varepsilon^2/\sigma_\delta^2$ is known; for the latter case see Shklyar (2008). In the particular case of $k = 1$, we obtain the *linear model*; an overview of methods in this MEM is given in Cheng and Van Ness (1999).

In the *loglinear Poisson model* we have $y \sim Po(\lambda)$ with $\lambda = \exp(\beta_0 + \beta_1 \xi)$; then $\eta = \log \lambda,\ c(\eta) = e^\eta$, and $\varphi = 1$.

Methods of Consistent Estimation in Classical MEM

Now, we deal with the general model (1) – (3). We distinguish between two types of estimators, functional and structural. The latter makes use the distribution of ξ, which therefore must be given, at least up to the unknown parameter, vector γ. The former does not need the distribution of ξ and works even when ξ is not random (functional case).

Functional Method: Corrected Score

If the variable ξ were observable, one could estimate β (and also φ) by the method of maximum likelihood (ML). The corresponding likelihood score function for β is given by

$$\psi(y, z, \xi; \beta, \varphi) = \frac{\partial \log f(y|z, \xi; \beta, \varphi)}{\partial \beta} = \frac{y - c'(\eta)}{\varphi} \frac{\partial \eta}{\partial \beta}.$$

We want to construct an unbiased estimating function for β in the observed variables. For this purpose, we need to find functions g_1 and g_2 of z, x, and β such that

$$\mathbf{E}[g_1(z, x; \beta)|z, \xi] = \frac{\partial \eta}{\partial \beta}, \quad \mathbf{E}[g_2(z, x; \beta)|z, \xi] = c'(\eta)\frac{\partial \eta}{\partial \beta}.$$

Then

$$\psi_C(y, z, x; \beta) = y g_1(z, x; \beta) - g_2(z, x; \beta)$$

is termed the corrected score function. The *Corrected Score* (CS) estimator $\hat{\beta}_C$ of β is the solution to

$$\sum_{i=1}^{n} \psi_C(y_i, z_i, x_i; \hat{\beta}_C) = 0.$$

The functions g_1 and g_2 do not always exist. Stefanski (1989) gives the conditions for their existence and shows how to find them if they exist. The CS estimator is consistent in

both functional and structural cases. It was first proposed by Stefanski (1989) and Nakamura (1990).

An alternative functional method, particularly adapted to ▶generalized linear models, is the conditional score method; see Stefanski and Carroll (1987).

Structural Methods: Quasi-Likelihood and Maximum Likelihood

The conditional mean and conditional variance of y given (z, ξ) are, respectively,

$$\mathbf{E}(y|z,\xi) = m^*(z,\xi;\beta) = c'(\eta),\ \mathbf{V}(y|z,\xi) = v^*(z,\xi;\beta) = \varphi c''(\eta).$$

Then the conditional mean and conditional variance of y given the observable variables are

$$m(z,x;\beta) = \mathbf{E}(y|z,x) = E[m^*(z,\xi;\beta)|x],$$
$$v(z,x;\beta) = \mathbf{V}(y|z,x) = \mathbf{V}[m^*(z,\xi;\beta)|x] + \mathbf{E}[v^*(z,\xi;\beta)|x].$$

For the quasi-likelihood (QL) estimator, we construct the quasi-score function

$$\psi_Q(y,z,x;\beta) = [y - m(z,x;\beta)]v(z,x;\beta)^{-1}\frac{\partial m(z,x;\beta)}{\partial \beta}.$$

Here we drop the parameter φ considering it to be known. We also suppress the nuisance parameter γ in the argument of the functions m and v, although m and v depend on γ. Indeed, in order to compute m and v, we need the conditional distribution of ξ given x, which depends on the distribution of ξ with its parameter γ. For instance, assume (5) where the elements of μ_ξ and Σ_ξ make up the components of the parameter vector γ. Then $\xi|x \sim N(\mu(x), T)$ with

$$\mu(x) = \mu_\xi + \Sigma_\xi(\Sigma_\xi + \Sigma_\delta)^{-1}(x - \mu_\xi),$$
$$T = \Sigma_\delta - \Sigma_\delta(\Sigma_\xi + \Sigma_\delta)^{-1}\Sigma_\delta.$$

The QL estimator $\hat{\beta}_Q$ of β is the solution to

$$\sum_{i=1}^{n} \psi_Q(y_i, z_i, x_i; \hat{\beta}_C) = 0.$$

The equation has a unique solution for large n, but it may have multiple roots if n is not large. Heyde and Morton (1998) develop methods to deal with this case.

Maximum likelihood is based on the conditional joint density of x, y given z. Thus, while QL relies only on the error-free mean and variance functions, ML relies on the whole error-free model distribution. Therefore, ML is more sensitive than QL with respect to a potential model misspecification because QL is always consistent as long as at least the mean function (along with the density of ξ) has been correctly specified. In addition, the likelihood function is generally much more difficult to compute than the quasi-score function. This often justifies the use of the relatively less efficient QL instead of the more efficient ML method.

Efficiency Comparison

For CS and QL, $\hat{\beta}$ is asymptotically normal with asymptotic covariance matrix (ACM) Σ_C and Σ_Q, respectively. In the structural model, it is natural to compare the relative efficiencies of $\hat{\beta}_C$ and $\hat{\beta}_Q$ by comparing their ACMs. In case there are no nuisance parameters, it turns out that

$$\Sigma_C \geq \Sigma_Q \tag{6}$$

in the sense of the Loewner order for symmetric matrices. Moreover, under mild conditions the strict inequality holds.

These results hold true if the nuisance parameters γ are known. If, however, they have to be estimated in advance, (6) need not be true anymore. For the Poisson and polynomial structural models, Kukush et al. (2007) prove that (6) still holds even if the nuisance parameters are preestimated. Recently Kukush et al. (2009) have shown that QL can be modified so that, in general, $\Sigma_C \geq \Sigma_Q$; for this purpose the γ must be estimated together with β and not in advance.

Estimation in Berkson Model

Now, we deal with the model (1), (2), and (4). Substituting x for ξ in the regression model (1) – (2) is equivalent to RC. Therefore, it leads to estimates with a typically small bias.

A more precise method is ML. The conditional joint density of x and y given z has a simpler form compared with the classical MEM. That is why ML is more reliable in the Berkson model.

Nonparametric Estimation

We mention two nonparametric problems overviewed in Carroll et al. (2006), Ch. 12: the estimation of the density ρ of a random variable ξ, and the nonparametric estimation of a regression function f, both when ξ is measured with error. In these problems under normally distributed measurement error, the best mean squared error of an estimator of $\rho(x_0)$ or $f(x_0)$ converges to 0 at a rate no faster than the exceedingly slow rate of logarithmic order. However, under a more heavy-tailed measurement error, estimators can perform well for a reasonable sample size.

About the Author

Dr. Alexander Kukush is a Professor, Department of Mechanics and Mathematics, National Taras Shevchenko University of Kyiv, Ukraine. He is an Elected member of the International Statistical Institute (2004). He has authored and coauthored more than 100 papers on statistics and a book: *Theory of Stochastic Processes With Applications to Financial Mathematics and Risk Theory* (with D. Gusak, A. Kulik, Yu. Mishura, and A. Pilipenko, Problem Books in Mathematics, Springer, 2009). Professor Kukush has received the Taras Shevchenko award for a cycle of papers on regression (National Taras Shevchenko University of Kyiv, 2006).

Measurement of Economic Progress

Marat Ibragimov[1], Rustam Ibragimov[2]
[1]Associate Professor
Tashkent State University of Economics, Tashkent, Uzbekistan
[2]Associate Professor
Harvard University, Cambridge, MA, USA

Broadly defined, measurement of economic progress focuses on quantitative analysis of the standard of living or quality of life and their determinants. The analysis concerns many elements of the standard living such as its material components, human capital, including education and health, inequality and other factors [see, among others, Barro and Sala-i Martin (2004), Howitt and Weil (2008), Steckel (2008), and references therein].

Theoretical foundation for empirical analysis of determinants of economic growth is provided by the Solow growth model. The human capital-augmented version of the model with the Cobb-Douglas production function [see Mankiw et al. (1992)] assumes that, for country i at time t, the aggregate output $Y_i(t)$ satisfies $Y_i(t) = K_i(t)^{\alpha} H_i(t)^{\beta} (A_i(t)L_i(t))^{1-\alpha-\beta}$, where $K_i(t)$ is physical capital, $H_i(t)$ is human capital, $L_i(t)$ is labor supply and $A_i(t)$ is a productivity parameter (the efficiency level of each worker or the level of technology). The variables L and A are assumed to obey $L_i(t) = L_i(0)e^{n_i t}$ and $A(t) = A(0)e^{gt}$, where n_i and g are, respectively, the population growth rate and the rate of technological progress. Physical and human capital are assumed to follow continuous-time accumulation equations $dK_i(t)/dt = s_{K,i}Y_i(t) - \delta K_i(t)$ and $dH_i(t)/dt = s_{H,i}Y_i(t) - \delta H(t)$ with the depreciation rate δ and the savings rates $s_{K,i}$ and $s_{H,i}$. Under the above assumptions, the growth model leads to the regressions $\gamma_i = a_0 + a_1 \log y_i(0) + a_2 \log(n_i + g + \delta) + a_3 \log s_{K,i} + a_4 \log s_{H,i} + \epsilon_i$, where $\gamma_i = (\log y_i(t) - \log y_i(0))/t$ is the growth rate of output per worker $y_i(t) = Y_i(t)/L_i(t)$ between time 0 and t [see, among others, Barro and Sala-i Martin (2004), Durlauf et al. (2005)]. Cross-country growth regressions typically include additional regressors Z_i and focus on estimating models in the form $\gamma_i = \mathbf{a}\mathbf{X}_i + \mathbf{b}\mathbf{Z}_i + \epsilon_i$, where $\mathbf{a} = (a_0, a_1, ..., a_4) \in \mathbf{R}^5$, $\mathbf{b} = (b_1, b_2, ..., b_m) \in \mathbf{R}^m$, the components of $\mathbf{X}_i = (1, \log y_i(0), \log(n_i + g + \delta), \log s_{K,i}, \log s_{H,i})'$ are the growth determinants in the Solow model and $\mathbf{Z}_i \in \mathbf{R}^m$ is the vector of growth determinants outside the Solow growth theory.

The statistical analysis of economic progress and its determinants presents a number of challenges due to

the necessity of using proxy measures and corresponding weights for different components of the standard of living and factors affecting it. The material standard of living is typically measured as per capita Gross Domestic Product (GDP) adjusted for changes in price levels. Proxies for education and human capital used in growth economics include school-enrollment rates at the secondary and primary levels, literacy rates, average years of secondary and higher schooling and outcomes on internationally comparable examinations. Many works in the literature have also used student-teacher ratios as a measure of quality of education. The two most widely used measures of health are life expectancy at birth or age 1 and average height used as a proxy for nutritional conditions during the growing years.

Barro (1991) and Barro and Sala-i Martin (2004) find that the growth rate of real per capita GDP is positively related to initial human capital, including education and health, proxied by school-enrollment rates, upper-level schooling and life expectancy and negatively related to the initial level of real per capita GDP. The results in Barro (1991) also indicate statistically significant negative effects of political instability (measured using the number of revolutions and coups per year and the number of political assassinations per million population per year) on growth. Other factors used in the analysis in Barro (1991) and Barro and Sala-i Martin (2004) include fertility and the ratio of real government consumption to real GDP (with statistically significant negative effects on growth), investment ratio, inflation rate as well as proxies for market distortions, maintenance of the rule of law, measures for democracy, international openness, the terms of trade, indicators for economic systems and countries in sub-Saharian Africa and Latin America and other variables.

A number of works in theoretical and empirical growth economics have focused on the development and analysis of performance of models with endogenous technological progress. Many recent studies have also studied the factors that lead to the observed differences in the determinants of economic growth in different countries, including capital components, technology and efficiency. In particular, several works have emphasized the role of geographical differences, cultural factors, economic policies and institutions as fundamental causes of the differences in growth determinants (Howitt and Weil 2008).

Statistical study of economic growth determinants is complicated by relatively small samples of available observations, measurement errors in key variables, such as GDP, heterogeneity in observations and estimated parameters, dependence in data and large number of potential growth regressors under analysis. Related issues in the analysis of economic growth concern difficulty of causal interpretation of estimation results, robustness of the conclusions to alternative measures of variables in the analysis, and open-endedness of growth theories that imply that several key factors matter for growth at the same time. Levine and Renelt (1992) focus on the analysis of robustness of conclusions obtained using cross-country growth regressions. They propose assessing the robustness of the variable Z of interest using the variation of the coefficient b in cross-country regressions $\gamma_i = \mathbf{a}\mathbf{X}_i + bZ_i + \mathbf{c}\mathbf{V}_i + \epsilon_i$, where $\mathbf{X}_i$ is the vector of variables that always appear in the regressions (e.g., the investment share of GDP, initial level of income, a proxy for the initial level of human capital such as the school enrollment rate, and the rate of population growth in country i), and $\mathbf{V}_i$ is a vector of additional control variables taken from the pool of variables available. Departing from the extreme bounds approach in Levine and Renelt (1992) that requires the estimate of the coefficient of interest b to be statistically significant for any choice of control variables $\mathbf{V}$, several recent works [see Sala-i Martin et al. (2004), Ch. 12 in Barro and Sala-i Martin (2004), and references therein] propose alternative less stringent procedures to robustness analysis. Several recent works on the analysis of economic growth and related areas emphasize importance of models incorporating disasters and crises and probability distributions generating ►outliers and extreme observations, such as those with heavy-tailed and power-law densities [see Barro (1991), Gabaix (2009) and Ibragimov (2009)].

Measurement of Uncertainty

K. R. Muraleedharan Nair
Professor
Cochin University of Science and Technology, Cochin, India

The measurement and comparison of uncertainty associated with a random phenomenon have been a problem attracting a lot of researchers in Science and Engineering over the last few decades. Given a system whose exact description is unknown its ►entropy is the amount of information needed to exactly specify the state of the system. The Shannon's entropy, introduced by Shannon (1948), has been extensively used in literature as a quantitative measure of uncertainty. If $A_1, A_2, \ldots, A_n$ are mutually exclusive events, with respective probabilities $p_1, p_2, \ldots, p_n$, the Shannon's entropy is defined as

$$H_n(P) = -\sum_{i=1}^{n} p_i \log p_i. \tag{1}$$

Earlier development in this area was centered on characterizing the Shannon's entropy using different sets of postulates. The classic monographs by Ash (1965), Aczel and Daroczy (1975) and Behra (1990) review most of the works on this aspect. Another important aspect of interest is that of identifying distributions for which the Shannon's entropy is maximum subject to certain restrictions on the underlying random variable. Depending on the conditions imposed, several maximum entropy distributions have been derived. For instance, if X is a random variable in the support of the set of non-negative real numbers, the maximum entropy distribution under the condition that the arithmetic men is fixed is the exponential distribution. The book by Kapur (1989) covers most of the results in this area.

For a continuous non-negative random variable X with probability density function $f(x)$ the continuous analogue of (1) takes the form

$$H(f) = -\int_{-\infty}^{\infty} f(x) \log f(x) dx. \tag{2}$$

Several modifications of the Shannon's entropy has been proposed and extensively studied. Renyi (1961) define the entropy of order α as

$$H_\alpha(P) = \frac{1}{1-\alpha} \log \frac{\sum_{i=1}^{n} p_i^\alpha}{\sum_{i=1}^{n} p_i}, \ \alpha \neq 1, \alpha > 0 \tag{3}$$

where $P = (P_{1,\ldots\ldots}P_n)$ is such that $p_i \geq 0$, *and* $\sum_{i-1}^{n} p_i = 1$.

As $\alpha \to 1$, (3) reduces to (1). Khinchin (1957) generalized the Shannon's entropy by choosing a convex function $\varphi(.)$, with $\varphi(1) = 0$ and defined the measure

$$H_\varphi(f) = -\int_{-\infty}^{\infty} f(x) \varphi[f(x)] dx. \tag{4}$$

Nanda and Paul (2006) studied (4) for two particular choices of φ in the form

$$H_1^\beta(f) = \frac{1}{\beta - 1}\left[1 - \int_0^\alpha f^\beta(x) dx\right] \tag{5}$$

and

$$H_2^\beta(f) = \frac{1}{1-\beta}\left[\log \int_0^\infty f^\beta(x) dx\right] \tag{6}$$

where the support of f is the set of non-negative reals and $\beta > 0$ with $\beta \neq 1$. As $\beta \to 1$, (5) and (6) reduces to the Shannon's entropy given in (2).

