Editor Biography

Dr. Kempf-Leonard is Professor of Sociology, Crime and Justice Studies, and Political Economy at the University of Texas at Dallas. Prior to her appointment at UTD in 2000, she was Associate Professor and Graduate Director of Criminology and Criminal Justice at the University of Missouri at St. Louis. She also served for ten years as a gubernatorial appointee to the Missouri Juvenile Justice Advisory Group. She received her Ph.D. at the University of Pennsylvania in 1986; M.A. at the University of Pennsylvania in 1983; M.S. at the Pennsylvania State University in 1982; B.S. at the University of Nebraska in 1980.

Her book *Minorities in Juvenile Justice* won the 1997 Gustavus Myers Award for Human Rights in North America. Her publications have appeared in: *Criminology*, *Justice Quarterly*, *Journal of Criminal Law & Criminology*, *Crime & Delinquency*, *Journal of Quantitative Criminology*, *Advances in Criminological Theory*, *Punishment & Society*, *Corrections Management Quarterly*, *the Journal of Criminal Justice*, *Criminal Justice Policy Review*, *The Justice Professional*, *Youth and Society*, *The Corporate Finance Reader*, and *The Modern Gang Reader*.

Foreword

Not long ago, and perhaps still today, many would expect an encyclopedia of social measurement to be about quantitative social science. The *Encyclopedia of Social Measurement* excellently defies this expectation by covering and integrating both qualitative and quantitative approaches to social science and social measurement. The *Encyclopedia of Social Measurement* is the best and strongest sign I have seen in a long time that the barren opposition between quantitative and qualitative research, which has afflicted the social sciences for half a century, is on its way out for good. As if the Science Wars proper—between the social and natural sciences—were not enough, some social scientists found it fitting to invent another war within the social sciences, in effect a civil war, between quantitative and qualitative social science. Often younger faculty and doctoral students would be forced to take sides, and the war would reproduce within disciplines and departments, sometimes with devastating effects. This, no doubt, has set social science back. We cannot thank the editors and contributors to the *Encyclopedia of Social Measurement* enough for showing us there is an effective way out of the malaise.

This volume demonstrates that the sharp separation often seen in the literature between qualitative and quantitative methods of measurement is a spurious one. The separation is an unfortunate artifact of power relations and time constraints in graduate training; it is not a logical consequence of what graduates and scholars need to know to do their studies and do them well. The *Encyclopedia of Social Measurement* shows that good social science is opposed to an either/or and stands for a both/and on the question of qualitative versus quantitative methods. Good social science is problem-driven and not methodology-driven, in the sense that it employs those methods which

for a given problematic best help answer the research questions at hand. To use a simple metaphor, asking whether social science is best served by qualitative or quantitative methods is about as intelligent as asking a carpenter whether a hammer or a saw is the better tool.

So far every effort has been unsuccessful in the social sciences at arriving at one canon for how to do science, most conspicuously the attempt at emulating the natural science model. Different explanations exist of this phenomenon, from Anthony Giddens' so-called double hermeneutic to Hubert Dreyfus' tacit skills argument. It is a great strength of the *Encyclopedia of Social Measurement* that it stays clear of the unity of science argument for social science, and of any other attempts at imposing one dominant paradigm on what social science is and how it should be conducted. The editors and most of the contributors have rightly seen that success in social science and social measurement lies with the type of methodological and epistemological pluralism, which is a distinguishing feature of the encyclopedia. Together with its impressive substantive breadth—covering the full range of social measurement from anthropology, sociology, political science, economics, and business administration over urban studies, environment, geography, demography, history, criminology, and law to neuroscience, biomedicine, nursing, psychology, linguistics, and communication—this healthy pluralism will prove the *Encyclopedia of Social Measurement* to be a robust and indispensable companion to all working social scientists for many years to come.

Preface

Methodology . . . [has] developed as a bent of mind rather than as a system of organized principles and procedures. The methodologist is a scholar who is above all analytical in his approach to his subject matter. He tells other scholars what they have done, or might do, rather than what they should do. He tells them what order of finding has emerged from their research, not what kind of result is or is not preferable. This kind of analytical approach requires self-awareness on the one hand, and tolerance, on the other. The methodologist knows that the same goal can be reached by alternative roads.

(Lazarsfeld and Rosenberg, 1955, p. 4)

In the social sciences we use methodology to try to answer questions about how and why people behave as they do. Some types of behavior are very common or routine, while others happen rarely or only in certain situations. When you realize that every conceivable type of behavior is within the realm of possible subjects for us to study, you can begin to appreciate the scope of social science. Beyond identifying human activities and the boundaries in which they occur, social scientists also want to explain why behaviors happen. In looking for causes, social scientists pursue all dimensions of the social world. We look at personal traits of individuals, characteristics of interactions between people, and contextual features of the communities and cultures in which they live. We study people who lived in the past, try to improve the quality of life today, and anticipate what the future will hold. It is difficult to think of a topic that involves people for which a social scientist could not investigate.

Given all we do, it is good that there are so many of us. You will find social scientists in university departments as professors of sociology, psychology, anthropology, political science, and economics. You will also find professors of geography, history, philosophy, math, management, planning, finance, journalism, architecture, humanities, and art who are social scientists. Even this multidisciplinary list is not exhaustive. There are important and prevalent social science investigations that influence decision-making in the world outside of universities too. Social scientists are world-wide and work in all branches of government, large and small organizations, and many types of businesses. Daily life for most people is influenced

by social science research in marketing, insurance, and government. However, not everyone in these positions is a social scientist; the distinction involves scientific inquiry, or the approach used to try to answer questions about behavior. As the definition cited above conveys, good science includes tolerance and appreciation for many methodological paths. This encyclopedia of social science methodology provides 356 entries written by social scientists about what they do.

The entries in this encyclopedia cover many forms of measurement used by social scientists to study behavior. Eleven substantive sections delineate social sciences and the research processes they follow to measure and provide knowledge on a wide range of topics. The encyclopedia has an extensive index too, because many topics include issues that are relevant in more than one section. From many perspectives and strategies, these volumes describe the research questions social scientists ask, the sources and methods they use to collect information, and the techniques they use to analyze these data and provide answers to the important questions.

Each section includes entries that address important components of quantitative and qualitative research methods, which are dissected and illustrated with examples from diverse fields of study. The articles convey research basics in sufficient detail to explain even the most complicated statistical technique, and references for additional information are noted for each topic. Most entries describe actual research experiences to illustrate both the realm of possibilities and the potential challenges that might be encountered. Some entries describe major contributions and the social scientists who made them. The authors are accomplished methodologists in their fields of study. They explain the steps necessary to accomplish the measurement goals, as well as provide their practical advice for ways in which to overcome the likely obstacles.

Collectively, the entries in this encyclopedia also convey that no single approach, type of data, or technique of analysis reigns supreme. Indeed, plenty of disagreements exist among social scientists about what constitutes the “best” measurement strategy. Often distinctions are made between quantitative and qualitative methodologies, or are

discipline-specific. Some preferences can be linked to a specific field of study or research topic; others, related to time and location, coincide with how new ideas and advances in technology are shared. Sometimes we don't even agree on what is the appropriate question we should try to answer!

Although our views differ on what is ideal, and even on what are the appropriate standards for assessing measurement quality, social scientists generally *do* agree that the following five issues should be considered:

1. We agree on the need to be clear about the scope and purpose of our pursuits. The benchmarks for evaluating success differ depending on whether our intent is to describe, explain, or predict and whether we focus extensively on a single subject or case (e.g., person, family, organization, or culture) or more generally on patterns among many cases.
2. We agree on the need to make assurances for the ethical treatment of the people we study.
3. We agree on the need to be aware of potential sources of measurement error associated with our study design, data collection, and techniques of analysis.
4. We agree it is important to understand the extent to which our research is a reliable and valid measure of what we contend. Our measures are reliable if they are consistent with what others would have found in the same circumstances. If our measures also are consistent with those from different research circumstances, for example in studies of other behaviors or with alternate measurement strategies, then such replication helps us to be confident about the quality of our efforts. Sometimes we'd like the results of our study to extend beyond the people and behavior we observed. This focus on a wider applicability for our measures involves the issue of generalizability. When we're concerned about an accurate portrayal of reality, we use tools to assess validity. When we don't agree about the adequacy of the tools we use to assess validity, sometimes the source of our disagreements is different views on scientific objectivity.
5. We also agree that objectivity merits consideration, although we don't agree on the role of objectivity or our capabilities to be objective in our research. Some social scientists contend that our inquiries must be objective to have credibility. In a contrasting view of social science, or epistemology, objectivity is not possible and, according to some, not preferable. Given that we study people and are human ourselves, it is important that we recognize that life experiences necessarily shape the lens through which people see reality.

Besides a lack of consensus within the social sciences, other skeptics challenge our measures and methods. In

what some recently have labeled "the science wars," external critics contend that social scientists suffer "physics envy" and that human behavior is not amenable to scientific investigation. Social scientists have responded to "anti-science" sentiments from the very beginning, such as Emile Durkhiem's efforts in the 19th century to identify "social facts." As entertaining as some of the debates and mudslinging can be, they are unlikely to be resolved anytime soon, if ever. One reason that Lazarsfeld and Rosenberg contend that tolerance and appreciation for different methodological pathways make for better science is that no individual scientist can have expertise in all the available options. We recognize this now more than ever, as multidisciplinary teams and collaborations between scientists with diverse methodological expertise are commonplace, and even required by some sources of research funding.

Meanwhile, people who can be our research subjects continue to behave in ways that intrigue, new strategies are proffered to reduce social problems and make life better, and the tool kits or arsenals available to social scientists continue to grow. The entries in these volumes provide useful information about how to accomplish social measurement and standards or "rules of thumb." As you learn these standards, keep in mind the following advice from one of my favorite methodologists: "Avoid the fallacy fallacy. When a theorist or methodologist tells you you cannot do something, do it anyway. Breaking rules can be fun!" Hirschi (1973, pp. 171–2). In my view nothing could be more fun than contemporary social science, and I hope this encyclopedia will inspire even more social science inquiry!

In preparing this encyclopedia the goal has been to compile entries that cover the entire spectrum of measurement approaches, methods of data collection, and techniques of analysis used by social scientists in their efforts to understand all sorts of behaviors. The goal of this project was ambitious, and to the extent that the encyclopedia is successful there are many to people to thank. My first thank you goes to the members of the Executive Advisory Board and the Editorial Advisory Board who helped me to identify my own biased views about social science and hopefully to achieve greater tolerance and appreciation. These scientists helped identify the ideal measurement topics, locate the experts and convince them to be authors, review drafts of the articles, and make the difficult recommendations required by time and space considerations as the project came to a close. My second thank you goes to the many authors of these 356 entries. Collectively, these scholars represent well the methodological status of social science today. Third, I thank the many reviewers whose generous recommendations improved the final product. In particular I extend my personal thanks to colleagues at the University of Texas at Dallas, many of whom participated in large and small roles in this project, and all of whom have helped me to broaden my appreciation of social

measurement. Finally, I thank Scott Bentley, Kirsten Funk, Kristi Anderson, and their colleagues at Elsevier for the opportunity and their encouragement when the tasks seemed overwhelming. Scott's insights to the possibilities of a project such as this and the administrative prowess of both Kirsten and Kristi helped make this a reality.

Good science is a cumulative process, and we hope this project will be ongoing and always improving. Despite our best efforts to identify topics and authors, sometimes we

failed. If you have suggestions, criticisms, or information worth considering, I hope you will let me know.

Access

Peter Kirby Manning

Northeastern University, Boston, Massachusetts, USA

Glossary

access A working opportunity to gather data in a social unit; the process of obtaining access may be met with success, partial success, or failure.

access types Can be preexisting, worked through via a series of stages, electronic, and global in implications.

craft vs. organizational studies One to two researchers engage in craftwork, but larger teams require organization (administration, accountability, and a hierarchy).

natural history of access Stages of access: preliminary work, the approach, entry, and role relations (or secondary access).

social units A working taxonomy of what might be accessed: places, organizations, scenes, databases, or persons.

study purpose A motivational account that focuses, ideally, on a scientific and intellectual aim.

study rationale A succinct summary of the aims and purposes of the research, usually vague initially.

All science requires access of some kind. In social measurement, this includes access to socially constituted data sources and to individuals in naturalistic settings. Access must be considered as a continuous process rather than as a single deciding point, and this process should be seen as complex, not as a linear progression of entries. Access can be sought in places, organizations, scenes, interactions, databases, and persons. The efforts required are based on the foci and rationale of the research, and although these may not be firmly specified at the outset of a study, they must be developed by the time of analysis and report writing. Important issues arise prior to acquisition of access: the size and organization of the research group, preexisting or ongoing access, and power relations and access. A natural history of access (preliminaries/preparation, the approach to the unit, the entry process,

role relations inside the unit, and situated and ongoing issues, or “secondary access”) is important when studies must be reconstituted or when avenues of research are blocked, new foci develop, and new team members are added. In many respects, the process of access is ongoing, nonlinear, episodic, and often repetitive. Although research technique skills and methods are variables, without patience, tenacity, some distance, and humor, access may never be fully managed, reworked, or rebuilt.

Introduction

Research of socially constituted data sources and people may require access to naturalistic social life settings, rather than artificially created settings. Successful social measurement of extant social settings requires consideration of a series of access points and access levels, from the initial steps through the completion of the study.

Social Units

It is useful and perhaps necessary to subdivide the process of obtaining access, and consider first the social units, and their related patterning of interactions, to be accessed. The units to be accessed range from the most general to the most specific:

- **Places.** Organized interactions occur both publicly and privately. Public places that may be accessed include parks, parades, restaurants, coffee bars, lobbies, and many other easily accessed areas.
- **Organizations.** Authoritatively coordinated and characterized by dense interaction of collections of people in a given ecological location, organizations contain internal social units that may be studied even more intensely than the whole organizational entity.

- Scenes. Characteristic encounters, episodes, and situations that are key or thematic within the setting vary from the banal (such as making change, emptying garbage, or attending meetings or dances) to the quasi-sacred (such as baptisms, weddings, or other ritual events). The idea of scenes includes typical or characteristic interaction patterns found within the settings.

- Databases. Collections of files, manuscripts, papers, clippings, or other archived material, in electronic or paper format, provide global access.

- Persons. Access to individuals, which includes physical access (e.g., studies of tattooing, disabilities, or maladies), is circumscribed by federal, state, and committee guidelines that oversee issues of human rights and protect the privacy and dignity of individuals and study participants.

Foci

Sociologists are concerned more with access to organizations, settings, and scenes in the sense provided here, and are less likely to seek access that invades privacy. Each social unit has a front stage, so to speak, as well as a back stage. Access to these unit components for any sort of study (even a brief survey) is often nested. For example, access to organizations is one initial step in gaining access to some other unit (records or recorded and memorialized daily routines), to participants, and/or to some part of the back stage of the studied social unit. Depending on the concern of the study, there may be relevant subparts of access to front stage material (e.g., what social means are involved in occupational routines), including the setting (props and paraphernalia), appearance (status displays), and manner (expectations of performance). Social science often contrasts the ideal and the real, and contradictions of such. Consider Enron. The front stage elements, such as the accounting system, the rationale in choice of published materials, the rhetoric used, and the public expectations (stockholders), may be fruitfully contrasted with conventions for concealing losses and spreading expenditures and indebtedness and the corruption in auditing reviews. To do so, however, requires some form of access to nonpublic (back stage) information.

Generalizing about Access

Social science literature contains a rich primary and secondary literature on access, but typically as part of an article, or featured as an appendix in a monograph, rather than as the sole topic of an article or book. A few classic articles on the process of access exist; of particular note is the work of Joseph Gusfield and Gerald Berreman, in the 1950s and 1960s. The process of access and the management of role-relations during a study are so much an

integral part of the fieldwork enterprise that they suffuse the narrative to the exclusion of considering other questions, such as reliability of the findings or their validity. Access is especially complex in the case of studying conflict-ridden settings and controversial people, such as the power elites, big business leaders, deviants, criminals, violent groups, and those with contact with such groups. Analytically sophisticated collections of such studies include the work of George McCall and J. L. Simmons, Howard Becker, and Robert Emerson. Notable for contrast and lessons about a crisis in the field that usually meant the project was compromised or abandoned are articles written by Rosalie Wax, Louis Yablonsky, Rik Scarce, and Richard Leo. Included here are additional examples—the often cited work by Irving Louis Horowitz on Project Camelot, a failed Central Intelligence Agency-sponsored study; Jack Douglas' study of “beautiful women”; and famous failed studies that were published nevertheless, such as *When Prophecy Fails*, by Leon Festinger and coauthors, and *Doomsday Cult*, by John Lofland. Every serious scholar has several abandoned (and perhaps much loved) projects cluttering up office and home, but few abandoned projects are deemed worthy of publication. This is odd, given that “falsification” and rejection of null hypotheses so shape social science work.

The difficulty in making sense of literature on access lies in deciding how to draw generalizations from case studies and qualitative works; this is very much shaped by the context (social, cultural, historical) in which the work was done. The case can disappear into the context. Each published field study omits details of many key matters, in part to satisfy journal reviewers and editors, in part because of space constraints and ethical obligations to informants. As a result, the oral tradition, including stories told at conferences, in bars, and at seminars, is a vibrant and salient part of teaching fieldwork. Furthermore, the classics of fieldwork, often read and referred to, are more likely to be cited and understood than are other references, and this corpus includes some famously failed, disastrous, and barely mentionable field studies. Although “semi-failed” studies contribute to the cumulative body of knowledge on access (and related issues), they are not likely to be widely known, read, and cited. Fieldwork as a craft bears an uneasy baggage, but projects that fail can provide lessons, guidance, and warning signs as well as, if not better than, completed, published (and perhaps cited) projects can. Finally, the development of university committees concerned with human “subjects” in research, and the requirement for impact statements for federal grants, have altered the terrain of what is acceptable. The differing interpretations of “risk” and “harm,” and provisions for neutralizing these, are confounded with general canons of research, local traditions, and past miscues, and are often given a distinctly local twist.

Purpose or Rationale

One of the most difficult matters to articulate in the access process, and in developing the approach, before, during, and after the negotiations for access, is creating a workable purpose (a motivational account) and a brief rationale for the study. This may take some time, and is not equivalent to simply articulating a precise aim or theoretical grounding of the study, nor to the “one-liner” description that might be used in casual conversation. Clarity of purpose should go to motive and expected rewards. Ideally, such clarity might ensure that creative research and its public dissemination would govern the work, rather more than writing an expose, or seeking financial gain. The long and emotionally draining efforts by John Van Maanen, for example, to obtain access to the “Union City” (large urban) police department were finally successful through indirect sponsorship of a local professor. Van Maanen explains that he used vague terms of reference with the police chief initially, and later, as he negotiated further access. The present author used similar omissions in London in 1973, expressing simply “interest in the job” (of policing) and by implication how it differed from policing in the United States. This vagueness was sharpened after the initial entrée, and remarks informants had made about what they thought was being studied were echoed! Although these glittering generalities serve well early on, because often a field study is not precisely focused initially (or is “defocused,” according to Jack Douglas), a stated rationale must be derived eventually. Mitch Duneier’s candid statement of his lack of precise grounding is a good example of an implicit rationale—his aim was to gather data and write a good book. A stated research purpose is essential to the eventual completion of a project, as is honesty to self, to informants, and to respondents. This clarity of focus generally emerges, not at once, because, as Kierkegaard wrote, “life is lived forward but understood backward.” If the aim is development of a grounded theory of some kind, this formulation of an account or vocabulary of motives, and specification via data, feedback, and reformulation is an intrinsic aspect of the process.

Some General Issues

A few sociological matters affect and shape the nature of access prior to explicit planning and orientation to a project. These include the size and organization of the research team, previous access, and power.

Size and Organization of the Research Unit (Individual or Group)

Access is shaped by and varies with the size of the team that is assembled to do the study. Dynamics vary,

depending on whether a study is carried out by an individual, by a loosely coupled set of teammates (a group project with interlocking facets), as a tightly integrated, organized, funded, and administered project, or as an established, funded, ongoing field study. Although most field studies are done by one person, teams of fewer than four people are still engaged in craftwork. The major contrast is between small (craft) studies and those involving more than three people; the larger groups are usually funded and include a hierarchy of administration and the requisite coordination. The larger size of the study group entangles the access process in bureaucratic maneuver; the access and administration of the project may be complex, handled by administrators who are not in the field, and may not be the responsibility of the field researchers. In effect, in larger groups, craftwork in the field is no longer sufficient to manage the project, but managerial decisions will directly affect the work in the field.

Preexisting or Ongoing Access

Access may depend on previous involvement in a setting and whether the goal is to “penetrate” it further, for purposes of analysis or application to current work or projects. Access may already have been granted or obtained on grounds other than research. Robert E. Park encouraged studies grounded in personal experience. He urged his students to study something they knew or experienced directly (the same advice is given to young novel writers). Thus, he urged studies of gangs, suicide, the ecology of the city, hotel life, hobos, waitresses, and teachers to those who had previous life experiences with these matters. Donald Roy’s classic articles in the 1950s, on piece work, perhaps the finest and most detailed fieldwork ever done, were carried out before, during, and after he was a graduate student at the University of Chicago. The very capable studies of Simon Holdaway, Malcom Young, and Melville Dalton followed the approach of Roy. After a period of work, they engaged in graduate work, and then gathered additional data. Some projects, such as Van Maanen’s lively discussions of workers at Disneyland (*The Smile Factory*) drew on previous work, and his initial reports did not require “access.” His continuing work on multiple Disneyland facilities (Toyko, Eurodisney, Epcot Center, and the original California site) required access and permission. Other variations on this approach are Erving Goffman’s studies of the Shetland Islanders, in which he worked in the hotel kitchen during his fieldwork, and his studies of St. Elizabeth’s Hospital, which resulted in *Asylums*, in which he acted as a recreational aide. In each case, his research role was partially secret, although he did negotiate initial entry. Another sort of research that requires no access in the formal sense is work that studies people in public settings such as bars, strip clubs, libraries, coffee bars, and other loosely

coordinated scenes, and “public” events such as outdoor drug dealing. Perhaps the most ambiguous kind of access is realized when engaging semiliterate or preliterate people, where no “gatekeepers” exist, or where the approach must be indirect and relies almost entirely on subsequent in-the-field negotiations and relations.

Power Relations and Access

Power relations affect both initial access and continued access within a place or organization. The more powerful the organizations, corporations, government agencies (secret or quasi-secret parts of the Central Intelligence Agency, Federal Bureau of Intelligence, National Security Administration, and Department of Defense, including the Pentagon), higher levels of state and federal government, and secret criminal organizations, the more difficult access will be. The published studies of these organizations are few. Consider the power elite studies of the 1950s and their modest achievements, and the absence of careful and systematic studies of corporate life, especially at the highest levels (studies of Robert Jackall, W. Lloyd Warner, and C. Wright Mills are exceptions), and of the servants of men of power (the corporate and Wall Street lawyers, consultants, brokers, and accountants). Most often, studies of elites are qualitative and or interview studies. We are beholden to journalists such as Seymour Hersh, Ronald Kessler, James Bamford, and former agents of the Central Intelligence Agency, such as Phillip Agee, for the limited public knowledge about these secret and secretive organizations. Our knowledge of criminal organizations is also very weak and thin. Whereas scholars such as Dick Hobbs, Richard Wright, and Scott Decker used observations, interviews, and informants, most of their studies were based in part on confessions and interviews with former members of organized crime or on semiautobiographical books.

A Natural History of Access

There is a natural history to gaining access. There must be preparation for failures, reorganization, contingencies that were unexpected, and “lucky breaks.” Many studies are never begun, or are abandoned, the oral tradition would suggest, because the investigator felt it was not possible to gain access and terminated the study. It is advisable to remain somewhat defocused on negotiating entry to the field. Yet, the more organized the approach, the easier it is to execute the study once initial access is gained. Although the logic of what follows here resembles a natural history, the stages are not linear; each step does not follow from the other but may be repeated, and the cycle begun again and again from various points. Institutional Review Boards (IRBs), committees that approve

research involving humans, can delay, stop, or terminate a project, or cause it to be redesigned or essentially emptied of scientific value. It is the rare study that proceeds from conception to execution in a direct and predictable line and results in publication. Access must be negotiated and renegotiated, and in this sense, we must learn from failed projects.

Preliminaries

Preliminaries involve preparation. Preparation may involve study of the setting or organization, its history and traditions, the people interacting within it, and organizational ideology and culture. Preparation may also involve assembling a rationale and gathering sponsorship and/or funding. After obtaining broad access, cultivating relationships and negotiating access to “targeted” persons or data may be required. Several alternative strategies for access may be required in addition to managed interactions (“in the unit,” or on site), such as developing ways around obstacles to information. Generally, one or more strategies will fail to yield the necessary results. A variety of instruments are generally assembled in a field study, and these may affect access. Different approaches (use of informants; formal/informal, structured/unstructured, or face-to-face interviews; questionnaire mailings; observation); may require different modes of access.

As a general rule, within any organization, social scientists have been most successful in studying the powerless and lower level participants, e.g., small-time criminals and ex-cons, young and midlevel gang members, officers on the street, solo lawyers, and failed members of marginal groups. This is perhaps equivalent to studying academic life by interviewing only those who failed to get tenure, life-time associate professors, or those who dropped out of graduate school or were thrown out for cheating. The systematic work of Mike Useem alone has focused on the “fat cats” and the “top dogs” in recent years. Professor of sociology Jack Katz has argued that the absence of literature reports on the powerful within social organizations may be a function of lack of access, social scientists’ choices of subjects, or the elites’ active strategies that prevent close study.

The Approach

The published literature suggests that the more a research effort is sponsored by powerful organizations and persons, the more likely access will result. It is possible this is an artifact based on what is published (and the need to write up results as part of the contract or grant) rather than ease of access. Seeking sponsorship is the opening move in a game. In the early days of police research, for example, it was rare that the researchers did not acknowledge the

support of the Department of Justice, Police Foundation, National Institutes of Mental Health, or the National Science Foundation. An individual researcher can make an approach in a straightforward manner, seeking direct access, or through intermediaries. “Middle men” or brokers can be fellow social scientists, former students or alumni of the researcher’s university, members of the sponsoring research organization (National Institute of Justice, the Police Foundation, Office of Community Oriented Police Services), neighbors, or friends. The more indirect the link leading to access (e.g., a casual acquaintance who suggests ways to open doors), the more that face-to-face negotiations will be required. The most difficult approach to gaining access is the “cold call” approach, even with some legitimate backing (indirect, or “name dropping”). Studies based on cold-call approaches are the most likely to fail, to not be published, or to be only the subject of technical reports. Thus, it is very difficult to assess the proportion of these approaches that “work.” The more connected the project to a larger framework or project structure, the more that final publication will reflect some joint constraints, timetables, opportunities to publish, and even conflicts about the final product.

Entry

Entry is profoundly shaped by what is being entered. Access to public places or to organization front stages (the official greeters and receptionists in organization offices), and even to other settings of interest, may be easily available without egregious costs or efforts. Access to bars, parks, coffeehouses, and public gatherings is easily accomplished. Semipublic events such as graduations, weddings, and religious services are quite accessible. However, after the preliminaries for researching organizations have been accomplished, very often negotiations for further access flounder. For example, in a large English constabulary where the present author had personal sponsorship, a presentation, lunch, a tour of the crime analysis facility, and introductions to the Deputy Chief Constable went well, but were followed by instructions to write a letter to the Chief Constable for further access. This all looked promising until the letter of refusal came a week or so later. There was no explanation for the refusal, but an indirect inquiry revealed that the Chief Constable was about to resign, and the new deputy to be appointed and the people running the crime analysis unit were wary of criticism of a nascent undertaking. Another study involved being given initial sponsorship by a London officer visiting Michigan State University on a study bursarship; the sponsorship was linked to a friend of the London officer, i.e., a Chief Superintendent in the Metropolitan London Police (now called Metropolitan Police Services). A phone call to the Chief Superintendent (yielding the response “What

took you so long to call? I’ve been expecting you!”) led to a full round of interviews and observations with detectives, canine units, sergeants, and constables, when, previously, access had been denied by letter from the Home Office and the Metropolitan London Police Commissioner. The process of “penetrating” an organization only begins once initial entry is permitted, and is not then finished. Persistence and patience cannot be over-emphasized as the basis for success.

Inside the Unit

The process of gaining initial access can alter subsequent role relations and the types of data it is possible to obtain or seek. This can be shaped by role relations in general within the unit. The entering bargain, what is promised implicitly or explicitly in order to do the study, may vary in time, because, as new contingencies arise, the researcher may have to adjust, regroup, withdraw for a time, or end the search. The promises made to those granting access, in general, will shape the nature of the access and in turn the data gathered in the resultant study. Observational data are fairly straightforward, because if there is access, there is at least one “window” into the organization. There may be backstage matters and “key scenes,” those that are expressive of the culture, such as the questioning of an arrested suspect, preparation of a fine meal, or inspection of a nuclear facility, within the setting to which access is desired. For example, as described in *Narcs’ Game*, this author had easy access to phone calls and meetings in public rooms, some access to raids and warrant-serving episodes, and almost no access to interviews with informants, to arrests, or to bookings and jail interviews (post-arrests or prior to trial). The study was focused on the interaction of information and action choices in drug enforcement, so lack of access to these latter scenes were not crucial. The picture of drug policing is thus partial and based on differential access. Stephen Mastrokfi’s study of police–public interaction relied on interviews with ranks above sergeants and observations and interviews with those of lower rank. In short, the meaning of the organization will appear to vary, depending on the point of access to it. Access can be systematic, as when files are requested on crimes for a given time period, or more idiosyncratic and adventitious, taking opportunities when they arise (e.g., when police fieldwork goes well, researchers may be asked to go on raids, to join social occasions such as after-work drinks or lunches, or to attend informal meetings).

Most fieldworkers have sought opportunistic glances at paper files, have opened notebooks, and have deciphered things left on desks when the owner is away, but such actions constitute *bricolage* (using random findings), and are unlikely to contribute to a study in any major fashion. Because fieldwork often begins in a defocused

fashion, without a clear empirical statement or hypothesis, it is best to keep alert for things on the periphery of a study, e.g., related issues in policing such as the media coverage of events, public parades and demonstrations, civic gathering places and ceremonies, and ethnic traditions of the city. This breadth of vision provides a set of connections that may in time come together and contextualize the central concern of the study, giving the work depth and breadth. Access remains something like a telescope: it must be adjusted depending on the target object.

“Occasioned” data represent yet another sort of information; examples include the marvelous detailed data Roy Rappaport gathered initially to calculate the carrying capacity of the land in New Guinea, including the weight of pigs, the acreage of taro plants, and the patterns of planting. Once inside the setting in the jungle among the Maring, systematic observations were made to support the argument. Material was gathered for later analysis. Occasioned data can also be obtained within public settings such as courthouses or employment offices; extraneous public materials can be gathered and analyzed without too much fear of retribution. The difficulty arises in gaining access to corroborative evidence or records, such as sentencing reports or background investigations by parole workers. It is crucial not to minimize the importance of the complex and changeable views of people and to accept that they may hold contradictory ideas, or may be confused, and that this confusion is data as well as that which connects in a satisfying fashion. As some scholars have emphasized, following the general orientation of capturing the actors’ perspectives, the viewpoints of the actors should not be invented, but should be reported.

Situated, Negotiated Secondary Access

Qualitative work and access to settings and scenes shape the process of negotiating roles and access at other levels within an organization or scene, once initial access has been managed. The degree of focus and precision in the research plan and the required instrumentation will affect the liminal period between initial access and secondary access. These are constraints having to do with the size of the studied population and sample, the nature of the interviews, and the length and complexity of the interviews (and language skills required, as well as translation and back-translation needed). Complexity also accompanies the length of the “to get” list items, such as a floor plan, organizational chart, paper files, key scenes to observe, and so on. The resulting dynamics might thus be called “secondary access problems” and they are related to matters of establishing, negotiating, and validating roles and aims within the place, interaction, organization, scene, database, or person. Initial access to data usually comes through a higher level sponsor or person, who then directs the researcher to a secondary person (a lieutenant,

middle manager, clerk, or trusted administrative assistant). Here, the usual vagueness obtains. Once negotiations ensue, those at the point of access and the access-producer, or “gatekeeper,” will shape the initial roles occupied by the researcher, and hence data access to some extent. Several researchers have suggested that fieldworkers should take on a fabricated, false, and agreeable pleasant *persona* in order to gather data; others disagree with this approach. The stereotypes of academics as confused, abstracted, distant, and slightly otherworldly can be both an advantage and a disadvantage. With police, who are attuned to lies and self-serving fronts, it may be essential to disagree directly with their views, and to take positions, particularly concerning issues such as gender relations (sexism) and race bias.

As a study progresses and data are gathered (whether from interviews, observations, or questionnaires), myths, questions, curiosities, and unanticipated events will shape the study and the nature of the secondary access. In the worst-case scenario, the researcher is subpoenaed, thrown out, and the data confiscated or destroyed. These events cannot be fully anticipated, but they are common and in that sense “predictable.” As access continues, the researcher takes on new depth or presence; personal features, habits, nicknames, and shared humor and jokes make data gathering more contextual and sensitive to gender, appearance, and interests. Jennifer Hunt, for example, in studies of the New York Police Department, was treated with great ambivalence by the officers, but her ability to shoot accurately and well was ultimately acknowledged and was a source of prestige. Responses to such events and patterns of interaction shape subsequent access and unfolding or closing of opportunities. One of the advantages of a multiperson team study is that people talk to researchers about the other researchers, thus facilitating role-building activities. Roles are built up over time, not immediately thrust into a setting. Some roles are a result of active decisions by a researcher, but others are beyond control. Clearly, gender, sexual orientation, and sexual preferences shape secondary access in important ways.

The question of what sort of “help” and assistance a researcher gives to the organizations’ members studied also arises in fieldwork (e.g., in an ambulance, at a fight, when gang members are fleeing police). Does a researcher carry a gun, wear a bulletproof vest, engage in fights, do medical procedures, type up documents, count money or evidence seized in raids, run errands for coffee, or become a “gopher”? In general, these little duties become bases for reciprocity and obligation that exceed the narrow purpose of the research. For examples, anthropologists in Chiapas always “overpaid” their informants just enough to keep them out of debt, but not so much as to elevate the standard rate among the Zinacantecos. This encouraged the informants to depend on the anthropologists for loans,

liquor, medicine, and succor. Finally, many researchers may provide feedback or agree to summarize findings to principal gatekeepers, and these meetings or brief reports in turn may lead to reactions from the organization or the people studied. Thus, exit etiquette and sensible behavior will define the current exit as well as the next one: every ending is a new beginning.

Future Issues

Global Ethics and Access

The points made in this article assume that the investigator or team has at least nominally set out a purpose and that the general purpose is known by the studied groups. Secret observers and disguised observations raise quite different questions about access, because access involving concealed observers in whole or part is patterned by their roles as they defined them within the organization, or only slightly expanded versions of these roles.

When access is gained with a broad mandate and/or a secret purpose that either is not disclosed or is hidden from the people being studied (or when they do not understand what is happening, given lack of research experience or because of poor reading and language skills), then access and field tactics become fraught with ethical questions. James O'Neel and Napoleon Chagnon entered the Amazonian forest to study the Yanomamo Indians as a genetic population, seeking to establish whether the dominance of headmen shown through fighting and conquests led to a natural selection process that sustained warfare and conflict and the social structure. Holding fast to their aim, O'Neel and Chagnon would not provide medical treatments; staged, stimulated, and filmed fights; gathered genealogies that were angering and a violation of tribal traditions; and in some sense eroded an already thin and dying culture. In this research, access increased vulnerability of the tribe to diseases and outside forces and contributed to the shrinking number of the remaining isolated, preliterate groups.

Electronic Access and Fieldwork

The potential for surveillance and simulation of social control is emergent in federal, state, and local agencies. No one is quite clear on how many databases exist, or how many bytes, persons, or files they contain, and their potential, but there is a clear concern that the civil liberties may be compromised by access to the databases. The power to control the files and databanks is still under contest, as is freedom to use and access the Internet. As commercialization of the Web increases, control and access will be in the hands of large corporations or governmental bodies that will charge for or conceal modes of

access. There is no doubt that in another decade, access questions will focus on manipulation, control, processing, and analyzing electronically formatted data.

From a research point of view, there are enormous advantages to the existence of and access to huge standardized, formatted, and shared databases. Three issues face future researchers concerned about these data and access to them. The first is that some "sites" and social worlds may well be electronic, or virtual. The problems and prospects of access here will be perhaps more dependent on the skills of the researchers to gain access electronically (Internet, "hacking," chat room, and individual computer technology skills). The second issue is that access to and manipulation of data via electronic files, databanks, folders, and other electronic modes of storing, transferring, and analyzing data raise new ethical questions of use, access, and distribution. Information can be stolen and used without the knowledge of the previous possessor. How to locate missing and partial information may be different when the system, the copies, and the "original" are all computer based. When accessing a series of paper files, what is physically present is obvious, unless major misfiling is involved. This is not true in electronic systems, and hidden files are accessible only by skilled computer users. It is more difficult to identify what is missing, and information can vanish (via copying) without a trace.

Comment

Fieldwork requires primary and secondary access, and some types of access are more troubling and will be negotiated more than others. Fieldwork requires diligence and open-mindedness. The shifting mandate of a project will move people in various directions, but research should always be guided by centered and peripheral concerns, i.e., the purpose of the research and the questions posed as well as the epistemological assumptions of gathering and seeking to access data. In addition, as every good research paper should state, pursuing access to new areas will produce the need for more research.

United Kingdom*

Glossary

accounting measurement converting physical numbers of items (such as physical quantities of sales and physical units of raw materials and components) into monetary amounts.

audit the validating of the financial reporting package and the confirmation that its contents comply with extant accounting regulations by independent qualified accountants.

free cash flow the amount of cash and financing available for future, as yet uncommitted activities.

intangible assets assets not having physical form.

internal goodwill the value of the firm over and above the total value of its net assets after deducting financing.

purchased goodwill the amount by which the price of an acquired firm exceeds its net asset value.

off-balance sheet not including some assets and liabilities in the balance sheet.

true and fair view an unbiased accounting representation of the economic situation of the business constrained by the accounting methods used.

working capital short-term assets net of short-term liabilities.

Accounting measurement has a wide range of uses both within and external to the organization. This article concentrates on external accounting measurement for profit-seeking enterprises. The theory underlying accounting and the regulation of published accounting reports has switched over time from seeking to provide information to help shareholders and creditors protect their investments to helping make investment decisions.

Introduction: Overview of the Scope of Accounting

Measurement using accounting methods is one of the oldest examples of measurement in society. Until the

industrial revolution and the rise of corporations, accounting reports were a matter for organizations and especially groups of partners in commercial ventures. Here they served mainly to determine profits and their distribution as dividends. With the arrival of limited liability corporations, accounting was more regulated and aimed mainly at protecting the investment of widely based shareholders and creditors.

Generally, accounting seeks to provide measurement in quantitative and financial terms denominated in the appropriate monetary unit. Such measures may apply to projects, to parts of organizations, to nonprofit organizations, and to profit-seeking organizations. Accounting measurement may report on performance in a past period both for intraorganizational purposes, such as performance reporting on managers and on departments and divisions, and for reporting in the public domain to some or all of an organization's stakeholders. The annual financial accounting reports of companies quoted on stock exchanges provide a familiar example of a published accounting report concerning a past period. Accounting measurements may also be future-oriented, that is, quantifying future expectations in, for example, budgets and project appraisal. With future-related accounting, actual performance may be compared with plans as operations proceed. Accounting measurement is usually categorized into financial accounting and management accounting, though the two areas overlap. Other areas of accounting include auditing, taxation, and consultancy.

Financial and Management Accounting

Financial accounting incorporates accounting book-keeping for past and actual transactions, often using highly sophisticated information systems, and external

reporting of the results of a past period to stakeholders. Management accounting includes booking costs and revenues, the costing of products and sections of the organization, the developing and operating of management information systems including budgets and long-term plans, and measuring performance against these plans. The scope of accounting measurement is vast and seeking to explain accounting in nontechnical terms is space-consuming; therefore, the remainder of this article concentrates on external financial reporting, which is the accounting information most frequently used by investors, creditors, and many other accounting users.

In most commercially developed countries, the requirements for external financial reporting are strongly regulated either by law or by the private sector with legal support. Such regulation determines the financial statements that must be published, the items that must be disclosed, and the methods of measurement that must or may be used to “value” or measure (to be further discussed) accounting items. Such financial reports must be audited for, at least in companies quoted on stock exchanges by auditors external to the organization. The legislation that governs the creation and operations of large, noncorporate organizations generally requires that their published financial statements must also be audited, either by external auditors or by specially created auditing bodies, often in a way that also considers organizational effectiveness, efficiency, and economy (in what is called value for money auditing). The corporate reporting package, at least in some countries, includes reports on compliance with any corporate governance requirements.

In contrast, management accounting is a matter for the firm. Generally, there are no external requirements that are imposed in this area of accounting except that market regulators may impose such requirements, as may powerful contracting organizations, such as governments and local authorities. Much of the cost accounting area and, in some regimes, the reliability of management information will be subject to external audit but any internal audit by the organization is a matter for management.

The Use of Accounting Information by Social Scientists

Most analyses of industries and of economies refer to accounting profits, the asset bases of firms, and the financing of firms. Much work has, for example, been carried out investigating any relationship between accounting profits and asset levels with developments in the economy. Time series of published accounting information and cross-sectional information by firms and industries are available on very sophisticated databases, often with related information, such as stock prices. This allows many econometric studies to be carried out relatively easily. Examples of

hypotheses that have been tested include regressing accounting profits on firm size, industry, technology, and firm type and testing the relation between accounting profits and innovation and market power. Regulators, especially in the United Kingdom, may seek to estimate whether accounting profits exhibit “above-normal” profits. Finance and accounting researchers have sought to determine any relationships between accounting information and stock prices. They have also sought to determine any information value that accounting information may have to, say, investors.

One important point for those who wish to use accounting information is that they are aware of the limitations of this information. External accounting does not provide anything like a stock market valuation for the firm and the release of some information is a matter for management; often, given information can be treated in a number of ways and some information can be released or smoothed over time. Similar firms might produce significantly different results in different countries under different accounting regimes.

The Financial Accounting Package

This section concentrates on the accounting requirements on profit-seeking enterprises. Generally acceptable accounting practices and principles (referred to as country GAAPs) differ fundamentally among countries reflecting, among other things, the country’s history, its culture, its industrial organization, its financial and legal systems, its method of regulation of the financial system and of corporate governance, and its system for regulating accounting. Until the 1960s, GAAPs in most commercially developed countries consisted of either some fairly general laws and “best” accounting practice and the recommendations of the professional societies of accountants (for example, the United States and United Kingdom) or more detailed laws augmented by best practice and professional recommendations (France and Germany). Many financial crises in a number of countries led to the tightening of law and in some countries the setting up of bodies of accounting regulators to determine external accounting disclosure and valuation methods. In the face of continuing crises and the perceived softness and the vested interests of the regulators, these were given more power and more independence and especially in countries with law-based GAAP. These processes have been intensified following U.S. crises (such as Enron) in the early 2000s.

The importance of country GAAP, which incorporates any legal requirements and private sector regulations, called accounting standards, is that, at least, firms quoted

on stock exchanges are generally required to follow them in preparing their accounting packages and generally the auditors must verify this. The most important GAAPs are that of the United States and that determined by the International Accounting Standards Board (IASB), which is composed of members from a number of leading commercial countries and which gains its authority from the willingness of most stock exchanges to accept accounting reports that confirm to their GAAP. The IASB accounting standards are or will be accepted in a number of countries for companies quoted on stock exchanges, including all those in the European Union by 2005.

This article is written from the perspective of U.K. GAAP (which is fairly similar to that of the IASB), which incorporates the accounting standards issued by the United Kingdom Accounting Standards Board (ASB) and which, with some exemptions, applies to all registered companies.

The Reporting Package

The reporting package in the United Kingdom and most other countries is the responsibility of the management of the firm. For details of current country GAAPs, see manuals issued by most large professional accountancy firms, for example, the 2003 manual by Wilson *et al.* The package shows comparative figures for the previous year and consists of the following elements:

The Financial Statements

The Profit-and-Loss or Income Statement for the Year This shows the revenues deriving from the firm's operations minus the cost of obtaining these revenues and the other costs of maintaining the business during the year, including interest on financing the business to obtain the profit (or earnings or income) for the year before tax. Other gains and losses not arising from operation may be added (or treated in the balance sheet). Finally, deducting tax and any planned dividends yields profits retained for the year, which can be used to finance future investments.

The Balance Sheet as at the End of the Year This contains two perspectives on the firm. First, it quantifies the firm's assets using a variety of valuation bases (see below) and second, it indicates how these assets are financed. The balance sheet normally commences with fixed assets: those held for long-term use in the business. These two major classes of fixed assets: (1) intangible assets, those with no physical form, such as patents, and (2) tangible assets. Both are shown gross and net of depreciation. Generally, net working capital (short-term assets less short-term liabilities) is then either added (if positive) or deducted (if negative), thereby yielding a measure of the firm's asset base. Deducting long-term financing (including a large variety of financial

instruments) and other liabilities yields the accounting equity value in the business. Accounting equity can be analyzed into issued shares, retained profits, and reserves, which comprise either profits retained, sometimes for a specific use, or gains or losses not allowed to be or not normally included in the profit-and-loss account (for example, gains on revaluing assets to a market price as such gains have not yet been received as revenue in some form).

The Cash Flow Statement for the Year This shows the net inflow or outflow of cash during the year. It starts by showing the inflow from operations and cash from other activities including returns from investments and from financing the activities of others. From these cash inflows, cash outflows are deducted. Cash outflows could include taxation paid, interest payments, capital expenditure, the cost or receipts from acquisitions or disposals, and the payments of any dividends. The sum of inflows and outflows shows the net cash inflow or outflow during the year. The financing of this cash inflow is then shown. This financing may be long-term and may be the result of any change in the balance of current assets and current liabilities (where this change is positive, that is, where current assets exceed liabilities, this means less cash than otherwise is required to meet liabilities). The difference between the net cash flow and its financing shows the change in cash during the year. The cash flow statement allows a very important figure to be calculated: the free cash flow. This measures the firm's financial flexibility by showing any free cash remaining for further investment after allowing for all known investments and other uses of cash.

Other Items

A management review for the year (in the United Kingdom, this is called the Operating and Financial Review) applies only to quoted companies and is voluntary in the United Kingdom. This reviews current operating and financial developments and trends in these items and uncertainties that may affect the business. Additionally, for quoted companies, a corporate governance statement indicates how and to what degree the firm has complied with the corporate governance code.

All the financial figures in these statements are stated as certain amounts. Even where they can be regarded as averages, no standard deviations are given. This limits the statistical analysis that can be applied to the accounting reports of companies.

It is important to understand that the three financial statements are linked together in that the items in one statement are either derivable from one of the others or form inputs into one of the others and usually provide more details of an item in one of the other statements. Thus, profits for the year are derived in the income

statement and form an entry into the balance sheet to increase the profits retained in past years. Costs incurred during the year provide another example. If paid by cash, they will affect the firm's cash flow statement and via this will change the cash balance shown in the balance sheet at the end of the year. If financed by credit and unpaid at the end of the year, this will be reflected in the amount of creditors shown in the balance sheet and any interest cost for the credit would be reflected in the income statement. This interrelationship between accounting items also indicates that the treatment of a given item must be consistent between statements.

Accounting Theory

Before examining the income statement and balance sheet in some detail and giving examples of some of the areas where care is required in interpreting their meaning, this article provides a theoretical background of accounting and briefly considers some controversies and difficulties.

Prior to the mid-1960s, accounting reports were not strongly regulated. The emphasis was on prudence (recognizing gains only when sure about them but recognizing all losses immediately and making allowances for likely future problems) and on conservatism (understate asset values and overestimate liabilities, thereby reducing the current value of the firm and current profits but increasing possible future profits). Such accounting results were seen as good for contracting purposes, which require as objective information as possible but were of little help for decision-making. The predominant accounting approach was to ensure that the revenues of any period were matched as best as possible with the costs of obtaining those revenues whenever these costs were incurred. This yields a reasonable picture of the profits earned in the period but at the expense of a balance sheet that may have little meaning (often being only collections of transactions that have not yet passed through the profit-and-loss account). In the United Kingdom, this meant that, generally, management were free to choose whatever accounting practices they wished and generally to disclose as little as they liked, subject to what was judged acceptable by the accountancy profession and the giving of a "true and fair" view. The latter is difficult to define and represents the exercise of professional judgment but relates to a reasonable representation of the economic situation of the corporation with the accounting model being used. This means there may be several degrees of freedom available in determining a true and fair view and there may be more than one true and fair view. Moreover, via conservatism and prudence, management were able to build up hidden reserves of profits in good times and release them in bad times (thus smoothing profits over

time). It also meant that management, as might be expected, could choose accounting methods that favored them. Similar practices occurred in other countries. Many scandals attended this regime.

Since the 1990s, most of this accounting theory has been overthrown but the state of accounting theory is still substantially unsettled and, at least recently, the scandals have not gone away. Leading country regulators have opted for accounting that seeks to aid decision-makers, predominantly investors who are seen as wishing to value investment based on their future cash flows, their timing, and their risk. This is subject to only using reliable figures, which represent faithfully the item being measured without bias. With this view, all assets and liabilities should be defined ideally in terms of the contribution they make to corporate cash flows and ideally valued on this basis through generally either historical cost (the price when obtained) or the current market price. Given that accounting values individual assets and liabilities, it can, at best, provide only some information relevant to these issues. Many items that could be treated in the past as assets or liabilities must now be treated as expenses or gains of the year. The balance sheet is thus promoted to being the more important statement and the profit-and-loss account includes items not backed by transactions because changes in market prices are seen as producing gains or losses during the year. There is much debate over what items should be included in the balance sheet (for example, intangibles) and how assets should be valued. There is a strong drive to value all financial items at their market prices without similarly revaluing physical assets. The advantage of market prices is claimed to be that such prices are objective and not subject to managerial manipulation.

A major concern of modern theory is to stop managerial manipulation of earnings. Thus, prudence and conservatism, which allow income smoothing over periods, have been downgraded as accounting principles has the ability to make provisions for likely later costs, which can augment future profits when they are released as not needed. For example, the ability to make allowance for the cost of future enterprise restructuring has been substantially restricted in the United Kingdom and by IASB. The cost of this approach is that it might deny accounting report users information about managerial beliefs. The belief that management generally will exploit their greater knowledge for their own benefit is mainly anecdotal, although there is some empirical evidence and some current extreme examples. The ability and rationality of management in using this practice seem to be limited from an analytical perspective.

Another major controversy is whether regulation should be highly detailed (as in the United States) or based on general principles and the emphasis placed on the duty to give a true and fair view or a similar

overriding objective. That in the United States companies are free to do anything that complies with the letter of the regulations (and are willing pay for advice as to how to honor the letter of regulations but not their spirit) has been argued to lay at the heart of some American financial scandals in the early 2000s. In contrast, similar things happen under other regimes and the more complex financial products that have become available need detailed rules under all accounting regimes.

Some Problems with Accounting

Space is not available to review the above accounting statements in detail. The aim is to briefly indicate some of the important contents of these statements and to give some indication of the flexibility available to management in accounting reports, which is important to understand if accounting figures are used in research and other studies.

Profit-and-Loss Account or Income Statement

The ability to recognize revenue in a given year may lead to over- or understating revenues, and therefore profits, and is being restricted by regulators. Examples of the overrecognition of revenues are the taking all revenues at the beginning of a long-term and complex contract, where, for example, a future warranty may have to be fulfilled or where later environmental clean-up work is required. Another example of the overrecognition of revenue is the recording of payments from “pseudo-independent” companies (as practiced by Enron).

Most costs in the profit-and-loss account will represent buying prices at the time of purchase, though the cost of any opening inventories used during the year may be calculated in a number of ways, which affects the costs charged to the year when items have been purchased at different prices. Depreciation represents an allocation of the cost of a long-lived asset to the year in mind. Ideally, such depreciation should reflect the loss of value of the asset in the year, but usually accounting depreciation follows an arbitrary formula of which a number are permissible, the use of which thereby generates different profits. Similarly, the cost of those intangible assets that are allowed to be incorporated into the accounts also may have to be spread over their lifetime on a reasonable basis. Provisions for future losses may also be spread over a number of years. The United Kingdom regulator and the IASB have restricted the ability to spread costs over years in order to avoid the possibility that management will use this facility to smooth profits (earnings) so that bad years are disguised using undeclared profits from better

years. Such smoothing is argued to mislead investors and other users of accounts. There are some expenses that are “off” the profit-and-loss statement, as they have no obvious accounting cost, but clearly affect enterprise value. Stock options granted to employees may have this characteristic (being looked at by regulators) as may some financial instruments (again being looked at by regulators) and pension costs.

The Balance Sheet

This shows the details of the firm’s assets, such as land, property, and equipment, and its liabilities in a logical sequence. An asset is an identifiable item that has been either acquired or constructed in-house in the past, is expected to yield future cash flows, and is in the control of the firm in the sense that the firm may decide whether and how to dispose of the asset or use it. The accounting approach to valuing items is a bottom-up approach with which each item is valued individually using a method appropriate to that item and these values are aggregated to obtain valuations for classes of assets and liabilities and overall asset and liability values that will generally incorporate different valuation bases for different classes of accounting items.

Intangible assets are expected to generate future cash flows but have no physical form, such as items of intellectual property, which include patents, licenses, trademarks, and purchased goodwill (the amount by which the price of an acquisition of a company exceeds the net value of all the other assets of the acquired company). Many intangibles obtained in an acquisition are allowed on the balance sheet valued at what is called their “fair value”: what they would exchange for in an arm’s length transaction by willing parties. Such fair values are not generally allowed to be changed to reflect changes in market prices over time. The inclusion of such intangibles is in contrast to the unwillingness to extend this treatment to either internally generated goodwill, which reflects the firm’s value-added operations, or internally created intangible assets, such as brands. Often in a modern, growing, high-tech firm, the values of such intangible assets may dominate physical assets. The possibilities for inclusion would be very large, including self-created brands, information technology systems, customer databases, and a trained work force. Generally, regulators have resisted attempts to treat such items as assets. Proponents of inclusion argue that this means that many of the sources of company value go unrecognized in the accounts and must be treated as costs in the year incurred. It is argued that this is one reason the accounting value of firms may fall far below their stock exchange values, especially for high-tech companies and companies in a growth phase. This is true even today; compare the accounting and stock market

values of Microsoft. This makes empirical work with accounting numbers very difficult. Where intangibles are important in such exercises, they must be estimated separately.

The value of an asset is either based on its original cost or in most accounting regimes, including the United Kingdom but not the United States, based on a revalued amount taking into account changes in prices over time. Any gains on holding assets increase the value of the firm in its balance sheet and not its operating profit, though such gains or losses are shown elsewhere in the profit-and-loss statement. Firms do not have to revalue assets and many firms may use different valuation bases for different asset classes. Any revaluation must be based on independent expert authority and such independent assessments must be obtained regularly. By not revaluing assets in the face of favorable price changes, firms build up hidden reserves of profits realized when the asset is sold or when used in production. Accounting regulators have acted to stop asset overvaluation by making assets subject to a test that their values in the accounts do not exceed either their selling value (which may be very low where assets are specific to the firm) or their value when used by the firm (an estimate by management that may be highly subjective).

It is generally agreed for useful empirical work that assets must be restated at their current market prices minus adjustments for existing depreciation and the assets' technologies relative to that currently available on the market. One example of the use of current cost is in calculating what is called Tobin's Q , the ratio between the firm's stock market value and the current cost of its net assets. One use of Tobin's Q is to argue that firms with a Q ratio of greater than 1 are making, at least temporarily, superprofits.

During the inflationary period of the mid-1970s to early 1980s, most leading accounting regimes allowed at least supplementary disclosure of generally reduced profits after allowing for current cost (adjusted replacement cost) depreciation and a balance sheet based on the increased current cost of assets. This movement fizzled out with the decline in inflation, the lack of recognition of current cost profits by tax authorities, managerial unhappiness with the generally lower profits disclosed by this type of accounting, and the need to maintain the current value of existing assets. More traditional accountants also argued that the revaluing of assets meant that profits would be reported (as an increase in the firm's value in the balance sheet) on revaluation and not when profits were realized either by use or by sale. Despite this, many experts believe that it is the intention of some accounting regulators (ASB and IASB) to move toward current cost accounting.

Regulators in most countries have acted and are planning to act further on off-balance items. Leased operating

assets, such as airplanes, ships, and car fleets, do not have to appear on the balance sheet and only the annual cost of such leasing appears in the income statement. This understates the firm's capital employed often by vast amounts and thereby inflates returns on investment. This is planned to change shortly. Other ways of maintaining assets on the off-balance sheet include setting up a supposedly independent entity that owns the assets and charges the "parent" firm for their use. Similar approaches are available to keep debt and other financial liabilities out of the financial statements.

The treatment of financial assets (those denominated in monetary terms, which include financial instruments) differs between accounting regimes and classes of financial assets. Long-term loans to and investments in other companies not held for sale are generally shown at their original cost. Most other financial assets and liabilities are usually valued at their market prices, with gains and losses usually going to the balance sheet until realized by sale. Almost all regulators are agreed that all financial assets and liabilities should be shown at their market prices or estimated market prices, where such prices do not exist, which is the case for complex financial instruments (including many derivatives). Any gains and losses would go to the profit-and-loss account. Using market prices means that there will be no need for what is called "hedge accounting." This accounting means that investments to cover other risks in the firm are kept at their original cost until the event that gives rise to the risk occurs, thereby hiding any gains or losses on the hedges. The aim is to let accounting "tell it as it is," under the view that market prices give the best unbiased view of what financial items are worth. There are problems here. The approach treats some financial items differently than other items, such as physical assets and intangibles; it records gains and losses before they are realized by sale or by use, whereas this not allowed for other items; and it abandons to a degree the prudence and matching concepts and, perforce, often uses managerial estimates for complex items not traded on a good market, which conflicts with the wish of regulators to minimize managerial discretion.

Conclusion

Overall, financial reports have changed enormously over, say, the past 20 years and greater changes can be expected but care still must be taken when using accounting measurements. There is still conflict between seeking to provide reliable information and information useful for decision-making. The valuation (measurement) bases used for different items still differ. Some liabilities and many assets (especially intangibles) are not included in the balance sheet. Income is moving

toward recognizing gains/losses in market prices rather than basing these on transactions. With restrictions on smoothing results, management must find other means to share their information with accounting reports users.

Accounting measurement in published financial reports seeks to be objective within its own terms and is validated in this sense by independent observers. It has the great advantage over many other measurement systems that accounting results measured at any level of the organization can be added up to give an overall view. As the measure is in financial terms, costs are automatically traded off from benefits. Thus, accounting allows the performance of areas of the corporation to be aggregated. This in contrast to other measurement systems, which measure items independently and cannot add these together because the trade-off between items cannot be easily determined other than by judgment. In contrast, published accounting reports do not provide the detailed targets common with other measurement systems, such as performance measurement systems including those that form part of management accounting. It is up to the user of accounting reports to determine the targets that they wish to use, though the literature contains much guidance.

Glossary

administrative record Data collected for an administrative purpose, as opposed to a formal research data collection effort.

coverage bias The systematic difference between the database and the population of interest.

database ontology The definition of objects that are in a database (e.g., What is a business entity? Do sole proprietors count as business entities? What is an address? Is a person living in the basement at the same address or a different address?) and the categories that are used in the database (e.g., Does race have three, five, eight, or sixty-three categories?).

microdata Information about individual persons, families, households, addresses, or similar objects, as opposed to tabulations or aggregate data.

reporting lag The systematic tendency of administrative records data to be reported in a time frame that is “behind” the actual behavior of interest. For example, a person may change addresses in one year, but that move may not be recorded in the administrative database until a later year.

response bias The systematic tendency of respondents or data collectors to respond in systematic ways that are different than the ontology intended or what was understood by the researcher.

Research with administrative records data is similar in some ways to more traditional forms of research, such as sample surveying, but it differs in several important respects. In particular, the data collection effort is not designed by the researcher, and so the researcher is “at the mercy” of the administrative agency; typically there is no sampling scheme (so that sampling variances are not

easy to calculate), and there are systematic response biases and coverage biases in the data that are caused by the administrative agency and their client base. An important concept in the use of administrative data is that of a database ontology, or the structure of the objects in the database and how data on those objects is collected—in particular, a database ontology that is perfectly suitable for the administrative agency may not be at all suitable for the researcher. In such cases, the researcher can sometimes estimate coverage biases or translate data from one ontology to another; but always with care.

What are Administrative Records?

Administrative records data are typically defined (1) as being collected as a result of legal or regulatory requirements or transactions, (2) as being a result of program operations rather than intentional research data collection, and (3) as being collected without regard to their potential multiple analytic uses. Administrative records databases represent a huge potential source of data, and research into their use has exploded with the advent of inexpensive electronic storage and processing.