Recently Rao et al. (2004) introduced cumulative residual entropy defined by

$$E(X) = -\int_0^\infty \overline{F}(x) \log \overline{F}(x) dx$$

which is proposed as an alternative measure of uncertainty based on the cumulative survival function $\overline{F}(x) = P(X > x)$. For various properties and applications of this measure we refer to Rao (2005) and Asadi and Zohrevand (2007).

There are several other concepts closely related to the Shannon's entropy. Kullback and Leibler (1951) defines the directed divergence (also known as relative entropy or cross entropy) between two distributions $P = (p_1, p_2, \ldots, p_n)$ and $Q = (q_1, q_2, \ldots, q_n)$ with

$$p_i, q_i \geq 0 \sum_{i=1}^{n} p_i = \sum_{i=1}^{n} q_i = 1$$

as

$$D_n(P,Q) = \sum_{i=1}^{n} p_i \log \frac{p_i}{q_i}. \tag{7}$$

Kannappan and Rathie (1973) and Mathai and Rathie (1975) have obtained characterization results based on certain postulates which naturally leads to (7). The continuous analogue of (7) turns out to be

$$D(f,g) = \int_{-\infty}^{\alpha} f(x) \log \frac{f(x)}{g(x)} dx \tag{8}$$

where $f(x)$ and $g(x)$ are probability density functions corresponding to two probability measures P and Q.

The concept of affinity between two distributions was introduced and studied in a series of works by Matusita [see Matusita (1961)]. This measure has been widely used as a useful tool for discrimination among distributions. Affinity is symmetric in distributions and has direct relationship with error probability when classification or discrimination is concerned. For two discrete distributions P and Q considered above the Matusita's affinity (Mathai and Rathie 1975) between P and Q is defined as

$$\delta(P,Q) = \sum_{i=1}^{n} (p_i q_i)^{1/2}. \tag{9}$$

If X and Y are non-negative random variables and if $f(x)$ and $g(x)$ are the corresponding probability density functions, the affinity between f and g takes the form

$$\delta(f,g) = \int_0^{\infty} \sqrt{f(x)g(x)} dx \tag{10}$$

$\delta(f,g)$ lies between 0 and 1.

Majernik (2004) has shown that

$$H(f,g) = 2[1 - \delta(f,g)]$$

where $H(f,g)$ is the Hellinger's distance defined by

$$H(f,g) = \int_0^{\infty} \left[\sqrt{f(x)} - \sqrt{g(x)}\right]^2 dx. \tag{11}$$

Affinity is a special case of the Chernoff distance considered in Akahira (1996) defined by

$$C(F,G) = -\log\left[\int f^{\alpha}(x) g^{1-\alpha} dx\right], 0 < \alpha < 1. \tag{12}$$

It may be noticed that when $\alpha = \frac{1}{2}$ (12) reduces to $-\log \delta(f,g)$, where $\delta(f,g)$ is the affinity defined in (10).

The concept of inaccuracy was introduced by Kerridge (1961). Suppose that an experimenter asserts that the probability for the i^{th} eventuality is q_i whereas the true probability is p_i, then the inaccuracy of the observer, as proposed by Kerridge, can be measured by

$$1(P,Q) = -\sum_{i=1}^{n} p_i \log q_i \tag{13}$$

where P and Q are two discrete probability distributions, considered earlier.

Nath (1968) extended the Kerridge's concept to the continuous situation. If $F(x)$ is the actual distribution function corresponding to the observations and $G(x)$ is the distribution assigned by the experimenter and $f(x)$ and $g(x)$ are the corresponding density functions the inaccuracy measure is defined as

$$1(F,G) = -\int_0^{\alpha} f(x) \log g(x) dx. \tag{14}$$

This measure has extensively been used as a useful tool for measurement of error in experimental results. In expressing statements about probabilities of various events in an experiment, two kinds of errors are possible: one resulting from the lack of enough information or vagueness in experimental results and the other from incorrect information. In fact, (14) can be written as

$$1(F,G) = -\int_0^{\infty} f(x) \log f(x) dx + \int_0^{\infty} f(x) \log \frac{f(x)}{f(x)} dx. \tag{15}$$

The first term on the right side of (15) represents the error due to uncertainty which is the Shannon's entropy while the second term is the Kullback–Leibler measure, defined in (8) representing the error due to wrongly specifying the distribution as $G(x)$. In this sense the measure of inaccuracy can accommodate the error due to lack of information as well as that due to incorrect information.

In many practical situations, complete data may not be observable due to various reasons. For instance, in lifetime studies the interest may be on the life time of a unit after a specified time, say t. If X is the random variable representing the life time of a component the random variable of interest is $X - t | X > t$. Ebrahimi (1996) defines the residual entropy function as the Shannon's entropy associated with the residual life distribution, namely

$$H(f,t) = -\int_t^{\infty} \frac{f(x)}{\overline{F}(t)} \log \frac{f(x)}{\overline{F}(x)}, \overline{F}(t) > 0. \tag{16}$$

In terms of the hazard rate $h(x) = \frac{f(x)}{F(x)}$, (16) can also be written as

$$H(f,t) = 1 - \frac{1}{\bar{F}(t)} \int_t^\infty f(x) \log h(x) dx. \qquad (17)$$

Ebrahimi points out that (16) can be used as a potential measure of stability of components in the reliability context. The problem of ordering life time distributions using this concept has been addressed in Ebrahimi and Kirmani (1996). Belzunce et al. (2004) has shown that the residual entropy function determines the distributions uniquely if $H(f,t)$ is increasing in t. Characterization of probability distributions using the functional form of the residual entropy function have been the theme addressed in Nair and Rajesh (1998), Sankaran and Gupta (1999), Asadi and Ebrahimi (2000) and Abraham and Sankaran (2005).

Recently Nanda and Paul (2006) has extended the definition of the Renyi entropy defined by (5) and (6) to the truncated situation. It is established that under certain conditions the Renyi's residual entropy function determines the distribution uniquely. They have also looked into the problem of characterization of probability distributions using the same.

Ebrahimi and Kirmani (1996) has modified the definition of the Kullback–Leibler measure to the truncated situation to accommodate the current age of a system. Recently Smitha et al. (2008) have extended the definition of affinity to the truncated situation and has obtained characterization results for probability distributions under the assumption of proportional hazard model. Nair and Gupta (2007) extended the definition of the measure of inaccuracy to the truncated situation and has characterized the generalized Pareto distributions using the functional form of the inaccuracy measure.

About the Author

Dr. K.R. Muraleedharan Nair is a senior Professor in the Department of Statistics of the Cochin University of Science and Technology, India. He had been teaching Statistics at the post graduate level for the past 39 years. He has served the University as the Head of the Department (2004–2007) and as the Controller of examinations (2000–2003). He is currently the Vice President of the Indian Society for Probability and Statistics, besides being reviewer for certain reputed journals. He has published 28 papers in international journals besides several conference papers. He is a member of the Board of Studies as well as Faculty of Science in some of the Indian Universities.

Measures of Agreement

Elisabeth Svensson
Örebro University, Örebro, Sweden

Agreement in repeated assessments is a fundamental requirement for quality of data from assessments on ►rating scales. Scale assessments produce ordinal data, the ordered categories representing only a rank order of the intensity of a particular variable and not a numerical value in a mathematical sense, even when the assessments are numerically labeled.

The main quality concepts of scale assessments are *reliability* and *validity*. *Reliability* refers to the extent to which repeated measurements of the same object yield the same result, which means agreement. In *intra-rater reliability* studies the agreement in test-retest assessments is evaluated. *Inter-rater reliability* refers to the level of agreement between two raters judging the same object.

The *percentage agreement* (*PA*) in assessments is the basic agreement measure and is also called *overall agreement* or *raw agreement*. When $PA < 100\%$ the reasons for disagreement can be evaluated by a statistical approach by Svensson that takes account of the rank-invariant properties of ordinal data. The approach makes it possible to identify and measure systematic disagreement, when present, separately from disagreement caused by individual variability in assessments. Different frequency distributions of the two sets of ordinal assessments indicate that the two assessments disagree systematically regarding the use of the scale categories. When higher categories are more frequently used in one set of assessments, X, than in the other, Y, there is a systematic disagreement in position. The measure *Relative Position, RP,* estimates the parameter of a systematic disagreement in position defined by $\gamma = P(X < Y) - P(Y < X)$.

A systematic disagreement in how the two assessments are concentrated to the scale categories is measured by the *Relative Concentration, RC,* estimating the parameter of a systematic shift in concentration $\delta = P(X_{l_1} < Y_k < X_{l_2}) - P(Y_{l_1} < X_k < Y_{l_2})$.

The measure of individual variability, the relative rank variance, $0 \le RV \le 1$ is defined $RV = \frac{6}{n^3}\sum_{i=1}^{m}\sum_{j=1}^{m} x_{ij}\left[\overline{R}_{ij}^{(X)} - \overline{R}_{ij}^{(Y)}\right]^2$ where $\overline{R}_{ij}^{(X)}$ is the mean augmented rank of the observations in the ijth cell of an $m \times m$ square contingency table according to the assessments X. In the aug-rank approach $\overline{R}_{i,j-1}^{(X)} < \overline{R}_{i,j}^{(X)}$ and $\overline{R}_{i-1,j}^{(Y)} < \overline{R}_{i,j}^{(Y)}$. $RV = 0$ means that the observed disagreement is completely explained by the measures of systematic disagreement. In that case the two sets of aug-ranks are equal and the paired distribution is the *rank-transformable pattern of agreement* (see ►Ranks).

The advantage of separating the observed disagreement in the components of systematic and individual disagreements is that it is possible to improve the rating scales and/or the users of the scale. Systematic disagreement is population based and reveals a systematic change in conditions between test-.retest assessments or that raters interpret the scale categories differently. Large individual variability is a sign of poor quality of the rating scale as it allows for uncertainty in repeated assessments.

The Cohen's *coefficient kappa* (κ) is a commonly used measure of agreement adjusted for the chance expected agreement. There are limitations with kappa. The maximum level of kappa, $\kappa = 1$, requires equally skilled raters, in other words lack of systematic disagreement (bias). The value of weighted kappa depends on the choice of weights, and the weighting procedure ignores the rank-invariant properties of ordinal data. The kappa value increases when the number of categories decreases, and depends also on how the observations are distributed on the different categories, the prevalence. Therefore kappa values from different studies are not comparable.

The calculations of Cronbach's alfa and other so-called reliability coefficients are based on the assumption of quantitative, normally distributed data, which is not achievable in data from rating scales.

There is also a widespread misuse of correlation in reliability studies. The correlation coefficient measures the *degree of association* between two variables and does not measure the level of agreement, see Fig. 1. The PA is 12%, and the observed disagreement is mainly explained by a systematic disagreement in position. The negative RP value

A. The observed pattern							B. The rank-transformable pattern of agreement					
X / Y	C_1	C_2	C_3	C_4	total		X / Y	C_1	C_2	C_3	C_4	total
C_4			1	1	2		C_4				2	2
C_3		2	2	14	18		C_3			1	17	18
C_2	1	1	11	3	16		C_2			16		16

Measures of Agreement. Fig. 1 The frequency distribution of 50 pairs of assessments on a scale with four ordered categories, $C_1 < C_2 < C_3 < C_4$ and the corresponding rank-transformable pattern of agreement, defined by the marginal distributions

(-0.48) and the constructed RTPA shows that the assessments Y systematically used a lower category than did X. A slight additional individual variability, $RV = 0.08$ is observed. The Spearman rank-order correlation coefficient is 0.66 in A and 0.97 in B, ignoring the fact that the assessments are systematically biased and unreliable. The same holds for the coefficient kappa (-0.14).

Measures of Dependence

Reza Modarres
Head and Professor of Statistics
The George Washington University, Washington, DC, USA

Let X and Y be continuous random variables with joint distribution function (DF) H and marginal DFs F and G. Three well-known measures of dependence are

1. Pearson's correlation:
$$\rho = \frac{1}{\sigma_X \sigma_Y} Cov(X, Y) = \frac{1}{\sigma_X \sigma_Y} \int_{-\infty}^{\infty} \int_{-\infty}^{\infty} [H(x,y) - F(x)G(y)]dxdy$$
where σ_x, σ_y and $Cov(X, Y)$ are the standard deviations and covariance of X and Y, respectively
2. Spearman's correlation: $s = 12 \int_{-\infty}^{\infty} \int_{-\infty}^{\infty} [H(x,y) - F(x)G(y)]dF(x)dG(y)$,
3. Kendall's correlation: $\tau = 4 \int_{-\infty}^{\infty} \int_{-\infty}^{\infty} H(x,y)dH(x,y) - 1$

Pearson correlation measures the strength of linear relationship between X and Y and has well-studied theoretical properties. However, it can be unduly influenced by ►outliers, unequal variances, non-normality, and nonlinearity. Spearman's correlation reflects the monotone association between X and Y and measures the correlation between $F(X)$ and $G(Y)$. Kendall's correlation is the probability of concordance minus the probability of discordance. Spearman's and Kendall's correlations remain invariant under a monotone transformation. However, Pearson's correlation remains only invariant under a location and scale change.

Using the probability integral transformations $u = F(x)$ and $v = G(y)$, the copula (see also ►Copulas) of X and Y is defined as $C(u, v) = H(F^{-1}(u), G^{-1}(v))$. Hence,

$$\rho = \frac{1}{\sigma_X \sigma_Y} \iint_{I^2} [C(u,v) - uv]dF^{-1}(u)dG^{-1}(v),$$

$$s = 12 \iint_{I^2} [C(u,v) - uv]dudv,$$

$$\tau = 4 \iint_{I^2} C(u,v)dC(u,v) - 1$$

where I^2 is the unit square. Schweizer and Wolff (1981) note that $C(u, v) - uv$ is the signed volume between the surface $z = C(u, v)$ and $Z = uv$ (the independence copula).

Copula representation of ρ clearly shows its dependence on the marginal distributions. Therefore, it is not a measure of nonparametric dependence. Daniels (1950) shows that $-1 \le 3\tau - 2s \le 1$. Nelsen (1991) studies the relationship between s and τ for several families of copulas and Fredricks and Nelsen (2007) show that the ratio τ/s approaches 2/3 as H approaches independence.

Hoeffding (1940) and Frechét (1951) show that for all $(x,y) \in R^2$ the joint DF is bounded: $H_1(x,y) \le H(x,y) \le H_2(x,y)$ where $H_1(x,y) = max(0, F(x) + G(y) - 1)$ and $H_2(x,y) = min(F(x), G(y))$ are distribution functions. Perfect negative correlation is obtained when H_1 is concentrated on the line $F(x) + G(y) = 1$ whereas perfect positive correlation is obtained when H_2 is concentrated on the line $F(x) = G(y)$. In fact, $H_0(x,y) = F(x)G(y)$ for all $(x,y) \in R^2$ reflects independence of X and Y. Let $C_1(x,y) = max(0, u + v - 1)$, $C_2(x,y) = min(u,v)$ and $C_0(x,y)$ denote the Frechét lower, upper and independence copulas, respectively. Similarly, $C_1(u,v) \le C(u,v) \le C_2(u,v)$.

Using Hoeffding lemma (1948)

$$Cov(X,Y) = \int_{-\infty}^{\infty}\int_{-\infty}^{\infty}[H(x,y) - F(x)G(y)]dxdy,$$

one can show $\rho_1 \le \rho \le \rho_2$ where ρ_1 and ρ_2 are the correlation coefficients associated with H_1 and H_2, respectively. Depending on the marginal distributions the range of ρ may be much smaller than $|\rho| \le 1$. For example, for the bivariate log-normal distribution with unit variances, one can show $\rho \in (-0.368, 1)$. Lancaster (1958) uses Chebyshev-Hermite polynomial to obtain the correlation coefficient of transformed bivariate random vectors. Freeman and Modarres (2005) obtain the form of the correlation after a ►Box-Cox transformation.

Moran (1967) states that the necessary and sufficient conditions for ρ to assume extreme values of +1 and −1 are

1. $X \overset{d}{=} aY + b$ for constants
2. $F(\mu + x) = 1 - F(\mu - x)$ where μ is the mean of X. Normal, uniform, double exponential and logistic distributions satisfy these conditions

Rényi (1959) considers a set of conditions that a symmetric nonparametric measure of dependence should satisfy. Schweizer and Wolff (1981) note that Rényi's conditions are too strong and suggest that any suitably normalized distance measure such as the L_p distance provides a symmetric measure of nonparametric dependence. They show that these distances, according to a modified set of Rényi conditions, enjoy many useful properties. Let $L_p = (K_p \int_{I^2} |C(u,v) - uv|^p dudv)^{1/p}$ where K_p is chosen such that L_p remains in $(0,1)$. We have

1. $L_1 = 12 \int_{I^2} |C(u,v) - uv| dudv$
2. $L_2 = \left(90 \int_{I^2} (C(u,v) - uv)^2 dudv\right)^{1/2}$
3. $L_\infty = 4\, Sup_{I^2} |C(u,v) - uv|$

In fact Hoeffding (1948) and Blum et al. (1961) base a nonparametric test of independence between X and Y on L_∞. Modarres (2007) studies several tests of independence, including a measure based on the likelihood of cut-points.

Median Filters and Extensions

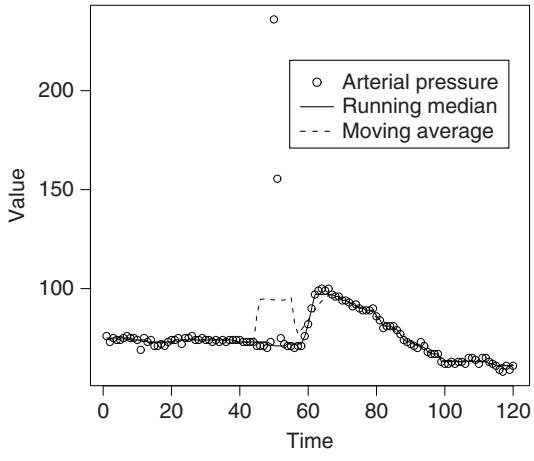
Roland Fried[1], Ann Cathrice George[2]
[1]Professor
TU Dortmund University, Dortmund, Germany
[2]TU Dortmund University, Dortmund, Germany

De-noising a time series, that is a sequence of observations of a variable measured at equidistant points in time, or an image, that is a rectangular array of pixels, is a common task nowadays. The objective is to extract a varying level (a "signal") representing the path followed by the time series or the true image which is overlaid by irrelevant noise.

Linear filters like moving averages are computationally simple and eliminate normal noise efficiently. However, their output is heavily affected by strongly deviating observations (called ▶outliers, spikes or impulses), which can be caused for instance by measurement artifacts. Moreover, linear filters do not preserve abrupt changes (also called step changes or jumps) in the signal or edges in an image. Tukey (1977) suggests median filters, also called running medians, for these purposes.

We focus on the time series setting in the following. Let $y_1, \ldots, y_N$ be observations of a variable at equidistant points in time. De-noising these data for extraction of the time-varying mean level underlying these data (the signal) can be accomplished by moving a time window $y_{t-k}, \ldots, y_t, \ldots, y_{t+k}$ of length $n = 2k+1$ through the series for estimation of the level μ_t in the center of the window. Whereas a moving average calculates the arithmetic average of the data in the time window for this, a running median uses the median of these values. If the window width is fixed throughout, we get estimates of the levels $\mu_{k+1}, \ldots, \mu_{N-k}$ at instances not very close to the start or the end of the time series. The levels at the start or the end of the time series can be estimated for instance by extrapolation of the results from the first and last window or by adding the first and the last observed value a sufficient number of times.

Figure 1 depicts observations of the arterial blood pressure of a patient in intensive care measured once a minute, as well as the outputs of a moving average and a running median, both with window width $n = 11$. The moving average is strongly affected by a few measurement artifacts, and it smooths the sudden increase at $t = 60$. The running median eliminates the spikes and preserves the shift.



Median Filters and Extensions. Fig. 1 Measurements of the arterial blood pressure of a patient and outputs of a running median and a moving average, both with window width $n = 11$

A possible disadvantage of running medians is that they implicitly rely on the assumption that the level is almost constant within each time window. While increasing the window width improves the reduction of noise if the signal is locally constant, this is no longer the case in trend periods. Davies et al. (2004) investigate application of robust regression to a moving time window to improve the approximation of trends in the presence of ▶outliers. Many further refinements of robust filters for signal extraction from time series or images and different rules for choosing a (possibly locally adaptive) window width from the data have been suggested in the literature. See Gather et al. (2006) for an overview on robust signal extraction from time series.

Medical Research, Statistics in

B. S. Everitt
Professor Emeritus
Institute of Psychiatry, King's College, London, UK

Statistical science plays an important role in medical research. Indeed a major part of the key to the progress in medicine from the 17th century to the present day has been the collection and valid interpretation of empirical evidence provided by the application of statistical methods to medical studies. And during the last few decades, the use of statistical techniques in medical research has grown more rapidly than in any other field of application. Indeed, some branches of statistics have been especially stimulated by their applications in medical investigations, notably the analysis of ►survival data (see, for example, Collett 2003). But why has statistics (and statisticians) become so important in medicine? Some possible answers are:

- Medical practice and medical research generate large amounts of data. Such data can be full of uncertainty and variation and extracting the "signal," i.e. the substantive medical message in the data, form the 'noise' is usually anything but trivial.
- Medical research often involves asking questions that have strong statistical overtones, for example: 'How common is a particular disease?'; 'Which people have the greatest chance of contracting some condition or other?'; 'What is the probability that a patient diagnosed with breast cancer will survive more than five years?'
- The evaluation of competing treatments or preventative measures relies heavily on statistical concepts in both the design and analysis phase.

In a short article such as this it is impossible to cover all areas of medicine in which statistical methodology is of particular importance and so we shall concentrate on only three namely, clinical trials, imaging and molecular biology. (For a more comprehensive account of the use of statistics in medicine see Everitt and Palmer (2010)).

Clinical Trials

If a doctor claims that a certain type of psychotherapy will cure patients of their depression, or that taking large doses of vitamin C can prevent and even cure the common cold, how should these claims be assessed? What sort of evidence do we need to decide that claims made for the efficacy of clinical treatments are valid? One thing is certain: We should *not* rely either on the views of 'experts' unless they provide sound empirical evidence (measurements, observations, i.e., *data*) to support their views, nor should we credit the anecdotal evidence of people who have had the treatment and, in some cases, been 'miraculously' cured. (And it should be remembered that the plural of anecdote is not evidence.) Such 'wonder' treatments, which are often exposed as ineffectual when exposed to more rigorous examination, are particularly prevalent for those complaints for which conventional medicine has little to offer (see the discussion of alternative therapies in Chapter 13 of Everitt 2008).

There is clearly a need for some form of carefully controlled procedure for determining the relative effects of different treatments and this need has been met in the 20th and 21st centuries by the development of the clinical trial, a medical experiment designed to evaluate which (if any) of two or more treatments is the more effective. The quintessential components of a clinical trial, the use of a control group and, in particular the use of ►randomization as a way of allocating participants in the trial to treatment and control groups, were laid down in the first half of the 20th century. The randomization principle in clinical trials was indeed perhaps the greatest contribution made by arguably the greatest statistician of the 20th century, Sir Ronald Aylmer Fisher. Randomization achieves the following:

- It provides an impartial method, free of personal bias, for the assignment of participants to treatment and control groups. This means that treatment comparisons will not be invalidated by the way the clinician might chose to allocate the participants if left to his or her own judgment.
- It tends to balance treatment groups in terms of extraneous factors that might influence the outcome of treatment, even in terms of those factors the investigator may be unaware of.

Nowadays some 9,000–10,000 clinical trials are undertaken in all areas of medicine form the treatment of acne to the prevention of cancer and the randomized controlled clinical trial is perhaps the outstanding contribution of statistics to 20th century medical research. And in the 21st century statisticians have applied themselves to developing methods of analysis for such trials that can deal with the difficult problems of patient drop-out, the longitudinal aspects of most trials and the variety of measurement types used in such trials (see Everitt and Pickles 2004).

Imaging

Examples of medical imaging systems include conventional radiology (X-rays), positron-emission tomography (PET), magnetic resonance imaging (MRI) and functional magnetic resonance imaging (fMRI). A significant advantage often claimed for medical imaging is its ability to visualize structures or processes in the patient without the need for intrusive procedures, for example, surgery; but this may also be a disadvantage and the question that may need to be asked is how well do the conclusions from an imaging experiment correspond to the physical properties that might have been found from an intrusive procedure?

Imaging studies generate large amounts of data and a host of statistical techniques have been employed to analyze such data and to extract as much information as possible from what is in many cases very 'noisy' data. Autoregressive models, linear mixed effects models, finite mixture models and Gaussian random field theory have all been applied to mixture data with varying degrees of success. Some important references are Besag (1986), Silverman et al. (1990) and Lange (2003).

Molecular Biology

Molecular biology is the branch of biology that studies the structure and function of biological macromolecules of a cell and especially their genetic role. A central goal of molecular biology is to decipher the genetic information and understand the regulation of protein synthesis and interaction in the cellular process. Advances in biotechnology have allowed the cloning and sequencing of DNA and the massive amounts of data generated have given rise to the new field of ►bioinformatics which deals with the analysis of such data. A variety of statistical methods have been used in this area; for example, hidden Markov models have been used to model dependencies in DNA sequences and for gene finding (see Schliep et al. 2003) and data mining techniques (see ►Data Mining), in particular, cluster analysis (see, for example, Everitt et al. 2010) have been used to identify sets of genes according to their expression in a set of samples, and to cluster samples (see ►Cluster Sampling) into homogeneous groups (see Toh and Honimoto 2002).

Statistical methods are an essential part of all medical studies and increasingly sophisticated techniques now often get a mention in papers published in the medical literature. Some of these have been mentioned above but others which are equally important are Bayesian modeling (see Congdon 2001) and generalized estimating equations (see Everitt and Pickles 2004). In these days of evidence-based medicine (Sackett et al. 1996), collaboration between medical researchers and statisticians is essential to the success of almost all research in medicine.

About the Author

Brian Everitt retired from his post as Head of the Department of Computing and Statistics at the Institute of Psychiatry, King's College, London in 2005. He is the author (or joint author) of about 100 journal papers and 60 books. In retirement he continues to write and with colleagues has nearly completed the 5th edition of *Cluster Analysis*, first published in 1974. Apart from writing his interests are playing classical guitar (badly), playing tennis, walking and reading.

Medical Statistics

Vern T. Farewell[1], Daniel M. Farewell[2]
[1]Associate Director
Medical Research Council, Biostatistics Unit, Cambridge, UK
[2]School of Medicine, Cardiff University, Cardiff, UK

Historical Background

The term statistics has at least three, related, meanings. It may refer to data in raw form, or to summaries thereof, or to the analysis of uncertainty associated with data. The phrase medical statistics, therefore, may reasonably be applied to the specialization to medical science of any of these understandings of statistics.

Raw medical statistics date back at least to the London Bills of Mortality, collected weekly between 1603 and 1836 in order to provide an early warning of plague. The early demographic work of John Graunt (1620–1674) was based on these Bills. The summaries of vital statistics undertaken by William Farr (1807–1883), working at the General Registry Office of England and Wales, became the basis of many important health reforms. However, the founding editors of the journal *Statistics in Medicine* described modern medical statistics as "the deployment of the ideas, principles and methods of statistics to stimulate deeper understanding in medicine" (Colton et al. 1982), emphasizing the third understanding of the term.

The history of the link between statistics and medicine includes key figures in the development of statistics itself. For example, Arbuthnot (1667–1753) and Bernoulli (1700–1782), often cited in the early use of significance tests, were each qualified in both mathematics and in medicine. Many individuals have contributed to the emergence of medical statistics as a scientific discipline in its own right. The French writers, Pinel (1745–1826), Louis (1787–1872) and Gavarret (1809–1890) and the Danish physician, Heiberg (1868–1963) provided early impetus. Subsequently, Pearl (1879–1940) and Greenwood (1880–1949) established research programmes in medical statistics in the USA and the UK respectively. In 1937, Hill (1897–1991) published the highly influential book, *Principles of Medical Statistics*, Hill (1937), of which twelve editions were published over the next 55 years. Two other important contributions of Hill were arguably the first modern randomized clinical trial on the effect of streptomycin in tuberculosis, and his discussion of criteria for causality in epidemiological studies. A useful source for information on the history of medical statistics is the Lind Library [http://www.jameslindlibrary.org].

The Nature of Medical Statistics

Much activity in medical statistics is necessarily collaborative. Over the course of a career, statisticians engaged in medical research are likely to work closely with physicians, nurses, laboratory scientists and other specialists. Communication across disciplines can present challenges but, in addition to its scientific merit, also frequently stimulates worthwhile methodological and theoretical research. Further, since medical research often raises ethical issues, these too must be considered by medical statisticians. Hill (1936) stressed that the statistician "cannot sit in an armchair, remote and Olympian, comfortably divesting himself of all ethical responsibility."

A dominant characteristic of the statistical methods arising in medical statistics is that they must make allowance for known variability. Comparisons of groups should adjust for systematic discrepancies between groups, for instance in terms of demographics. This has been reflected for many years by the high profile given to regression methodology, which allows multiple explanatory variables to be incorporated. A more recent manifestation is in the monitoring of medical performance, where quality control procedures developed for industrial application have been modified to allow for predictable heterogeneity in medical outcomes (Grigg et al. 2003).

Illustrative Methodological Developments

In 1984, Cox identified three important periods in the development of modern statistical methodology. The first was linked to developments in agriculture, the second to industrial applications, and the third to medical research. Developments linked to medical research flourished in the 1970s; where earlier statistical methodology placed particular emphasis on normally distributed data, there was a need for methods more suited to survival (or time-to-event) and categorical data. A distinguished example of the former is Cox's own pioneering paper (Cox 1972), presenting a semiparametric regression model for ▶survival data that did not require full specification of an underlying survival distribution. In addition, and in contrast to virtually all other regression methods then available, this model allowed the incorporation of explanatory variables that varied over time. A wealth of subsequent extensions to this already very general methodology followed, many facilitated by Aalen's (1978) reformulation of the problem in a counting process framework [see also Andersen et al. (1993)].

An important application of statistical models for categorical data was to ▶case- control studies. These epidemiological investigations of the relationship between a disease

D and exposure E, a possible risk factor, involve separate sampling of diseased and disease-free groups, from which information on E and other disease risk factors is obtained. Binary ►logistic regression would seem to provide a natural tool for the analysis of these studies, but for the fact that it focuses on $\mathrm{pr}(D|E)$ whereas the sampling is from the distribution $\mathrm{pr}(E|D)$. Building on a series of earlier papers, Prentice and Pyke (1979) established how a prospective logistic regression model for $\mathrm{pr}(D|E)$ could be used with case-control data to provide valid estimates of the odds-ratio parameters. This rapidly became the standard methodology for the analysis of case-control studies (Breslow 1996).

Study Design

The design of medical studies is also a major area of activity for medical statisticians. The paradigmatic design is perhaps the Phase III clinical trial, of which a key aspect is often randomized treatment assignment. While ►randomization can provide a basis for statistical inference, its primary motivation in trials is to enable statements of causality, critical for Phase III trials where the aim is to establish treatment efficacy. Nevertheless, the need for, and methods of, randomization continue to generate discussion, since randomization can be seen to sacrifice potential individual advantage for collective gain. Other design questions arise in Phase I trials that establish the tolerability of treatments and basic pharmacokinetics, and Phase II trials aimed at finding potentially efficacious treatments or dosages.

For ethical reasons, ongoing monitoring of data during a clinical trial is often needed, and this has been an area of methodological investigation within medical statistics since the pioneering work of Armitage (1975) (a comprehensive discussion may be found in Jennison and Turnbull (2000)). There is also an increasing role for statisticians on formal committees that monitor trial data and safety, where their expertise is combined with that of physicians, ethicists, and community representatives to ensure the ethical conduct of trials more generally.

In the 1980s, two important variations on the standard case-control design emerged, namely case-cohort studies (Prentice 1986) and two stage case-control designs (Breslow and Cain 1988); both have proved very useful in epidemiology. Epidemiological cohorts where individuals are followed to observe disease incidence, or clinical cohorts for which information on patients with specified conditions is collected routinely – both usually implemented over long periods of time – also continue to present design and analysis challenges to the medical statistician.

More Recent Topics of Interest

Typically, medical studies are conducted not only to discover statistical associations, but also in the hopes of suggesting interventions that could benefit individuals or populations. This has led to a preference for investigations incorporating randomization or multiple waves of observation, based on the idea that cause should precede effect. Randomized or not, information gathered repeatedly on the same subjects is known as longitudinal data, and its analysis has become a major subdiscipline within medical statistics. Two distinct approaches to longitudinal data analysis have risen to prominence: likelihood-based models (incorporating both classical and Bayesian schools of thought) and estimating-equation techniques.