Two errors might be made when researchers are faced with these large, challenging databases, especially those with data problems spread throughout. The first error is simply to assume that the databases are wrong. The second mistake, made because administrative records are official, is to assume automatically that they are correct. Both assumptions are errors. The superior view is to envision a constantly changing population of interest that the database is trying to “keep up” with, “slippage”

(of coverage and of individual data collection) constantly occurring; thus, a model of the relationship between the “real world” and the database is necessary.

How are Administrative Records Data Generated?

Administrative records are both the same as and different from other forms of collected data. All of the same biases occur in administrative records that might occur even in carefully controlled research data collection; however, administrative records are characterized by some additional biases that are exacerbated by the context in which data collection occurs. Thus, it is appropriate to deal with administrative records (e.g., assessor’s records) and mixed administrative/research data (e.g., census forms, traffic count data), and not with secondary data generally. It is the widespread and growing use of such administrative data sets that creates this concern and focus.

Administrative records data can be generated by an agency responsible for administering a program (for example, unemployment insurance or food stamps). Similarly, administrative records data can be generated as a “side effect” of business operations (for example, address lists and sales data for a retail bookseller). Finally, administrative records data may be generated by “respondents” (for example, when a small business becomes incorporated). All of these operations generate data that can be used for analytic purposes. In no case was the data collection “planned” for research purposes—its primary purpose was different.

Figure 1 illustrates the creation, use, and potential errors in an administrative records data set. A record begins as an event or an object in the “real world” outside the database. Some of these events and objects are actually identified (note also that some are there, but do not get identified) as observed events and objects. Some of these observed events and objects get recorded (again, some do not) and become part of the administrative record. These are then arranged in some form of database. Later, when the analyst approaches these records, he or she develops analyses (“queries” in the language of databases) and makes presentation of the results.

At each step in this process, there is potential for error or misinterpretation. At the event/object level, policy changes can change the definition of an event or object (as when the program Aid to Families with Dependent Children ceased to exist, or when a mobile home is recorded from “real” property to “personal” property). As events and objects become observed, the “ontologies” (described in more detail later) that observers use to categorize the world enter in; likewise, some events and objects do not reach a threshold for official notice (as in the deviance literature, wherein the “officer on the

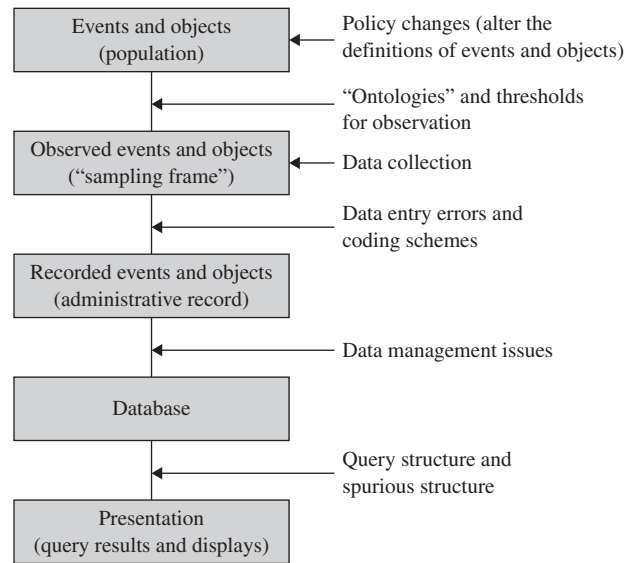

Figure 1 How administrative records data are created and used, and sources of error.

beat” makes the call whether to identify an event as a problem or not). Some of those observed events become recorded, and there is potential for data entry errors and limitations of coding schemes for mapping the real-world events into their database representations. As data are moved from place to place in computer systems, data management problems (corruption in transit, changes in formatting, etc.) potentially arise. Finally, as the analyst uses queries of various kinds to extract data, he or she may discover that the query is either syntactically incorrect in a nonobvious way, or that the query generates results, of which the structure is spurious.

Where do We Find Administrative Records Data?

Typically, “administrative records” is a public sector term. In the private sector, transactions data are typically collected in “data warehouses” and are used for business-related analytic purposes. Both kinds of databases satisfy the preceding definition.

Private Sector Databases

A tremendous variety of business mechanisms generate data that are used by private sector firms for analytic purposes. The credit records that make up individual credit reports and ratings are the most telling example of business records. As an example of the use of these data in a context completely outside their original purpose, these credit records have been used to make small area population estimates. As a further example, consider customers’ sales records. Businesses keep a database on

customer buying habits; the customer data are then linked with external demographic or similar data about those same customers. Using the linked database, a firm can begin to make inferences about which kinds of customers will exhibit which kinds of buying habits.

As a final example, consider medical records. By linking medical records to demographic data obtained from a client, or by linking recorded mortality information to survey data, inferences can be made about the mortality history of certain kinds of survey respondents, or about how certain medical procedures lead to later outcomes.

Public Sector Databases

The public sector is a substantial generator of administrative data. For example, vital records (births, deaths, marriages), although of important civil use, are also very important sources of demographic information for the construction of fertility information, actuarial life tables, and the like. Tax assessor records can be used to augment other address list construction (such as the Census Bureau's Master Address File), or can be used directly to develop housing-unit-based population estimates. Unemployment insurance records are used for evaluating job-training programs, as benchmarks for survey data collected from business establishments, and as sample frames for business surveys.

At the federal level, Internal Revenue Service data collection is used to produce public use data such as the Statistics on Income. But it is also used as a comparison for survey reports of income, for small area income and poverty estimates, for net migration calculations, and for modeling the effects of welfare reform efforts.

How are Administrative Records Data Similar to Other Social Science Data?

Administrative records data are typically most similar to survey data or to secondary data analyses. It is a rare occasion when administrative data approach experimental data. Even some measurements that appear objective (e.g., diagnostic information or demographic information) can be affected by the data collector's motives. In survey research, the researcher would care about respondent's motives (for example, social desirability bias), but even though the respondent does not write a single thing on a survey form, the data collector also has motives and biases.

Administrative records data are similar to other social science data in that the unit of analysis varies across data collection needs. The term "unit of collection" is used here for the administrative unit; for research purposes,

the "unit of analysis" might be something different than the unit of collection. That is, the unit of collection in an administrative database might be a person, a family, or a household, establishment, or firm. However, the unit of analysis for the researcher might be something entirely different from the unit of collection. For example, the Social Security Administration (SSA) maintains a file, the Numerical Identification (Numident) file, that is transaction based; every time a person interacts with the SSA, a new transaction record is generated. But if the researcher wishes to analyze the characteristics of persons, the researcher must somehow translate from transactions to people. As an example of translation problems, about 25% of the persons in the Numident file have transactions with different race codes, because race definitions (both official definitions and self-definitions) have changed over time. Similar variations occur in other codes (for example, gender codes change over time), and it is often not clear which transaction code is "better" for the researcher's purpose. Similarly, Internal Revenue Service 1040 forms have been proposed as a mechanism by which the U.S. population can be enumerated in lieu of a census. However, a Tax Filing Unit (the basic "object" of the 1040 form) is not a housing unit, nor is it necessarily a family, and, further, an address that might be perfectly suitable for interacting with the tax system could be entirely unsuitable for enumeration purposes (e.g., a post office box).

Administrative records data are also similar to other social science data in that, typically, the source agency has its own targeted or defined population of interest. However, again, the researcher must be careful to determine that the source agency's definition of population of interest is close enough to the researcher's population of interest to be useful. [Figure 2](#) illustrates the problem for two examples: On the left is an attempt to capture the resident population of the United States (for example, in the Numident file); on the right is an attempt to capture all employees who work at a particular company (for example, in a company employee database).

Finally, administrative records data are similar to other social science data in that there is an important distinction between cross-sectional versus longitudinal data collection. Certain databases (for example, Internal Revenue Service 1040 forms) are necessarily cross-sectional in some aspects (e.g., number of dependents), and necessarily longitudinal in others (e.g., depreciation of capital assets). But the data collection effort is primarily cross-sectional. In contrast, the maintenance of unemployment insurance wage records (by state Employment Security agencies) is necessarily primarily longitudinal; in order to calculate unemployment insurance benefits, it is necessary to have a "wage history" for the unemployment insurance applicant. The researcher, when using administrative data, must be very careful to ascertain its nature

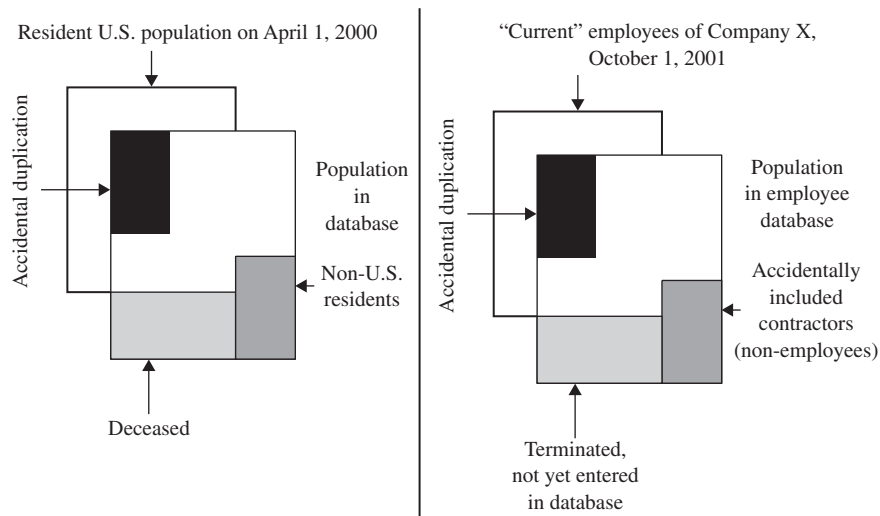

Figure 2 Illustration of coverage differentials between the database and the population of interest.

in this regard, and, of course, the researcher is completely dependent on the administrative agency's definitions.

How are Administrative Records Data Different from Other Social Science Data?

The most important distinction of administrative records data from other kinds of social science data is that the data collection mechanism is not designed by the researcher who wishes to use the data—or by any researcher at all, in most instances. This means that the researcher must become intimately familiar with the program so as to understand the coverage of the data file, unit and item nonresponse patterns in the data, and any response biases that might be present in the data. Furthermore, often there is little the researcher can do to influence the timing and often the format of data receipt.

The second distinction is related to the first: the first or primary goal of the data collected is not research. This means that the usual quality control checks that are usually put in place with the best research data collection are not necessarily in place for the administrative data. There is considerable evidence that, if a particular field is “important” to the administrative agency (either because it ties directly to the agency's funding or to its provision of services), then that field will likely be recorded with some care and some quality control. But if the field is an “add on” or is otherwise superfluous to the agency's mission, it should be used with caution because it is often neglected. (A water company economist's remark is illustrative: “I have 20 years of household level

water consumption data . . . all entered by people who didn't care.”)

A third distinction of administrative records from research data collection is that typically there are no sampling or randomization procedures applied, and therefore statistical techniques that assume such procedures are not strictly appropriate. So, for example, because the administrative database is not a “sample” from any particular “population,” it is generally not possible to estimate sampling variances for statistical tests. If the database contains groups that the researcher wishes to compare (for example, a group that received a special program or treatment and a group that did not), then the researcher most emphatically cannot assume that cases were assigned at random to the treatment and control groups.

Finally, administrative records data have systematic coverage and response biases that research databases usually attempt to address or correct. For example, in the Internal Revenue Service's 1040 Master File, families whose income does not reach the filing threshold are not required to file at all, and hence are systematically undercovered in the database. Care must be taken in using the database; for example, in one study, it was discovered that the systematic undercoverage had noticeable and systematic effects on the county-level population estimation method that used the 1040 database for net migration calculations. Similarly, systematic race response trends have been discovered in Census files; for example, between 1990 and 2000, the number of persons of “American Indian” race increased in far greater numbers than could be accounted for by natural increase. This suggested that people became more willing to indicate “American Indian” heritage in 2000.

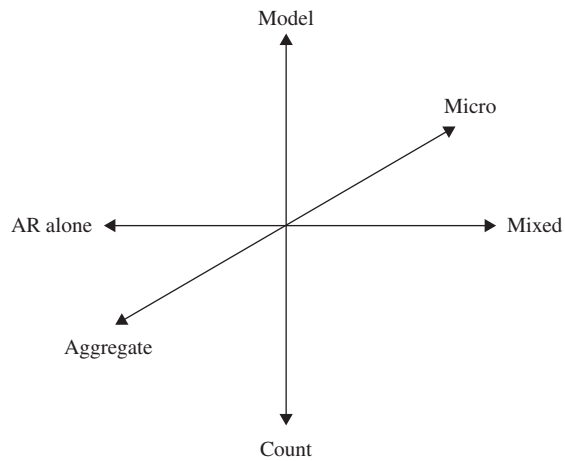

Figure 3 A diagram illustrating the strategic dimensions for using administrative records (AR) effectively.

How can Administrative Records Data be Used Effectively in Social Science?

A plethora of researchers and program evaluators have attempted to test and use administrative records. When deciding to use such a database, it is important to remain clear about how the data are to be used. [Figure 3](#) illustrates strategic dimensions. The representation is as dimensions rather than categories because different approaches use more or less of each strategy, and there is not a clear demarcation between strategies. The vertical dimension is “count-based” versus “model-based” use. In the count-based approach, the administrative data are generally taken as a direct indicator of the phenomenon of interest. In the model-based approach, the administrative record (AR) is used as an indicator or predictor of the events of interest, so a measurement error model or a model in which the administrative data are “auxiliary variables” is more appropriate. The horizontal dimension is using administrative records “alone” or in combination with other data, or “mixed.” This dimension represents the degree of mixing, calibration, or use of multiple data sources with the administrative database. The third dimension is using aggregate tabular data (e.g., counts of Medicare recipients by county) versus using microdata referring to individual records (e.g., individual Medicare recipient data).

Historically, approaches tended to be count based, AR alone, and aggregate in nature. In more modern uses, analysts have tended toward model-based, mixed data, whereby individual microdata records are put to use. A first major count-based/AR alone/micro use of administrative records is program evaluation. In the 1990s, when

the Job Training Partnership Administration used performance measures to evaluate job training outcomes, unemployment insurance (UI) wage records were proposed as an alternative to a 13-week follow-up survey, and certain states determined to use UI records for performance measurement. A similar measure has been proposed for block grant evaluations under welfare reform. The immediate research question emerges: Do these different outcome measures paint the same basic picture? Can they be used interchangeably? The answer is in part “yes” and “no”: although the overall pattern of outcome measures is similar for the two data sources, there are significant “slippages” in which data captured by one source are not captured by the other. A similar requirement is the required reporting under the Community Reinvestment Act (CRA) of 1977. CRA requires that each insured depository institution’s record in helping to meet the credit needs of its community, especially including low-income neighborhoods, be assessed periodically by examining bank operating data on persons who receive loans.

A second major count-based/AR alone/aggregate use of administrative records data is in benchmarking other kinds of data collection or estimates. For example, the Current Employment Statistics (CES) program is a survey of establishments, with the intention of providing current information about the number of jobs in various industries. Later, when the Unemployment Insurance wage records files are complete, these CES statistics are then “benchmarked” to the UI wage records and adjusted to account for coverage differentials. A second example of benchmarking would be comparisons of survey-based or demographic estimates of phenomena (such as food stamp receipt or levels of Medicaid insurance coverage) with independent calculations of food stamp distribution or of Medicaid client data.

A third, major user of aggregate/mixed administrative records (with both count and model aspects) is the Bureau of Economic Analysis (BEA), which produces the National Income and Product Accounts (NIPA). These are the sum of all output or expenditures, or the sum of income or payments to business, government, and individuals. In a simplifying assumption, over a given period of time, one must equal the other. Expenditures (or output) are measured by the value or final price of the nation’s output of goods and services or Gross Domestic Product (GDP). National Income (NI) is simply GDP minus depreciation and consumption allowances. Personal Income (PI) is NI minus indirect business taxes and other adjustments. As such, PI is composed of payments to individuals in the form of wages and salaries (including personal income taxes and nontax payments net of social insurance payments) plus income from interest, dividends, and rent, plus transfer payments (private and public).

Data for NIPA estimates come primarily from administrative records and economic census data. The census

data used are primarily state estimates from the census of agriculture and the census of population and housing. The administrative records used include those originating with the income recipients or from the source, which are a by-product of the administration of various federal and state programs. The most important of these agencies include the U.S. Department of Labor, the social insurance programs of the Social Security Administration and the Health Care Financing Administration, the U.S. Department of Health and Human Services, the federal income tax program of the Internal Revenue Service, the U.S. Department of the Treasury, the veterans' benefit programs of the U.S. Department of Veterans Affairs, and the military payroll systems of the U.S. Department of Defense. The Bureau of Economic Analysis has noted that there is a trade-off to using these data—namely, the cost of collection to businesses and households is low; however, the data do not precisely “match” the series that is being estimated, thus there are adjustments made to compensate for differences in coverage, geographic detail, and definitions. Thus, although this approach is primarily count based, it does incorporate some modeling and adjustment.

A fourth major micro/AR alone/count use of administrative records data is in list construction for surveys and other frames. Two very important examples are the U.S. Census Bureau's Master Address File (MAF) and the Standard Statistical Establishment List (SSEL; now known as the Business Register). The MAF obviously serves as the frame for a decennial census and for the nascent American Community Survey. It is updated on a quarterly basis by the U.S. Postal Service's Delivery Sequence File (DSF). The Standard Statistical Establishment List is a list of all business establishments having one or more employees, including selected data such as name, address, employment size, payroll, Standard Industrial Classification code, etc. It serves as a frame for economic censuses. Prior to the 1997 census, The Census Bureau used administrative records from various federal agencies [primarily the Internal Revenue Service (IRS), the Social Security Administration (SSA), and the Bureau of Labor Statistics] to update the SSEL. Although the MAF and SSEL databases are mixed, the source files used in this example for updating them are pure administrative records sources.

A fifth major example of use of administrative records is in population accounting and similar estimates. The earliest demographic analyses of mortality by Graunt in 1662 were performed using a database of birth and death records obtained from parish registers. (Interestingly, the issues Graunt considered in his work, notably, confidentiality of the data and significant questions about data definitions and quality, are still current and highly relevant.) In evaluating coverage of a decennial census, a standard tool known as “demographic analysis” is used.

Demographic analysis is an aggregate/AR (almost) alone/count approach to population accounting, whereby aggregates are generated from administrative data on births, deaths, immigration, and Medicare enrollment, combined with estimates of emigration and undocumented immigration, to generate a “hard” population estimate. A similar, but microoriented, approach was used in the Administrative Records Experiment in 2000 (AREX 2000), when administrative microdata (individual person, household, and address records) were combined, unduplicated, and allocated geographically to census blocks, generating a low-level “snapshot” of the population in a simulated Administrative Records Census. Finally, the U.S. Census Bureau's postcensal county total population estimates program uses administrative records data for virtually all components of the population estimate. A few similar efforts using private sector credit rating databases have emerged, in which the credit database was used to generate a small area estimate as a “what if” scenario.

Moving away from aggregate/AR alone/count-based uses, it is possible to see much more use of statistical modeling tools. A major example of the use of administrative data in aggregate/mixed/model-based fashion is the U.S. Census Bureau's Small Area Income and Poverty Estimates (SAIPE) program, and related small area estimates. The SAIPE program is tasked with developing estimates of persons in poverty, children in poverty, and median income levels for U.S. counties and areas as small as school districts, for funding allocation purposes. Instead of using administrative data (such as numbers of food stamp recipients) directly in the estimates, these data (and Internal Revenue Service data) are used as predictor variables in a statistical model that combines direct survey-based estimates with model-based estimates in an empirical Bayes framework. Other small area estimation techniques have proposed and/or used administrative data in a similar fashion (as “auxiliary variables” in the model rather than as “direct counts”). Similarly, administrative data have been used as a third source in a multiple-system estimate of population size.

An early example of aggregate/mixed/count- and model-based use is the Local Area Unemployment Statistics (LAUS) program by the Bureau of Labor Statistics, which generates estimates of employment and unemployment for counties. The LAUS program uses unemployment insurance claims in concert with state-level unemployment estimates from the Current Population Survey to generate these estimates. In this case, the estimate is not strictly count based, nor is it strictly model based. Instead, the Current Population Survey generates a number of employed and unemployed persons at the state level, and this number is “distributed” to counties using unemployment insurance claims in those counties (the “population-claims” method). This

general approach, “distributing” a direct estimate using administrative data, appears to have great promise.

A second example of aggregate/mixed (and mostly count-based) use is actuarial life table construction. In order to construct a typical period life table, an age-specific death rate is calculated. Typically, this uses three years of administrative data on deaths, bracketing a census year. These counts are averaged and these deaths are taken as the numerator, with the census midyear population as the denominator, in the calculation of the age-specific death rate.

As the move into modern use of administrative data progresses, researchers have shown more interest in, and seen promise in, linked microdata. In these analyses, individual person, household, or address records are linked to a comparable administrative data source. This linkage has been used for comparisons of survey responses with administrative data. It has also been used for analyses of greater historical scope; for example, the National Longitudinal Mortality Survey links microdata from the Current Population Survey (CPS) to death microdata, in order to make inferences of mortality differentials from CPS characteristics.

A suite of models in use at the U.S. Census Bureau serves as an illustration of the power of linked microdata combined with statistical modeling. The race model estimates the race and ethnic origin of Social Security Number (SSN) holders on the Numident file. The model was needed because the Numident did not categorize race according to Census definitions, and the model effectively estimates what a Numident respondent would have said if their race were recorded using Census definitions. A gender model, similarly developed, estimates the gender of SSN records that do not have a gender recorded (about 6% of the Numident); this model uses first-name sex ratios and name-change flags to predict gender. Finally, a mortality model estimates the probability that a person in the Numident file is deceased, when they are not recorded as deceased on the file. The mortality model uses cohort life tables combined with Numident and other microdata to make this estimate.

What are the Major Strengths and Weaknesses in Using Administrative Records Data?

Strengths

The first major strength of administrative records databases in general is their broad coverage. It is erroneous to assume that the database represents the entire population, as is sometimes asserted (without proof), but nonetheless typically the administrative records

database covers more of the population of interest than does a comparable sample survey. A second strength of administrative records databases is that, typically, the data collection is repeated on a regular basis, as, for example, the Medicare Enrollment Database collects data on new recipients over time. This is a significant advantage for longitudinal analyses. In the performance measurement use of administrative data, such repeatability means that follow-up on job-training clients can take place much later, chronologically, than would be feasible with follow-up or follow-along surveys.

A third strength of administrative records databases is that, again typically, the data collection is continued over relatively long time frames, as, for example, the Social Security Numident file covers essentially every transaction on every Social Security Number since the program’s inception (ignoring the relatively minor “coverage error” caused by the transition from a paper to an electronic system). This has been used to advantage in analyses that compare the Numident file to U.S. population estimates.

Weaknesses

The first, and major, weakness of administrative records comes under the heading of “data quality.” Defining data quality is in itself a challenge. For example, what does it mean for a measured data element to be “right”? How “wrong” is “too wrong”? To illustrate with a simple example, involving a relatively simple element, consider race. Prior to 1980, the Social Security Administration recorded three races (White, Black, and Other or unknown); beginning in 1980, the race codes reflected five races (White, Black, Asian or Pacific Islander, Hispanic, American Indian or Eskimo), and included the codes for Other, Blank, and Unknown. At the same time, the U.S. Census Bureau collected race data using four races (White, Black, Asian or Pacific Islander, and American Indian), which were crossed with ethnicity (Hispanic or non-Hispanic). In Census 2000, an additional race was added (Hawaiian native) and a “mark all that apply” rule was applied, resulting in 63 possible combinations. Thus, if a researcher wishes to link SSA data with Census data, the differential recording of race over time would create substantial comparability problems, but who can say which coding scheme is right?

Every preceding comment can be echoed about every conceivable data element, and the analyst must firmly keep in mind that social definitions and the uses of a database are changing, and that when a coder (either agency personnel or an individual respondent) does not have the categories that are appropriately descriptive, they will most likely choose the best fitting. Choosing the “best fitting” response, rather than choosing the “right” one, is constructing social reality, not necessarily

reflecting it. Because even the simplest data elements run into definitional questions, it follows that the notion of “data quality” must follow from what database experts refer to as an ontology. At its basic level, the branch of philosophy known as ontology is the study of what is—the nature of reality. For a computer database expert, an ontology is a method for encoding the real world in a computer representation. For the analyst of administrative data, differing database ontologies are the primary challenge to proper use.

A second weakness of administrative data is timing of data receipt, especially time lag between the population of interest and delivery of a usable database. Sometimes these time lags are structural in nature; obviously, a database of wage records for a particular year requires that the calendar year is complete and also that all firms have completed reporting their wage records to the state employment security agency. Sometimes these lags are definitional; for example, a child born after December 31 of a calendar year cannot, by definition, be counted as a dependent on the tax return for that calendar year, and thus will not be recorded. Some lags are caused by limited updating of the database; for example, if a person who has a driver’s license dies, that death information is typically not returned to the motor vehicle agency, resulting in systematic overcoverage of older persons.

A third weakness of administrative records data is the requirement for record linkage across databases, with the attendant potential for linkage error, both false links and false nonlinks. If the databases contain unique identifiers, such as a Social Security Number, the linkage is easier, but, even so, some studies have found that 1 in 10 SSNs may be recorded in error in public databases. Without unique identifiers, linkage can still occur, but the problem is harder by several orders of magnitude.

A fourth weakness of administrative records databases can broadly be called coverage error, both in terms of net undercoverage, net overcoverage, and duplication within the database. As noted several times in this article, the population of interest is constantly moving, and the database attempts to keep up with the population, but with slippages. Obviously, some segments of society do not wish to be captured by administrative systems (e.g., undocumented and illegal immigrants, and dedicated criminals), and some persons remain in databases when they should be removed (e.g. émigrés and the deceased).

A final weakness of administrative records databases can broadly be called data limitations. First, administrative records databases often have a very limited scope of data collection, much more limited than a researcher would normally desire. Second, for some databases, missing data are ubiquitous (this is effectively the equivalent of survey item nonresponse, except that “missing at random” and similar assumptions rarely apply). Third, often

administrative data are of limited quality or suffer from systematic bias, which affects their usefulness. Fourth, inconsistent data collection strategies and quality control across different agencies can create a situation wherein a field collected by one agency does not have the same meaning as the same field collected by a different agency. Finally, policy changes may change the definition of events and objects, and the researcher or analyst must be careful to interpret the new definition properly.

A Solution to Some Weaknesses

As more and more researchers and analysts analyze administrative records databases, and discover their strengths and weaknesses, some general frameworks for their use are emerging. Probably the most important technique is “calibration” to external data. The approach is illustrated in Fig. 4. For this illustration, imagine that the administrative records database [consisting of household (HH) characteristics] is being used to make an estimate of the number and amount of food stamp (FS) recipients. In Fig. 4., begin with the initial administrative records database, which will be considered a collection of records X on households across the entire United States. A representative sample of records is chosen from the database and linked (see computerized record linkage and statistical matching) to carefully collected data. In this application, either the Current Population Survey March (Annual Social and Economic) Supplement or Survey of Income and Program Participation would serve this function. The carefully collected survey data are treated as representing “ground truth,” to which the administrative records data will be calibrated. (The external data are treated as metaphorical “ground truth,” recognizing that every data collection contains error.)

The next step is to estimate a model that “predicts” the carefully collected data (Y) from the data in the administrative records database for the same household. This model is crucial; it must have very strong goodness-of-fit properties. The final step is to use the fitted model to augment the database. Because the database contains the right-hand side variables X , the database can be augmented with estimated values \hat{Y} , using the model $\hat{Y} = f(X)$. This model can have hierarchical structure, can be Bayesian if needed, and is, by design, calibrated to the survey data. The augmented database is the best estimate of what the database would have said, if the careful data collection had taken place over the entire database. The strength of this approach is that it makes use of the best of both worlds: the high quality and content of a sample survey, and the wide coverage of the administrative records database. By no means is this model the only approach to improving data quality in administrative records databases, but it and close

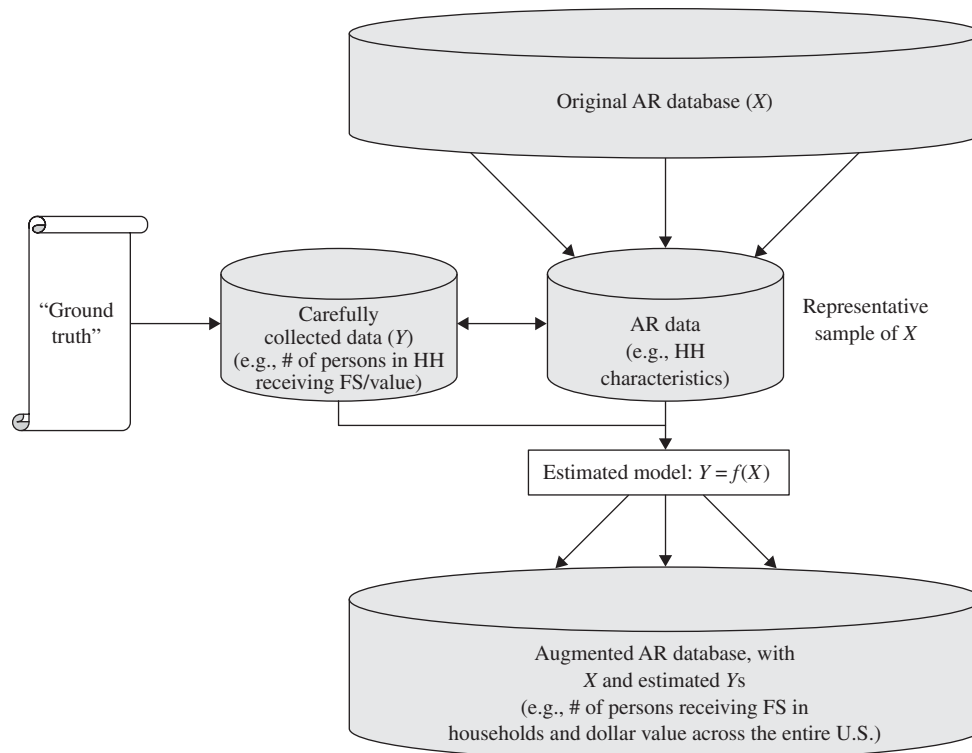

Figure 4 Illustration of “calibrating” administrative records (AR) data to an external data source. HH, Households; FS, food stamps.

relatives are currently the most common approach and appear to have the most promise.

What is the Future of Administrative Records Research?

Researchers of social measures stand on what can be described as an historical cusp: the new statistical era touted by Prevost in 1996 is coming, and a whole array of new databases will be compiled for a wide range of purposes. Many of these will be linked; others will be analyzed in a standalone fashion. No matter what the form of the analysis, decision-makers will be clamoring for information from their databases. Thus, the researcher who can work with such records and apply substantive reasoning to the results will have plenty to do over the coming decades. However, with widespread linkages of microdata from different databases, major privacy concerns have emerged. Who shall be the “data steward”? Or, more directly: Who shall watch the watchmen? No doubt the future will see greater legal definition and organizational regulation of linked administrative and mixed databases.

Age, Period, and Cohort Effects

Norval D. Glenn

University of Texas, Austin, Texas, USA

Glossary

age effect A consequence of influences that vary by chronological age.

age–period–cohort conundrum A specific case of the identification problem in which the interrelated independent variables are age, period, and cohort.

birth cohort The individuals born during a given period, such as a year or a decade (the kind of cohort usually studied in cohort analyses).

cohort The individuals (human or otherwise) who commonly experienced a significant event during a specified period of time.

cohort effect A consequence of influences that vary by time of birth or time of some other event (such as marriage) that defines a cohort.

identification problem The situation that exists when three or more independent variables that may affect a dependent variable are interrelated so that the multiple correlation of each independent variable to the others is unity.

period effect A consequence of influences that vary through time.

Age, period, and cohort effects are estimated by sociologists and other social scientists primarily to understand human aging and the nature of social, cultural, and political change.

Introduction: The Age–Period–Cohort Conundrum

In the social and behavioral sciences, there are often reasons to think that three or more independent variables simultaneously affect a dependent variable when each of the independent variables is a perfect linear function

of the others. When all but one of the independent variables are held constant, the variance of the remaining variable is zero, because the multiple correlation of each variable to the others is unity. Therefore, it is impossible through any straightforward method to estimate the effects of all of the variables, and yet omitting one of them from the analysis will almost certainly render the estimates of the effects of the other independent variables inaccurate. This condition, known as the “identification problem,” almost always afflicts research designed to assess the effects of a difference between two variables, as when quality of marriage may be affected by the wife’s values, the husband’s values, and the difference between the spouses’ values.

The classic case of the identification problem, however, is the age–period–cohort conundrum, or the confounding of the effects of influences associated with chronological age, time of measurement, and date of birth (if human individuals are the units of analysis). Hypotheses abound about the effects of all three of these classes of influences. For instance, it is believed that participation in conventional crime may diminish due to declines in energy and risk-taking propensities associated with biological aging, which would be an age effect. Any changes in attitudes, behaviors, or emotions as a result of current events, such as the terrorist attacks on the United States on September 11, 2001, are period effects. And any enduring consequences of being born at a particular time, and thus of growing up during a particular era (such as the Great Depression or the Cold War) are examples of birth cohort effects. Another important kind of birth cohort effect is the result of the number of persons in the cohort relative to the numbers in earlier and later ones. For instance, members of large and small cohorts experience different degrees of competition for the good jobs when they enter the labor force, which in turn may affect several kinds of attitudes and behaviors.

The age–period–cohort conundrum can be illustrated by the use of a standard cohort table, in which multiple sets of cross-sectional data (data for one point in time) relating age to a dependent variable are juxtaposed and in which the intervals between the periods for which there are data are equal in years to the range in each age category. For instance, if 10-year age categories are used, data gathered at 10-year intervals are presented, as in Table I, in which the dependent variable is whether respondents to the 1974, 1984, and 1994 American General Social Surveys said they favored the death penalty for persons convicted of murder. In such a table, the trend within a cohort can be traced by starting with any but the oldest age category in the left-hand column and reading diagonally down and to the right. For instance, according to the data in Table I, in the cohort that was 20–29 years old in 1974, the percentage approving of the death penalty went from 58.2 in 1974 to 73.6 in 1984, to 79.5 in 1994. This increase may have been an age effect, because the cohort grew 20 years older, or it may have been a period effect reflecting general changes in society during the two decades covered. Or it may have been a combination of age and period effects. In other words, in this or any other cohort diagonal, age and period effects may be confounded. Likewise, age and cohort effects may be confounded in each column, and period and cohort effects may be confounded in each row, of a standard cohort table.

It is obvious that a simple examination of Table I cannot reveal the extent and nature of any age, period, and cohort effects reflected in the data. What has not been evident to many researchers interested in the age–period–cohort conundrum is that no routinely applied statistical analysis of the data can, by itself, be relied on to provide accurate estimates of the effects. The reason is illustrated by the different combinations of effects that could account for the data in Table II, which is a standard cohort table reporting hypothetical data. The simplest interpretation of the data is that they reflect pure linear age effects, whereby each additional 10 years of age produces a five-point increase in the dependent variable. For

Table I Percentage of Respondents to the 1974, 1984, and 1994 American General Social Surveys Who Said They Favored the Death Penalty for Persons Convicted of Murder^a

Age (years)	1974		1984		1994	
	%	n	%	n	%	n
20–29	58.2	385	79.9	368	78.5	467
30–39	67.7	279	73.6	289	80.0	651
40–49	68.5	265	76.4	231	79.5	578
50–59	74.8	257	78.0	181	78.9	387
60–69	70.4	187	76.7	155	82.3	238

^aTo increase representativeness, data are weighted by number of persons age 18 and older in respondent’s household.

some dependent variables, this might be the only plausible interpretation, but, as the alternative explanations at the bottom of the table indicate, it is not the only logically possible one. Rather, an infinite number of combinations of age, period, cohort effects could produce the pattern of variation in the dependent variable shown in the table. When the pattern of variation is not as simple as that in Table II, which is usually the case, the combination of effects producing the data must be somewhat complex. It should be obvious that no mechanically applied statistical analysis can reveal which of the many possible complex combinations is the correct one. One kind of complexity, however, sometimes aids interpretation of the data. If there is an almost completely nonlinear pattern of variation by either age, period, or cohort that is uniform across the categories of the other two variables, as in Table III, there is only one reasonable explanation for the data. In the case of Table III, for instance, it is hard to imagine that any kinds of effects besides nonlinear age

Table II Pattern of Data Showing Pure Age Effects, Offsetting Period, and Cohort Effects, or a Combination of Age Effects and Offsetting Period and Cohort Effects^a

Age (years)	Year					
	1950	1960	1970	1980	1990	2000
20–29	50	50	50	50	50	50
30–39	55	55	55	55	55	55
40–49	60	60	60	60	60	60
50–59	65	65	65	65	65	65
60–69	70	70	70	70	70	70
70–79	75	75	75	75	75	75

^aNumbers in the cells are hypothetical values of a dependent variable. Alternative explanations: (1) Each 10 years of aging produces a 5-point increase in the dependent variable. (2) There is a 5-point per 10 years positive period effect on the dependent variable and a 5-point per 10 years negative cohort effect. (3) There is some combination of age and offsetting period and cohort effects on the dependent variable. An infinite number of combinations of such effects could produce the pattern of variation in the dependent variable shown in the table.

Table III Pattern of Data Showing Nonlinear Variation in a Dependent Variable That Can Reasonably Only Be Interpreted to Reflect Age Effects^a

Age (years)	Year					
	1950	1960	1970	1980	1990	2000

40–49	62	62	62	62	62	62
50–59	62	62	62	62	62	62
60–69	50	50	50	50	50	50
70–79	45	45	45	45	45	45

^aAssuming no effects from differential mortality. Numbers in the cells are hypothetical values of a dependent variable.

effects are reflected. On the rare occasions when the data fall into such a pattern, interpretation can defensibly be based on simple inspection of the data in tabular form. Usually, however, no such straightforward interpretation of cohort data is justified, which has led researchers to use statistical methods to try to disentangle age, period, and cohort effects.

Statistical Attempts to Separate Age–Period–Cohort Effects

The most widely used statistical method to try to separate age, period, and cohort effects was introduced three decades ago by Mason and co-workers. Variants of the method are still frequently used, a recent example being in Robinson and Jackson's study of trust in others. The Mason *et al.* method is a way to estimate simultaneously the effects of age, period, and cohort by making simplifying assumptions—identifying restrictions—that break the linear dependence of each variable on the other two and thus allow estimation of a regression model in which each of the variables (or occasionally just one or two of them) is entered as a set of dummy variables. The method requires only that the effects of two categories (usually two adjacent ones) of either age, period, or cohort be assumed to be equal (for examples, see Tables IV and V). Of course, when a set of dummy variables is entered as independent variables in a regression equation, one of the variables must be omitted, and the Mason *et al.* method requires only that one additional variable from one of the sets be dropped. This simple procedure allows the regression program to run and generates estimates of the effects on the dependent variable of the age, period, and cohort dummy variables. Stronger identifying restrictions can be made, and proponents of the method recommend additional assumptions if they seem justified on the basis of theory or what is already known about the phenomena being studied. If it is known with confidence that either age, period, or cohort has no effects, that variable can be omitted from the analysis and the age–period–cohort conundrum disappears.

This method has often been used as an all-purpose solution to the identification problem in cohort analysis (though Mason *et al.* essentially say in a footnote that it cannot be used to separate linear effects) that is assumed to yield reasonable estimates as long as the assumptions on which identifying restrictions are based are not gross distortions of reality. The reasoning has been that the effects of adjacent narrowly defined age, period, or cohort categories are unlikely to be very different and that the error involved in assuming equal effects is only on the order of that involved in grouping the values of a continuous variable. Use of rudimentary “side information” (information

^b Reference category; value set at zero.

from outside the cohort data being analyzed) should, according to this point of view, assure that the estimates of effects will be about as nearly correct as the levels of sampling and measurement error allow.

Applying the Mason *et al.* method to the data in Tables II and III illustrates that this reasoning is flawed (see Tables IV and V). (For these analyses, individual-level data sets were constructed, with 20 cases in each cell of the tables and identical variable values for all cases in each cell.) In each of the first three models in Table IV, the equality restriction is applied to two adjacent categories of either age, period, or cohort. Although the restrictions in the different models are equally defensible and involve equal and small distortions of reality, which restriction is used makes a huge difference. Assuming two categories of either period or cohort to have equal effects leads to a pure age-effects interpretation, whereas assuming two categories of age to have equal effects leads to an offsetting-period-and-cohort-effects explanation.

Making two equality assumptions in Model 4 leads to a three-variable solution to the age–period–cohort conundrum. It follows that it must be known *a priori* whether the one-, two-, or three-variable solution is the correct one; the Mason *et al.* method cannot be used to decide which is correct when the variation in the data is linear, as it is in Table II.

Although the Mason *et al.* method has often been applied to data in which the pattern of variation in the data is basically linear, a careful reading of the 1973 article by Mason *et al.* would prevent such use. Buried in a footnote of the article is the following statement: “These pure effects [the hypothetical effects used to illustrate the method] have deliberately been made nonlinear in form We create our data in this way because perfectly linear pure effects are inherently ambiguous to interpret, and can be estimated equally well by the pure effect variable or by the two remaining variables in cohort analysis” (p. 248). When the effects are nonlinear, the Mason *et al.*

method theoretically could work well, but in practice, it is unlikely to do so. The accuracy of estimates of effects can be assessed when the method is applied to the data in Table III (Table IV), because the nature of the effects is not in doubt. The first three models in Table V use equality restrictions that are precisely correct, and each model estimates the effects correctly. The fourth model, however, uses an equality restriction when the effects of the two categories are similar but not identical. Although the assumption of equality is not a gross distortion of reality, the estimates of effects are grossly in error. Unfortunately, a researcher is almost never able to make an equality restriction based on an assumption known to be precisely correct, and precise correctness is necessary for the method to work well.

Other statistical methods to deal with the age–period–cohort conundrum have been rarely used and are even less satisfactory than the Mason *et al.* method and its variants. An example is a method developed by Japanese scholar T. Nakamura and introduced to American social scientists by Sasaki and Suzuki. Based on Bayesian statistics, the method selects the simplest combination of age, period, and cohort effects that could account for a set of cohort data, as simplicity is operationally defined by the method. Stated differently, the method is based on the invariant assumption that “successive parameters change gradually” (p. 1063). This assumption may often be correct, but because neither theory nor “side information” is used to assess its probable correctness in the case at hand, the method cannot be relied on to select the proper combination of age, period, and cohort effects. If this method is used, theory and side information should be used to assess the credibility of the estimates it yields.

An additional reason for being wary of statistical attempts to separate age, period, and cohort effects is that the Sasaki and Suzuki method and all major variants of the Mason *et al.* method are based on the assumption that the effects are additive, even though it is likely that age, period, and cohort interact in their effects on most dependent variables of interest to social scientists and psychologists. According to theory, supported by a great deal of empirical evidence, young adults tend to respond more to stimuli for change than do older adults, so that period effects generally vary by age and thus among cohorts of different ages. For instance, when major changes in attitudes occur, the change tends to be greater at the younger than at the older adult ages. Furthermore, many kinds of age effects are likely to change through time and thus to vary among birth cohorts. Social expectations for behavior at various chronological ages have shifted considerably in recent decades, an example being an increased expectation for middle-aged and older people to be sexually active. Biological aging has changed only moderately, but some aspects

of social and psychological aging have changed more substantially.

If, as is argued here, age–period–cohort interactions are ubiquitous, additive age–period–cohort statistical models would not be very useful, and would often be misleading, even if they were not afflicted with other problems.

Alternatives to Age–Period–Cohort Statistical Models

The fact that age–period–cohort statistical models are rarely useful and often lead to incorrect conclusions does not mean that social and behavioral scientists must stop asking questions about the kinds of effects the models estimate. Other kinds of statistical models and informal assessments of data can often lead to defensible conclusions about the effects.

If the interest is in the effects of cohort size, for instance, an age–period–cohort-characteristic (APCC) model can be employed. Although it is impossible to control age and period and let cohort vary, it is possible to control age and period and let certain characteristics of cohorts, such as size, vary. The only requirement is that the characteristic must not bear a strong linear relationship to cohort, because, if it does, its effects will be confounded with those of age and period. O'Brien and his collaborators have used APCC models to estimate the effects of cohort size and certain family characteristics that vary by cohort on such variables as homicide commission and victimization.

Often hypotheses about age, period, or cohort effects can be made more specific, because usually it is other variables associated with these three demographic variables that are believed to have effects. For instance, it may be career progression or the taking on of family responsibility that is believed to have a particular “age effect.” Or cohort effects may be attributed to differences in the sizes of communities of origin among people born at different times. If these more specific variables can be measured and incorporated into analyses, it may be possible to avoid the age–period–cohort conundrum.

Informal means of examining data for evidence of age, period, or cohort effects are varied and must be tailored to the task at hand. There is no formula, no cookbook approach, that will work well on all occasions. Often, however, examining the trend in the dependent variable among the youngest adults is useful for detecting evidence of period influences. Although period and cohort effects may be confounded in this trend, in the case of many behavioral, attitudinal, and other psychological dependent variables, both kinds of effects are likely to be rooted in changes in period influences. Consider, for instance,

how the data in Table I should be interpreted. The cross-sectional data in the first column and the intracohort trends both suggest a positive age effect on approval of the death penalty; all eight 10-year intracohort changes shown are upward. However, the upward trend at ages 20–29 from 1974 to 1984 is evidence for rather strong period influences toward approving of the death penalty. Therefore, the intracohort trends could well be entirely period rather than age effects. And the positive relationship between age and support of the death penalty shown for 1974 could have resulted from earlier anti-death-penalty period influences that affected younger persons more than older ones. Of course, no serious cohort study of attitudes toward the death penalty would be based only on the data in Table I, especially because the question yielding the data has been asked on other American General Social Surveys, nor would the study stop with a simple examination of tabular data. However, given the basic evidence available, a definitive answer as to whether there has been an age effect on attitudes toward the death penalty would elude even the most sophisticated study possible.

Informal means of examining cohort data may not be satisfying to persons who have a high need for certainty, but accepting the fact that there is always some ambiguity in the evidence concerning age, period, and cohort effects is more scientific than dogmatically embracing statistical model estimates that are likely to be substantially in error.

Conclusions

Social and behavioral scientists have formulated many important hypotheses about the effects of age, period, and cohort, and research to test these hypotheses should not be abandoned. However, researchers should recognize that definitive evidence concerning many of the hypothesized effects may never be forthcoming. Belief that statistical age–period–cohort models can provide such evidence has led to much pseudorigorous research and almost certainly to many incorrect conclusions. If statistical model testing is used to estimate the effects, the credibility of the estimates should be evaluated on the basis of theory, common sense, and *a priori* knowledge of the phenomena being studied. It is important to avoid letting the model testing create an illusion of rigor that will prevent the proper application of human judgment in the research process. It is often preferable to skip the statistical model testing and proceed directly to more informal means of distinguishing age, period, and cohort effects. Although these methods are fallible, they are generally recognized as such and thus are less likely than formal model testing to lead to overly confident conclusions.

Aggregation

D. Stephen Voss

University of Kentucky, Lexington, Kentucky, USA

Glossary

aggregation bias Systematic inaccuracy induced in a method of statistical inference because of patterns in the process of grouping data.

areal units problem The recognition that the same individual-level data can produce a wide variety of aggregate-level statistics depending on the geographical areas into which the individuals are grouped.

cross-level inference When analysts attempt to generate statistics, derive estimates, or draw inferences for units of analysis at one level of measurement using data measured at a different level.

ecological inference A generic phrase describing the attempt to estimate individual-level behavior using aggregate data.

ecological regression Usually associated with Leo Goodman, refers to the use of linear regression to estimate individual-level behavior using aggregate data.

King's EI A method of ecological inference based on maximum-likelihood estimation using the truncated bivariate normal distribution. King's approach has no formal name, but it is commonly called "EI" after the software distributed to implement it.

neighborhood model An ecological inference model that assumes variations from aggregate unit to aggregate unit are entirely contextual, and therefore not compositional.

weighted average A version of the standard mean or average that is invariant to the level of aggregation because of the method of weighting each unit.

Aggregation describes a broad condition in which social indicators have been clustered together, resulting in a loss of information. Data may be clustered across time or within time periods. They may be clustered across space or within geographical boundaries. They may be clustered across social groups or across countable events.

Furthermore, the method of aggregation may be through summation, through compilation into ratios or some other summary statistic, through collection in data tables such as cross-tabulations that reach across multiple variables, or through some other form of compilation. The motives for aggregation in social measurement also vary widely. Aggregation can result from an inherent limitation in how social behavior is observed and therefore must be measured, from a desire to simplify data collection and storage on the part of the researcher, or from an attempt to constrain the scope of an analysis.

The wide variety in dimensions, methods, and motives means that aggregation embraces an entire class of social measurement issues. It is not a single dilemma of data collection or analysis with its own conventional terminology or its own conventional solutions; indeed, many of them have very little in common. Aggregation is not a problem endemic to one social science discipline but one that embraces just about all of them. This article therefore lays out the conceptual issues involved with aggregation as inclusively and broadly as possible. It illustrates the problems with aggregation by concentrating on the most commonly discussed example in social science research: the ecological inference problem.

Introduction

Social science research often relies on quasi-experimentation, in which the researcher analyzes data produced incidentally by the social system rather than data produced experimentally as a direct and controlled outgrowth of the work. In fact, it is not irregular for analysts to exercise minimal control over the data available for research, aside from choosing among one or more preformed data sets to exploit in secondary analysis. Analysts

therefore may not be able to select the measurement theory guiding collection of raw data.

The separability of data generation and data analysis presents a particular risk. Available information on a social phenomenon may be measured at a level distinct from the level at which relevant theories operate. The researcher may wish to theorize about the forces determining whether individuals commit crime but may have access only to neighborhood crime statistics. The researcher may wish to understand why nations protect free expression through their domestic policies, but may be stuck using survey data measured at the individual level. The researcher may wish to characterize school districts demographically, but may have data collected on zip codes. The causal process linking behavior at one level with behavior at another may be fairly complicated.

At root, determining the proper unit of analysis is a theoretical as well as a technical question. Hypothetical narratives intended to describe particular social processes may operate differently from one level of analysis to the next and may not offer any observable implications at all for some levels. A researcher, therefore, must specify theoretical claims carefully to avoid fallacious inference—that is, to avoid looking for social phenomena where a theory does not posit they ought to appear.

Awareness of this conceptual problem has a long history, although statistical attempts to escape the frustrations of “cross-level inference” have a much more recent vintage. For example, classical liberal theorists recognized that a successfully functioning economy did not need careful mercantile policymaking; it could result from the actions of individualistic profit seekers with no intent to improve social productivity or even awareness that their actions were creating that public good. Successful public policy did not require a philosopher king trained in the art of decision making; it could emerge from the multitude of highly individual and even parochial demands placed on a political system through electoral competition or legislative representation. Spiritual truth need not emerge through a religious bureaucracy dedicated to specialized theological study; it could emerge from the decentralized moral insights of a humble but literate people who read their Bible or learned the spiritual lessons of the natural world. Such a complex mechanism as the human body could function although composed of nothing more than a cluster of body parts unaware that they are sustaining life, unaware of each other, and for that matter entirely lacking in self-awareness. This was a key insight of the Enlightenment in particular: collect a large enough sample of workers or citizens or religious seekers, and their individual errors will cancel out sufficiently to bring the aggregate much closer to truth than a centralized process would. The process of aggregation could produce a whole much greater than the sum of its parts.

This central insight has remained with the social sciences as they have grown more formalized. Each social science discipline has its own language for discussing the problem of linking theory and data at the proper unit of analysis. Economists have termed the danger a “fallacy of composition.” Microeconomic and macroeconomic patterns and relationships may differ sharply. Anthropologists worry that the results of etic observation (simplified, observation from the perspective of the outsider) may produce sharply different results from emic observation (again, simplified, observation from the perspective of someone within a social system). Quantitative researchers have long recognized that regressions performed on a cross-section of data will produce different results from those produced within a single panel or identifiable unit across time. In each case, the specific problem falls into this same general class: theories may have different observable implications, depending on the sort of data collected and how they are analyzed.

Cross-Level Inference

Aggregation most commonly poses a threat to inference when the theory and the data for an analysis appear at different levels. Practitioners are especially aware of the pitfalls of cross-level inference when they need to derive individual-level quantities of interest from data aggregated to a higher level. In these circumstances, it is common to fear “an ecological fallacy” caused by aggregation bias. However, the problem can be just as serious in less familiar circumstances, as when the analyst wishes to understand the phenomena driving aggregate-level patterns using only individual-level data, or when data for an analysis appear at multiple levels of aggregation.

Seeking Statistics Invariant to Aggregation: The Conceptual Problem

Regardless of the nature of any particular cross-level inference, the essential problem is the same: statistics computed at one level of analysis need not correspond to parallel statistics (or parameters) applicable at another level. Averages computed at one level of aggregation usually will not be the same as averages computed at another level of aggregation, or at the individual level. The average per capita income in the United States is not the same as the average state-level per capita income. The proportion of voters backing the Republican U.S. presidential candidate is never the same as the average level of Republican support across the various states.

Correlations also change depending on the level of statistical analysis. To take one famous example: just because literacy tended to be higher in places where

immigrants were more numerous, at least during the early 20th century, literacy was not actually higher among the immigrants themselves. The correlation at the individual level went in the opposite direction from the correlation at the aggregate level. Similarly, education is highly related to political participation in the United States—educated citizens are much more likely to vote. Over time, however, the population has become more educated, but voter turnout has declined; the correlation goes in the opposite direction temporally.

As a final example, measures of dispersion can change sharply across levels of analysis. For example, the African American population varies much more widely across voter precincts or census blocs, because of patterns of residential segregation, than it does across counties or states. By contrast, during any one term the U.S. Supreme Court may vary substantially in its ideological orientation from case to case, but the typical Supreme Court justice is fairly consistent.

In theory, a set of individuals could be divided up in an infinite number of ways, making aggregate-level statistics arbitrary—more a function of the aggregation decisions than the underlying behavioral regularities. Of course, the analyst rarely makes these aggregation decisions. Indeed, if the analyst's theoretical interests lie at the individual level, the logical solution would be to avoid aggregating in the first place. The aggregation usually emerges from a process that the analyst cannot manipulate and, even worse, may not be able to observe. Various areal units—nations, states or provinces, counties or wards or cities, and neighborhoods or precincts—are defined by borders that emerge haphazardly and may change over time. Furthermore, the people who live in them can move around, which further complicates any attempt to discern the pattern sorting individuals into units. Statistics may be variant with respect to geography, in other words, a phenomenon known as the areal unit problem.

Seeking Statistics Invariant to Aggregation: The Weighted Average

The usual burden for methodologists working on cross-level inference is to identify statistics that are invariant to aggregation, which will produce quantities of interest at the proper level of aggregation even if computed from data at a different level. The best-known example of a statistic invariant to aggregation is the weighted average. A standard mean for variable x computed at the individual level takes the following form:

$$\frac{\sum_{i=1}^n x_i}{n} \quad \text{or} \quad \sum_{i=1}^r x_i f(x_i),$$

where n is the number of individuals, r is the number of values that the variable takes on, i serves as the index for

counting each individual, and $f(\cdot)$ represents the relative frequency (in a sample) or probability (in a population) for each value x_i .

If variable x is computed at the aggregate level, the formula for its mean looks almost identical. Indeed, it is parallel except that the values of x describe quantities for an aggregate unit rather than for an individual, and the values are summed for m aggregate units across the index j :

$$\frac{\sum_{j=1}^m x_j}{m} \quad \text{or} \quad \sum_{j=1}^m x_j f(x_j).$$

These two formulas may look the same, but the quantities may be quite far apart, depending on how the individual-level values of x are distributed. Let us say, for example, that x represents per capita income. If groups were divided into quartiles, with per capita income averaged for each quartile, the mean of those numbers probably would resemble the individual-level mean fairly closely. But suppose that the richest half of the population appeared in one group, whereas the remaining half of the population was divided up into nine other groups. The group-level average would be especially low, because it would include nine per capita figures below the median income level and only one above it.

The weighted average solves this problem by taking into account how many people are clustered into each group. It prevents dilution of individual-level information contained in large groups and prevents overemphasis of individual-level information contained in smaller groups. The formula for the weighted average might be expressed as such:

$$\sum_{j=1}^m x_j \frac{n_j}{n},$$

where n_j represents the number of individuals in group j . In short, each aggregate quantity receives a weight representing its proportion of the overall population or sample. Group the people in different ways, and their average will always be weighted according to each group's size.

While the weighted average is a useful statistic, the most common problem with cross-level inference is not so simple to solve: the ecological inference problem. Sometimes the aggregation process tosses away individual-level information such that no simple computation or weighting can restore it—yet the analyst wishes to estimate how individuals behaved. When faced with this near-intractable (if not intractable) barrier, the analyst customarily needs to make an assumption about the aggregation process or the pattern of lost information in order to derive useful quantities of interest. The next

section therefore turns to this critical instance of data aggregation and its pitfalls.

Ecological Inference and Aggregation Bias

Aggregating data almost always discards information. To take one example, which will appear throughout this section: whites and blacks choose whether to register, whether to turn out, and how to vote—but analysts seldom know how racial groups differ in these forms of behavior. Instead, they usually only possess aggregated statistics that summarize the behavior observed in entire areal units. They will know how an electoral unit voted; they often know the racial breakdown of an electoral unit. Occasionally the analyst might know how groups differed in their registration rates, or even in their turnout rates. Thanks to the secret ballot, however, analysts never know for sure how groups voted. Studying racial voting behavior requires some form of estimation.

Table I summarizes the typical situation for areal unit i , with the simplifying assumption that the population is divided into only two groups, blacks and whites. One knows the totals for each row and each column, represented by the quantities appearing along the margins of the table. These quantities can be re-expressed as proportions by dividing each cell and each marginal by N_i . The ecological-inference problem is that one does not know the internal cells of the cross-tabulation, thus the question marks. Data sources seldom provide this information. Some method of inference is necessary.

It is usually helpful to think of this table as a series of discrete two-by-two cross-tabulations: the decision to register or not, to turn out or not, and to vote for one candidate or another (say, for left-wing or right-wing candidates). An analyst may choose to disregard the three-stage nature of the mobilization process, say by estimating directly the proportion of eligible adults who vote or even who select a particular candidate. However, leaving the three-stage process as a black box and simply estimating vote choices increases the likelihood of

Table I The Ecological Inference Problem^a

	Left-wing vote	Right-wing vote	No vote	Unregistered
Voting-age whites	?	?	?	?
Voting-age blacks	?	?	?	?
All races	V_i^L	V_i^R	$(R_i - T_i)$	$(1 - R_i)$

^a Table presents the typical situation faced in areal unit i , for which marginal data is available but crosstabulations are not.

unreliable and poorly understood estimates. Analysts therefore customarily isolate portions of the three-stage process to recognize that they are politically distinct phenomena. Conceptually, if we divide eligible voters into black voters and white voters, the process for areal unit i would consist of three equations:

$$R_i = \phi_i^b \times X_i + \phi_i^w \times (1 - X_i),$$

where R is the general registration rate for eligible adults, X represents the proportion of the voting-age population that is African American, and ϕ^b and ϕ^w represent the registration rates among blacks and non-blacks, respectively.

$$\begin{aligned} T_i &= \beta_i^b \times \phi_i^b / (\phi_i^b + \phi_i^w) X_i + \beta_i^w \times \phi_i^w / (\phi_i^b + \phi_i^w) \\ &= \beta_i^b \times R_i^b + \phi_i^w \times R_i^w, \end{aligned}$$

where T is the general turnout rate for eligible adults, R_i^b and R_i^w represent the proportion of registrants who were black and non-black, and β^b and β^w represent the turnout rates among blacks and non-blacks, respectively.

$$\begin{aligned} V_i^L &= \lambda_i^b \times \beta_i^b / (\beta_i^b + \beta_i^w) + \lambda_i^w \times \beta_i^w / (\beta_i^b + \beta_i^w) \\ &= \lambda_i^b \times T_i^b + \lambda_i^w \times T_i^w, \end{aligned}$$

where V_i^L is the general rate of left-wing voting among those who turned out, T_i^b and T_i^w represent the proportion of voters who were black and non-black, and λ_i^b and λ_i^w represent the left-wing rate of support from black and non-black voters. Customarily, analysts skip the first step and simply use X_i and $(1 - X_i)$ rather than the racial registration rates in the second identity.