A consequence of this emphasis on studies monitoring subjects over several months (or even years) has been an increased awareness that data, as collected, are often quite different from what was intended at the design stage. This may be due to subjects refusing treatment, or choosing an alternate therapy, or dropping out of the investigations altogether. Likelihood approaches to longitudinal data may be extended to incorporate an explicit model for the observation process (Henderson et al. 2000), while estimating equations can be modified with subject- or observation-specific weights (Robins et al. 1995) to account for departures from the study design. Non-compliance, dynamic treatment regimes, and incomplete data are all areas of active methodological research within medical statistics.

Two other major areas of current interest are meta-analysis and genetic or genomic applications. Meta-analysis is often taken to refer to the technical aspects of combining information from different studies that address the same research question, although the term is sometimes used to describe the more general systematic review, which includes broader issues such as study selection. Study heterogeneity is an important aspect of ►meta-analysis that the statistician must address. The size and complexity of genetic and genomic data present major statistical and computational challenges, notably due to hypothesis test multiplicity.

Conclusion

Medicine remains a major area of application driving methodological research in statistics, and the demand for medical statisticians is considerable. A comprehensive introduction to the area can be found in Armitage et al. (2002) and a less technical introduction is Matthews and Farewell (2007).

About the Author

Prior to moving to the MRC Bistatistics Unit, Vern Farewell held professorial positions at the University of Washington, the University of Waterloo and University College London. He has published over 200 papers in the statistical and medical literature and is co-author of the four editions of the book *Using and Understanding Medical Statistics*. Since 2007, he has been Editor of *Statistics in Medicine*.

Introduction

Given several studies on the same topic, a *meta-analysis* synthesizes the information in them so as to obtain a more precise result. The proper procedure of conducting a *systematic review* of literature, the selection of which studies to include and the issues of *publication bias* and other possible biases are important aspects not covered here and we refer the interested reader to Cooper and Hedges (1994) and Higgins and Green (2008). We assume all studies estimate the same *effect*, which is often a comparison of outcomes for control and treatment groups via clinical trials. Examples for two binomial samples with parameters $(n_1, p_1), (n_2, p_2)$ are the *risk difference* $p_1 - p_2$, *relative risk* p_2/p_1 and *odds ratio* $\{p_2/(1-p_2)\}/\{p_1/(1-p_1)\}$. Other examples comparing normal samples are the difference in means $\mu_1 - \mu_2$, or *effect sizes* such as the *standardized mean difference, or Cohen's-d* $d = (\mu_1 - \mu_2)/\sigma$ from Cohen (1988), where σ^2 is an assumed common variance, and Glass's $g = (\mu_1 - \mu_2)/\sigma_1$ from Glass (1976), where σ_1^2 is the variance of the control group.

Traditional Meta-Analysis Methodology

We are given K independent studies, in which the estimated effects $\hat{\theta}_k$ based on N_k observations are asymptotically normal such that $\hat{\theta}_k$ is for large enough N_k approximately normally distributed with mean θ_k and variance σ_k^2/N_k. This is denoted $\hat{\theta}_k \sim AN\left(\theta_k, \sigma_k^2/N_k\right)$ for each $k = 1, \ldots, K$. Examples satisfying the above assumptions are the risk difference, the log-relative risk, the log-odds ratio and the Cohen's-d. The goal is to combine the estimators $\hat{\theta}_k$ in some way so as to estimate a representative θ for all K studies, or even more ambitiously, for all potential studies of this type. Thus there is the conceptual question of how to define a representative θ, and the inferential problem of how to find a confidence interval for it.

Confidence Intervals for Effects

Note that for each individual study, one can already form large sample confidence intervals for individual θ_k, $k = 1, \ldots, K$. For *known* σ_k, a $100(1-\alpha)\%$ large-sample confidence interval for θ_k is $[L_k, U_k] = \left[\hat{\theta}_k - z_{1-\alpha/2}\sigma_k/N_k^{1/2},\ \hat{\theta}_k + z_{1-\alpha/2}\sigma_k/N_k^{1/2}\right]$, where $z_\beta = \Phi^{-1}(\beta)$ is the β quantile of the standard normal distribution. If σ_k is *unknown*, and there exists estimators $\hat{\sigma}_k$ with $\hat{\sigma}_k/\sigma_k \to 1$ in probability as $N_k \to \infty$, then the same can be said for $[L_k, U_k] = \left[\hat{\theta}_k - z_{1-\alpha/2}\hat{\sigma}_k/N_k^{1/2}, \hat{\theta}_k + z_{1-\alpha/2}\hat{\sigma}_k/N_k^{1/2}\right]$.

Unequal Fixed Effects Model (UFEM)

Standard meta-analysis proceeds by choosing a weight w_k for each study and combines the estimated $\hat{\theta}_k$ through weighted means. If we interpret θ_k as the true effect for the study k and if this effect is of interest in its own right, then the following definition can be adopted. Consider a representative effect for the K studies defined by $\theta_w = \sum_k w_k\theta_k/W$ with $W = \sum_j w_j$. This *weighted effect* is the quantity that we want to estimate by meta-analysis. There is a good dose of arbitraryness in this procedure, because the weighted effect does not necessarily have a readily interpreted meaning. An exception occurs if the weights are all equal to one, in which case θ_w is simply the average of the study effects.

The weights are, however, often chosen to be proportional to the reciprocals of the variances in order to give more weight to θ_k that are estimated more accurately. If this is the choice, it follows that $w_k = N_k/\sigma_k^2$ and $\hat{\theta}_w = \sum_k w_k\hat{\theta}_k/W$ satisfies $\hat{\theta}_w \sim AN(\theta_w, W^{-1})$. Therefore a $100(1-\alpha)\%$ large-sample confidence interval for θ_w is given by $[L, U] = [\hat{\theta}_w - z_{1-\alpha/2}W^{-1/2},\ \hat{\theta}_w + z_{1-\alpha/2}W^{-1/2}]$.

In practice the weights usually need to be estimated, (w_k by $\hat{w}_k$ and W by $\hat{W} = \sum_k \hat{w}_k$), but a large sample confidence interval for θ_w can be obtained by substituting $\hat{\theta}_{\hat{w}}$ for $\hat{\theta}_w$ and $\hat{W}$ for W in the above interval.

Fixed Effects Model (FEM)

When statisticians speak of the fixed effects model they usually mean *equal* fixed effects which makes the very strong assumption that all $\theta_k = \theta$. This has the appeal of simplicity. The UFEM just described includes the FEM as a special case. In particular the target parameter θ_w reduces to $\theta_w = \theta$ and thus becomes a meaningful quantity no matter what weights are chosen.

However, one of the preferred choices still uses the weights inversely proportional to the variance, because in this case $\sum_k w_k\hat{\theta}_k/W$ has the smallest asymptotic variance amongst all unbiased (for θ) linear combinations of the individual study estimators of θ. The same confidence interval given above for θ_w is used for θ. The methodology for the UFEM and FEM models is the same, but the target parameter θ_w of the UFEM has a different interpretation.

Random Effects Model (REM)

The REM assumes that the true effects θ_k, $k = 1, \ldots, K$ are the realized values of sampling from a normal population with mean θ and variance γ^2 for some unknown inter-study variance γ^2, and further that the above results for the UFEM are all *conditional* on the given θ_k, $k = 1, \ldots, K$. The justification for this assumption is that the K studies are a 'random sample' of all possible studies on this topic. Inference for θ can now be interpreted as saying something about the larger population of possible studies.

Formally, the REM assumes $\theta_1, \ldots, \theta_K$ are a sample from $N(\theta, \gamma^2)$, with both parameters unknown; and $\hat{\theta}_k|\theta_k \sim AN\left(\theta_k, \sigma_k^2/N_k\right)$ for each k. If the *conditional* distribution of $\hat{\theta}_k$, given θ_k, were exactly normal, then the *unconditional* distribution of $\hat{\theta}_k$ would be exactly $\hat{\theta}_k \sim N\left(\theta, \gamma^2 + \sigma_k^2/N_k\right)$. However, in general the unconditional distributions are only asymptotically normal $\hat{\theta}_k \sim AN\left(\theta, \gamma^2 + \sigma_k^2/N_k\right)$. It is evident that one needs an estimate $\hat{\gamma}^2$ of γ^2 in order to use the inverse variance weights approach described earlier, and this methodology will be described below.

Choosing between Fixed and Random Effects Models

Qualitative Grounds

If one assumes the K studies are a random sample from a larger population of potential studies and that the true effects θ_k are each $N(\theta, \gamma^2)$ then θ is the target effect, and γ^2 is a measure of inter-study variability of the effect. In

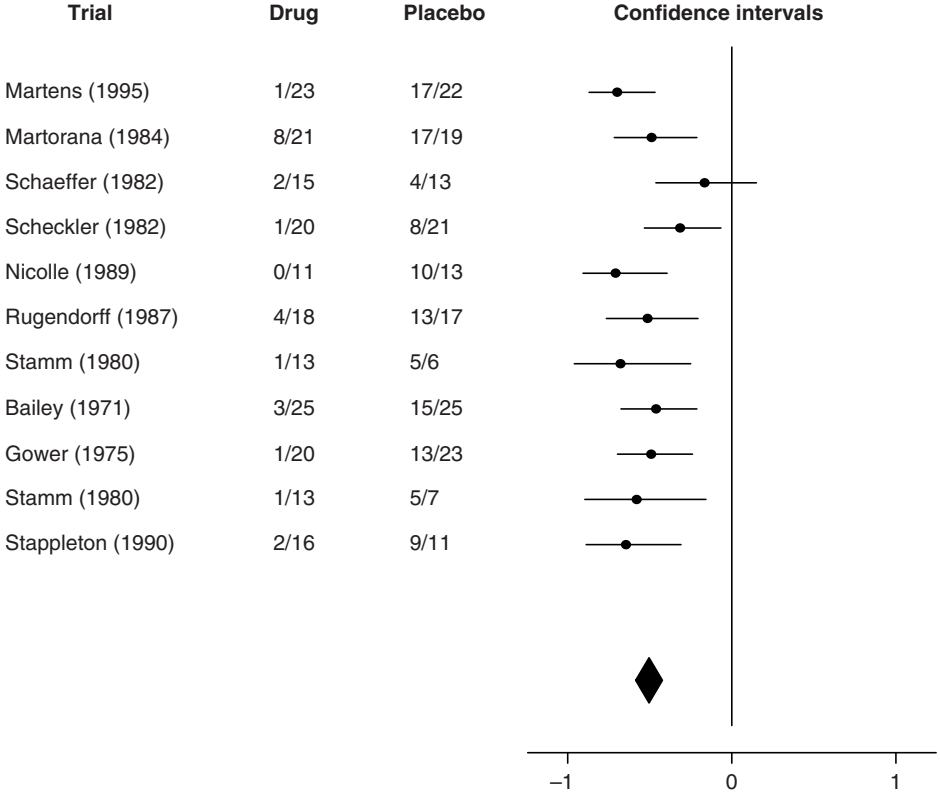
this case choose the REM. If there is reason to believe that the θ_k are different, but not the result of random sampling, then use the UFEM. In this case, it may be possible to explain a good part of the variation in the effects θ_k by *meta-regression*. The differences between the studies can sometimes be captured by variables that describe the circumstances of each study and by regressing the $\hat{\theta}_k$ on such variables, these differences can be explained and corrected. Meta-regression may thus turn a UFEM into a FEM. In both models, the target is $\theta_w = \sum_k w_k \theta_k / W$. If there is reason to believe all $\theta_k = \theta$, (the *homogeneous case*), use the FEM with target θ. For the FEM and UFEM inferential conclusions only apply to the K studies.

Quantitative Grounds

It is clear that if $\gamma^2 = 0$ in the REM, or all $\theta_k = \theta$ in the UFEM, one obtains the FEM. It is a special case of both. One way to test the null hypothesis of homogeneity (all $\theta_k = \theta$) is to use Cochran's Q, defined by $Q = \sum_k w_k (\hat{\theta}_k - \hat{\theta}_w)^2$, where w_k are the inverse variance weights and $\hat{\theta}_w = \sum_k w_k \hat{\theta}_k / W$. One can show that under the null hypothesis of homogeneity, and when each $\hat{\theta}_k$ is normally distributed, $Q \sim \chi^2_{K-1}$, so a level α test of homogeneity rejects when $Q \geq \chi^2_{K-1,1-\alpha}$. Further, under the UFEM model, the statistic Q has a non-central chisquared distribution $Q \sim \chi^2_{K-1}(\lambda)$, where $\lambda = \sum_k w_k (\theta_k - \theta_w)^2$. This result and others allowing for the weaker assumption $\theta_k \sim AN\left(\theta_k, \sigma_k^2 / N_k\right)$ and estimated weights are derived in Sect. 24.1, Kulinskaya et al. (2008). In the asymptotic case, the χ^2 distributions are only approximate. Testing for heterogeneity is strongly discouraged in Higgins and Green (2008) in favor of the quantification of inherently present heterogeneity.

Inference for the REM

Let $M_r = \sum_k w_k^r$ for inverse variance weights w_k, and $a = M_1 - M_2/M_1$. It can be shown that for this model $\mathrm{E}[Q] = K - 1 + a\gamma^2$. This "justifies" the DerSimonian and Laird (1986) estimator $\hat{\gamma}^2_{DL} = \{Q - (K-1)\}^+ / a$, where $\{\ldots\}^+$ means set the quantity in brackets equal to 0 if it is negative and otherwise leave it. Using this estimator and $\hat{\theta}_k \sim AN\left(\theta, \gamma^2 + w_k^{-1}\right)$, we have new weights $w_k^* = \left(\gamma^2 + w_k^{-1}\right)^{-1}$



Meta-Analysis. Fig. 1 The data of eleven independent studies of antibiotic treatment to prevent recurrent urinary tract infection are presented in this forest plot. The confidence intervals for the individual studies are shown on the right-hand side. The lozenge at the bottom shows the combined confidence interval, the result of the meta-analysis

and estimator $\hat{\theta}^* = \sum_k w_k^* \hat{\theta}_k / W^* \sim AN(\theta, \{W^*\}^{-1})$, where $W^* = \sum_k w_k^*$. In practice w_k^* is usually estimated by $\hat{w}_k^* = 1/\left(\hat{\gamma}_{DL}^2 + \hat{w}_k^{-1}\right)$. Anotherestimator of γ^2 is proposed in Biggerstaff and Tweedie (1997).

Meta-Regression

In some cases there is information regarding the K studies which may explain the inter-study variance. In this case the estimated effects $\hat{\theta}_k$ can be considered as responses to be regressed on explanatory variables $x_1, \ldots, x_p$, also called *moderators*. Thus one has $y_k = \beta_0 + \beta_1 x_{k1} + \cdots + \beta_p x_{kp} + \epsilon_k$, where y_k is the estimated effect $\hat{\theta}_k$ (or a transformed effect), and ϵ_k is the random error in the kth study, $k = 1, \ldots, K$. Weighted least squares (with known or estimated weights) can be used to estimate the coefficients. When the variance stabilizing transformation is applied to estimated effects, generalized linear models techniques (see ►Generalized Linear Models) with Gaussian family of distributions can be used, see Chap. 14 of Kulinskaya et al. (2008).

Example

As illustration, consider a series of 11 studies of antibiotic treatment to prevent recurrent urinary tract infection. The sources of the data, the data themselves, and the confidence intervals are shown in Fig. 1. These studies are part of those reviewed by Albert et al. (2004) and have been discussed in Chap. 19 (p. 158) of Kulinskaya et al. (2008). The total sample sizes range from $N = 19$ to $N = 50$. The parameter of interest is the risk difference $p_1 - p_2$ between the placebo group and the treated groups. The studies show a more or less strong benefit of the treatment, while the meta-analysis gives a fairly convincing result. This depiction of results is known as a *forest plot*.

Additional Literature

The traditional approach is general, only requiring asymptotically normal effects and estimates for the weights. However the methodology is overly simple, because it assumes known weights, when in fact they usually need to be estimated. Recent studies indicate that typical sample sizes are woefully inadequate in order for the approximations that assume known weights to be reliable (Malzahn et al. 2000; Viechtbauer 2007). One way of overcoming this problem is to employ variance stabilization of the estimated effects before applying the traditional approach, see Kulinskaya et al. (2008). For further reading we recommend the classical work Hedges and Olkin (1985), as well as the recent books Böhning et al. (2008), Borenstern et al. (2009), Hartung et al. (2008) and Whitehead (2002).

About the Authors

Prof. Elena Kulinskaya is a recently appointed Aviva Chair in Statistics, University of East Anglia. Previously she has been Director of the Statistical Advisory Service at Imperial College London (2004–2010). She is also a Visiting Professor at The Center for Lifespan and Chronic Illness Research (CLiCIR), University of Hertfordshire. She has a long standing interest in statistical evidence and its applications in meta-analysis. She has authored and co-authored 78 papers, including numerous theoretical and applied papers on meta-analysis, and a recent book on meta analysis (*Meta-analysis: A Guide to Calibrating and Combining Statistical Evidence*, Wiley, 2008) co-authored with Stephan Morgenthaler and R.G. Staudte and dedicated to a new approach based on variance stabilization.

Dr. Stephan Morgenthaler is Professor of Applied Statistics in the Institute of Mathematics Ecole Polytechnique Fédérale de Lausanne in Switzerland. He has authored, co-authored and edited more than 80 papers and eight books. He is a member of the ISI and a Fellow of the American Statistical Association. He served as a vice-president of ISI from 2004 to 2008.

Dr. Robert G. Staudte is Professor and Head, Department of Mathematics and Statistics, La Trobe University, Melbourne, Australia. He has authored and co-authored more than 50 papers and four books, including *Robust Estimation and Testing*, Wiley 1990, co-authored with Professor Simon J. Sheather; and *Meta Analysis: a Guide to Calibrating and Combining Statistical Evidence*, Wiley 2008, co-authored with Professors Elena Kulinskaya and Stephan Morgenthaler. He was Associate Editor of the *Journal of Statistical Planning and Inference* (1995–1998).

Method Comparison Studies

Graham Dunn
Professor of Biomedical Statistics and Head of the Health Methodology Research Group
University of Manchester, Manchester, UK

We are here concerned with the comparison of the performance to two or more measurement devices or procedures. At its simplest, a method comparison study involves the measurement of a given characteristic on a sample of subjects or specimens by two different methods. One possible question is then whether measurements taken by the two different methods are interchangeable. Another is whether one of the two methods is more or less precise than the other. A third, more difficult task, is to calibrate one set of fallible measurements (using Device A, for example) against another set of fallible measurements produced by device B. A potentially-serious problem in all of these situations is the possibility that the measurement errors arising from the use of these two devices may be correlated. A slightly more complicated study involves replication of each of the sets of measurements taken using the two different procedures or devices, usually carried out on the naïve assumption that the measurement errors of the within-device replicates will be uncorrelated and that replication will enable the investigator to obtain an unbiased estimate of the instruments' precisions (based on the standard deviations of the replicates).

Let's return to the simplest situation – measurement of a given characteristic on a sample of subjects by two different methods that are assumed to provide independent measurement errors. Are the two methods interchangeable? How closely do the measurements agree with each other? Is this agreement good enough for all our practical purposes? A method suggested by Bland and Altman (1986) is to determine *limits of agreement*. One simply subtracts the measurement arising from one method from the corresponding measurement using the other. The average of these differences tells us about the possibility of relative bias (and the so-called Bland-Altman plot – a graph of the difference against the average of the two measurements – may tell us that the bias is changing with the amount of the characteristic being measured, but it is not 100% fool-proof since a relationship between the difference between and the average of the two measures may arise from differences in the instruments' precisions). The standard deviation of the differences tells us about the variability of the difference of the two measurement errors. The 95% limits of agreement are simply defined as the range of differences between the 2.5th and 97.5th percentiles or, assuming normality, approximately two standard deviations either side of the mean. If the measurement errors for the two methods are positively correlated then the variability of the differences will be less than one would expect if they were uncorrelated and the limits of agreement will be too small. If the measurement methods use different scales (comparison of temperatures in °C and °F, for example) then this simple procedure will break down and the limits of agreement will fail to tell the investigator that the two methods are interchangeable (after suitable rescaling).

One might be tempted to plot results using one of the methods (in °F, for example) against the other (in °C) and carry out a simple regression to calibrate one against the other. But the hitch is that both methods are subject to error (the classical errors-in-variables problem) and the estimate of the regression coefficient would be biased (attenuated towards zero). If one knows the ratio of the variances of the measurement errors for the two methods then it is possible to use orthogonal regression, widely-known as Deming's regression, to solve the problem. The

catch is that one does not normally have an unbiased estimate of the ratio of these two variances – the problem again arising from the lack of independence (i.e., correlation) of any replicate measures used to determine these variances (Carroll and Ruppert 1996).

A third relatively simple approach is to look for and make use of an instrumental variable (IV) through IV or ►two-stage least squares (2SLS) regression methods. Here we need a variable (not necessarily a third measurement of the characteristic, but it may be) that is reasonably highly correlated with the characteristic being measured but can be justifiably assumed to be uncorrelated with the associated measurement errors. If we label the measurements using the two methods as X and Y, and the corresponding values of the instrumental variable as Z, then the instrumental variable estimator of the slope of Y on X is given by the ratio Cov(Y,Z)/Cov(X,Z) – see Dunn (2004, 2007). From here it's a relatively simple move into factor analysis models for data arising from the comparison of three or methods (Dunn 2004).

Statistical analyses for the data arising from more the informative designs, with more realistic measurement models (heteroscedasticity of measurement errors, for example), is beyond the scope of this article but the methods are described in considerable detail in Dunn (2004). The methods typically involve software developed for covariance structure modelling. Analogous methods for the comparison of binary measurements (diagnostic tests) can also be found in Dunn (2004).

Methods of Moments Estimation

Martin L. Hazelton
Chair of Statistics
Massey University, Palmerston North, New Zealand

The method of moments is a technique for estimating the parameters of a statistical model. It works by finding values of the parameters that result in a match between the sample moments and the population moments (as implied by the model). This methodology can be traced back to Pearson (1894) who used it to fit a simple mixture model. It is sometimes regarded as a poor cousin of maximum likelihood estimation since the latter has superior theoretical properties in many settings. Nonetheless, the method of moments and generalizations thereof continue to be of use in practice for certain (challenging) types of estimation problem because of their conceptual and computational simplicity.

Consider a statistical model defined in terms of a parameter vector $\boldsymbol{\theta} = (\theta_1, \ldots, \theta_p)^{\mathsf{T}}$. We denote by $\mu_k = \mathsf{E}[X^k]$ the kth moment about zero of a random variable X generated by our model. This moment will be a function of $\boldsymbol{\theta}$, and so we will write $\mu_k = \mu_k(\boldsymbol{\theta})$ to emphasize this dependence.

Suppose that we have a (univariate) random sample $X_1, \ldots, X_n$ from the model, which we want to use to estimate the components of $\boldsymbol{\theta}$. From this we can compute the kth sample moment, $\hat{\mu}_k = n^{-1} \sum_{i=1}^{n} X_i^k$. The rationale for the method of moments is that the sample moments are natural estimators of the corresponding model-based moments, and so a good estimate of $\boldsymbol{\theta}$ will reproduce these observed moments. In practice it is usual (although not essential) to use moments of the lowest possible orders in order to obtain parameter estimates. The method of moments estimator $\hat{\boldsymbol{\theta}}$ is hence defined to be the solution of the system of equations

$$\mu_k(\boldsymbol{\theta}) = \hat{\mu}_k \qquad k = 1, 2, \ldots, q$$

where q is the smallest integer for which this system has a unique solution.

As an example, suppose that $X_1, \ldots, X_n$ are drawn from a ►gamma distribution with shape parameter α and scale parameter β. Then $\mu_1 = \alpha\beta$ and $\mu_2 = \alpha(\alpha + 1)\beta^2$. The method of moments estimators $\hat{\alpha}$ and $\hat{\beta}$ therefore satisfy the pair of equations

$$\hat{\alpha}\hat{\beta} = \hat{\mu}_1$$
$$\hat{\alpha}(\hat{\alpha} + 1)\hat{\beta}^2 = \hat{\mu}_2.$$

Solving these we obtain

$$\hat{\alpha} = \frac{\hat{\mu}_1^2}{\hat{\mu}_2 - \hat{\mu}_1^2} \quad \text{and} \quad \hat{\beta} = \frac{\hat{\mu}_2 - \hat{\mu}_1^2}{\hat{\mu}_1}.$$

Method of moments estimators are, in general, consistent. To see this, note that the (weak) law of large numbers ensures that the sample moments converge in probability to their population counterparts. It then follows that if $\mu_k(\boldsymbol{\theta})$ is a continuous function of $\boldsymbol{\theta}$ for $k = 1, \ldots, q$ then the method of moments estimators will converge in probability to their true values. However, method of moments estimators are less efficient than maximum likelihood estimators, at least in cases where standard regularity conditions hold and the two estimators differ. Furthermore, unlike maximum likelihood estimation, the method of moments can produce infeasible parameter estimates in practice. For example, if $X_1, \ldots, X_n$ are drawn from a uniform distribution (see ►Uniform Distribution in Statistics) on $[0, \theta]$ then the method of moments estimator is $\hat{\theta} = 2\bar{X}$, but this estimate is infeasible if $\max\{X_i\} > 2\bar{X}$.

Despite the theoretical advantages of maximum likelihood estimation, the method of moments remains an important tool in many practical situations. One reason for this is that method of moments estimates are straightforward to compute, which is not always the case for maximum likelihood estimates. (For example, the maximum likelihood estimators for the gamma distribution parameters considered above are only available implicitly as the solution to the non-linear likelihood equations.) Furthermore, estimation by the method of moments does not require knowledge of the full data generating process. This has led to various extensions of the basic method of moments that can be applied in complex modeling situations.

One such extension is the generalized method of moments Hansen (1982) which is a type of generalized estimating equation methodology, widely used in econometrics. This technique works by utilizing sample and population moment conditions (or "orthogonality conditions") of the statistical model, and can provide estimates of parameters of interest in a model even when other model parameters remain unspecified. Another useful extension is the simulated method of moments (e.g., Gelman 1995). This technique can be employed when the model is so complex that neither the density function for the data nor the theoretical moments are available in closed form. It therefore provides a means of fitting micro-simulation and mechanistic stochastic models (Diggle and Gratton 1984).

About the Author

Professor Hazelton was appointed to the Chair of Statistics at Massey University in 2006. His current research interests include modeling and inference for transport networks, and multivariate smoothing problems. Professor Hazelton is an Associate Editor of the *Journal of the Korean Statistical Society* and a member of the Editorial Advisory Board for *Transportation Research Part B*.

Minimum Variance Unbiased

Czesław Stępniak
Professor
Maria Curie-Skłodowska University, Lublin, Poland
University of Rzeszów, Rzeszów, Poland

The term *minimum variance unbiased* refers to a property of statistical decision rules.

Idea. Any statistical experiment may be perceived as a random channel transforming a deterministic quantity θ (parameter) into a random quantity X (observation). *Point estimation* is a reverse process of regaining θ from X according to a rule $\widehat{\theta} = \delta(X)$ called *estimator*. Formally, estimator is a function from the set $\mathcal{X}$, of possible values of X, into the set Θ, of possible values of θ. As a measure of imprecision of such estimator one can use the function $R_\delta(\theta) = E_\theta(\delta(X) - \theta)^2$ called the Mean Squared Error. It may be rewritten in the form

$$var_\theta \delta(X) + [b(\theta)]^2, \text{ where } b(\theta) = E_\theta \delta(X) - \theta$$

is the bias of δ.

If $b(\theta) = 0$ for all θ then $\widehat{\theta} = \delta(X)$ is said to be *unbiased*. Minimizing the MSE among the unbiased estimators reduces to minimizing its variance. Any estimator δ_0 realizing this minimum (if such exists) is said to be a *minimum variance unbiased estimator* (MVUE). Searching for such estimator or verifying whether it is a MVUE needs some special statistical tools.

Example 1 (Urn problem). An urn contains N balls, where any ball is black or white, while the number θ of black balls is unknown. To search θ we draw without replacement n balls. Let k be the number of black balls in the sample. Estimate θ.

A potential number X of black balls in the sample has the hypergeometric distribution (see ►Hypergeometric Distribution and Its Application in Statistics) taking values k with probabilities

$$P_\theta(X = k) = p_{\theta,k} = \begin{cases} \frac{\binom{\theta}{k}\binom{N-\theta}{n-k}}{\binom{N}{n}} & \text{if } k \in [\max(0, n-N+\theta), \\ & \quad \min(n, \theta)] \\ 0 & \text{otherwise.} \end{cases} \quad (1)$$

Since $EX = \frac{n\theta}{N}$, the rule $\widehat{\theta} = \frac{N}{n}X$ is an unbiased estimator of θ. This is, formally, not acceptable unless n is a divisor of N, because $\widehat{\theta}$ takes values outside the parameter set. Thus one can seek for an acceptable unbiased estimator. According to the formula (1) we get

$$p_{0,k} = \begin{cases} 1, & \text{if } k = 0 \\ 0, & \text{otherwise,} \end{cases}$$

and

$$p_{1,k} = \begin{cases} \frac{N-n}{N}, & \text{if } k = 0 \\ \frac{n}{N}, & \text{if } k = 1 \\ 0, & \text{otherwise.} \end{cases}$$

Thus any unbiased estimator $\widehat{\theta} = \widehat{\theta}(X)$ must satisfy the conditions $\widehat{\theta}(X) = 0$ if $X = 0$ and $\frac{N}{n}$ if $X = 1$. Therefore the desired estimator exists if and only if n is a divisor on N.

Basic Concepts. Let $X = (X_1, \ldots, X_n)$ be a random vector, interpreted as a potential observation in a statistical experiment. Assume that distribution P of the vector belongs to a family $\mathcal{P} = \{P_\theta : \theta \in \Theta\}$, where θ is an unknown parameter identifying P. Thereafter by distribution we shall mean density or probability mass function. Any potential estimator of θ is a function $T = t(X)$ called a statistic. If T involves the entire information on θ then one can reduce the problem by considering only these estimators which depends on X through T.

We say that a statistic T is *sufficient* for θ if the conditional probability $P_\theta(X/T)$ does not depend on θ. Determining a sufficient statistic directly from this definition may be a laborious task. It may be simplified by the well known Fisher-Neyman factorization criterion. A statistic $T = t(X)$ is sufficient for θ, if and only if, P_θ may be presented in the form $P_\theta(x) = g_\theta[t(x)]h(\theta)$. A sufficient statistic T is minimal if it is a function of any other sufficient statistic. In particular, the vector statistic $T = [t_1(X), \ldots, t_k(X)]$ in so called exponential family $P_\theta(x) = C(\theta)\exp\left[\sum_{j=1}^{k} Q_j(\theta)t_j(x)\right]h(x)$, for $\theta \in \Theta$, is sufficient.

We say that a statistic T is *complete* if for any (measurable) function f the condition $E_\theta f(T) = 0$ for all θ implies that $P[f(T) = 0] = 1$. It is known that any complete sufficient statistic (if exists) is minimal but a minimal sufficient statistic may not be complete. Moreover the above sufficient statistic in the exponential family distributions is complete providing Θ contains a k-dimensional rectangle.

Now let us consider a family of densities $\{p(x, \theta) : \theta \in \Theta\}$, where Θ is an open interval of a real line, satisfying some regularity conditions. Function $I = I(\theta)$ defined by the formula $I(\theta) = E\left[\frac{\partial \log p(X,\theta)}{\partial \theta}\right]^2$ is said to be Fisher information.

Advanced Tools. Let $X = (X_1, \ldots, X_n)$ be a random vector with a distribution P belonging to a family $\mathcal{P} = \{P_\theta : \theta \in \Theta\}$ and let $T = t(X)$ be a sufficient statistic for θ. In searching MVUE's one can use the following results.

►*Rao-Blackwell theorem*: If $U = u(X)$ is an unbiased estimator of a parametric function $g(\theta)$ then the conditional expectation $E[U/T]$ is also unbiased and its variance is not greater than $var(U)$.

Lehmann-Scheffé theorem: If T is, moreover, complete then any statistic $h(T)$ is a MVUE of its expectation. This MVUE is unique (with probability 1).

Rao-Cramer inequality: Let $\{p(x, \theta) : \theta \in \Theta\}$, where Θ is an open interval of a real line, be a family of densities satisfying some regularity conditions, such that $I(\theta) > 0$ for all θ. Then for any statistic $U = u(X)$ the inequality $var_\theta(U) \geq \frac{1}{I(\theta)}$ is met.