These three equations are called identities because if all four quantities on the right-hand side of each equation were known, they would compute exactly to the left-hand side. There would be no error term. For example, the combined black and white registration in an electoral unit consists of the registration rates for the two groups weighted by their relative sizes. As should be clear, however, some of the terms on the right-hand side of each equation do not appear among the marginals. Those are the frequencies missing from the cross-tabulation that ecological analysis typically seeks to estimate or contextual analysis wishes to probe. They also represent the unavailable numbers that cause ecological inference techniques to dominate the evidentiary record in voting rights cases.

Conventional Solutions to the Ecological Inference Problem

Different researchers approach aggregate data with different motives. Some seek descriptive information

about how groups behaved within an areal unit. That is, they seek across-group comparisons. For example, litigants may wish to establish the existence of racial bloc voting within a particular locale. Others would like to consider how a group's behavior shifted over various locales. That is, they seek within-group comparisons. For example, a political scientist might wish to establish that wealthier voters supported the candidate who promised tax breaks or that more-educated voters supported a gay rights referendum. These differing incentives shape the solutions that analysts prefer.

Informed Assumptions

Sometimes researchers possess such strong prior assumptions about racial behavior that they are willing to assume how one group behaved. If the right-wing candidate is a vicious race baiter, such as George Wallace or former Klansman David Duke, researchers may be willing to assume that no blacks appeared in the constituency (i.e., that $\lambda^b = 0$). If the left-wing candidate is a black Democrat, researchers may be willing to assume that no black voter crossed over to support a white Republican (i.e., $\lambda^b = 1$). Relying on informed assumptions is particularly tempting, because it allows researchers to assume that they can fill in every question mark in the cross-tabulation.

The most obvious limitation of this approach, of course, is that it is only feasible for severely polarized elections. For whatever bizarre reason, even the most extreme race baiters will draw some black supporters. Blacks never support black candidates unanimously. Once the researcher's interest expands to more mainstream elections, absolute priors of this sort become extremely difficult to defend. Furthermore, the bias introduced by incorrectly assuming behavior will be proportionate to group densities in each locale. Let us say, for example, that the true black rate of support is 0.025 but analysts assume it is 0.00. This error will throw off estimates of white behavior by 0.025 in a locale that is half black, but would not distort it much at all in a heavily white locale.

The informed assumptions approach also provides no method for considering the multilevel process that leads to voting behavior. Even in the rare case when informed assumptions about racial voting behavior are plausible, there are no defensible prior assumptions about racial turnout rates. Of course, analysts sometimes assume (implicitly or explicitly) that black and white turnout rates are the same, skipping straight to an analysis of vote choice. Research on political participation regularly contradicts this claim, however, and to assume equal turnout rates fallaciously will cause bias in the estimated white vote to vary systematically with African American mobilization rates.

Homogeneous Unit Analysis

The previous approach satisfies those who wish to study within-group variation. It requires no computer-intensive

analysis and generates no measures of uncertainty. A different, but equally simple, alternative appeals to analysts who wish to compare across groups. They single out fully segregated areal units—say, those that are 90 or 95% homogeneous—and presume that the dominant group in these locales is representative of how group members behaved everywhere. This method has the virtue of certainty because we know almost exactly how blacks and white voted within the small subset of segregated units. The analyst merely looks at units that are all white, using their turnout and vote choice figures to fill in quantities for the white row of the cross-tabulation, and then similarly examines all-black units to fill in the black row.

This approach can be disastrously misleading if mixed-race communities differ from more-uniform areas. The most common name for the approach—homogeneous precinct analysis—underscores other drawbacks. It is useful only when residential patterns are highly segregated, as one often finds in urban precincts when looking at race. It is useless for county-level analysis, since counties are seldom almost entirely black. This method is also unreliable when the bulk of aggregation units fall between the extremes, such as when one wishes to study gender; only a negligible (and highly unrepresentative) selection of units will appear in the analysis.

Ecological Regression

Ecological regression is the most common approach for estimating how groups voted. It is sometimes called Goodman's ecological regression, after the scholar who developed it, but most applications of the technique stray far from Goodman's intent. The basic intuition is fairly simple. Goodman argued that ecological inference using linear regression would be possible if underlying racial vote choices were constant (e.g., $\beta_i^b = \beta_{i+1}^b = \beta_{i+2}^b = \dots = \beta^b$) or at least constant aside from random variation. Researchers could collect data from areal units smaller than the aggregation of interest and run one or more linear regressions to estimate quantities missing from the cross-tabulation.

Consider a one-stage version of the equations introduced above, with the racial support rates expressed as constants:

$$V_i^L = \beta^b X_i + \beta^w (1 - X_i).$$

Assume a normally distributed error term e_i to make room for stochastic processes, and this equation looks like a linear regression formula with no intercept—which makes sense, given that a candidate who receives neither white nor black votes will not have any votes at

all. A simple application of the distributive property provides a bivariate regression version:

$$\begin{aligned} V_i^L &= \beta^b X_i + \beta^w (1 - X_i) + e_i \\ &= \beta^b X_i + \beta^w - \beta^w X_i + e_i \\ &= \beta^w + (\beta^b - \beta^w) X_i + e_i. \end{aligned}$$

The intercept reports the white rate; adding the two coefficients together provides the black rate.

This one-stage version conflates registration, turnout, and vote choice. Conventional applications, both in research and in voting-rights litigation, use two stages—first estimating racial turnout, then plugging estimates for turnout from the first stage directly into the vote-choice equation. This ad hoc solution, which cannot produce measures of uncertainty, goes by the name double regression.

Some of the problems with ecological regression may seem obvious. Turnout and voting rates cannot be linear or normally distributed because they are bounded at 0 and 1. Areal units vary significantly in size, so coefficients that report the average properties of areal units may not parallel the individual-level behavior of interest. These are typical problems found in linear regressions; social scientists usually know how to look out for them. Weighting an ecological regression by population size can help address unequal areal units, although some scholars argue that this is an inappropriate solution.

Less obvious, perhaps, is that an identity equation cannot contain a random error term. Once we know the black population proportion and the racial voting rates, the observed vote cannot vary. Thus, if the right-hand side of the equation does not add up to the left-hand side value for any areal unit, then the noise must appear in the coefficient rather than in some separate residual. Varying coefficients violate ordinary least squares (OLS) assumptions.

The greatest barrier to ecological regression appears when group behavior varies by locale depending on the demographic context. Any contextual pattern that correlates with the independent variable, whether directly or indirectly, violates the assumption that group behavior is constant (or at least mean-independent) across units. The result is a distortion of the ecological regression results, usually called aggregation bias. Aggregation bias explains why applications of ecological regression often return impossible results. Not all instances of aggregation bias will be obvious, however.

Ecological regression can accommodate simple instances of aggregation bias. Consider a case in which white support for the left-wing candidate increases linearly as areal units become more diverse. The formula now

contains a shifting parameter, $\beta_i^w = \gamma^0 + \gamma^1 X_i$, a function of racial density. Straightforward ecological regression, performed on data of this sort, will not estimate the desired quantities (i.e., β^b and the weighted average of β_i^w , presuming all other assumptions of the model were correct). Instead, it would turn up the following:

$$\begin{aligned} V_i^L &= \beta_i^w + [\beta^b - \beta_i^w] X_i + e_i \\ &= (\gamma^0 + \gamma^1 X_i) + [\beta^b - (\gamma^0 + \gamma^1 X_i)] X_i + e_i \\ &= \gamma^0 + (\beta^b - \gamma^0 + \gamma^1 - \gamma^1 X_i) X_i + e_i \\ &= \gamma^0 + [\beta^b - \gamma^0 + \gamma^1 (1 - X_i)] X_i + e_i. \end{aligned}$$

The estimated intercept, assumed to represent white support for Wallace, will be γ^0 only. How does γ^0 differ from the real white rate? If the contextual effect γ^1 is positive, as hypothesized, then the missing component is also positive because X_i will never fall below zero. The estimate of white leftism will be too low. Similarly, the estimated black vote for left-wing candidates will be too high.

Fixing the aggregation bias in this case requires a simple application of the distributive property:

$$V_i^L = \gamma^0 + (\beta^b + \gamma^1 - \gamma^0) X_i - \gamma^1 X_i^2 + e_i.$$

Results generated from this equation could serve as ecological-regression estimates. Subtracting γ^0 and γ^1 from the coefficient generated by X_i , for example, would produce the black rate. The estimate for whites is more complicated, because it contains X_i and therefore requires a weighted average, but is also obtainable. The problem with this simple fix is if black behavior also changes with racial density, say by becoming more Republican in whiter communities. The second shifting parameter, $\beta_i^b = \rho^0 + \rho^1 X_i$, would produce the following:

$$\begin{aligned} V_i^L &= \gamma^0 + (\rho^0 + \rho^1 X_i - \gamma^0 + \gamma^1 - \gamma^1 X_i) X_i + e_i \\ &= \gamma^0 + (\rho^0 + \gamma^1 - \gamma^0) X_i + (\rho^1 - \gamma^1) X_i^2 + e_i. \end{aligned}$$

Now there are four constants to identify instead of three: γ^0 , γ^1 , ρ^0 , ρ^1 . Doing so is impossible, though, because the equation only produces three coefficients. The results are “underidentified.”

Aggregation bias will be present in a naive ecological regression even if the coefficients are not a direct linear function of racial density (i.e., X_i), but instead change based upon some other community demographic that correlates with racial density and therefore creates an indirect relationship. For example, the poverty rate might increase as X_i increases, and poorer whites

might support left-leaning candidates at a higher rate. The solution would look about the same as when racial density changed white voting behavior directly. If Z_i represents the poverty rate, then:

$$\begin{aligned} V_i^L &= \gamma^0 + (\beta^b - \gamma^0 + \gamma^1 - \gamma^1 Z_i)X_i + e_i \\ &= \gamma^0 + (\beta^b + \gamma^1 - \gamma^0)X_i - \gamma^1 Z_i X_i + e_i. \end{aligned}$$

Instead of a parabolic model with a simple squared term, the indirect form of aggregation bias simply requires an interaction term. Indeed, one could include the parabolic form plus add a whole series of interactions, each representing the product of X_i and some relevant variable that might condition the effect of race on voting behavior. These interaction terms would allow black and white voting behavior to change with relevant community demographics. Nevertheless, ecological regression provides no solution when both groups change their voting behavior with the community's racial density.

The Neighborhood Model

Ecological regression represents one extreme: the presumption that voting behavior changes systematically across groups but only changes randomly, if at all, within groups. But what if group behavior tends to converge when people live in close proximity to each other? Aggregation bias pushes estimates for each group apart, giving the appearance of greater polarization. Advocates of ecological regression quickly recognized this danger, and pointed out that the data could not rule violations of the constancy assumption: that groups behave similarly in particular locales and differ in part because their geographic distribution is unequal.

Freedman *et al.* popularized this concern when they proposed the neighborhood model. Rather than accept the extreme constancy assumption, this model goes to the opposite extreme: it supposes that groups behave identically when they reside in the same locale ($\beta_i^w = \beta_i^b$) and differ only because they reside in different locales. Presume, for example, that voting behavior shifts linearly with racial density. Assuming that the black and white responses to community density are identical (i.e., $\rho^0 = \gamma^0$ and $\rho^1 = \gamma^1$) means that:

$$\begin{aligned} V_i^L &= \gamma^0 + (\rho^0 + \gamma^1 - \gamma^0)X_i + (\rho^1 - \gamma^1)X_i^2 + e_i \\ &= \gamma^0 + (\gamma^0 + \gamma^1 - \gamma^0)X_i + (\gamma^1 - \gamma^1)X_i^2 + e_i \\ &= \gamma^0 + \gamma^1 X_i + e_i. \end{aligned}$$

This is the exact same regression required for ecological regression when conducted with the constancy (or

mean-independence) assumption. The interpretations change dramatically, however. Now γ^0 represents voting behavior in all-white locales and γ^1 reports the contextual shift for each group as the community holds greater black density.

Social scientists knowledgeable about race would never accept any assumption that whites and blacks exhibit the same political preferences when they reside close to each other. They may converge somewhat, producing aggregation bias, but across-group variation clearly swamps within-group variation. The black vote for Democratic candidates varies little across geography, for example. More generally, the absurdity of each assumption—let us call it constancy versus convergence—depends upon the particular application at hand. Only theory can guide the choice; aggregate data provide no insight. In most cases neither assumption applies perfectly and the equation is underidentified. The truth lies somewhere in between, and the best an analyst can do, within the limits of linear regression, is select the assumption closest to what is known about the particular behavior under observation.

The Method of Bounds

This next solution for dealing with ecological inference is not really a method of estimation so much as a key insight that the other approaches neglect—which is that marginal quantities greatly limit the possible range of group behavior in each areal unit. Consider a locale in which the Democratic candidate wins 50% of the vote, and 25% of the voters are black. Even if every African American voted Democratic, whites must account for the remaining 25% of the Democratic candidate's votes. At least one-third of whites mathematically must have voted that way (although more may have, if some blacks voted Republican). So the possible white vote in this hypothetical example is not between 0 and 100%; the minimum is 33%.

These bounds can limit the maximum, the minimum, or both. Their helpfulness depends upon the size of each group. It is difficult to determine how a handful of blacks acted in a heavily white locale because their behavior does not make much of a dent in aggregate statistics. In heavily black locales, however, the aggregate statistics mostly reflect their choices. Bounds will be narrow on large groups and wide on small groups. The helpfulness of these bounds also depends on how extreme the outcome behavior happens to be. If almost everyone voted in a mixed-race precinct, then obviously blacks and whites both had to turn out at high levels. Added up over many small areal units, the implications for a larger electoral district can be quite informative.

The limit on the method of bounds, when used in isolation, is that the bounds identify only a range of

possible behavior rather than a specific estimate. Analysts desiring to pin down a particular number cannot say whether the truth approaches one extreme or the other. Taking the midpoint may seem most sensible, since researchers familiar with the substance of their topic probably know about any phenomenon that would push rates of behavior in a consistent fashion across many small areal units (such as the strong tendency of blacks to vote for the Democratic party). But the data alone provide no guidance.

King’s Solution to the Ecological Inference Problem

Gary King innovated aggregate data analysis by combining the best traits of each competing method into one relatively convenient solution to the ecological inference problem. His approach constrains estimates within the range of possible answers, consistent with the method of bounds. It selects specific quantities within those bounds through statistical inference rather than guesswork, consistent with ecological regression. For homogeneous units, his method takes advantage of the certainty about racial behavior. At the same time, it allows the possibility that behavior will differ in more diverse communities, either randomly or in some systematic contextual fashion. If the research holds particularly strong theoretical priors about how groups behave, either in general (as with the informed assumptions approach) or across particular contexts (as with the neighborhood model), then the model accommodates at least partial incorporation of those substantive insights. Best of all, King implemented his method in a convenient, and free, software package that produces estimates for the smaller areal units used as source data, not just for the electoral districts in which those smaller units are nested, and that also provides the user with a series of graphical and statistical diagnostic tools.

The method is fairly easy to describe with reference to the identities and the cross-tabulation introduced earlier. King’s software, EI (or EzI), begins by identifying the complete set of values that might fill a table’s cells—not for the electoral district as a whole, but for each areal unit. The method of bounds provides a range of possible behavior for both blacks and whites. However, the identity equation means that the estimate for one group must be linearly related to the estimate for the other group. Assume that one is known, the other must be known too:

$$V_i^L = \beta^b X_i + \beta^w (1 - X_i)$$

$$V_i^L - \beta^b X_i = \beta^w (1 - X_i)$$

$$\beta^w = (V_i^L - \beta^b X_i) / (1 - X_i).$$

Similarly,

$$\beta^b = [V_i^L - \beta^w (1 - X_i)] / X_i.$$

EI has reduced the range of possible estimates to a series of exclusive pairs, all within the range of possible values. The same process is possible for the observed behavior in each area unit *i*.

If we graph possible black and white behavior, then, the known information about each parish will be represented by a line segment, the set of all possible combinations. Figure 1 presents a “tomography plot,” King’s name (drawn from medical imaging) for the combined line segments of all areal units in an electoral district. It contains data for 64 Louisiana counties from 1968 and represents possible racial registration rates. This plot summarizes all deterministic information contained in the registration and demographic data available; no assumptions were required to produce it. Horizontal lines—that is, lines with very narrow bounds for white registration—correspond to almost entirely white counties. They contain so few African Americans that we know quite precisely how whites behaved (β^w), but almost nothing about blacks (which is why the slant of such a line only allows a small range of possible values on the *y* axis but any value on the *x* axis). A segment becomes more vertical, however, as the black population increases. We are less sure how many

Figure 1 Tomography plot for Louisiana registration, 1968. Each line segment represents one parish (county). The vertical axis represents possible white registration rates; the horizontal axis represents possible black registration rates. Overall, this plot represents all known information about parish registration from the voting-age population and the overall registration rates. See text for more details. Plot was produced using King’s EI.

whites registered in these mixed counties, because the aggregate data also include a large black population.

Somewhere on each line segment is a single point that represents the true black and white turnout rates. Deriving more specific estimates is impossible without making distributional assumptions of some kind. The usual assumption would be that the real points tend to cluster wherever the lines converge. More formally, King's proposal is to make three assumptions about the process generating racial voting behavior: (1) each areal unit's black rate and white rate together are one draw from a bell-shaped probability curve, called the bivariate normal distribution, truncated so that neither rate is outside the limits of 0 and 100%; (2) each areal unit's rates are mean independent of racial density; and (3) a racial group's behavior in one areal unit is independent of that in others. In fact, an elaborated version of King's model allows the introduction of covariates that might explain systematic variation in group behavior, therefore requiring that these assumptions hold only after controlling for the covariates.

EI estimates (using maximum likelihood) the truncated bivariate normal distribution with the greatest probability of generating an electoral district's data. Roughly speaking, it selects a bell shape that is highest where the tomography lines cluster most densely and then tapers off where the tomography lines become scarce, ending at the border of the unit square. The estimated distribution is three-dimensional, but one can imagine slicing it along any one tomography line segment to produce a simple two-dimensional (and therefore univariate) probability distribution. Where that curve is high, the pair of estimates is highly probable. Where it is low, the estimates are unlikely.

EI then takes a series of random draws from this univariate distribution, resulting in hundreds or thousands of simulations for the voting behavior in that areal unit. The mean of these simulations will represent the best estimate of how whites and blacks behaved; the variation in these simulations will represent the level of certainty. Note that, because the final estimates for each areal unit always appear on the tomography line, they will always be possible. Accumulating these estimates for each areal unit results in an estimate for the electoral arena as a whole, which also must be consistent with the known information in the data. Thus the estimate for each areal unit "borrows strength" from the other areal units. The locations of the other tomography lines determine the point estimate on any one.

This method of ecological inference is still imperfect, as indicated by early evaluations from the point of view of statistical theory, but it also has been found to operate well in actual social science data. In particular, it helps separate out contextual and compositional patterns when they are combined in an aggregation process.

Conclusion

The last section focused on one particular, and particularly intractable, example of data aggregation. It exhibits all of the traits of aggregation that appear in other methodological contexts: loss of information, statistics that vary based upon the level or unit of analysis, a search for statistics that are invariant to the level at which they are computed so that they will tap into the underlying quantities of interest. Nonetheless, there is a wide variety of examples in social measurement that represent attempts to deal with aggregated or grouped data, each with its own vocabulary and notation, but usually with the same underlying concerns.

Sometimes data are clumped across time—for example, when they are computed as five-year averages. This form of aggregation is usually considered a concern when performing time-series analysis. Often researchers attempt to combine their data into indices or scales, which often result in a loss of information at the same time they provide the researchers with relatively tidy proxies for a social phenomenon. Sometimes researchers wish to combine individual-level data with aggregate data, or for some other reason wish to work with multiple levels of data at once. Events may not be measured directly, but instead may be summed into "event counts" or recorded according to their durations—both forms of grouping. In short, aggregation as a concern in social measurement is an almost universal consideration across numerous methods and numerous disciplines.

Aggregative Macro Models, Micro-Based Macro Models, and Growth Models

David C. Black

The University of Toledo, Toledo, Ohio, USA

Michael R. Dowd

The University of Toledo, Toledo, Ohio, USA

Glossary

ad hoc Improvised and often impromptu; an ad hoc model is one in which the structural equations have not been derived from microfoundations (i.e., either utility or profit maximization) but rather are postulated from the beliefs of the modeler.

aggregative model A macroeconomic model with structural equations postulated by the modeler to describe the economic relationships in the macroeconomy.

balanced growth path A rate of economic growth that has the capital-stock-per-worker and the output-per-worker growing at a constant rate. In this situation, output-per-worker is determined solely by the rate of technological progress.

break-even investment The level of investment in a growth model that is required to keep the capital-to-effective-labor ratio constant.

fiscal policy Altering government expenditures and taxes to affect the level of national income, prices, unemployment, and other key economic variables.

growth model A framework designed to examine the long-run movements in output, capital, and labor in terms of economic growth.

IS curve A curve that illustrates the combinations of interest rate and income consistent with equilibrium between investment (I) and saving (S).

IS–LM model A postulated static aggregative macroeconomic framework of aggregate demand that considers the interaction of its real side (investment–saving, or IS) with its nominal side (money demand and supply, or LM) to determine equilibrium income and interest rates.

LM curve A curve that illustrates the combinations of interest rate and income consistent with equilibrium between money demand (L) and money supply (M).

microfoundations The need for macroeconomic models to derive structural equations from utility and/or profit maximization.

monetary policy Altering the money supply and/or interest rates to affect the level of national income, prices, unemployment, exchange rates, and other key economic variables.

overlapping generations model A dynamic micro-based macro model that employs utility and/or profit maximization to determine the equilibrium consumption, saving, and employment allocations in an economy.

Phillips curve A curve illustrating the short-term negative relationship between the unemployment rate and the rate of inflation.

stabilization policy The deliberate manipulation of fiscal and/or monetary policies to affect the level of economic activity in a particular way, e.g., lessening the severity of the business cycle.

Macroeconomics analyzes the economy as a whole; the key variables macroeconomists want to explain are output, prices, interest rates, exchange rates, and unemployment. In contrast, microeconomics analyzes the behavior of individuals and firms; in this case, prices for particular products are determined by demand and supply. It is all but impossible to summarize all of the differences between macro- and microeconomic models, thus the focus here is only on three theoretic models that have had a substantial impact on economic modeling over the past 60 years. The three classes of models examined are the IS–LM, overlapping generations, and growth models. The IS–LM model is the traditional (static)

aggregative macro model, which excels in short-run stabilization issues. The overlapping generations model, with production, is a general equilibrium, intertemporal micro-based macro model. It incorporates both utility and profit maximization. Growth models examine the importance of technology and human capital and convergence to equilibria; its long-run focus sharply contrasts that of the IS–LM model.

Aggregative Macro Models: IS–LM

A Simple IS–LM Model

The IS–LM model is a description of the economy's demand side; the focus of the IS–LM model is on short-run analysis of monetary and fiscal policy variables. In varying form, this model has been widely used since its introduction by Sir John Hicks in 1937. An IS–LM model is composed of a number of postulated relationships between variables, including those describing consumption demand, investment demand, and money demand. Equations (1)–(4) provide a paradigmatic version of a rudimentary IS–LM model:

$$\text{Income identity} \quad Y = C + I + G, \quad (1)$$

$$\text{Consumption function} \quad C = C(Y - T, r), \quad (2)$$

$$\text{Investment function} \quad I = I(Y, r), \quad (3)$$

$$\text{Money market} \quad M = L(Y - T, P, r). \quad (4)$$

The endogenous variables are income (Y), consumption (C), investment (I), and the interest rate (r). The exogenous variables are the money stock (M), price level (P), taxes (T), and government expenditures (G).

The IS curve is obtained by using Eqs. (2) and (3) in Eq. (1). In effect, as Eqs. (1) and (2) produce the saving curve; the IS curve portrays the interaction between saving and investment. This is commonly referred to as the goods market. The LM curve is equilibrium between money demand (L) and money supply (M) in Eq. (4). The IS is typically represented as the interest rate, being a positive function of government spending and negatively related to income and taxes; with LM, the interest rate is a positive function of income and prices and negatively related to money supply and taxes. The interaction between IS and LM determines the equilibrium income level and the interest rate, which, in turn, determines consumption, investment, and money demand. In contrast, an aggregative model with no interaction between saving and investment was provided by James Tobin.

The IS–LM model is particularly adept at providing short-run stabilization policy prescriptions, an ability that

(by design) is absent in both the overlapping generations and growth models. Fiscal policy does this in the IS–LM model by driving a wedge between saving and investment. Unlike the classical model, fiscal stimuli in the IS–LM model will not necessarily alter saving and investment in the same direction nor in the same proportion (there is an overlapping generations model that assumes the contrary). The independent movements of saving and investment allow income to adjust in order for the economy to reach a new equilibrium. Monetary policy affects income by, first, altering the interest rate and, in turn, the incentives for savers and investors.

The IS–LM framework has been used to analyze the choice of how best to use monetary policy to minimize the fluctuations in the business cycle. With the central bank choosing between controlling either the interest rate or the money stock, eminently reasonable guidelines have been proposed: if disturbances originate in the money market, the central bank should choose to control the interest rate (so that no such interest rate disturbances are later transmitted to the goods market). Alternatively, if disturbances originate in the goods market, the central bank should instead control the money stock. Doing so will minimize the impact disturbances have on income. There are two reasons such a choice is not typically relevant in dynamic models such as the overlapping generations framework (OLG). First, money in an OLG model operates through different channels because it acts merely as a store of value (as opposed to the medium of exchange function in an IS–LM model). Second, in a choice-theoretic framework (such as the OLG model), utility-maximizing agents are concerned only with the real interest rate: nominal changes will not affect equilibrium consumption, saving, and labor market decisions in a dynamic model.

Two other attractive features of the IS–LM model may account for its continued use. The first is its flexibility in allowing the modeler to introduce into the theoretic model prior beliefs about the behavior of people and of the economy. For example, consider the ad hoc money demand relationship specified in Eq. (4): choosing that specification reflects the belief that the transactions' demand for money is a function of disposable income instead of gross income. As another example, it has been demonstrated that a procyclical money multiplier allows for the possibility of a downward sloping LM curve and nontraditional policy prescriptions. Over the years, this flexibility has produced innumerable variants to the relationships described in Eqs. (1)–(4), with each variant employed to emphasize the particular interests of the modeler. That said, however, it is the responsibility of the modeler to justify empirically his/her assumptions and model specification.

The second attractive feature of the IS–LM model is its rich intuitive framework. For example, consider the

interaction between saving and investment, both of which are demand theories. How could IS theory be an equilibrium obtained from the interaction between two demand curves? The framework is general enough to afford the modeler the opportunity to provide the needed intuitive justification/rationalization. Saving can be interpreted as the demand for new securities: people buy an “I.O.U.”—a bond—when they deposit money into their savings account. Investment can be interpreted as the supply of new securities: firms issue new securities to finance new investment spending. Using this interpretation, the IS curve is viewed as the equilibrium between the supply and demand for new securities, not two demand curves. In other words, the goods market can be viewed as the primary market for new securities. And what of LM? Because LM reflects portfolio choice between money demand and existing bonds, it can be viewed as the secondary market for securities. The particular interpretation here implies that the interest rate and national income are determined by the interaction between the primary and secondary markets of securities. As an alternative interpretation, consider that saving and investment can, respectively, be viewed as the private supply and demand of new loanable funds. Incorporating the government’s budget deficit and net exports with the private supply and demand for loanable funds will determine the economy’s real interest rate.

We are quick to point out that the interpretations here are not, by far, the only intuitive interpretations of the relationships behind IS–LM. As with the flexibility in model specification, so too there is flexibility in intuitive explanations of this framework. As one additional example, consider a further interpretation of the IS–LM framework: the act of saving and the act of investment are acts of accumulating wealth. In contrast, the money market determines how people would allocate their wealth (i.e., between money and bonds). This suggests that income and interest rates are determined by the interaction between the desire to accumulate wealth and the desire to allocate that wealth. As a last example of the intuitive flexibility of the IS–LM model, consider the difference between stock and flow variables. A stock variable has no reference to time. Examples of this are money and bond holdings. In contrast, flow variables, such as investment and saving, have a reference to time: they are measured in terms of \$/week or \$/year—in other words, they are measured with respect to their accumulation over time. Hence, the interaction between the IS and the LM curves yields an equilibrium that is a reconciliation between the stock and flow variables within aggregate demand.

These alternative intuitive interpretations (as well as all of those not discussed here) must be consistent with each other. This is one of the most intriguing aspects of the IS–LM framework. Its ability to lend itself to alternative explanations allows both the modeler and the reader to

apply prior beliefs, interests, etc. when interpreting the structure and results of the model.

Adding Aggregate Supply to the Simple IS–LM Model

Because IS–LM models describe only the demand side of the economy, they were ill equipped to be used in modeling the supply-side shocks that occurred in the mid- and late-1970s. In response, adaptations to the IS–LM model included a “summary” of the economy’s supply side, such as the Phillips curve relationship described in Eq. (5).

$$\text{Phillips curve} \quad \frac{\dot{P}}{P} = H \left[\frac{(Y - Y^F)}{Y^F} \right] + \pi, \quad (5)$$

where \dot{P}/P and π are the actual and expected inflation rates, respectively, Y^F is full-employment output, and $H' > 0$. A complete analysis of policy prescriptions resulting from a model such as that described by Eqs. (1)–(5) is not possible here, but in general terms, appending Eq. (5) to the model in Eqs. (1)–(4) alters the role of variables and the policy prescriptions in a number of important ways. First, and probably most important, this model allows for \dot{P} to be determined in the short run and P to be determined in the long run. (Whereas this attribute may now seem a prerequisite to any acceptable model, when introduced, it marked a substantial innovation from the simple demand-side IS–LM models used prior to the mid-1970s.) In terms of short-run policy analysis, endogenous prices tend to dampen the effect of well-established policy prescriptions or, in the extreme, render ambiguous the effects of such policy options. Second, with the inclusion of Y^F , a “long-run” benchmark was introduced into this short-run model. With that came discussions of the possibility of “long-run” neutrality of money and a reduced stabilization role for government policy variables within this framework. However, any discussion of the Phillips curve must include the seminal work of Milton Friedman, which contains not only a precautionary analysis of the Phillips curve models but also includes the now-famous discussion of the natural rate of unemployment, the role of monetary policy, and other issues.