It is worth to add that the equality in the Rao-Cramer inequality is attained if and only if the family $\mathcal{P}$ of distributions is exponential. However this condition is not necessary for existing a MVUE; for instance, if $X_1, \ldots, X_n$ are i.i.d. according to the normal law $N\left(\alpha^{\frac{1}{3}}, 1\right)$. In this case the attainable minimum variance is $\frac{9\alpha^4}{n} + \frac{18\alpha^2}{n^2} + \frac{6}{n^3}$ while $\frac{1}{I(\theta)} = \frac{9\alpha^4}{n}$.

Example 2 (Bernoulli trials). Let $X_1, \ldots, X_n$ be independent and identically distributed zero-one distributions with probability $P(X_i = 1) = \theta$, where θ is unknown for $i = 1, \ldots, n$. In this case the family $\mathcal{P} = \{P_\theta : \theta \in (0,1)\}$ is exponential with complete sufficient statistic $\overline{X} = \frac{1}{n}\sum_i X_i$. Since $E\overline{X} = \theta$, the statistic $\overline{X}$ is the unique MVUE of θ. In this case the Fisher information takes the form $I(\theta) = \frac{n}{\theta(1-\theta)}$ while $var_\theta(\overline{X}) = \frac{\theta(1-\theta)}{n}$. Thus the lower bound $\frac{1}{I(\theta)}$ in the Rao-Cramer inequality is attained. It is worth to note that, similarly as in Example 1, this unique MVUE takes, with positive probability, the values 0 and 1, which lie outside the parameter set $(0,1)$.

Minimum Variance Invariant Unbiased Estimator. If distribution of the observation vector depends on several parameters, some of them may be out of our interest and play the role of nuisance parameters. Such a situation occurs, for instance, in linear models. In this case the class of all unbiased estimators is usually too large for handle. Then we may seek for an estimator which is invariant with respect to a class of transformations of observations or its variance does not depend on the nuisance parameters. An estimator minimizing variance in such a reduced class is called a minimum variance invariant unbiased estimator.

Misuse and Misunderstandings of Statistics

Atsu S. S. Dorvlo
Professor
Sultan Qaboos University, Muscat, Sultanate of Oman

Introduction

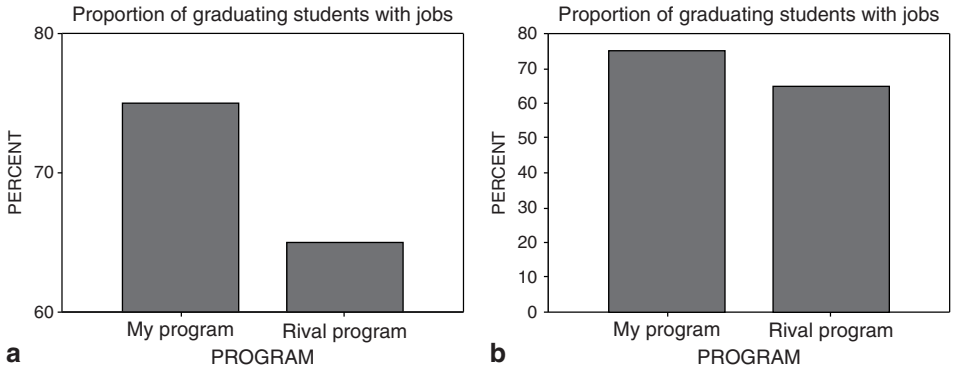
Because of the advent of high speed computers statistics has become more visible. Almost any discipline has an element of statistics in it. In fact one cannot publish in most journals when the statistics used or misused is not stated. Newspapers, magazines, etc are now awash with one form or other of "statistics". Now it is fashionable to take data, shove it into a computer and come out with nice tables, graphs and ►p-values. Clearly such practices are a gross ►misuse of statistics and do a disservice to the subject. There is no wonder we are in the company of "lies, damned lies and statistics."

So What Is Statistics?

There are several definitions of statistics, some not so flattering:

1. The American heritage dictionary says: Statistics is the mathematics of collection, organization and interpretation of numerical data.
2. Brase and Brase, in their beginning level statistics textbook define statistics as the science of how to collect, organize, analyze and interpret numerical information from data.
3. Evan Esar says statistics is the only science that enables different experts using the same figures to draw different conclusions.

The first two capture the essence of statistics. Ms. Esar captures the abuse that is possible. However, these definitions do not capture the true essence of statistics and that is: to make a deduction in the face of uncertainty. The true essence of statistics is captured when it is stated that statistics is the science that tells whether something we observe can be generalized or applied to a new or different but similar situation (the author of this statement is unknown). That is I observe a group of people in a community and found that 20% have cancer, can I generalized to say that the cancer rate in that community is 20%? Of course not without first saying how the sample was observed. The other definitions come into play then. I need to know how the data was collected/observed, how it was organized, analyzed, and then the interpretation.



In this author's opinion most of the problems, misunderstandings and misrepresentations in statistics originate from the observation – collection process. Invariably the data is observed/collected before thought is put in what to do with it. So therefore the inference which is finally made does not take account of how the data was observed in the first. Maybe in the everyday sense it is natural to observe first and then ask what to do with the data observed. However in complex tasks the research questions need to be asked first. Then thought put into how to collect the relevant data, organize and analyze it and make the inference supporting the research question or refuting it. Hence in large scale work, effort should be put in the "how to collect" the data stage. If this is done, only the relevant data will be collected, and there will be savings on resources, time and money.

In most instances the way data is collected, the data type collected determines the types of analysis that can be carried out. Data collection is an expensive, time consuming activity. It is unfortunate that lots of time and effort are wasted on collecting data only to find out that the data is not useful or the exercise could have been done in an easier and cheaper manner. Should 50 experiments be performed or can 10 be sufficient? Unfortunately more data does not necessarily equate to more valid or better results. In fact the opposite could be the case. Hence the design of the experiment or data collection, the estimation of the necessary sample sizes taking into consideration the error, precision and last but not least the use to which the results will be put, such as, will the results be generalized, should be well thought out at the very beginning of the study.

Another area where statistics has a bad name is the pictorial representation of results. The saying goes that "a picture is worth a thousand words." Simple clear graphs can help bring out the important aspects of the study. However there is room for abuse. More often than not attention is not paid to the scale of the graph. For example in comparing two teaching programs, what impression is graph (a) conveying? Are our students actually better? It is the duty of statisticians to point out at every opportunity the pitfalls that need to be avoided when reading graphs.

With the advent of fast computers computations that were near impossible or would take ages to accomplish a few years ago, now takes only seconds of computer time. Coupled with this is the fact that there are very good and easy to use software. Are computers taking the place of statisticians, especially applied statisticians? There is a lot more to data analysis than calculations. The computer is there to remove the drudgery out of number crunching. What calculations to perform, that is what analysis to do and foremost, the check of the validity of assumption under which the procedures are valid, is the domain of the statistician.

Conclusion

In my view statistics is simply whether one can generalize ones observation to a different or future situation. The difficulty is how the "observation" was obtained – data collection – and the generalization made – summarized, analyzed and interpreted. In all these the expert input of a statistician is invaluable.

Misuse of Statistics

Chamont Wang
Professor
The College of New Jersey, Ewing, NJ, USA

Statistics as an academic discipline is widely held as a science that is related to experiments and the quantification of uncertainty. This is true, but if used without caution, statistics can add more uncertainty to an already murky problem. A rich source on this topic would be "*How to Lie with Statistics* Turns Fifty," a 56-page Special Section of *Statistical Science* (2005, p. 205–260).

Misuses of statistics at a non-technical level can be roughly grouped in the following three categories, often with the three types of misuses feeding each other in a complicated, dynamic fashion.

1. Data Quality: A complete statistical project consists of the following components: (a) data collection, (b) data preprocessing, (c) data exploration, (d) data analysis and statistical modeling, and (e) summary report. The process is not entirely linear and often goes from one middle step back to another, and roughly 60–95% of the project effort is needed on data quality to ensure that the entire process will not go off the rails.

   In their 2005 article, "How to Lie with Bad Data," De Veaux and Hand pointed out that "Data can be bad in an infinite variety of ways." This is not an exaggeration. Fortunately, statistical design of experiments and survey methodology, if done right, are capable of producing data with high-quality. In the real world, the problem is that the majority of data are collected in non-controlled environments without much statistical guidance. Consequently, data might have been corrupted, distorted, wrong-headed, ill-defined, and with loads of missing values – the list goes on forever. De Veaux and Hand (2005) provided suggestions on how to detect data errors and how to improve data quality. The suggestions are very useful for practitioners.

   In journals and real-world applications, statistical reports often shine with tremendous amounts of energy on exotic models but with questionable effort (and insufficient details) on data quality. Statistics as a science is supposed to provide a guiding light for research workers and decision-makers. Without good data, exotic statistical models are unlikely to help. The situation is like a person who is nearly blinded by cataracts and tries to sharpen the lenses for better vision. The effort will be futile unless an operation is conducted to take away the clouding.

   A related note on data quality is the ▶outliers and unusual numbers in the data. Resistant and robust statistical procedures are often used to handle this kind of problem. But if the data was not collected in controlled experiments, then the efforts are mostly misguided. Furthermore, outliers often are the most interesting numbers that may reveal surprising features of the study. Blind applications of ▶robust statistics thus can be counterproductive if not altogether misleading.
2. Statistical tests and ▶*p*-values: A continuing source of mistake is the confusing of *statistical significance* with *practical significance*. Mathematically, if the sample size increases indefinitely, then the power of the statistical test will increase as well. Consequently, even a tiny difference between observed and the predicted values can be statistically highly significant. Certain large scale examples regarding the confusion of *practical significance* are discussed in Wang (1993, pp. 1–2, 117–119, 128). Other cautions on the misuse of statistical tests can be found in Freedman et al. (2007) and in the "What Can Go Wrong" sections of De Veaux et al. (2009, pp. 523, 549, 570, 604–605, 634–635, 662–663, 708) which discuss "no peeking at the data" and other caveats on the tests of significance.

   Freedman (2008a) further pointed out a potential problem in research journals when publications are "driven by the search for significance." The problem can be rather acute when research grants or academic careers hinge on publications. In short, researchers may conduct many tests, ignore contradictory results and only submit findings that meet the 5% cutoff. A possibility to deal with this problem, according to Freedman (2008a), is a journal requirement to document search efforts in the research process.
3. Statistical Inference of Cause-and-Effect: Causal inference is a foundation of science and is indeed a very tricky business. As an example, Aristotle maintained that cabbages produce caterpillars daily – a well-known assertion only to be refuted by controlled experiments carried out by Francesco Redi in 1668. For new comers to the field of statistics, it may be baffling that much of the practice of modern statistics is still Aristotelian in nature. For instance, a rough estimate indicates that in clinical research, "80% of observational studies fail to replicate or the initial effects are much smaller on retest" (Young et al. 2009; a la Ioannidis 2005).

Freedman (2008a) further discussed the related controversies and a diverse set of large-scale contradictory studies. The problem should be a concern to the statistical community as our trade is indeed widely used. For example, in the study of coronary heart disease, there are more than 3,600 statistical articles published each year (Ayres 2007, p. 92), and this is only the tip of the iceberg.

A potential problem with statistical causality is the use of regression models, directed graphs, path analysis, structural equations, and other law-like relationships. Take the example of regression; on a two-dimensional scatterplot, it is easy to see that *mathematically* it does not matter whether we put a variable on the left or the right of the equation. Any software package would produce the estimates of the slope and the intercept, plus a host of diagnostic statistics that often says the model is an excellent fit. Compounding the problem of causal inference, a third variable may be the reason behind the phenomenon as displayed by the scatterplot. For instance, a scatterplot can be drawn to show that the incidence of polio (Y-variable) increases when soft-drink sales (X-variable) increases, but in fact a lurking variable (warm weather) is the driving force behind the rise (Freedman et al. 1978, p. 137).

The problem quickly turns worse in higher-dimensional spaces. Try the following example in a regression class: draw 20 or 30 right triangles and then measure the values of (X_1, X_2, Y), with X_1, X_2 being the adjacent sides of the 90° angle. The Pythagorean Theorem says that $Y = \sqrt{X_1^2 + X_2^2}$. In an experiment (Wang 1993, p. 73–77), students of regression came up with all kinds of equations with R^2 of 96–99.93%. The equations all passed stringent tests of diagnostic statistics, but none of them comes close to the Pythagorean equation. A further twist makes the problem statistically intractable when the legs of the triangles are not orthogonal (Wang 1993, p. 77–78).

For causal inference, the misgivings of statistical models happen not only in the observational studies, but also in the analysis of experimental data. In an in-depth discussion, Freedman (2008b) examined the ▶Kaplan-Meier estimator and proportional-hazards models which are frequently used to analyze data from randomized controlled experiments. Specifically, Freedman investigated journal papers on the efficacy of screening for lung cancer (*New England Journal of Medicine*), the impact of negative religious feelings on survival (*Archives of Internal Medicine*), and the efficacy of hormone replacement therapy (*New England Journal of Medicine* and *Journal of the American Medical Association*). Freedman discussed reverse causation plus a host of other issues such as measurements, omitted variables, and the justification of the models. Freedman concluded that "the models are rarely informative," that "as far as the model is concerned, the ▶randomization is irrelevant," that "randomization does not justify the model," and that it "is a mistake" to apply the models in the first place.

In yet another example, Freedman (2008c) investigated ▶logistic regression in the experimental setting for drawing conclusions on cause-and-effect. Again, Freedman noted that the model is not justified by randomization. He further questioned "Why would the logit specification be correct rather than the probit – or anything else? What justifies the choice of covariates? Why are they exogenous? If the model is wrong, what is $\widehat{\beta}_2$ supposed to be estimating?" Furthermore, in a summary of a vast variety of investigations, Freedman (2008a) concluded that "Experimental data are frequently analyzed through the prism of models. This is a mistake."

Taken together, Freedman et al. (1978, 1991, 1998, 2007), Freedman (2005, 2008a, b, c), Wang (1993, p. 72–79), and a very long list of references all indicate that sophisticated statistical models are often detached from the underlying mechanism that generated the data. In other words, many law-like equations produced by statistical models are as structure-less as *Amoeba Regression* (Wang 1993) and need to be viewed with caution. This is indeed a big disappointment to countless researchers who spend their lives on statistical models (see, e.g., Pearl 2009, p. 100), but this is a truth that we have to face.

Nevertheless, the models should be treasured for a number of reasons. To begin with, recall Newton's theory on celestial mechanics. The story is well-known and is relevant to statistical modeling in the following ways: (1) The Newtonian theory relies on observational studies, yet its prediction accuracy rivals most of the tightly controlled experiments. In other words, there is nothing wrong with observational studies, as long as they are accurate and they are consistent in subsequent studies. (2) Statistical models represent the intellectual accomplishment of the statistical community that may one day produce useful results on both experimental data and observational studies. History is the witness that ivory tower research often produces surprising results decades or hundreds of years later. And when the model is correct, the consequences can be enormous. Take the example of proportional-hazards model,

even Freedman (2008b, p. 116) acknowledged that "Precise measures of the covariates are not essential" and that if the model "is right or close to right, it works pretty well." (3) If used for descriptive or exploratory purposes, fancy statistical models may indeed reveal unexpected features in the data. For certain examples on non-parametric structural equations and counterfactual analysis, see references in Pearl (2009). For another example on hot spot detection, see Wang et al. (2008).

As a matter of fact, in the past 15 years or so, statistical models have taken a new life in the realm of ►data mining, predictive modeling, and statistical learning (see, e.g., Wang et al. 2008). In these applications, the concerns are not cause-and-effect or the specific mechanism that generates the data. Instead, the focus is the prediction accuracy that can be measured by profit, false positive, false negative, and by other criteria to assess the model utility. This is a sharp departure from causation to prediction. The great news is that the new applications have been ranked by the 2001 *MIT Technology Review* as one of the ten emerging technologies that will change the world – and it is arguable that the successes of this new technology will eventually feedback to traditional statistics for other breakthroughs. In fact, countless examples with ingenious twists have already happened (see, e.g., Ayres 2007). It is a triumph of statistical models.

A cautionary note is that statistical learning and the new breed of predictive modeling can easily go wrong and misinformation can propagate with unprecedented speed in the modern age of internet blogging and social networks. Newcomers to the field should consult, for examples, "Top 10 Data Mining Mistakes" (Elder 2009) and "Myths and Pitfalls of Data Mining" (Khabaza 2009). For unsupervised learning, one may want to read "The Practice of Cluster Analysis" (Kettenring, 2006) and "A Perspective on Cluster Analysis" (Kettenring 2008). For supervised learning, given a dozen or thousands of predictors, statistical tools are frequently used to generate predictor importance scores, but these scores are often wildly different from one algorithm to the next (see e.g., Wang et al. 2008, Sect. 4).