As an alternative to the Phillips curve, others added slightly more realistic descriptions of the supply side. For example, combining Eqs. (1)–(4) with Eqs. (6)–(8) produces an aggregate supply–aggregate demand model that now solves for Y , r , C , I , P , W (nominal wages), and N (employment).

$$\text{Production function} \quad Y = F(N, K), \quad (6)$$

$$\text{Labor demand} \quad F_N(N, K) = W/P, \quad (7)$$

$$\text{Labor supply} \quad S(N) = (1 - \tau)W/P. \quad (8)$$

Here, K is the capital stock and τ is a marginal tax rate on labor. This aggregate supply–aggregate demand model added much-needed detail of the supply side of the economy and it allowed rudimentary supply-side analysis via changes in τ . However, the postulation of the supply side to the economy only exacerbated the need for microfoundations of the model specification. One example responding to the need for microfoundations on the supply side was Carl Shapiro and Joseph Stiglitz’s provision of an intuitively plausible explanation for endogenously determined involuntary unemployment.

Expectations

Though “expectations” can be introduced into an IS–LM model via a number of avenues, the method most widely used has been that of specifying an adaptive expectations scheme, whereby the change in inflationary expectations ($\dot{\pi}$) is proportional (λ) to the error in expectations in the previous period:

$$\text{Adaptive expectations} \quad \dot{\pi} = \lambda \left[\frac{\dot{P}}{P} - \pi \right]. \quad (9)$$

Adding Eq. (9) to Eqs. (1)–(5) provides a mechanism for tracking the “step-by-step” movement toward “long-run” equilibrium (defined as when all expectations are satisfied). The underlying problem, of course, is that including a relationship such as Eq. (9) in an IS–LM model is an attempt to proxy dynamics in a static model.

Criticisms of the IS–LM model

Though the IS–LM model provides an intuitively rich framework, it possess other characteristics that are troublesome to many theorists. First is the fact that the IS–LM model is a static model. With no reference to time, the IS–LM model restricts in important ways the behavior of some of the variables within the model. For example, money is postulated to act as a medium of exchange. Without a reference to time, the effects of the “store of value” function of money cannot be represented in an IS–LM model. However, the most enduring criticism of the IS–LM model is that its structural equations are postulated and are not derived from utility or profit maximization. This criticism reduces to the following question: If the structural equations are ad hoc, are the policy prescriptions that follow equally ad hoc? For example, consumption in Eq. (2) is assumed to respond positively with changes in disposable income and negatively with the interest rate. Critics of IS–LM models correctly point out that important parameters such as the marginal propensity to consume (MPC) cannot be postulated. Critics could also argue as to whether saving today and, hence, whether consumption today are functions of the interest rate. Similar microfoundation

arguments can be applied to the other structural equations as well.

Though the need for microfoundations in macro models is justified, the rhetorical gap between critics and defenders of IS–LM models is not unbridgeable. With regard to the preceding examples, defenders of IS–LM models would agree with the critics that the value of parameters such as the MPC, as well as the relevance of interest rates on consumption, can be determined only empirically: if empirical evidence does not support the postulated structural equation, then the postulated equation must be altered to reflect the data.

As the following discussion shows, the overlapping generations model can provide microfoundations for the examination of macroeconomic issues. In particular, the OLG model allows for an examination of whether some of the relationships postulated in IS–LM analysis can be derived from either utility or profit maximization.

The Overlapping Generations Model

The ad hoc nature of the IS–LM framework, coupled with the lack of a realistic portrayal of the economy’s supply side, prompted an intense search during the 1970s and 1980s for microtheoretic macro models that could establish from first principles the behavioral relationships typically discussed in aggregative macro models. Though various models were proposed, one model that fit the dual needs of microfoundations and macro applications was the overlapping generations framework, originally suggested by Paul Samuelson in 1958.

The OLG model differs from aggregative models in a number of ways. First, it is a dynamic model: “time” matters. Agents live for two periods. They are termed “young” and “old” in their first and second period of life, respectively. In a particular period, say t , there are N_t young agents born in that period and N_{t-1} old agents that were born in the previous period. In the following period, $t+1$, the current young agents become old and the current old agents die and another N_{t+1} young agents are born. A very common assumption is that of a constant population (i.e., $N_t = N \forall t$). However, care needs to be given when making such an assumption, because policy prescriptions can depend critically on whether population is assumed constant in OLG models. Such assumptions impact on whether insights not available in the IS–LM framework are incorporated into the OLG model. For example, a growing population with a constant money supply results in an increase in the real interest rate, which will impact other real variables. Though this result is easy to establish in an OLG framework, it is not available to IS–LM analysis.

The second and perhaps more important structural difference is that young agents base their decisions (e.g., consumption and saving allocations) on intertemporal utility maximization. As expected, the structural differences between the OLG and IS–LM models result in a number of significantly different policy implications.

A Simple Utility-Maximizing Model

First, consider an abstraction employed in almost all OLG models: agents are endowed with a fixed income when young (W^y) and when old (W^o). In this simple OLG model, young agents at time 1 choose consumption when young (C_t^y) and old (C_{t+1}^o), and saving when young (S_t), which maximizes their utility function, $U(C_t^y, C_{t+1}^o)$, subject to their budget constraints in each period. Assume population is constant.

Saving when young can take many different forms: money, government bonds, land, etc. Though alternative vehicles for savings can differ (along with corresponding budget constraints), the primary characteristics of such assets do not: agents purchase these assets when young and carry them to the next period, at which time they sell the asset in order to augment second-period consumption. Hence, saving provides young agents the ability to smooth consumption over the two periods of their life.

For illustrative purposes, assume $U(C_t^y, C_{t+1}^o)$ is log-linear and saving occurs when young agents purchase money balances from old agents and/or the government. In this case, the young agent's choice problem is

$$\begin{aligned} \text{Max}_{C_t^y, C_{t+1}^o, M_t/P_t} \quad & U = \ln C_t^y + \ln C_{t+1}^o \\ \text{Subject to:} \quad & C_t^y + M_t/P_t = W^y \\ & C_{t+1}^o = W^o + (M_t/P_t)R_t. \end{aligned} \quad (10)$$

Here P_t is the money price of the consumption good at time t . The interest rate equals the gross real rate of return on money balances, $R_t = P_t/P_{t+1}$. There are no explicit taxes in this example, though lump-sum taxes can easily be introduced into the model by way of defining $W^y = \overline{W}^y - T_t^y$ and $W^o = \overline{W}^o - T_{t+1}^o$, where T_t^y and T_{t+1}^o are lump-sum taxes when young and old. However, because such taxes are not distortionary, they do not qualitatively affect the equilibrium allocations. Therefore, with lump-sum taxes it is possible to discuss “disposable income” instead of gross income and to obtain the same qualitative results with this semantic change.

This general equilibrium model is closed by the government's budget constraint, which states that government expenditures are financed through money creation: $G_t/N = (M_t - M_{t-1})/P_t$. The young agent's

equilibrium consumption and saving allocations implied by Eq. (10) are as follows:

$$\begin{aligned} C_t^y &= \frac{1}{2} \left(W^y + \frac{W^o}{R_t} \right), \\ C_{t+1}^o &= \frac{1}{2} (W^y R_t + W^o), \\ \frac{M_t}{P_t} &= \frac{1}{2} \left(W^y - \frac{W^o}{R_t} \right). \end{aligned}$$

These consumption and saving allocations are both intuitive and consistent with assumptions normally postulated in aggregative models. An example of such microfoundations is that an increase in the interest rate increases saving, decreases current consumption, and increases future consumption.

There are a number of general characteristics of equilibrium allocations in the OLG model. First, consumption and saving decisions are based on lifetime income (appropriately discounted). From a young agent's perspective, lifetime income is $W^y + W^o/R_t$; from the perspective of an old agent, lifetime income is $W^y R_t + W^o$. Hence, agents consume in each period half of their lifetime income. This consumption smoothing is made possible by transferring excess income in one period to the other. From a young agent's perspective, the present values of income in the two periods are W^y and W^o/R_t . Whichever income is larger, the young agent must transfer (via saving) one-half of the excess income to the other period in order to smooth consumption in each period. Because $W^y > W^o$ is typically assumed, the relationship for M_t/P_t indicates that saving in this example is chosen appropriately. The usual assumption of $W^y > W^o$ can be interpreted as the “young” period of an agent's life (the working years of that agent) and the “old” period of an agent's life (his/her retirement years). The situation of $W^y < W^o/R_t$ implies that young agents would have to borrow (perhaps from the government) in order to smooth consumption.

The second characteristic of an OLG model to note is the role that money plays. In an IS–LM model, money is postulated to act as a medium of exchange and not as a store of value. In contrast, money in an OLG model is derived from utility maximization to be a store of value and not as a medium of exchange. This makes intuitive sense because the IS–LM model is relevant for the short run and the OLG model is more applicable to long-run analysis—given its “generational” motivation. In IS–LM, short-run changes in the money supply influence real variables by first altering the nominal interest rate and then the real interest rate. In OLG, changes in the money supply (completely independent of fiscal actions) will alter the nominal interest rate, but that will not be transmitted to either the real interest rate or to other real variables.

The third OLG characteristic centers on the alternatives to holding money. The demand for money in

an IS–LM model is based on transaction demand and the interest rate paid by competing assets (that is, both money and various bonds are held simultaneously). In a typical OLG model, competing assets are redundant: because competing assets all potentially serve as a store of value only, agents will demand only the asset that returns the largest interest rate and all other assets will be discarded. Attempts to model money as a medium of exchange in OLG models have included postulating utility as depending on real money balances. In such models, both money and alternative assets may be held by agents despite the fact that their respective interest rates are not identical.

Expectations

In an IS–LM model, expectations usually serve merely to provide a mechanism for moving from a short-run equilibrium toward a long-run equilibrium. In contrast, expectations play a crucial role in determining the current and future equilibrium allocations in an OLG model. The reason is straightforward: if young agents are to choose consumption now and in the future, they must form expectations of future prices to make such decisions today. In order to form expectations of prices, agents necessarily must form expectations of both fiscal and monetary policy actions now and in the future. Typically, strict government policy “rules” are imposed to facilitate expectation formation. To achieve this, OLG modelers typically assume that young agents possess complete information on all past variables, have perfect foresight of all future variables, and know with certainty all present and future government policy actions. In general terms, imposing such assumptions obtains neoclassical policy prescriptions, and relaxing any such assumptions yields neo-Keynesian results.

The common imposition of such strong assumptions has prompted an examination of rational expectations equilibria versus nonrational expectations equilibria. One reason the OLG model has been so widely used was the belief that the assumption of rational expectations in a choice-theoretic framework would deliver to the economic agent the highest level of utility obtainable. This belief has been shown to be without foundation. In a choice-theoretic framework, the utility of an agent with nonrational expectations will be higher than that of an agent with rational expectations. This results from the macro application of a micro model: what is true for an individual is not necessarily true for the group.

Adding Aggregate Supply to the Simple OLG Model

Though the IS–LM model has received substantial criticism for its lack of a realistic description of the

economy’s supply side, the alternative adopted by many, the OLG model, very rarely alters its specifications to address this criticism. Equation (11) represents an exception to this:

$$\begin{aligned} \text{Max}_{C_t^y, \mathcal{L}_t^y, C_{t+1}^o, \mathcal{L}_{t+1}^o, M_t/P_t} \quad & U = U(C_t^y, \mathcal{L}_t^y, C_{t+1}^o, \mathcal{L}_{t+1}^o) \\ \text{Subject to:} \quad & C_t^y + M_t/P_t = W^y, \quad T = L_t^y + \mathcal{L}_t^y \\ & C_{t+1}^o = W^o + (M_t/P_t)R_t, \quad T = L_{t+1}^o + \mathcal{L}_{t+1}^o. \end{aligned} \quad (11)$$

Here T is the total amount of time in a period, \mathcal{L} is leisure, and L is labor supply. In such a model, young agents facing both budget and time constraints must choose consumption and labor supply when young and old, as well as saving. With the government budget constraint, the model is closed with the addition of the firm’s maximizing profits according to the production function $I_t = f(N_t^y, N_t^o)$ and standard labor costs, where N_t^y and N_t^o are labor demand of young and old workers alive at time t . The firm’s optimization problem produces a demand for labor from the current young agents and the current old agents. Equating labor demand and supply of the young and old at time t determines the equilibrium employment and real wage rate for each agent alive at time t . From this equilibrium, allocations of output, consumption, and saving are determined.

The characteristics of the simple OLG model continue, in general, to hold in models that include production. The single, general, exception is that young agents not only smooth consumption but also smooth leisure time across their lifetime. However, inclusion of the economy’s supply side in a micro-based macro model allows for analyses that are not possible in the aggregative IS–LM model (for example, given unexpected disturbances, why unemployed workers choose to remain unemployed instead of negotiating a new real wage).

The OLG model is but one framework employing a microfoundation to macroeconomic analysis. Another is the representative agent model, with the most common form having the agent at time t maximize lifetime utility by choosing consumption/saving (and, perhaps labor supply) allocations in each period over an infinite time horizon (i.e., $t, t+1, \dots, t+\infty$). Though both the OLG and the representative agent models provide microfoundations to their analysis, there are two important differences to note. First, of course, the time horizon in an OLG model is much more restrictive compared to that in the typical representative agent model. Second, though growth modeling is possible in the OLG framework, a representative agent model appears to be better suited for such analysis, given its focus on long-term equilibria. Such long-term issues are discussed in the following section.

A Growth Model

Preliminary Descriptions

The Solow growth model focuses on the long-run movements of output (Y), capital (K), labor (L), and knowledge (or the effectiveness of labor) (A). With the subscript t denoting time period, the basic model consists of the following system of equations:

$$Y_t = F(K_t, A_t L_t), \quad (12)$$

$$L_{t+1} = (1 + n)L_t, \quad (13)$$

$$A_{t+1} = (1 + g)A_t, \quad (14)$$

$$Y_t = C_t + I_t, \quad (15)$$

$$S_t = Y_t - C_t = sY_t, \quad (16)$$

$$I_t = K_{t+1} - K_t + \delta K_t. \quad (17)$$

Equation (12) is the production function, with $A_t L_t$ representing effective labor. Equations (13) and (14) indicate how the stocks of labor and knowledge change over time, with n and g , respectively, representing the exogenous growth rates of labor and knowledge. Equation (15) is the income identity. Equation (16) assumes saving is a constant fraction (s) of income. Equation (17) indicates that gross investment is equal to change in the capital stock plus depreciation of the existing capital stock, with δ representing the rate at which capital depreciates.

The production function is assumed to exhibit constant returns to scale in both of its arguments. [That is, doubling K and AL leads to a doubling of output. This assumption allows us to work with the production function in intensive form: $F(K/AL, 1) = F(K, AL)/AL$.] In intensive form, the production function can be written as $y = f(k)$, where $k = K/AL$ is the amount of capital per unit of effective labor and $y = Y/AL = F(K, AL)/AL$ is the amount of output per unit of effective labor. Thus, output per unit of effective labor depends only on capital per unit of effective labor. For example, consider a particular production function that exhibits these properties, the Cobb–Douglas production function: $F(K, AL) = K^\alpha (AL)^{1-\alpha}$, where $0 < \alpha < 1$. Written in intensive form, this production function is $f(k) = k^\alpha$, where $f(0) = 0$, $df/dk > 0$, $d^2f/dk^2 < 0$.

To simplify notation, let a dot over a variable indicate the change in that variable from one period to the next (e.g., $\dot{A}_t = A_{t+1} - A_t$). Combining Eqs. (15) and (16) implies that $S_t = I_t$; this and Eq. (17) yield $K_{t+1} - K_t = sY_t - \delta K_t$. Dividing both sides of this relationship by effective labor and using

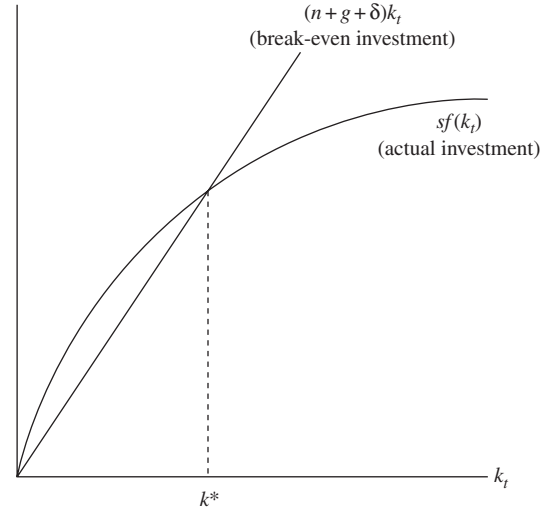

Figure 1 Determining the change in the capital stock in a Solow growth model.

$\dot{k}_t = k_t(\dot{K}_t/K_t - \dot{L}_t/L_t - \dot{A}_t/A_t)$, we can write this relationship in intensive form:

$$\dot{k}_t = sf(k_t) - (n + g + \delta)k_t, \quad (18)$$

where \dot{k}_t is the change in the capital-to-effective-labor ratio from time t to time $t + 1$. The first right-hand-side term in Eq. (18) is saving (and, hence, investment) and the second term is referred to as break-even investment. This is the level of investment that would be needed to keep the ratio of capital to effective labor constant.

Figure 1 plots each term on the right-hand side of Eq. (18). Given the assumptions regarding the production function, actual saving in intensive form is portrayed as increasing at a decreasing rate. Break-even investment is simply a ray from the origin with slope $(n + g + \delta)$. There are two steady states: $k = 0$ and $k^* > 0$, the attracting steady state being k^* . If k_0 (the initial capital-to-effective-labor ratio) is $0 < k_0 < k^*$, then actual investment is greater than break-even investment. Equation (18) therefore implies $\dot{k}_t > 0$ (i.e., this ratio is growing). In contrast, $k_0 > k^*$ implies that actual investment is less than break-even investment and $\dot{k}_t < 0$ (i.e., this ratio is declining).

The Balanced Growth Path

Because k is constant in the long run and effective labor grows at the rate $n + g$, the capital stock (K) and, in turn, output (Y) grow at the rate $n + g$. Finally, capital per worker, K/L , and output per worker, Y/L , are growing at the rate g . Thus, all variables are growing at a constant growth rate, i.e., a balanced growth path. On the balanced growth path, output per worker is determined solely by the rate of technological progress (g). The balanced growth path in the Solow model is

consistent with several of the stylized facts about economic growth. First, the growth rates of labor, capital, and output are roughly constant. Second, the growth rates of capital and output are roughly equal. Third, the growth rates of capital and output are larger than the growth rate of labor (so that output per worker and capital per worker are rising).

Remarks on the Simple Growth Model

Growth models address a fundamentally difficult question: What are the factors that influence long-term economic growth? Neither IS–LM nor OLG models can address this question. The contrasts between growth models and the IS–LM and overlapping generations models are rather sharp, due to the intended focus of each model. To some, the long run may be adequately described by the length of time between generations. However, the relevance of some variables as well as policy prescriptions that follow from a growth model indicate what is truly long-run analysis. For example, though money is a rather important policy variable in IS–LM models, and it may affect some equilibrium allocations in the dynamic OLG framework, money is not relevant in growth models.

In terms of considering the role of expectations across the three classes of models we (almost) approach a continuum with respect to its importance. The short-run IS–LM model can clumsily postulate expectational relationships, but in most cases these tend merely to adjust equilibrium allocations instead of determining them. In contrast, expectations in the longer term OLG framework play a crucial role in determining all equilibrium allocations. Finally, the long-run nature of growth models renders a discussion of expectations moot: expectations in the long run are, by definition, satisfied, so there is no point to such a discussion.

IS–LM is aggregate demand (i.e., the aggregate demand curve is derived from the IS–LM curves). Moreover, notwithstanding its dynamic framework, few OLG models specify a supply side to the economy. In contrast, the emphasis of growth models is almost entirely on the supply side of the economy: What influences an economy's long-run productive capabilities? The emphasis of these models with respect to aggregate demand versus aggregate supply is reflected in their application to monetary and fiscal policy prescriptions. When policymakers are interested in short-run impacts on the business cycle, the preferred model is IS–LM, and both monetary and fiscal options are available to policymakers. When interested in how decisions are made in a dynamic framework, the OLG model serves nicely: fiscal policy can influence equilibrium allocations while monetary policy plays a diminished role. When policymakers are interested in long-run effects, growth models provide clear guidance

to appropriate policy actions. First, monetary policy is irrelevant in the long run. Second, there are two avenues that fiscal policy can use to influence the growth rate of the economy. The first avenue is to lower real interest rates in order to promote capital accumulation. The second avenue is to promote education and technological advancement (e.g., via research and development). In contrast to the policy prescriptions emanating from IS–LM and OLG models, the benefits of either of these avenues can be expected only to be reaped in the long run.

Glossary

Agricultural Marketing Service (AMS) An agency that provides high-frequency, geographically delineated data and information on prices, marketing, and distribution of numerous agricultural commodities for the United States Department of Agriculture and the agricultural industry.

Economic Census The U.S. Census Bureau profile of the U.S. economy, conducted every 5 years, from the national to the local level; provides data on establishments, revenue, value of shipments, payroll, and employment.

Economic Research Service (ERS) The primary source of economic research and analysis for the United States Department of Agriculture (its department home); provides information and analysis on a broader set of agriculture, agribusiness, consumer, and rural issues.

National Agricultural Statistics Service (NASS) Primary statistics collector and information provider for the United States Department of Agriculture (its department home) and the production agriculture industry.

North American Industry Classification System (NAICS) A system that has replaced the U.S. Standard Industrial Classification system. NAICS provides more detailed classifications and new industries, reflecting the changing economy and the way business is done.

United States Census Bureau An agency of the United States Department of Commerce; collects a wide variety of data about the nation's people and economy.

United States Department of Agriculture (USDA) A cabinet-level department with seven major divisions overseeing 19 different services.

Agriculture statistics have been collected for over two centuries, but the detail and breadth of agricultural production, business, and food data have changed significantly over the years. One way to categorize

agricultural statistics is by the focus of analyses and public issues they help to describe, including production, markets, trade, price levels, and behavior (of producers and consumers); emerging technologies and differentiated products (grades and certifications); rural development, demography, and social concerns; as well as food safety, security, and nutrition. The economic, social, environmental, health, and cultural aspects of farming and food influence a variety of programs, policies, and research questions related to farming and food. This article provides a summary overview of the types of data available, and an evolution of how agricultural statistics have come to include an increasingly broad set of informative data on production, natural resources, farm and food prices, economic activity, and the food sector.

Introduction to Agricultural Statistics and Data

Some of the earliest data collection in the United States was based on agriculture; the 1790 census counted 9 out of 10 Americans as living on farms. In 1791, President George Washington wrote to several farmers requesting information on land values, crops, yields, livestock prices, and taxes; this was, in effect, the first agricultural survey in the United States. According to the historical information on the United States Department of Agriculture web site (www.usda.gov), in 1840, detailed agricultural information was collected through the first Census of Agriculture, which provided a nationwide inventory of production. Yearly estimates established the general pattern of annual agricultural reports that continues to this day.

The United States Department of Agriculture (USDA) was established by Abraham Lincoln in 1862, and its first

crop report was distributed in 1863 by the Division of Statistics [now the National Agricultural Statistics Service (NASS)]. Early on, the USDA helped farmers assess the value of their goods, to better negotiate with commodity buyers and get a fair price. In assessing the more recent evolution of the USDA, much of it has been guided by policy (farm bills and other price supports, data to assess market power in eras of antitrust concern, and food security and consumption data as nutrition and health have become topics of greater interest).

The importance of the agriculture sector in early U.S. history is clear: a vast majority of households were involved in the industry. However, it may be less clear why data continue to be independently collected for this industry, now that the relative importance of agriculture to the economy is diminished (less than 2% of U.S. households now operate farms). Beyond the basic need for food, and the economic activity that farming and its marketing channels create (inputs, processors, distributors, retailers, and food service), there are several potential reasons why public and private agencies prioritize agricultural statistics. First, there is the persistence of interest and institutions to serve agriculture (including the USDA); second, very few numbers of agricultural companies are publicly owned or assessed retail sales tax, so no data are available from the Security and Exchange Commission (SEC) or state Departments of Revenue; third, the nature of agriculture as an industry is complex, including its role in natural resource usage, trade activity, and government transfer programs; and finally, market outlook and production information are important factors for national food security, because short-term supply response is constrained by climate in the United States.

Still, the data and statistics discussed here, and used for analysis of agriculture, food, and rural issues, have evolved to serve a broader audience than agricultural producers and the agencies and institutions that service them. The broadening scope of agriculture and its allied sectors has led the USDA to widen its analysis and attention to a broad set of public issues. These evolving issues and the data collection efforts to provide information for analysis are discussed throughout this article. It is important to understand that this increasing complexity is likely due to the integration of food, land, and rural business activity in economic, social, and policy development and research.

Agricultural Production and Financial Statistics

As mentioned previously, the earliest scope of work for the USDA and NASS (and predecessors) was basic resource usage, production, and financial data for farms.

Subsequently, early statistics included information on land in farms, market value of agricultural products (crop and animal), farm production expenses, and value of land, buildings, and, as new innovations came about, machinery and equipment.

As the agricultural industry and society evolved, so did the statistics to record structural change in food production. Every 5 years, the Census of Agriculture provides data based on over 50 reports for each state and county, with statistics on production, income, government support, inventories, and irrigation delineated by a number of enterprises and farm typologies [ethnicity of owner, tenure of operator, size in terms of sales or assets, type of legal organization, and principal occupation of operator (because nonfarm income is now such an important influence on farm households)]. The 2002 Census also allowed for the possibility of multiple operators on one farm.

In addition to more detailed data on agricultural production and structure of farms, the USDA/NASS collects annual data on acreage, production, yields, prices, and production forecasts for a set of agricultural commodities set forth by Congress this is variable by state, depending on enterprises and production in each region. A major shortcoming of these data is the limited set of agricultural commodities, but beyond congressional appropriations for the commodities that are required to be tracked, state agricultural statistics agencies must rely on industry-based financial contributions to collect data on other crops.

NASS recently began collecting data on a more diverse set of enterprises related to food production or with similar industry characteristics. The ornamental horticulture (1988) and aquaculture (1998) industries now collect census data every 5 years (similar to the agriculture census). In addition, data of broader interest to scientists and policymakers are collected in specialized surveys, including surveys on the economics of agriculture and ownership of land, farm labor usage, computer usage, agricultural practices (chemical usage; genetically modified organisms), injuries, and women's role on farms.

With the move to a new classification system, the North American Industrial Classification System (NAICS), the U.S. Census Bureau now has more detailed information on firm numbers, payroll, and employees for allied food and resource industries (timber, horticultural services, wholesale and garden centers, processors, distributors, and retailers). In addition to this information for all industrial categories, revenue, value-added, and manufacturer capital expenditure and inventory data are available, in addition to monthly revenue and inventory estimates for food service and retailers. Overall, agriculture production data is quite complete for traditional commodities and easy to disaggregate by enterprise and geography. More recently, it became a bit easier for those interested in broader issues related to food production to explore

emerging technology and social and economic trends for a diverse set of agriculture, resource, and consumer topics. Yet, less frequent data gathering for some statistics (similar to the U.S. Census) makes it more difficult to assess production and finance issues relative to pricing and trade.

Agricultural and Food Prices

The availability of commodity, wholesale, and market prices for agricultural products is equaled only by data on publicly traded stocks and companies. Early on, the USDA invested money through the Agricultural Marketing Service (AMS) to place market news professionals in all major production areas of the United States. These professionals report prices being received at wholesale markets, shipping points, and terminal markets, and when possible, a sense of the relative volume, quality, and types of products moving through markets. These data are very rich in detail across time, with 400 daily, weekly, monthly, and summary annual reports covering most major foods and some ornamental horticulture products. The high frequency of the data is important because of the industry's seasonality and the perceived need for real-time information for planning by producers, shippers/distributors, and processors. The USDA now has all of these data products available on-line for researchers, and in some cases, offers compiled reports for those doing historical price analysis across a longer time period.

Beyond USDA/AMS price reports, the Chicago Board of Trade, the Chicago Mercantile Exchange, the Kansas City Board of Trade, and the Minneapolis Grain Exchange provide daily updates on futures market pricing information for most major grains (corn, soybeans, and a variety of wheat varieties) and livestock products (pork and beef). There are also some analysis-oriented organizations that track prices and provide it to industry and academic professionals. The Livestock Marketing Information Center provides prices, production, situation, and outlook data for several livestock products, and several Internet web sites offer free or reasonably priced databases for vegetables and fruits (www.todaymarket.com and www.produceforsale.com).

To track the share of consumer food dollars that return to farms, the USDA estimates the value of a market basket consisting of a fixed quantity of food at the retail and farm level, to determine the price of providing services associated with marketing foods. In recent years, the USDA has also been exploring investments in retail scanner data to get more detailed information on retail prices for differentiated meat and produce, including how feature sales pricing influences marketing margins and prices paid by consumers.

The attention to farm and retail price spreads motivates discussion of some of the limitations of available agricultural price data. As consolidation in the food retail, distribution, and food service industries has led to fewer companies making fewer public transactions, the validity of prices from remaining cash-based open markets is called into question. Still, the volume and frequency of price data for food at the farm, wholesale, and terminal market levels provide a rich informational resource for business planning and research.

Agricultural and Agribusiness Trade Data

With increased globalization, international trade is an important issue for any industrial sector, but the agricultural sector is especially influenced by trade because of related political, development, and historical issues. There are two key sources of food trade data. The USDA's Foreign Agricultural Service offers several different databases for data on international agricultural trade, including different market levels (bulk commodity, intermediate food inputs, and more fully processed food products), and breakdowns at the commodity level for both imports and exports. These data can also be disaggregated by the sending or receiving industry and country. The USDA's Economic Research Service then uses state-level historical production data from NASS to determine state export shares for crops and livestock. The FAS also provides outlook and data reports on various world markets by country and commodity.

The U.S. Census Bureau also tracks imports and exports by major product category on a monthly basis. This information is provided for imports and exports to and from each major trading partner. A fairly rich historical series is available, but these data are not delineated by commodity, so agricultural products cannot be specifically tracked. Again, these data exist for not only farm commodities, but also for agricultural inputs and processed food and textiles. There is also pertinent information from the general U.S. Census Bureau, which calculates expected world population by country, data often used when developing world food demand forecasts. The USDA's Economic Research Service reports these data, together with other macroeconomic data useful in analyzing international trade prospects, including inflation, gross domestic product (GDP), and real exchange rates for major agricultural trading partners. Following the reduction in apparent, tariff-based trade restrictions and new political economy issues, the USDA/ERS is beginning to develop typologies to measure trade barriers to agricultural trade, but there are only limited data. This is one limitation of agricultural statistics

available for international trade. The other weakness of any available data is that, with increasing integration across borders, less and less information is available from public institutions.