For yet another example, a model such as a Neural Network may produce higher profit and higher prediction accuracy than other tools, yet the model may also be more volatile in repeated uses and hence pose considerable hazards in the long run. ►Sensitivity analysis and similar techniques are thus needed to prevent misleading conclusions (see, e.g., Wang et al. 2009).

The hallmark of empirical science is its replicability. Much of the current statistical practice, unfortunately, does not really meet this criterion. Just look at how many authors are unwilling to disclose their data and how many journals are unwilling to archive the datasets and the code (see also Freedman, 2008a, c). Exceptions include *American Economic Review, American Economic Journals* and *Science*.

Data disclosure reduces the cost of research and cost of replicating results. It also deters unprofessional conduct and improves collective findings of the research community. Certain online journals (see e.g., http://www.bentley.edu/csbigs/csbigs-v1-n1.cfm) post both the research article and the data side-by-side. If more journals are willing to make available the datasets used in their publications, the situation of misuse and misconduct of statistics will be greatly improved.

About the Author

Dr. Chamont Wang received the Ph.D. degree in Statistics from Michigan State University, East Lansing (1983). He is Full Professor at the Department of Mathematics and Statistics, the College of New Jersey, serving as an Associate Editor of a research journal, CSBIGS (*Case Studies in Business, Industry and Government Statistics*), serving as an expert witness of a premier expert witness referral firm. He is author of the book, *Sense and nonsense of statistical inference: controversy, misuse, and subtlety* (Taylor and Francis, 1993), and also of journal papers in the field of Chaos and Dynamical Systems. He is a member of American Statistical Association, the Mathematical Association of America, and the Institute of Mathematical Statistics.

The notion of mixed membership arises naturally in the context of multivariate data analysis (see ▶Multivariate Data Analysis: An Overview) when attributes collected on individuals or objects originate from a mixture of different categories or components. Consider, for example, an individual with both European and Asian ancestry whose mixed origins correspond to a statement of mixed membership: "1/4 European and 3/4 Asian ancestry." This description is conceptually very different from a probability statement of "25% chance of being European and 75% chance of being Asian". The assumption that individuals or objects may combine attributes from several basis categories in a stochastic manner, according to their proportions of membership in each category, is a distinctive feature of mixed membership models. In most applications, the number and the nature of the basis categories, as well as individual membership frequencies, are typically considered latent or unknown. Mixed membership models are closely related to latent class and finite ▶mixture models in general. Variants of these models have recently gained popularity in many fields, from genetics to computer science.

Early Developments

Mixed membership models arose independently in at least three different substantive areas: medical diagnosis and health, genetics, and computer science. Woodbury et al. (1978) proposed one of the earliest mixed membership models in the context of disease classification, known as the *Grade of Membership* or GoM model. The work of Woodbury and colleagues on the GoM model is summarized in the volume *Statistical Applications Using Fuzzy Sets* (Manton et al. 1994).

Pritchard et al. (2000) introduced a variant of the mixed membership model which became known in genetics as the *admixture model* for multilocus genotype data and produced remarkable results in a number of applications. For example, in a study of human population structure, Rosenberg et al. (2002) used admixture models to analyze genotypes from 377 autosomal microsatellite loci in 1,056 individuals from 52 populations. Findings from this analysis indicated a typology structure that was very close to the "traditional" five main racial groups.

Among the first mixed membership models developed in computer science and machine learning for analyzing words in text documents were a multivariate analysis method named Probabilistic Latent Semantic Analysis (Hofmann 2001) and its random effects extension by Blei et al. (2003a, b). The latter model became known as *Latent Dirichlet Allocation* (LDA) due to the imposed Dirichlet distribution assumption for the mixture proportions. Variants of LDA model in computer science are often referred to as *unsupervised generative topic models*. Blei et al. (2003a, b) and Barnard et al. (2003) used LDA to combine different sources of information in the context of analyzing complex documents that included words in main text, photographic images, and image annotations. Erosheva et al. (2004) analyzed words in abstracts and references in bibliographies from a set of research reports published in the *Proceeding of the National Academy of Sciences* (PNAS), exploring

an internal mixed membership structure of articles and comparing it with the formal PNAS disciplinary classifications. Blei and Lafferty (2007) developed another mixed membership model replacing the Dirichlet assumption with a more flexible logistic normal distribution for the mixture proportions. Mixed membership developments in machine learning have spurred a number of applications and further developments of this class of models in psychology and cognitive sciences where they became known as *topic models* for semantic representations (Griffiths et al. 2007).

Basic Structure

The basic structure of a mixed membership model follows from the specification of assumptions at the population, individual, and latent variable levels, and the choice of a sampling scheme for generating individual attributes (Erosheva et al. 2004). Variations in these assumptions can provide us with different mixed membership models, including the GoM, admixture, and generative topic models referred to above.

Assume K basis subpopulations. For each subpopulation $k = 1, \ldots, K$, specify $f(x_j|\theta_{kj})$, a probability distribution for attribute x_j, conditional on a vector of parameters θ_{kj}. Denote individual-level membership score vector by $\lambda = (\lambda_1, \ldots, \lambda_K)$, representing the mixture proportions in each subpopulation. Given λ, the subject-specific conditional distribution for *jth* attribute is

$$Pr(x_j|\lambda) = \sum_k \lambda_k f(x_j|\theta_{kj}).$$

In addition, assume that attributes x_j are independent, conditional on membership scores. Assume membership scores, the latent variables, are random realizations from some underlying distribution D_α, parameterized by α. Finally, specify a sampling scheme by picking the number of observed distinct attributes, J, and the number of independent replications for each attribute, R.

Combining these assumptions, the marginal probability of observed responses $\left\{x_1^{(r)}, \ldots, x_J^{(r)}\right\}_{r=1}^{R}$, given model parameters α and $\boldsymbol{\theta}$, is

$$Pr\left(\left\{x_1^{(r)}, \ldots, x_J^{(r)}\right\}_{r=1}^{R} | \alpha, \boldsymbol{\theta}\right) = \int \left(\prod_{j=1}^{J}\prod_{r=1}^{R}\sum_{k=1}^{K}\lambda_k f\left(x_j^{(r)}|\theta_{kj}\right)\right) dD_\alpha(\lambda). \quad (1)$$

In general, the number of observed attributes need not be the same across subjects, and the number of replications need not be the same across attributes. In addition, instead of placing a probability distribution on membership scores, some mixed membership model variants may treat latent variables as fixed but unknown constants. Finally, other extensions can be developed by specifying further dependence structures among sampled individuals or attributes that may be driven by particular data forms as, e.g., in relational or network data (Airoldi et al. 2008b; Chang and Blei 2010; Xing et al. 2010).

Estimation

A number of estimation methods have been developed for mixed membership models that are, broadly speaking, of two types: those that treat membership scores as fixed and those that treat them as random. The first group includes the numerical methods introduced by Hofmann (2001), and joint maximum likelihood type methods described in Manton et al. (1994) and Cooil and Varki (2003), and related likelihood approaches in Potthoff et al. (2000) and Varki et al. (2000). The statistical properties of the estimators in these approaches, such as consistency, identifiability, and uniqueness of solutions, are yet to be fully understood (Haberman 1995) – empirical evidence suggests that the likelihood function is often multi-modal and can have bothersome ridges. The second group uses Bayesian hierarchical structure for direct computation of the posterior distribution, e.g., with Gibbs sampling based on simplified assumptions (Pritchard et al. 2000; Griffiths and Steyvers 2004) or with fully Bayesian MCMC sampling (Erosheva 2003). Variational methods used by Blei et al. (2003a, b), or expectation-propagation methods developed by Minka and Lafferty (2002), can be used to approximate the posterior distribution. The Bayesian hierarchical methods solve some of the statistical and computational problems, and variational methods in particular scale well for higher dimensions. Many other aspects of working with mixed membership models remain as open challenges, e.g., dimensionality selection (Airoldi et al. 2008a).

Relationship to Other Methods of Multivariate Analysis

It is natural to compare mixed membership models with other latent variable methods, and, in particular, with factor analysis and latent class models (Bartholomew and Knott 1999). For example, the GoM model for binary outcomes can be thought of as a constrained factor analysis model: $E(x|\lambda) = A\lambda$, where x is a column-vector of observed attributes $x = (x_1, \ldots, x_J)'$, $\lambda = (\lambda_1, \ldots, \lambda_K)'$ is a column-vector of factor (i.e., membership) scores, and A is

a $J \times K$ matrix of factor loadings. The respective constraints in this factor model are $\lambda' I_K = 1$ and $AI_K = I_K$, where I_K is a K-dimensional vector of 1s.

Mixed membership models can also address objectives similar to those in ►Correspondence Analysis and Multidimensional Scaling methods for contingency tables. Thus, one could create a low-dimensional map from a contingency table data and graphically examine membership scores (representing table rows or individuals) in the convex space defined by basis or extreme profiles (representing columns or attributes) to address questions such as whether some table rows have similar distribution over the table columns categories.

Finally, there is a special relationship between the sets of mixed membership and latent class models, where each set of models can be thought of as a special case of the other. Manton et al. (1994) and Potthoff et al. (2000) described how GoM model can be thought of as an extension of latent class models. On the other hand, Haberman (1995) first pointed out that GoM model can be viewed as a special case of latent class models. The fundamental representation theorem of equivalence between mixed membership and population-level mixture models clarifies this nonintuitive relationship (Erosheva et al. 2007).

Mixture Models

Wilfried Seidel
Professor, President of the German Statistical Society
Helmut-Schmidt-Universität, Hamburg, Germany

Introduction

Mixture distributions are convex combinations of "component" distributions. In statistics, these are standard tools for modeling heterogeneity in the sense that different elements of a sample may belong to different components. However, they may also be used simply as flexible instruments for achieving a good fit to data when standard distributions fail. As good software for fitting mixtures is available, these play an increasingly important role in nearly every field of statistics.

It is convenient to explain finite mixtures (i.e., finite convex combinations) as theoretical models for cluster analysis (see ▶Cluster Analysis: An Introduction), but of course the range of applicability is not at all restricted to the clustering context. Suppose that a feature vector X is observed in a heterogeneous population, which consists of k homogeneous subpopulations, the "components." It is assumed that for $i = 1, \ldots, k$, X is distributed in the i-th component according to a (discrete or continuous) density $f(x, \theta_i)$ (the "component density"), and all component densities belong to a common parametric family $\{f(x, \theta), \ \theta \in \Theta\}$, the "component model." The relative proportion of the i-th component in the whole population is p_i, $p_1 + \cdots + p_k = 1$. Now suppose that an item is drawn randomly from the population. Then it belongs to the i-th component with probability p_i, and the conditional probability that X falls in some set A is $\Pr(X \in A \mid \theta_i)$, calculated from the density $f(x, \theta_i)$. Consequently, the marginal probability is

$$\Pr(X \in A \mid P) = p_1 \Pr(X \in A \mid \theta_1) + \cdots + p_k \Pr(X \in A \mid \theta_k)$$

with density

$$f(x, P) = p_1 f(x, \theta_1) + \cdots + p_k f(x, \theta_k), \qquad (1)$$

a "simple finite mixture" with parameter $P = ((p_1, \ldots, p_k), (\theta_1, \ldots, \theta_k))$. The components p_i of P are called "mixing weights," the θ_i "component parameters." For fixed k, let $\mathcal{P}_k$ be the set of all vectors P of this type, with $\theta_i \in \Theta$ and nonnegative mixing weights summing up to one. Then $\mathcal{P}_k$ parameterizes all mixtures with not more than k components. If all mixing weights are positive and component densities are different, then k is the exact number of components. The set of all simple finite mixtures is parameterized by $\mathcal{P}_{\text{fin}}$, the union of all $\mathcal{P}_k$.

This model can be extended in various ways. For example, all component densities may contain additional common parameters (variance parameters, say), they may depend on covariables (mixtures of regression models), and also the mixing weights may depend on covariables. Mixtures of time series models are also considered. Here I shall concentrate on simple mixtures, as all relevant concepts can be explained very easily in this setting. These need not be finite convex combinations; there is an alternative and more general definition of simple mixtures: Observe that the parameter P can be considered as a discrete probability distribution on Θ which assigns probability mass p_i to the parameter θ_i. Then Eq. 1 is an integral with respect to this distribution, and if ξ is an arbitrary probability distribution on Θ, a mixture can be defined by

$$f(x, \xi) = \int_\Theta f(x, \theta)\, d\xi(\theta)\,. \qquad (2)$$

It can be considered as the distribution of a two-stage experiment: First, choose a parameter θ according to the distribution ξ, then choose x according to $f(x, \theta)$. Here, ξ is called a "mixing distribution," and mixture models of this type can be parameterized over every set Ξ of probability distributions on Θ.

In statistical applications of mixture models, a nontrivial key issue is identifiability, meaning that different parameters describe different mixtures. In a trivial sense, models parameterized over vectors P are never identifiable: All vectors that correspond to the same probability distribution on Θ describe the same mixture model. For example, any permutation of the sequence of components leaves the mixing distribution unchanged, or components may be added with zero mixing weights. Therefore identifiability can only mean that parameters that correspond to different mixing distributions describe different mixture models. However, also in this sense identifiability is often violated. For example, the mixture of two uniform distributions with supports $[0, 0.5]$ and $[0.5, 1]$ and equal mixing weights is the uniform distribution with support $[0, 1]$. On the other hand, finite mixtures of many standard families (normal, Poisson, ...) are identifiable, see for example Titterington et al. (1985). Identifiability of mixtures of regression models has been treated among others by Hennig (2000). A standard general reference for finite mixture models is McLachlan and Peel (2000).

Statistical Problems

Consider a mixture model with parameter η (vector or probability measure). In the simplest case, one has i.i.d.

data $x_1, \ldots, x_n$ from $f(x, \eta)$, from which one wants to gain information about η. Typical questions are estimation of (parameters of) η, or mixture diagnostics: Is there strong evidence for a mixture (in contrast to homogeneity in the sense that η is concentrated at some single parameter θ)? What is the (minimum) number of mixture components?

A variety of techniques has been developed. The data provide at least implicitly an estimate of the mixture, and Eqs. 1 and 2 show that mixture and mixing distribution are related by a linear (integral) equation. Approximate solution techniques have been applied for obtaining estimators, and moment estimators have been developed on basis of this structure. Distance estimators exhibit nice properties. Traditionally, mixture diagnostics has been handled by graphical methods. More recent approaches for estimation and diagnostics are based on Bayesian or likelihood techniques; likelihood methods will be addressed below. Although Bayesian methods have some advantages over likelihood methods, they are not straightforward (for example, usually no "natural" conjugate priors are available, therefore posteriors are simulated using MCMC. Choice of "noninformative" priors is not obvious, as improper priors usually lead to improper posteriors. Nonidentifiability of $\mathcal{P}_k$ causes the problem of "label switching"). A nice reference for Bayesian methods is Frühwirth-Schnatter (2006).

Let me close this section with a short discussion of robustness. Robustness with respect to ▶outliers is treated by Hennig (2004). Another problem is that mixture models are extremely nonrobust with respect to misspecification of the component model. Estimating the component model in a fully nonparametric way is of course not possible, but manageable alternatives are for example mixtures of log-concave distributions. Let me point out, however, that issues like nonrobustness and nonidentifiability only cause problems if the task is to interpret the model parameters somehow. If the aim is only to obtain a better data fit, one need not worry about them.

Likelihood Methods

In the above setting, $l(\eta) = \log(f(x_1, \eta)) + \cdots + \log(f(x_n, \eta))$ is the log likelihood function. It may have some undesirable properties: First, the log likelihood is often unbounded. For example, consider mixtures of normals. If the expectation of one component is fixed at some data point and the variance goes to zero, the likelihood goes to infinity. Singularities usually occur at the boundary of the parameter space. Second, the likelihood function is usually not unimodal, although this depends on the parameterization. For example, if the parameter is a probability distribution as in Eq. 2 and if the parameter space Ξ is a convex set (with respect to the usual linear combination of measures), the log likelihood function is concave. If it is bounded, there is a nice theory of "nonparametric likelihood estimation" (Lindsay 1995), and "the" "nonparametric maximum likelihood estimator" is in some sense uniquely defined and can be calculated numerically (Böhning 2000; Schlattmann 2009).