Rural Development and Agribusiness

Agriculture tends to drive the economies of many rural areas and plays a role in rural development policy and research. Calculating the contribution of agriculture to a local or state economy can be measured many ways. Often, employment, personal income, sales, and value-added data are used as measures, but these data are not necessarily readily available from one source. Additionally, the contribution of production agriculture extends beyond the farm gate to include the input, processing, and marketing sectors (cumulatively known as “agribusiness”), which are also important to many rural economies and communities.

Employment

Data on farm labor employment are collected by four major agencies: the U.S. Department of Labor, the Bureau of Labor Statistics, the National Agricultural Statistics Survey, and the Census of Agriculture from various surveying efforts. Reliable data on farm employment are difficult to collect due to the part-time and transitory nature of the employment, as well as the number of family members working on farms. Employment data for the other industries comprising agribusiness are developed and disseminated primarily by the Bureau of Economic Analysis (BEA) and can be disaggregated to a county level and downloaded from their web site. Often, the publicly released BEA Regional Economic Information System (REIS) data cannot be disaggregated to a small enough industrial classification. Special requests for unsuppressed, more detailed county employment data are often granted through the BEA. Additionally, data from an individual state’s Department of Labor and Employment can be used to supplement the BEA data.

Income

Data from the BEA are the primary source for both farm labor and proprietor income, as well as for other agribusiness industries. These data can also be supplemented by data from a state Department of Labor and Employment. Because employment and income data are available annually, they are a comparatively useful measure in determining the overall and changing impact of agriculture on a local economy in response to various shocks (policy,

climatic changes such as drought or flood, and trade balance).

Sales

Production and price data for commodities leaving the farm gate were discussed in Sections II and III. Still, it is important to note that, although the data are available on an annual basis, geographic delineations of these data are more limited due to the nature of production agriculture. Sales or output data for the input, processing, and marketing sectors are somewhat restrictive to work with because they are available only every 5 years from the various economic censuses.

Multipliers

Multipliers are often used to estimate broader economic impact by estimating the indirect and imputed economic activity related to direct revenues and input expenditures. The two primary sources for regional multipliers are the Regional Input–Output Modeling System (RIMS II) by the BEA and the Impact Analysis for Planning (IMPLAN) model by the Minnesota IMPLAN Group. Sometimes the data used to create the multipliers in IMPLAN have been used to supplement employment, income, and output data needs. Using the data directly is not recommended because, in cases, local estimates can be simple adaptations of national averages, but can offer data ranges and magnitudes when other sources are limited.

Social Concerns

Indicators of rural economic and social conditions are also important when addressing the economic condition of agriculture. The Economic Research Service (ERS) branch of the USDA researches and compiles data for measuring the condition of rural America. Some of the data they monitor include farm and nonfarm rural employment, labor and education, wages and income, poverty, infrastructure (including telecommunications and transportation), federal funding, and general demographics (including age distribution and changes in ethnic and racial composition). The ERS has also worked extensively defining more detailed geographic descriptors that enable richer county-level research. This detail is especially rich for analyzing nonmetropolitan area trends that may be related to degree of rurality and metropolitan area proximity. The ERS measures the “rurality” of an area based on characteristics of the area in addition to the federal definitions provided by the Office of Management and Budget (OMB). The ERS has developed various codes and spatial aggregations useful for understanding rural areas, including typology, urban influence, rural–urban continuum, commuting zones, and labor market areas. Most of

the demographic (including income and poverty) measures that the ERS monitors are collected by the U.S. Census Bureau and most of the employment, labor, and wages are collected by the Bureau of Labor Statistics.

Land Use

The number of acres planted and harvested by state and county are available annually through the National Agricultural Statistics Service, although collection is limited to the major commodities. The Census of Agriculture collects information on land use every 5 years. Variables can include land in farms, harvested cropland by size of farm, value, water use, and crop use—in essence, the productive resource base of agricultural-based rural areas. The National Resources Inventory through the Natural Resources Conservation Service (also the USDA) conducts a survey of land every 4 to 5 years as a means to monitoring the status, condition, and trends of soil, water, and other natural resources in the United States.

Food Security

The Economic Research Service leads federal research on food security and hunger in U.S. households and communities. They also provide data access and technical support to facilitate food security research in the United States. The USDA web site provides a list of publicly available national surveys on food security in the United States. Food security for a household, as defined by the ERS, means access by all members at all times to enough food for an active, healthy life. Food security includes at a minimum (1) the ready availability of nutritionally adequate and safe foods and (2) an assured ability to acquire acceptable foods in socially acceptable ways (that is, without resorting to emergency food supplies, scavenging, stealing, or other coping strategies). The Current Population Survey—Food Security Supplement (CPS—FSS) conducted by the Census Bureau for the Bureau of Labor Statistics is the primary source of national and state-level statistics on food security in the United States. The data are primarily national, with state-level data available for “food insecure” and “food insecure with hunger.” Related to food security is food consumption. The ERS also annually calculates the amount of food available for human consumption in the United States. This series tracks historical national aggregate consumption of several hundred basic commodities and nutrient availability annually; the data date from 1909 and go through 2001. Although there are full time series on many foodstuffs and their subsequent nutrients, more commodities have been gradually added through the years.

Food security is also based on the availability of safe foods. The ERS provides a variety of resources and research on food safety, including estimating the costs of

foodborne disease. The Centers for Disease Control, using several surveillance systems, are the primary agencies that collect data on food-related illness in the United States. Currently, only national data are available. Data on food-related illness are limited for many reasons, including nonreporting and unknown sources of transmission of pathogens. State Departments of Health are also a source for food-related illness information.

For those facing food security shortfalls, the USDA administers numerous domestic food assistance programs through the Food and Nutrition Service (FNS). Programs include the Food Stamp Program, the Special Supplemental Nutritional Program for Women, Infants, and Children (WIC), and the Child Nutrition Programs (School Lunch, School Breakfast, and Summer Food Service). These programs account for about half of total USDA outlays. Expenditures for the USDA’s food assistance programs totaled \$20.9 billion during the first half of fiscal 2003 (October 1, 2002, to March 31, 2003), a 7% increase over the first half of fiscal 2002. The entire USDA budget, including allocations to these programs, is available at the USDA web site.

Several organizations maintain information on food assistance programs. For research, start with the ERS data, and for data and information on the programs, consult the Food and Nutrition Service division of the USDA; the USDA web site is the source for all of this type of information. The Bureau of Census also conducts a survey on program participation, known as the Survey of Income and Program Participation (SIPP). Information on statistical sampling methods, variables, and access to the survey data is available at www.sipp.census.gov. Substate participation rate data for the food assistance programs can be difficult to acquire from the federal agencies, but state agencies administering the food assistance programs can also be sources for county-level program participation data.

The Food and Nutrition Service division of the USDA also administers food distribution programs that provide food and nutrition assistance to eligible individuals and institutions, and provides data on total participation and assistance in these programs at the USDA web site. The Farm Service Agency Commodity Operations Office provides data on purchases of basic nonperishable commodities such as cereals, grains, peanut products, nonfat dry milk, and vegetable oils for eligible outlets participating in food distribution programs. Beyond providing food assistance, the USDA also provides nutrition education through the FNS, which provides some research on usage and effectiveness of programs.

Summary Overview

The scope and detail of agricultural statistics has increased greatly since the first agricultural census of

the United States. The economic, social, environmental, health, and cultural aspects of farming and food have led to a complex set of programs, policies, and research questions that are served by, and contribute to, the data resources available on agricultural issues. This article has given a very broad overview of the types of data available, and an evolution of how agricultural statistics have come to include an increasingly broad set of information. Still, the breadth of agriculture's reach does not compromise the need for heightened attention to this sector, as there are so many unique natural resource, production methods, food security, and international factors related to agriculture.

Further Reading

The following entities maintain Internet web sites that publish a variety of topics of national, state, county, or local interest.

Agriculture Marketing Service (www.ams.usda.gov). Price data on crops and livestock.

Bureau of Economic Analysis (www.bea.gov). Annual state and county employment and personal income data, by industry.

Bureau of Labor Statistics (www.bls.gov). Annual, quarterly, and monthly state, county, and subcounty employment, labor force, and wage data.

Census of Agriculture (www.nass.usda.gov/census/). Every 5 years (years ending in 2 and 7), publishes state and county production, financial, land use, and demographic data.

Economic Research Service (www.ers.usda.gov). Farm labor employment and demographic data are published on an irregular basis.

Foreign Agricultural Service (www.fas.usda.gov). United States and individual state import and export data.

National Agricultural Statistics Service (www.usda.gov/nass/). Annual state and county crop and livestock production data.

Natural Resources Conservation (www.nrcs.usda.gov). Every 4 to 5 years, publishes state land use and natural resource conditions and trends.

United States Census Bureau (www.census.gov). Annual and decennial state, county, and subcounty population, age, race, poverty, and education data; a state and county economic census of employment, payroll, business establishment, and sales data is conducted every 5 years.

Alpha Reliability

Doris McGartland Rubio

University of Pittsburgh, Pittsburgh, Pennsylvania, USA

Glossary

coefficient alpha An index of the internal consistency of the measure. It is a lower-bound estimate of the reliability of a measure.

Cronbach, Lee The creator of the coefficient alpha or Cronbach's alpha.

Cronbach's alpha Coefficient alpha (named after the developer of the index).

correlation The degree to which two variables are related.

essential tau-equivalence The items that measure a particular factor have the same factor loadings on that factor.

homogeneity An assumption of alpha that all of the items are equally related and come from the same content domain.

internal consistency A type of reliability that indicates the extent to which the responses on the items within a measure are consistent.

items The individual questions, statements, phrases, sentences, or other word arrangements on a measure.

measurement error The amount of variance present in an item or measure that is not attributable to the construct.

multidimensional measure A measure that assesses more than one attribute of a variable.

reliability The extent to which a measure is consistent; this can be demonstrated by either stability within the measure (consistency) or stability over time.

unidimensional measure A measure that assesses only one attribute of a construct. Unidimensionality is an assumption of coefficient alpha.

Reliability is concerned with the consistency of a measure, either at one point in time or over time. When measures are administered at one point in time, the type of reliability that is of primary concern is the internal consistency of the measure. Coefficient alpha is widely used as a measure of the internal consistency. Coefficient alpha

assumes that the items are homogeneous and unidimensional. A high coefficient alpha indicates that one item can be used to predict the performance of any other item on the measure. A low coefficient alpha can indicate either that the measure has poor reliability or that the items are not homogeneous. Having a high coefficient alpha does not provide any information as to the construct validity of the measure. Even if the measure has perfect reliability, this does not address what the measure is measuring. The measure must be subjected to further psychometric testing in order to ascertain its level of validity.

Introduction

Reliability is the degree to which a measure is consistent. The consistency of a measure can be shown by either the consistency of the measure over time or the consistency of the responses within a measure. When examining the consistency, we are concerned with the extent to which the responses vary (either between measures or within a measure) as a result of true variability or as a consequence of error. Reliability has been shown to represent the degree to which the variability in scores exemplifies the true variance in responses. In other words, the reliability of a measure reflects the amount of true variability, as opposed to variability attributable to error.

When assessing the psychometric properties of a measure, researchers often begin by assessing the reliability of a measure. At a minimum, the reliability provides an indication of the amount of error present in a measure. However, reliability does not address whether the measure is accurately assessing the construct. Nevertheless, an important component of validity is that the measure is reliable. In other words, reliability is necessary but not sufficient for validity.

When studying social phenomena at one point in time, researchers administer measures at one time. For this reason, the internal consistency of a measure is of paramount concern. Internal consistency assesses the reliability within a measure. It is this type of reliability that is the focus of this paper.

Definitions

Classical test theory indicates that:

$$X = T + E \quad (1)$$

where X is the observed score, T is the true score, and E is the error. Reliability is:

$$r = 1 - E \quad (2)$$

Because error and reliability directly correspond to one another, the type of reliability that we assess for a measure depends on the type of error that we seek to evaluate. When the measurement error within a measure is of concern, we seek to ascertain how much variability in the scores can be attributed to true variability as opposed to error. Measurement error within a measure manifests as a result of content sampling and the heterogeneity of behavior sampled. Content sampling refers to the sampling of items that make up the measure. If the sampled items are from the same domain, measurement error within a measure will be lower. Heterogeneity of behavior can lead to an increase in measurement error when the items represent different domain of behaviors. Other sources of measurement error within a test can occur, including guessing, mistakes, and scoring errors.

Internal consistency indicates the extent to which the responses on the items within a measure are consistent. Coefficient alpha is the most widely used reliability measure of internal consistency. Others measures of internal consistency include split-half and Kuder-Richardson 20.

Development of Alpha

Cronbach

Perhaps Lee Cronbach's most famous work stemmed from his 1951 article in which he presented coefficient alpha. Cronbach was able to demonstrate that coefficient alpha is equivalent to averaging all the split-half correlations. More specifically, if a measure consists of 20 items, the items on the measure can be split into two groups of 10 items each. Computing a correlation between the two groups provides a rough estimate of the reliability of a measure, but only for one-half of the test. If all the

possible groups of two are correlated and the average of these correlations is computed, this is equivalent to the coefficient alpha. This statement is only true if (1) the measure is tau-equivalent (discussed later) or (2) the formula for split-half is computed using the 1939 Rulon method. The Rulon method for split-half reliability is based on the variance of the differences between the two halves, as opposed to correlating the two halves and then computing the Spearman-Brown prophecy formula.

Relationship to Other Measures of Internal Consistency

Coefficient alpha is the most common measure of internal consistency. It is a function of the number of items and the interrelatedness of the items. Specifically:

$$\alpha = (k/k - 1) \left(1 - \sum \sigma_i^2 / \sigma_y^2 \right) \quad (3)$$

where k is the number of items, $\sum \sigma_i^2$ is sum of the item variances, and σ_y^2 is the variances of the total scores on the measure. Other measures of internal consistency are computed differently and are used for different purposes.

Split-Half Method

Prior to the proliferation of computers, internal consistency was computed using the split-half method. The split-half method entails splitting the measure in half, either by setting the top half versus the bottom half or by using the odd and even numbers. A correlation is computed between the halves. This estimate can then be generalized to the entire measure by using the Spearman-Brown prophecy formula (discussed later). The main limitation of the split-half method is that different splits produce different reliability estimates. How do we determine which split to use? Even more problematic is a speeded test or a test in which the items are ordered. Because most (if not all) computer packages for statistics include an option to calculate coefficient alpha, split-half method no longer is used.

Kuder-Richardson 20

As seen in formula (3), coefficient alpha is based on the variance of the item scores. With dichotomous data, a more appropriate method can be used to assess the internal consistency of a measure. This method is known as Kuder-Richardson 20 (KR20):

$$r_{KR20} = (k/k - 1) \left(1 - \sum pq / \sigma_y^2 \right) \quad (4)$$

where $\sum pq$ is the summation for each item of the proportion of people who pass that item times the proportion of people who do not pass that item. As can

be seen in formula (4), KR20 is the dichotomous equivalent to the coefficient alpha.

Characteristics and Assumptions

Measure of Internal Consistency

Coefficient alpha is a measure of the internal consistency of a measure. As such, alpha varies with the number of items and with the degree of interrelatedness between the items. The relationship among the items indicates the extent to which the responses on the items are consistent. When a measure is said to be internally consistent, the performance on one item can predict the performance on another item because the responses across items are consistent. For example, if a person is depressed, that person should consistently score high on a measure of depression. However, the internal consistency only documents that the responses are consistent and not the extent to which the items accurately measure the construct.

Not a Measure of Unidimensionality

Coefficient alpha does not assess the unidimensionality of a measure. A high coefficient alpha does not imply that the measure is unidimensional, nor does it imply that the items are homogeneous. However, if the measure is homogeneous, it will by definition be internally consistent.

Assumptions

Many people mistake the assumptions of coefficient alpha as being synonymous with the properties of the index. Coefficient alpha has three assumptions that cannot be ignored. The first assumption is that all the items have equal reliability. That is, the items contain the same amount of measurement error, indicating that the error cannot be correlated across items. Second, coefficient alpha assumes that the items are homogeneous. For items to be homogeneous, they all should measure the same latent variable. The third assumption is unidimensionality. The dimensionality of the items can be discovered by the pattern of correlations among the items. If different patterns exist, this could indicate the presence of different dimensions in the measure. In order for a measure to be unidimensional, three conditions must be present: (1) the measure must be homogeneous, (2) the measure must be internally consistent, and (3) the measure must be externally consistent. To be external consistent, all the items must correlate equally to an outside variable, taking into account sampling error. Therefore, internal consistency, as represented by coefficient alpha, is necessary but not sufficient for unidimensionality.

Properties of the Items

Number of Items

Researchers have repeatedly commented on one property of coefficient alpha, that alpha varies by the number of items in the measure. Although perceived as a weakness by some, if we accept coefficient alpha as a measure of reliability and not simply as a measure of the extent to which the items are homogenous, then this property is consistent with reliability.

If alpha were a measure of homogeneous items, we could argue that it should not vary by the number of items. As pointed out by Cronbach, a gallon of milk should be no more homogenous than a quart. Reliability, on the other hand, does increase as the number of items in a measure increases. Reliability is a function of the number of items and the reliability of the items. For example, 10 observations of a behavior are more reliable than only three observations. More items generate more information and therefore should be more reliable.

A limitation of coefficient alpha is that alpha becomes invariant as the number of items increases. Because a curvilinear relationship exists between the number of items and alpha (see [Figure 1](#)), as the threshold is reached coefficient alpha does not increase substantially. This relationship is true provided all the items have the same correlation with the total score. The threshold is dependent on several factors such as the homogeneity of the behaviors sampled. The measure may actually increase in its reliability, but this will not be manifested in the coefficient.

Direction of Relationships Between Items

In order to accurately assess the internal consistency of a measure using coefficient alpha, all the items should

Figure 1 Relationship between the number of items and alpha citation. Adapted from Nunnally and Bernstein (1994, p. 307)

be positively related to one another. In fact, if we fail to reverse code the necessary items, a negative coefficient alpha could surface. Coefficient alpha actually ranges from $-\infty$ to 1, and it is negative if negative covariances exist between the items.

Magnitude of the Relationship Between Items

It is unlikely that all the items in the measure will be equally related to one another. However, to the extent that the items equally relate to a single common factor, we can assume the essential tau-equivalence of the items. When the items are essential tau-equivalent, the true scores of the items are the same or the items' true scores only vary by a constant. If essential tau-equivalence is met, coefficient alpha is equal to the true reliability. Without tau-equivalence, coefficient alpha is a lower-bound estimate of reliability.

Uses for Alpha

Coefficient alpha is used to assess the degree to which the items are internally consistent. A high coefficient indicates that the items are interrelated. More specifically, the performance on any one item can predict the performance on each of the remaining items.

Coefficient alpha can also be used to determine the strength of the dimensionality of a measure. This can only be done, however, if unidimensionality has been previously determined. In this sense, coefficient alpha is used as a confirmatory measure of dimensionality.

A low coefficient alpha can indicate two things. First, the measure may not be homogeneous. That being the case, coefficient alpha could be reestimated on the items that are homogeneous. Second, and more problematic, the measure may have poor reliability. It is this second reason that leads us to reevaluate the measure to determine why the measure performed so poorly in the sample.

Spearman-Brown Prophecy Formula

The Spearman-Brown prophecy formula is used to estimate the change in reliability of a measure as a function of the measure's length. If the number of items in a measure is doubled, the formula can estimate the reliability for the longer measure. Similarly, if the measure is reduced by half, the formula can estimate the reliability for the shortened form.

The formula can be used in two ways. First, the formula can be used to estimate the reliability of a measure when the split-half method is used. In order to use the formula, the measure must be split in half and the two halves correlated. Once the correlation between the halves is known, the Spearman-Brown prophecy formula can be used to estimate the reliability for the entire measure. The formula is:

$$r_{sh} = \frac{2 * r_{12}}{1 + r_{12}} \quad (5)$$

where r_{12} is the correlation between the two halves.

The second application of the Spearman-Brown prophecy formula involves estimating what the reliability of a measure will be if that measure is shortened or lengthened:

$$r = \frac{k * r_{ij}}{1 + (k - 1)r_{ij}} \quad (6)$$

where k is the factor that the test will be increased by (e.g., 1/2 or 2) and r_{ij} is the reliability of the measure. For example, consider a test consisting of 50 items that has strong reliability ($r = 0.95$). If the test is reduced in half so that 25 items remain, the projected reliability of the test is $r = 0.90$:

$$r = \frac{1/2 * 0.95}{1 + (1/2 - 1)0.95} = \frac{0.475}{1 - 0.475} = 0.90$$

Conclusion

Internal consistency indicates the amount of measurement error present within a measure. This type of reliability provides useful information about the consistency of responses in a measure. If a measure has a high internal consistency, then we can assume a high degree of interrelatedness among the items.

Coefficient alpha is a measure of reliability that represents the degree to which a measure is internally consistent. A high coefficient only indicates that the items measure something consistently. Even with a sufficient coefficient alpha, we cannot draw any conclusions as to the validity of the measure. Alpha does not provide any information about *what* the measure is measuring; the construct validity of a measure still needs to be assessed. Reliability is necessary but not sufficient for validity.

At a minimum, coefficient alpha should be computed for every measure at each administration. Given the ease with which this index is calculated, we would be remiss if we did not study the reliability of the measure given in their specific sample.

Anthropology, Psychological

Steven Piker

Swarthmore College, Swarthmore, Pennsylvania, USA

Glossary

anthropology A discipline historically dedicated to a holistic understanding of humankind, including the diversity of cultural lifeways now and in the past, the social evolution of same, language, human biology, and the relationship of humankind to its close evolutionary relatives, extant and extinct. Psychological anthropology is a part of (mainly American) anthropology.

culture, general and evolutionary The mode of adaptation of the human species, featuring, e.g., speech, learned and diversifiable social relationships, religion, technology, and material culture, all of which presuppose capacity for symbol use.

culture, specific The way of life of a specific group, including especially meaning.

evolution The processes by which species, including the human species, arise and endure and change and become extinct.

personality Enduring psychological dispositions. Psychological anthropology workers, variably, emphasize emotional or cognitive and conscious or unconscious dispositions. Sometimes the dispositions are understood in the terms of an established psychological school (e.g., psychoanalysis, cognitive psychology), sometimes not.

relativism Everything that human beings do and think is relative, to a significant extent, to the specific cultural context in which the doing and thinking occur.

Anthropology emerged as a discipline in Europe and America in the last half of the 19th century. From the outset, it was, importantly, part psychological, and it has remained so throughout its history, especially in America. This article draws on and extends previous attempts by the author to make psychological anthropology sensible to the nonanthropologist reader. The approach is broadly

intellectual-historical, with emphasis given to recent and current developments.

Introduction

Psychological anthropology is a recognized subfield of (mainly) American anthropology. Its organizational focus is The Society for Psychological Anthropology, which is a branch of the American Anthropological Association, and its official journal is *Ethos*. Arguably, the central and enduring concern of psychological anthropology is the psychological mediation of the individual/culture relationship. The first organized school within psychological anthropology was culture and personality, established at about the time of World War II. Over the subsequent three decades or so, the subfield of culture and personality grew and diversified, and a number of its emphases remain active today. In part in reaction to culture and personality, and with reference to its major issues, new schools also arose, both within and outside anthropology.

Precursors (1920–1940): Anthropology and Psychoanalysis

In the first decades of the 20th century, anthropology and psychoanalysis attended to each other, and important anthropologists and psychoanalysts sometimes communicated directly with each other. For anthropologists, of course, Freud's still emerging oeuvre was the initial and main focus of attention. Significantly, attention was paid mainly not to Freud's "cultural" writings, but rather to his theory of mental symbolism and ontogenesis. And anthropologists (e.g., Bronislaw Malinowski and Margaret

Mead) began to take Freudian ideas and inspirations into the field with them in the service of understanding the psychological bases for the individual's relationship to his or her culture. This at once brought psychoanalysis into the domain of culture as lived day in and day out by natives—surely a far cry from the clinical chamber of the psychotherapist—and prompted preliminary personality/culture formulations on the part of anthropologists.

Emergence of Classical Culture and Personality: Abram Kardiner

For the study of psychology and culture, the period 1930–1945 was one of ferment and growth across the fields of psychoanalysis (e.g., Freud, A. Freud, Horney, Klein, Roheim, Erikson, Devereux, and Sullivan) and anthropology (e.g., Malinowski, Mead, Benedict, Sapir, Linton, and Hallowell). Amid this bustle, classical culture and personality took shape at Columbia University under the guidance and inspiration of the eclectic psychoanalyst, Abram Kardiner. In a series of seminars, a handful of anthropologists presented cultural material from their fieldwork, and Kardiner provided psychodynamic interpretation with suggested personality and culture relationships. From this collaboration emerged a general model of culture and personality, as well as a method for testing its validity. The model posits that basic personality, with its reality (conscious) and projective (unconscious) subsystems, mediates between primary institutions (subsistence, kinship and family, and socialization) and secondary institutions (especially religion; also, e.g., recreation, art, and folklore). Specifically, socialization practices give rise especially to the projective system of the basic personality, which expresses itself psychosymbolically, as posited by psychoanalysis, in projective institutions, in much the same manner that unconscious material is said by psychoanalysis to express itself in, e.g., the manifest content of dreams and neurotic symptoms. This model, therefore, suggests both that basic personality maintains projective institutions and that projective institutions serve important psychological functions for basic personality. Basic personality also has a collective referent. In small-scale socially relatively homogeneous cultures, Kardiner supposes there to be approximate uniformity of personalities; hence, it is possible to refer to the basic personality of a culture as well as of an individual.

The Kardinerian empirical test of this model was a culture-by-culture exercise in triangulation: For one culture, an anthropologist provided ethnographic accounts of socialization practices and religion, as well as projective test (Rorschach) protocols. From each of the first two, Kardiner attempted clinically informed inferences to

basic personality; independently, a Rorschach expert interpreted the test protocols. If the personality interpretations from all three sources agreed, then, for that culture, the model was validated.

Growth and Diversification of Culture and Personality

Much, arguably most, of the midcentury growth of psychological anthropology (then more likely to be called culture and personality) pertained to issues intrinsic to Kardiner's work, or suggested by it—hence, retrospectively, Kardiner's stature as a founder. Many of the figures involved in this growth, however, were not specifically inspired by Kardiner.

The Whiting School

The Whiting school, founded by John and Beatrice Whiting in the 1950s, may properly be considered second-generation Kardiner, at least in its early stages. The school accepted Kardiner's culture and personality model (renaming it the "personality integration of culture"), but strenuously disputed Kardiner's method for testing the model. Rather than treating personality as something to be measured, Whiting and associates treated the personality terms in the model as theoretical constructs, from which hypotheses positing covariation between primary and secondary institutions were deduced, and then tested in the cross-cultural survey manner. From this Kardiner-focused beginning, the Whiting school extended the personality integration of culture model to several domains of culture and pioneered the methods for cross-cultural study of socialization that continue to set standards for the field.

Projective Tests, Modal Personality, and National Character

For psychological anthropology, the Kardiner model brought to stage center the issues of cross-cultural study of personality and the intracultural distribution of personality traits. Because of its apparent success in psychiatry in the 1930s, and because the test stimuli were culture free and did not presuppose literacy, the Rorschach test seemed to be made to order for the cross-cultural study of personality. Early culture and personality optimism about the Rorschach, however, evaporated in the face of emerging difficulties, and the test fell largely into disuse in psychological anthropology. But not quite. DeVos and Boyer provided, arguably, the strongest and best organized justification for continued use of the Rorschach for the cross-cultural study of personality.

Meanwhile, *contra* Kardiner, some culture and personality workers were not finding approximate uniformity of personalities in small-scale, socially homogeneous cultures. On several personality dimensions, rather, weak modality and much overall diversity seemed to be the pattern. Wallace, with an elegant argument, demonstrated in 1961 that this should be expected to be so in socially homogeneous small-scale cultures, and that this circumstance is consistent with and, arguably, favorable for social stability.

As a sidelight to all of this, the “national character” school projected a broadly Kardinerian understanding of personality and culture onto a vastly larger cultural screen, that of the modern nation state. However, whereas the modal personality folks made the establishment of personality traits and their distribution in a culture an empirical question, and ditto for socialization practices, the national character school did not hold itself to this standard. Not surprisingly, then, although national character often purports to explain features of culture by reference to personality traits supposedly generated by socialization practices, its interpretations are often insubstantial. Arguably, the school’s greatest contribution is a number of rich and nuanced and informative depictions of national cultures. These depictions usually arise from study of the target culture through written sources (in other words, at a distance). In this methodological respect, the national character school (along with psychohistory) departs from the time-honored fieldwork, the empirical methodology of cultural anthropology, including most of psychological anthropology.

Psychoanalytic Anthropology and Psychohistory

As noted, psychoanalysis was central to the founding of culture and personality, and psychohistory is heavily dependent on psychoanalysis. So, regarding culture and personality and psychoanalytic anthropology and psychohistory, it is something of a judgment call where one leaves off and the other begins. Kardiner’s debt to psychoanalysis has been noted. Perhaps the main distinction between classical (Kardinerian) culture and personality and psychoanalytic anthropology is that (mainly) the anthropologists who practice the latter are more literally psychoanalytic in interpretation of their cultural case materials than are classical culture and personality anthropologists. Perhaps the main distinction between psychoanalytic anthropologists and psychohistorians is that the former are typically anthropologists who employ fieldwork to collect their empirical materials; psychohistorians primarily perform mainly psychoanalytic interpretations of, e.g., historical figures (such as Luther, Ghandi, Hitler, and Saddam Hussein) or cultural phases (such as

Nazism, racism, and reactionary politics) at a distance, relying on literature. Psychohistory is also often judgmental, and a curious feature of the field is that the same terminology is sometimes used for both analysis and insult.

Culture and Mental Health

The interest shown by psychological anthropologists in culture and mental health was evident in the writings of the pre-Kardinerians and has persisted. Recent and current workers in this field are more likely to call themselves medical anthropologists than psychological anthropologists. But recent and current work partakes of heartland psychological anthropology issues, including especially the transcultural validity of psychological (including psychiatric, or diagnostic) categories. Much of this work departs from, and criticizes, two Western biomedical postulates, which are enshrined in the *Diagnostic and Statistical Manual*, viz., that broad swaths of the emotional and experiential spectrum are properly medicalized, and that the diagnostic categories for doing so are transculturally valid.