Nonparametric methods, however, work in low dimensional component models, whereas "parametric" estimation techniques like the Expectation-Maximization (EM) method work in nearly any dimensional. The EM is a local maximizer for mixture likelihoods in $\mathcal{P}_k$. Here the mixture likelihood is usually multimodal; moreover, it can be very flat. Analytic expressions for likelihood maxima usually do not exist, they have to be calculated numerically. On the other hand, even for unbounded likelihoods, it is known from asymptotic theory, that the simple heuristics of searching for a large local maximum in the interior of the parameter space may lead to reasonable estimators. However, one must be aware that there exist "spurious" large local maxima that are statistically meaningless. Moreover, except from simple cases, there is no manageable asymptotics for likelihood ratio.

Some of the problems of pure likelihood approaches can be overcome by considering penalized likelihoods. However, here one has the problem of choosing a penalization parameter. Moreover, the EM algorithm is a basic tool for a number of estimation problems, and it has a very simple structure for simple finite mixtures. Therefore it will be outlined in the next section.

EM Algorithm

The EM algorithm is a local maximization technique for the log likelihood in $\mathcal{P}_k$. It starts from the complete-data log-likelihood. Suppose that for observation x_i the (fictive) component membership is known. It is defined by a vector $z_i \in \Re^k$ with $z_{ij} = 1$, if x_i belongs to j-th component, and zero elsewhere. As a random variable Z_i, it has a ▶multinomial distribution with parameters $k, p_1, \ldots, p_k$. Then the complete data likelihood and log likelihood of P, respectively, are $L_c(P) = \prod_{i=1}^n \prod_{j=1}^k (p_j f(x_i, \theta_j))^{z_{ij}}$ and $l_c(P) = \log(L_c(P)) = \sum_{i=1}^n \sum_{j=1}^k z_{ij} \log p_j + \sum_{i=1}^n \sum_{j=1}^k z_{ij} \log f(x_i, \theta_j)$.

The EM needs a starting value P_0, and then proceeds as an iteration between an "E-step" and an "M-step" until "convergence." The first E-step consists in calculating the conditional expectation $E_{P_0}(l_c(P) \mid x_1, \ldots, x_n)$ of $l_c(P)$ for

arbitrary P, given the data, under P_0. As the only randomness is in the z_{ij}, we obtain

$$E_{P_0}(l_c(P)\,|\,x_1,\ldots,x_n) = \sum_{i=1}^{n}\sum_{j=1}^{k}\tau_j(x_i|P_0)\log p_j + \sum_{i=1}^{n}\sum_{j=1}^{k}\tau_j(x_i|P_0)\log f(x_i,\,\theta_j),$$

where

$$\tau_j(x_i|P_0) = \Pr_{P_0}(Z_{ij}=1\,|\,x_i) = \frac{p_j f(x_i,\,\theta_j)}{f(x_i,\,P_0)}$$

is the conditional probability that the i-th observation belongs to component j, given the data, with respect to P_0.

In the following M-step, $E_{P_0}(l_c(P)\,|\,x_1,\ldots,x_n)$ is maximized with respect to P. As it is the sum of terms depending on the mixing weights and on the parameters only, respectively, both parts can be maximized separately. It is easily shown that the maximum in the p_j is achieved for $p_j^{(1)} = (1/n)\sum_{i=1}^{n}\tau_j(x_i|P_0), j = 1,\ldots,n$. For component densities from exponential families, similar simple solutions exist for the θ_j, therefore both the E-step and the M-step can be carried out here analytically. It can be shown that (1) the log-likelihood is not decreasing during the iteration of the EM, and (2) that under some regularity conditions it converges to a stationary point of the likelihood function. However, this may also be a saddle point.

It remains to define the stopping rule and the starting point(s). Both are crucial, and the reader is referred to the literature. There are also techniques that prevent from convergence to singularities or spurious maxima. A final nice issue of the EM is that it yields a simple tool for classification of data points: If $\hat{P}$ is an estimator, then $\tau_j(x_i|\hat{P})$ is the posterior probability that x_i belongs to class j with respect to the "prior" $\hat{P}$. The Bayesian classification rule assigns observation i to the class j that maximizes $\tau_j(x_i|\hat{P})$, and the $\tau_j(x_i|\hat{P})$ measure the plausibility of such a clustering.

Number of Components, Testing and Asymptotics

Even if one has an estimator in each $\mathcal{P}_k$ from the EM, the question is how to assess the number of components (i.e., how to choose k). Usually information criteria like AIC and BIC are recommended. An alternative is to perform a sequence of tests of k against $k+1$ components, for $k = 1, 2\ldots$.

There are several tests for homogeneity, i.e., for the "component model", as for example goodness of fit or dispersion score tests. For testing k_0 against k_1 components, a likelihood ratio test may be performed. However, the usual χ^2-asymptotics fails, so critical values have to be simulated. Moreover, the distribution of the test statistic usually depends on the specific parameter under the null hypothesis. Therefore some sort of bootstrap (see ►Bootstrap Methods) is needed, and as estimators have to be calculated numerically, likelihood ratio tests are computationally intensive.

Let me close with some remarks on asymptotics. Whereas ►asymptotic normality of estimators is guaranteed under some conditions, the usual asymptotics for the likelihood ratio test fails. The reason is that under the null hypothesis, the parameter P_0 is on the boundary of the parameter space, it is not identifiable and the Fisher information matrix in P_0 is singular. There is an asymptotic theory under certain restrictive assumptions, but it is usually hard to calculate critical values from it.

Model Selection

Walter Zucchini[1], Gerda Claeskens[2], Georges Nguefack-Tsague[3]
[1]Professor
Georg-August-Universität, Göttingen, Germany
[2]Professor
Leuven, Belgium
[3]University of Yaoundé I, Yaoundé, Cameroon

Introduction

In applications there are usually several models for describing a population from a given sample of observations and one is thus confronted with the problem of model selection. For example, different distributions can be fitted to a given sample of univariate observations; in polynomial regression one has to decide which degree of the polynomial to use; in multivariate regression one has to select which covariates to include in the model; in fitting an autoregressive model to a stationary time series one must choose which order to use.

When the set of models under consideration is nested, as is the case in polynomial regression, the fit of the model to the sample improves as the complexity of the model (e.g., the number of parameters) increases but, at some stage, its fit to the population deteriorates. That is because the model increasingly moulds itself to the features of the sample rather than to the "true model," namely the one that characterizes the population. The same tendency occurs even if the models are not nested; increasing the complexity eventually leads to deterioration. Thus model selection needs to take both goodness of the fit and the complexity of the competing models into account.

Reference books on model selection include Linhart and Zucchini (1986), Burnham and Anderson (2002), Miller (2002), Claeskens and Hjort (2008). An introductory article is Zucchini (2000).

Information Criteria – Frequentist Approach

The set of models considered for selection can be thought of as approximating models which, in general, will differ from the true model. The answer to the question "Which approximation is best?" depends, of course, on how we decide to measure the quality of the fit. Using the Kullback-Leibler distance for this leads to the popular ▶Akaike Information Criterion (AIC, Akaike 1973):

$$AIC(M) = 2\log(L(\hat{\theta})) - 2p,$$

where M is the model, L the likelihood, and $\hat{\theta}$ the maximum likelihood estimator of the vector of the model's p parameters. The first term of the AIC measures the fit of the model to the *observed sample*; the fit improves as the number of parameters in the model is increased. But improving the fit of the model to the sample does not necessarily improve its fit to the population. The second term is a penalty term that compensates for the complexity of the model. One selects the model that maximizes the AIC. Note, however, that in much of the literature the AIC is defined as minus the above expression, in which case one selects the model that minimizes it.

A *model selection criterion* is a formula that allows one to compare models. As is the case with the AIC, such criteria generally comprise two components: one that quantifies the fit to the data, and one that penalizes complexity. Examples include Mallows' C_p criterion for use in ▶linear regression models, Takeuchi's model-robust information criterion TIC, and refinements of the AIC such as the 'corrected AIC' for selection in linear regression and autoregressive time series models, the network information criterion NIC, which is a version of AIC that can be applied to model selection in ▶neural networks, and the generalized information criterion GIC for use with influence functions. Several of these criteria have versions that are applicable in situations where there are outlying observations, leading to robust model selection criteria; other extensions can deal with missing observations.

Alternative related approaches to model selection that do not take the form of an information criterion are *bootstrap* (see, e.g., Zucchini 2000) and *cross-validation*. For the latter the idea is to partition the sample in two parts: the calibration set, that is used to fit the model, and the validation sample, that is used to assess the fit of the model, or the accuracy of its predictions. The popular "leave-one-out cross-validation" uses only one observation in the validation set, but each observation has a turn at comprising the validation set. In a model selection context, we select the model that gives the best results (smallest estimation or prediction error) averaged over the validation sets. As this approach can be computationally demanding, suggestions have been made to reduce the computational load. In "five-fold cross-validation" the sample is randomly split in five parts of about equal size. One of the five parts is used as validation set and the other four parts as the calibration set. The process is repeated until each of the five sets is used as validation set.

Bayesian Approach

The Bayesian regards the models available for selection as candidate models rather than approximating models; each of them has the potential of being the true model. One begins by assigning to each of them a prior probability, $P(M)$, that it is the true model and then, using ▶Bayes'

theorem, computes the posterior probability of it being so:

$$P(M|\text{ Data}) = \frac{P(\text{ Data}|M)P(M)}{P(\text{ Data})}.$$

The model with the highest posterior probability is selected. The computation of $P(\text{ Data}|M)$ and $P(\text{ Data})$ can be very demanding and usually involves the use of Markov chain Monte Carlo (MCMC) methods (see ►Markov Chain Monte Carlo) because, among other things, one needs to 'integrate out' the distribution of the parameters of M (see e.g., Wasserman 2000).

Under certain assumptions and approximations (in particular the Laplace approximation), and taking all candidate models as a priori equally likely to be true, this leads to the Bayesian Information Criterion (BIC), also known as the Schwarz criterion (Schwarz 1978):

$$\text{BIC}(M) = 2\log(L(\hat{\theta})) - p\log(n),$$

where n is the sample size and p the number of unknown parameters in the model. Note that although the BIC is based on an entirely different approach it differs from the AIC only in the penalty term.

The difference between the frequentist and Bayesian approaches can be summarized as follows. The former addresses the question "Which model is best, in the sense of least wrong?" and the latter the question "Which model is most likely to be true?".

The Deviance Information Criterion (Spiegelhalter et al. 2002) is an alternative Bayesian method for model selection. While explicit formulae are often difficult to obtain, its computation is simple for situations where MCMC simulations are used to generate samples from a posterior distribution.

The principle of minimum description length (MDL) is also related to the BIC. This method tries to measure the complexity of the models and selects the model that is the least complex. The MDL tries to minimize the sum of the description length of the model, plus the description length of the data when fitted to the model. Minimizing the description length of the data corresponds to maximizing the log likelihood of the model. The description length of the model is not uniquely defined but, under certain assumptions, MDL reduces to BIC, though this does not hold in general (Rissanen 1996). Other versions of MDL come closer to approximating the full Bayesian posterior $P(M|)$ Data. See Grünwald (2007) for more details.

Selecting a Selection Criterion

Different selection criteria often lead to different selections. There is no clear-cut answer to the question of which criterion should be used. Some practitioners stick to a single criterion; others take account of the orderings indicated by two or three different criteria (e.g., AIC and BIC) and then select the one that leads to the model which seems most plausible, interpretable or simply convenient in the context of the application.

An alternative approach is to tailor the criterion to the particular objectives of the study, i.e., to construct it in such a way that selection favors the model that best estimates the quantity of interest. The Focussed Information Criterion (FIC, Claeskens and Hjort 2003) is designed to do this; it is based on the premise that a good estimator has a small mean squared error (MSE). The FIC is constructed as an estimator of the MSE of the estimator of the quantity of interest. The model with the smallest value of the FIC is the best.

Issues such as consistency and efficiency can also play a role in the decision regarding which criterion to use. An information criterion is called *consistent* if it is able to select the true model from the candidate models, as the sample size tends to infinity. In a weak version, this holds with probability tending to one; for strong consistency, the selection of the true model is almost surely. It is important to realize that the notion of consistency only makes sense in situations where one can assume that the true model belongs to the set of models available for selection. Thus will not be the case in situations in which researchers "believe that the system they study is infinitely complicated, or there is no way to measure all the important variables" (McQuarrie and Tsai 1998). The BIC is a consistent criterion, as is the Hannan-Quinn criterion that uses $\log\log(n)$ instead of $\log(n)$ in the penalty term.

An information criterion is called *efficient* if the ratio of the expected mean squared error (or expected prediction error) under the selected model and the expected mean squared error (or expected prediction error) under its theoretical minimizer converges to one in probability. For a study of the efficiency of a model selection criterion, we do not need to make the assumption that the true model is one of the models in the search list. The AIC, corrected AIC, and Mallows's C_p are examples of efficient criteria. It can be shown that the BIC and the Hannan-Quinn criterion are not efficient. This is an observation that holds in general: consistency and efficiency cannot occur together.

Model Selection in High Dimensional Models

In some applications, e.g., in radiology and biomedical imaging, the number of unknown parameters in the model is larger than the sample size, and so classical model selection procedures (e.g., AIC, BIC) fail because the parameters cannot be estimated using the method of maximum likelihood. For these so-called high-dimensional models regularized or penalized methods have been suggested in

the literature. The popular Lasso estimator, introduced by Tibshirani (1996), adds an l_1 penalty for the coefficients in the estimation process. This has as a particular advantage that it not only can shrink the coefficients towards zero, but also sets some parameters equal to zero, which corresponds to variable selection. Several extensions to the basic Lasso exist, and theoretical properties include consistency under certain conditions. The Dantzig selector (Candes and Tao 2008) is another type of method for use with high-dimensional models.

Post-model Selection Inference

Estimators that are obtained in a model that has been selected by means of a model selection procedure, are referred to as *estimators-post-selection* or *post-model-selection estimators*. Since the data are used to select the model, the selected model that one works with, is random. This is the main cause of inferences to be wrong when ignoring model selection and pretending that the selected model had been given beforehand. For example, by ignoring the fact that model selection has taken place, the estimated variance of an estimator is likely to be too small, and confidence and prediction intervals are likely to be too narrow. Literature on this topic includes Pötscher (1991), Hjort and Claeskens (2003), Shen et al. (2004), Leeb and Pötscher (2005).

Model selection can be regarded as the special case of model averaging in which the selected model takes on the weight one and all other models have weight zero. However, regarding it as such does not solve the problem because selection depends on the data, and so the weights in the estimator-post-selection are random. This results in non-normal limiting distributions of estimators-post-selection, and requires adjusted inference techniques to take the randomness of the model selection process into account. The problem of correct post-model selection inference has yet to be solved.

About the Authors

Walter Zucchini previously held the Chair of Statistics at the University of Cape Town. He is a Fellow of the Royal Statistical Society and the Royal Society of South Africa. He is Past President of the South African Statistical Association (1992) and Editor of the *South African Statistical Journal* (1986–1989). He was awarded the "Herbert Sichel Medaille" of the South African Statistical Association (2008), and the Shayle Searle Visiting Fellowship in Statistics, Victoria University, New Zealand (2008). Walter Zucchini is the co-author of the text *Model Selection* (with H. Linhart, Wiley 1986).

Gerda Claeskens is Professor at the Faculty of Business and Economics of the K.U. Leuven (Belgium). She is Elected member of the International Statistical Institute and recipient of the Noether Young Scholar Award (2004) "for outstanding achievements and contributions in nonparametric statistics." She is the author of more than 40 papers and of the book *Model selection and model averaging* (with N.L. Hjort, Cambridge University Press, 2008). Currently she is Associate editor of the *Journal of the American Statistical Association*, of *Biometrika*, and of the *Journal of Nonparametric Statistics*.

Georges Nguefack-Tsague is lecturer of Biostatistics in the Department of Public Health at the University of Yaounde I, Cameroon. He is head of the Biostatistics Unit and deputy speaker of the Master Program in Public Health. He was awarded a Lichtenberg Scholarship for his PhD studies, which he completed at the University of Goettingen (Germany). The title of his PhD thesis was *Estimating and Correcting the Effects of Model Selection Uncertainty*. He was teaching assistant (2001–2003) in the Department of Statistics and Econometrics at the University Carlos III of Madrid (Spain). Other awards included a Belgium Ministry of External Affairs (MSc) Scholarship and a Cameroon Ministry of Economy and Finance (MA) Scholarship.