Issues

The diversification of culture and personality in the 1970s and 1980s can be glimpsed by noting major issues treated by leading practitioners. The early work of Anthony Wallace has already been mentioned. Wallace built organically on his work to treat acculturation and revitalization, and to explore the interfaces among anthropology, psychiatry, human biology, and neuroscience. In the manner of Kardiner, Erik Erikson, also an eclectic psychoanalyst, lavishly imbibed anthropology in pursuit of an understanding of personality and culture. His conception of ontogenesis is epigenetic, life history is his method par excellence, identity his master concept, and biography his main vehicle for relating personality to culture and history. Although psychological anthropology has largely moved away from psychoanalysis, the careers of Weston LaBarre and George Devereux have remained faithful to the early charter, and to excellent effect. Nowhere is there a fuller and more psychoanalytically informed depiction of religion as a projective institution than in LaBarre’s work in 1972, and Devereux, whose renaissance-like career touched so many important bases within and beyond psychological anthropology, leads the field in adapting the clinical methodology of psychoanalysis to field work. Alfred Irving Hallowsell, whose brilliant and eclectic career predated and outlasted classical culture and personality, worked out, especially as regards self and culture, the basics of what cultural psychology, 30 years later, claimed to have invented. Regarding psychological functions of religion, the psychology of

culture change, and psychocultural evolution, Hallowell was a pioneer. Gilbert Herdt's work in Papua showed that hypo macho masculinity and obligatory male homosexuality can co-occur. In a culture and personality framework, Herdt deployed these data to revise and vastly extend accepted wisdom on the content and development of gender identity. Gananath Obeyesekere has brilliantly employed a theoretical integration of Freud and Max Weber, tied to his own Sinhalese Buddhist case materials, to extend the concept of religion as a projective institution, and has recast "both psychoanalysis and anthropology in pursuit of a general conception which at once embraces psychoanalytic universals and . . . cultural variability, and relates the two . . . biographically and historically." Psychoanalysis and culture and personality agree in assigning analytic primacy to the universal conditions of early life. However, adult behavior, much of which projectively expresses the unconscious psychological residues of early life, is endlessly variable. Melford Spiro incisively discriminates the culturally variable from the universals, characterizes the latter, and grounds the latter evolutionarily.

Recent and Current Directions

Three current schools treat issues that have been at the heart of psychological anthropology for half a century or longer. One issue, cultural psychology, is by its affirmation a part of psychological anthropology. The others, evolutionary psychology and cross-cultural psychology, are not, but their relevance to psychological anthropology, now and in the past, is great, hence mention of them here.

Cultural Psychology

Cultural psychology, now probably the largest part of psychological anthropology, is founded on a reaction against much of the discipline of psychology as well as much of earlier psychological anthropology, and what purports to be a new and better psychological anthropology inquiry agenda. Cultural psychology dislikes four things:

1. Psychic unity conceptions, which posit central psychological processing mechanisms that can be learned about and characterized independent of any of their real-life instances, but which everywhere operate to generate thought, feeling, and behavior. Presumably these mechanisms include the perceptual processes that the psychologist studies in the laboratory, and the ontogenetic developmental processes that psychoanalysis posits and that culture and personality adopted and adapted.

2. Nomothetic interpretation, for reasons shortly to be seen.

3. The new cognitive psychology, grounded in brain science and driven by computer simulations, because of its mechanistic and deterministic implications.

4. Much of earlier psychological anthropology.

What, then, does cultural psychology favor? To begin, take "cultural psychology" literally: human psychology is irreducibly culture specific. A central emphasis is that neither culture nor the individual is analytically prior—rather, they are mutual and they interact continually. From this emerges and reemerges the "constituted self," which is the repository of the higher order mental processes that provide the psychological mediation between individual and culture. Because for cultural psychology each culture is a unique historical product, and because higher order mental processes emerge from individual/culture interaction, there can be no panhuman culturally relevant psychology. Human mental processes must be locally and particularly and variably constituted; e.g., it is not possible that depression in middle-class America and depression on the Ifaluk Atoll in Micronesia can be the same things. Cultural psychology emphasizes that human life is creative and agency driven; its writing abounds with verbs such as "negotiate," "translate," "constitute," and "construct." For the empirical domain of cultural psychology (the psychologically mediated individual/culture relationship), successful general theory is not possible; good interpretation must be idiographic. The conceptual baggage of cultural psychology purports to provide guideposts for this. For many cultural psychologists, hermeneutics is or could be the watchword; positivistic methods in search of general laws are disparaged.

With such a charter, the field's payoff could be expected to be in the case studies and the specific interpretations built on them. And this expectation is borne out by a large and growing body of admirable empirical cross-cultural studies, many but not all ethnographic. Now, just a little taste of this: The Cartesian mind/body dualism, coupled with the idea that the body houses a panhuman emotional repertoire that opposes the rational cognitive workings of the mind, suffuses Western culture and thought, including the academic disciplines that treat humankind. Cultural psychology rebuts this with well-executed studies of specific cultures. The superb study of the Ifaluk Atoll stands tall in this genre, and pays as well the traditional anthropological dividends of enabling incisive perspectives on our own culture. Ambitiously, Anna Weirzbicka has proposed, from lexical evidence, panhuman moral and emotional concepts, in seeking to reconcile the general and the culturally specific.

Identifying schools of thought can convey an overly compartmentalized view of a field, e.g., psychological anthropology. Cognitive anthropology, or culture and cognition, arguably the main focus of which is native knowledge and its relationship to culture as lived, evokes

this conundrum. Cognitive anthropology is at once an important part of cultural psychology and predates it. A specific culture, understood as the body of knowledge of which natives partake to be socially competent, has been and remains a conceptual bedrock of the field. Methodologies for investigating cultural knowledge, and how it informs everyday life, have been and remain the meat and potatoes of the field.

Evolutionary Psychology

Evolutionary psychology is the child of sociobiology, in the lineage of bioevolutionary theses on human nature and cultural elaboration of same. Few psychological anthropologists study evolutionary psychology, but, along with psychological anthropology, it is centrally concerned with the psychological bases for culture and how they arise. Unlike psychological anthropology, evolutionary psychology posits evolutionary sources and draws heavily on evolutionary science to make its case, especially those parts of evolutionary science that examine how natural selection operates to maximize reproductive fitness. To cut right to the chase, as expressed by Robert Wright, “what the theory of natural selection says . . . is that people’s minds were designed to maximize fitness in the environment in which those minds evolved . . . the . . . environment of evolutionary adaptation . . . Or . . . the ancestral environment.” For humans, the environment of evolutionary adaptation is the world of the foraging band, in which all of humankind lived for (conservatively) the first 90% of human history. In short, the evolved, biologically rooted human psychological and behavioral repertoire was fine tuned with reference to the adaptive exigencies of foraging band lifeways. By the evolutionary clock, it has been but the blink of an eye since human ancestors relinquished forager lifeways, and that is still basically human nature. From all of this, evolutionary psychology sets itself, *inter alia*, two large tasks: (1) to identify behavioral expressions of human forager psychologies in contemporary lifeways and (2) to illustrate the (perhaps cruel) ironies of history, viz., how historical change has consigned humans to modern lifeways that are often radically at odds with the most fundamental evolved aptitudes.

Accepting that humans are an evolved species, and that this entails that everything human is in some sense grounded in and/or an expression of an evolutionary odyssey, has evolutionary psychology advanced understanding of the specific sense in which those aspects of humanness that interest us are expressions of the nature of the evolved, biologically rooted human species? A “yes” answer includes the following dicta:

1. Evolutionary science provides the core theory (e.g., natural selection, reproductive fitness, kin selection, and reciprocal altruism) for evolutionary psychology.

2. The environment of evolutionary adaptation, which is knowable from studies of contemporary foragers and the archeological record, provides the initial empirical conditions.

3. Aligning (2) with (1), evolutionary psychology deduces a wealth of hypotheses about what to expect humankind to be like, behaviorally, and tests them against cross-cultural data. The linchpin of the system is supposition about what psychological traits made good adaptive sense in the environment of evolutionary adaptation. The hypotheses reach into many domains of human lifeways, but key domains for evolutionary psychology are the scope and content of altruistic behavior and female and male sexual behavior, or strategies.

A “no” answer might include the following statements:

1. In contrast to evolutionary psychology, it is not known in specific detail what foragers were like, behaviorally and socially, tens of thousands of years ago, and there is good reason to believe that forager lifeways then were so diverse that the taxon is valid only on a uselessly (to evolutionary psychology) high level of generality. Hence, the initial empirical conditions are not established.

2. The hypotheses that guide evolutionary psychology empirical work are not deduced. Rather, they allude to evolutionary science by positing functional “just so” stories, which arbitrarily posit an “environment of evolutionary adaptation” adaptive significance for the contemporary traits under investigation.

3. For a school of thought that purports to be evolutionary to the core, it is astonishing how little real biology is found in evolutionary psychology.

A “no” answer means that the strong and general explanatory claims of evolutionary psychology are not wrong, but rather empty. But even if this is thought, there is a lot in evolutionary psychology that merits careful attention. The inquiry agenda is of the first importance; evolutionary psychology pursues it with an intellectual rigor almost unknown in earlier bioevolutionary formulations on humankind, including especially the sound grounding of evolutionary psychology in evolutionary science, and the empirical studies are usually of interest in their own right.

Cross-Cultural Psychology

To begin, take “cross-cultural psychology” literally: it largely intends to deploy the concepts and methods of Western (positivistic) psychology in other cultures. In doing so, it has fostered lavish communication and collaboration among scholars from many nations and cultures. For (at least) two reasons, it is fitting to conclude this discussion with brief mention of cross-cultural psychology, even though it is not studied by anthropologists.

First, in its several iterations, psychological anthropology is mainly about both psychology and culture relationships, studied cross-culturally. And so, largely, is cross-cultural psychology, as the following titles from the authoritative *Journal of Cross Cultural Psychology* illustrate: “Sex differences in visual–spatial performance among Ghanaian and Norwegian adults”; “Intimacy: a cross-cultural study”; “Relationship of family bonds to family structure and function across cultures.” In addition, cross-cultural psychology has taken all of the main branches of academic psychology (e.g., perception, personality, cognitive) around the world.

Second, anthropology, including psychological anthropology, often posits that culturally relevant psychology is, to a significant extent, irreducibly culturally specific. Cultural psychology, specifically, sometimes takes this to the limit by eliminating the dependent clause. Cross-cultural psychology goes in the opposite direction, viz., human psychology fundamentally comprises panhuman processes that can be measured, anywhere, with the methodologies that psychologists have developed, or may develop. Within cross-cultural psychology, this view has been extensively developed and applied by the five-factor model, which posits five panhuman personality dimensions and claims a cross-culturally valid methodology for measuring them. Given the importance of especially personality for psychological anthropology, this disagreement between cultural psychology and cross-cultural psychology is emblematic of a (perhaps the) fundamental metatheoretical issue in play here—viz., concerning the study of psychology cross-culturally, can the conceptual and empirical methodologies of a “scientific” psychology neutralize or otherwise cut through the relativizing fog of specific cultures? Within psychological anthropology as treated here, the Whiting school sides with cross-cultural psychology, albeit its concepts and methods are vastly different. Acknowledging the fundamental importance of this issue, some suppose that it may not be amenable to empirical resolution.

Archaeology

Patricia A. Urban

Kenyon College, Gambier, Ohio, USA

E. Christian Wells

University of South Florida, Tampa, Florida, USA

Glossary

culture history The school of thought that dominated American archaeology prior to World War II; concerned with determining the time depth of past cultures and their spatial extent; little attention paid to explanation, group, or individual dynamics.

interpretive archaeology A subset of postprocessual archaeology; focus is on understanding past cultures, rather than explaining processes or change, and finding meaning in the material remains of the past.

postprocessual archaeology A catch-all term used for theory developed in opposition to processualist approaches; rejects fixity of knowledge, holding that all knowledge, and therefore all reconstructions of the past, are contingent on the individual and that person's social and historical context; focus is on human agency, identity, hegemony and counterhegemony, or resistance; also includes many gender/feminist and Marxist approaches.

processual (new) archaeology The school of thought dominant in American archaeology from the 1960s through the 1980s; focus is on archaeology as a science, on hypothesis testing, and on development of laws of human behavior.

This article addresses two related topics concerning the relationship of archaeology and other social sciences. First, both theory and methods are discussed, with the emphasis on theory that has been adopted from other social sciences and adapted to the specific circumstances of archaeology. The second section looks at what formal and quantitative methods archaeology shares with other social sciences.

Archaeology and Social Science Theory and Method

Introduction

In the United States, archaeology has two intellectual homes: the classics, in which the focus is Greek and Roman culture in the Mediterranean world, and anthropology, which encompasses everything else from ancient times, as well as certain approaches to more modern eras. Classical archaeology is definitely allied with the humanities, but anthropological archaeology, hereafter simply called archaeology, is firmly within the social sciences. The methods and ideas used in archaeology are drawn from the natural sciences (^{14}C dating, neutron activation studies of artifact composition, and so forth), the humanities (art historical analysis; some postmodern approaches to interpretation), and the social sciences. There is a relationship between theory in anthropological archaeology and other social science theories, i.e., cultural anthropology, sociology, economics, political science, history (arguably a social science), geography, and women's and gender studies (also a discipline that straddles the humanities and social sciences). The focus here is more on the theories derived from the social sciences than on methods, for the simple reason that archaeology shares few actual methods with other social sciences: most procedures are either unique to the field, or similar to procedures from other field-based disciplines, particularly geology.

The common roots of American archaeology and anthropology lie in the particularities of the New World, in which colonists encountered societies with demonstrable ties to prehistoric cultures. The juxtaposition of "primitive" Native Americans and "advanced" Europeans led to the

development of cultural evolutionary frameworks for evaluating and classifying contemporary and extinct peoples, theories used by archaeologists and cultural anthropologists alike. For archaeology, the presence of living decedents of ancient peoples gave rise to the direct historical approach, that is, using contemporary people and their cultures as analogies for interpreting the past. Interpretation using analogy remains a common method in contemporary archaeology. In the 20th century, the evolutionary approach of 19th century practitioners withered and died, but the direct historical approach lives on, informing much current interpretation.

The earliest school of archaeological thought in the 20th century, the cultural historical approach, focused on the systematics of space (where groups were located, how they migrated through time, and how sites and regions were organized) and time (dating). To gather spatial data, archaeologists in the early 20th century developed basic methods used to this day, including ground survey (generally on foot) and recording by mapping the site and determining the geographic location. Lacking the precise dating techniques developed after World War II, culture historians in the first half of the century developed regional chronologies based on stratigraphy (the study of the natural and cultural layers found in sites) and cross-dating through artifact similarities and traded items; both of these methods are borrowed from geology, but adapt well to archaeology. Artifacts, for example, substitute for geology's type fossils in comparisons. Artifacts, botanical and faunal samples and other materials, and stratigraphic profiles are obtained through controlled excavations, a method not employed by other social sciences. The first chronologies developed were imperfect (e.g., Stonehenge was thought to date to the time of the Phoenicians, although it is 3000 years earlier), but they laid the framework for later work. Though it is unlikely that any modern archaeologists would characterize themselves as culture historians, space–time systematics are still fundamental to archaeology, as is the social science theory that cultural historians borrowed from history: the present situation of a site or area can be explained in terms of its antecedent conditions. This is sometimes known as genetic explanation, not due to any connection to biology, but because of the relationship through descent of modern and ancient cultures.

After World War II, technical dating methods, largely based on newly understood atomic decay processes, brought refinement to cultural historical sequences. At the same time, American archaeologists became dissatisfied with the normative picture of the past delineated by culture history. That approach did not deal well with behavioral variation within cultures, nor did its practitioners seek to explain change except by antecedent conditions or supposedly self-evident processes such as population migration or diffusion of objects and, to a lesser extent,

ideas. The school developing in the 1960s and onward was self-named the “new archaeology” to emphasize its break with the past. The goal was explicit explanation, development of covering laws to aid both in explanation and the deduction of hypotheses and test implications, and a greater understanding of human–ecology relationships. Many of the ideas borrowed from other social sciences (see later) became part of “normal science” during the heyday of the new, or processualist, archaeology (because of its interest in the processes of cultural change and adaptations), which was considered a science modeled after natural sciences, particularly physics and chemistry.

The inevitable backlash against the excesses of processualist approaches is the unfortunately named postprocessual archaeology. This set of diverse approaches has a number of goals, among which are looking at decision making and agency; understanding sites in their particular landscapes; looking at identity, including the components of individual identity such as gender, age, sexual orientation, and ability/disability; and promoting the idea that knowledge is contingent, and that we cannot escape the ideas and language of our own era. Thus what we say about the past is as much about our times as ancient days. Inspiration is drawn from both the social sciences and the humanities.

The following discussions highlight the models and theories drawn from other social sciences that have been particularly important to anthropological archaeology since World War II. The text is telegraphic, and citations are at a minimum; nonetheless, readers should obtain enough background to follow up on particular approaches.

History

History and archaeology clearly overlap in temporal periods, methods (some archaeologists are able to use texts, whereas some historians rely on materials and goods to amplify the textual record), and societies studied (civilizations/high cultures—e.g., Egypt, Greece, China, the Aztecs). Archaeology covers the larger time span, and without written records tends to focus on long-term processes and group activities, defining societies on the basis of differences in material culture rather than in language or self-ascription. Nevertheless, both history and archaeology are concerned with diachronic and synchronic change and have similar approaches to explanation. Despite this, little conscious attention has been paid by archaeologists to history, except for recurring enthusiasms for Collingwood's contention that it is possible to think one's way into the past—that is, to understand it on its own terms. Recently, the Annales school of history, founded by Fernand Braudel, whose most influential work for archaeologists is *The Mediterranean and the Mediterranean World in the Age of Phillip II*, has

affected a few archaeologists, but in different, almost opposite, ways. One objective of this school is to examine human history in the *longue duree*, the long-term relationship between humans and their environment. Such inquiry has been basic to archaeology: the current difference is a greater concordance between archaeological and historical theory about investigating these issues. The smaller scale aspects of Braudel's theory are also of interest to archaeology. These include medium-range processes such as conflict and economic change and shorter trends, such as group or individual decisions. The latter concern, agency, is of particular interest to postprocessualists, although they derive much of their inspiration not from the Annalists, but from sociology and cultural anthropology. More recently, the Annales school has de-emphasized the extreme long term, instead providing detailed descriptions of events, with special attention to agency. The descriptive aspects are similar to thick description as defined by Clifford Geertz, again of interest in contemporary archaeological theory. Postprocessual, or interpretive, archaeologists also concur with Annalists in rejecting the positivism of natural science. Works such as *Interpreting Archaeology: Finding Meaning in the Past*, by Ian Hodder and associates, amply illustrate the trend toward understanding and away from explanation, particularly of a positivistic sort.

Political Science

Archaeology and political science overlap in their concern for the development of the state and the forms of society leading up to it. In archaeology, this is known as the origins of social complexity, and archaeologists have drawn most inspiration from cultural anthropologists, both theorists (e.g., considerations of evolutionary stages such as bands, tribes, chiefdoms, and states) and ethnologists (for example, ethnographers working on African polities). Political science theories have been tested against archaeological data and largely found wanting; for example, humans have never lived in a state of nature. To be fair, political scientists are more concerned with modern governmental structures, international relations, and ideal types of social organization than with the pottery and stone tools of actual early states. Nonetheless, the connections between political science and archaeology are few because the overlap in subject material is more apparent than real. A classic work addressing both political science perspectives and archaeology is *Origins of the State*, edited by Ronald Cohen and Elman Service.

Economics

Manufacturing, distribution, and consumption activities are central to archaeological inquiry, because these processes leave material remains. Interpreting the

remains and understanding the economic systems behind them require ideas, and here economics and archaeology have had many points of contact. The central question is whether ancient economic systems can or should be interpreted using models drawn from modern times; this is the formalist approach, where it is assumed that the ancients lived by, say, maximizing efficiency and minimizing effort. Examples of this approach are common, whether the society being examined is complex or a simple hunting and gathering society, and can be typified by the work of William Sanders and Barbara Price.

The opposite position is that of the substantivists, as exemplified by the early work of Karl Polanyi and others in *Trade and Market in the Early Empires*. Substantivists propose that ancient economic processes differ substantially from modern ones and that previous economic systems can only be understood in their own terms. Substantivist approaches appear to dominate archaeology, and practitioners have myriad models about the relationship between craft producers and elites (attached vs. independent), the location of production areas (households or distinct workshops), the level of production (part versus full time, specialized versus occasional), and the nature of exchange (market based, administrated, redistributive, tribute based).

Geography

The new archaeology movement was preceded some 10 years by similar changes in geography. The "new geography" sought to make geography more scientific, more explicit about its concepts and models, and prepared to explain, rather than just describe, geographic phenomena. The table of contents for Peter Haggett's original 1965 version of *Locational Analysis in Human Geography* is a virtual textbook of matters that concerned archaeologists interested in space: the nature of regions, describing regions and settlements, the nature and meaning of settlement hierarchies, modeling movement across space, conceiving settlements as nested in networks of interactions, and more. Much of what archaeologists saw as vibrant and new in the new geography has become internalized in contemporary archaeology. Many undergraduates learn about central places and their sustaining areas, but even at advanced levels, the fathers of central place analysis, Christaller and Lösch, may not be remembered.

There are some perduring gifts from geography to archaeology. The first is the idea of the "region," a space delimited physically or culturally that is a meaningful unit of analysis larger than the settlement, or even a site and its immediate hinterland. In archaeology, regions defined physically may be places, such as the Valley of Mexico or the Tigris–Euphrates drainage. Regions may also be defined on cultural grounds (the Levant, the Adena–Hopewell area, Mesoamerica). Whether physical

or cultural, regions are likely to have smaller units nested within them, such as sites of a variety of sizes and levels of complexity, resource zones, roads or pathways, and fields and other agricultural installations.

Typically, archaeological attention has been drawn first to sites, which can be defined as any space that has been used or modified by humans. Sites are described based on surface remains and excavation information in order to grasp their plans. Natural factors, such as the location of water, certainly influence site location and internal planning, but cultural factors (social differences, craft working, religious and ceremonial practices) are equally, and at times more, important. Such factors also influence the design or internal plan of sites. To assess site spacing and interaction, techniques such as “nearest neighbor analysis” have been borrowed from geography and used by archaeologists to examine how relatively equal settlements are spaced across large territories. Methods for analyzing network characteristics, such as minimizing length, maximizing traffic, or optimizing both, as well as how cultural and natural factors impact route location and form, have been adopted and adapted by archaeologists to discuss trade routes, road systems, and traffic patterns within sites.

Another major concern of archaeologists is whether the sites within a region are uniform in size and/or complexity, or if there is some sort of hierarchy present. Geographic models have been particularly important to modeling hierarchy. Walter Christaller first proposed “central place” theory based on his studies of German cities and industries; the English version of his core work is *Central Places in Southern Germany*. His classic model has constraints that are not realistic for the real world: sites are located in a uniform plain, without edges; resources are equally distributed; and, implicitly, culture is uniform across the space. He proposed that site hierarchies were developed based on a number of basic principles, such as administration, transportation, or security; and that once a system was developed with respect to a particular principle, it remained the guideline throughout time. His model, therefore, did not adequately deal with change. Nonetheless, many archaeologists were inspired by his work to look at settlement patterns in terms of central places. Norman Hammond, among others, applied Christaller’s principles to the Maya lowlands, and Henry Wright looked at lowland Mesopotamia. Wright realized that the standard hexagonal lattice presupposed by central place theory could not work in Mesopotamia, because of the linearity of the two rivers, and therefore modified Christaller’s conceptions to allow for a rectangular lattice of main sites and dependencies. Other archaeologists have made similar modifications.

August Losch followed Christaller (*The Economics of Location*, a translation of his second German edition, was published in 1954), but proposed that no one basic

principle defined the settlement pattern for any given area; rather, multiple principles were at work simultaneously, resulting in a heterarchical, rather than hierarchical, landscape that was richer and more complex than that of Christaller. Losch’s ideas appear to be more useful in real-world situations, but his work had less of an impact on archaeologists than did his predecessor’s. Nonetheless, the idea of a central place as the focus of a region, or at least a sustaining area or hinterland, is basic to contemporary archaeological analysis. These and other geographic approaches have also helped archaeologists think of sites in relation to one another—that is, as parts of networks, rather than isolated entities. Volumes such as *Network Analysis in Geography* by Peter Haggett and Richard Chorley have been heavily cited.

Three practical areas of congruency exist between archaeology and geography. First is sampling. Geographic samples often take the form of areas, for example, when a researcher is working on ground cover. At other times, the samples are point samples, such as resource locations or cities. Archaeological samples of space are similar; they are areas defined geographically, culturally, or expediently, or are specific points on the landscape, such as settlements, quarries, and so forth. Therefore, methods of sampling used by geographers can be useful in archaeology, and indeed have been adopted: transects and quadrats are two prime examples. The second area is testing or confirmation. Quantitative methods are discussed in Section II and are not covered further here. More qualitative methods are, however, shared between the fields, and the usual transmission pattern is from geography to archaeology. Nonstatistical tests can involve models (intellectual and physical) or simulations, as seen in the work of David Clarke (*Spatial Archaeology*) and Ian Hodder (*Simulation Studies in Archaeology*, and, with Clive Orton, *Spatial Analysis in Archaeology*), and in the classic articles in Kent Flannery’s *The Early Mesoamerican Village*; Richard Chorley and Peter Haggett’s *Models in Geography* was also highly influential. The third area of overlap is the presentation of spatial data. Both disciplines are concerned with maps and other ways of representing three-dimensional phenomena in two-dimensional media. The recent advances in geographic information systems (GIS) and computer-based mapping programs have been a boon to both fields. Beyond mapping, GIS will also be of inestimable value for analysis in archaeology, as it is in geography, because it is constructed to correlate, analyze, and visually display spatial data.

Women’s and Gender Studies and Psychology

Women’s/gender studies and psychology have been combined here for several reasons. First, neither is

considered wholly a social science, although both have some social science aspects. Second, the subject material they share with archaeology is limited. Social psychology is the subdiscipline that shares with women's and gender studies and archaeology a concern with individual behavior, and the formation of individual and group identity. The latter—identity formation—involves both self- and other-ascription and can concern issues such as race and ethnicity. Gender is, however, the subject most often addressed by archaeologists using ideas adopted from psychology and gender studies that are reworked to fit the peculiar nature of archaeological data.

Feminism has had many influences on archaeology, although the “waves” of feminist thought so often discussed by others flow somewhat differently in the archaeological discipline, compared to others. First-wave archaeological feminists forced the field to acknowledge that women had been neglected in prehistoric studies. The contributions of “woman the gatherer” were likely more important to ancient diet than were those of “man the hunter.” In the second wave, more explicitly feminist ideas were brought to the field. Archaeologists sought methods by which to see women in the archaeological record, and ideas to account for their activities as active agents, rather than as passive followers of charismatic males. Finally, the third wave has expanded archaeology's view to include a wider range of differences—age, sex, gender, disability, ethnicity, nation—and an appreciation of the active participation of all prehistoric peoples in the formation of their daily lives and choices about the future. People do not passively accept the slings and arrows of fortune, but learn how to fight back, protest, and subvert. The theoretical aspects of gender studies continue to be important, but few technical methods for recovering gender-related data, or even recognizing data, have been developed. Archaeologists, however, are learning not to project their own or their society's ideas about sex and gender onto ancient societies.

Sociology

The relationship between sociology and archaeology is not direct, and is for the most part mediated by cultural anthropology. Archaeology's recent concern with group and individual identity, as mentioned previously, is related to sociology's work with race and ethnicity. More significant are four sociologists who have had a profound influence on the postprocessual, or interpretive, school of archaeological thought: Wallerstein, Foucault, Giddens, and Bourdieu.

Emmanuel Wallerstein, an historical sociologist, developed the body of thought known as “world systems theory,” which is concerned with understanding the relationships between core and peripheral states in systems made up of multiple polities; his central works are

the three volumes of *The Modern World System*. In Wallerstein's view, peripheral states produce raw materials in bulk, which are shipped to the core states for processing. The manufactured goods produced in the core states are then shipped back to the peripheries, the members of which, lacking industries of their own, are forced to purchase the core's goods. Raw materials have less value than finished products, so the peripheral states are kept in perpetual subjugation to the more prosperous cores. Wallerstein's prime example of such a system, which need not literally cover the world, is the Mediterranean in the early stages of capitalism.

Because it was developed to explain relationships within capitalist economic systems, world system theory is not applicable in its original formulation to prehistoric states. The general idea of central, developed, core areas with dependent, underdeveloped peripheries has, however, been significant in much recent archaeological debate. Counterarguments have been mounted stating that dependency, “coreness,” and peripherality are in the minds of the analyst, and that use of the terms “core” and “periphery” prejudge the relationships to be found within systems of interaction. Despite any specific problems with Wallerstein's ideas, the interconnectedness he posits among political units has been crucial to understanding ancient interpolity interactions, and many archaeologists focus, as does world systems theory, on the study of networks of political entities, rather than on specific political units. The 1999 edited volume of *World Systems Theory in Practice* by P. Nick Kardulias and the chapters in *Resources, Power, and Interregional Interaction* (1992) by Edward Schortman and Patricia Urban show how archaeologists have amended and/or abandoned aspects of Wallerstein's conceptions.

Wallerstein's concerns with economic patterns makes his work of natural interest to archaeologists; the attraction of the more abstract notions of Michel Foucault (who is variably considered an historical sociologist or an historian), Anthony Giddens, and Pierre Bourdieu (who is either a sociologist or an anthropologist, depending on the commentator) are often more difficult to grasp. Christopher Tilley was among the first to utilize Foucault's self-proclaimed “archaeological method” to examine not the past, but how archaeologists view and reconstruct the past. Subsequently, writers such as Julian Thomas and Trevor Kirk (e.g., in Tilley's *Interpretative Archaeology*) have shown how Foucault's work can aid in a reconceptualization of archaeology, one that recognizes the near impossibility of gaining a true understanding of the past. Because what is claimed about ancient peoples' lives is determined not by their intellectual systems, but rather by our own, we must be aware that there is no definitive past, only contingent pasts shaped by contingent presents. Finally, Foucault calls our attention to power: it is part of all social relations and actions. Individuals

have “power to,” that is, they can through their own agency, try to ensure that events redound to their benefit. The complementary idea of “power over” reminds us that some individuals or groups can affect activities by manipulating other people. These others need not be complacent in the face of manipulation, but may resist or subvert the actions of dominants. Thus, power, like knowledge or identity, is contingent on circumstance. Responding to evolutionary thought as applied to culture change, Giddens has adumbrated structuration theory. Humans know their history, and act in accordance with it. Their actions are reinterpretations of and reactions to social structures; as they act, they change existing conditions, but within the constraints of their own history.

Finally, contemporary archaeological theory manifests considerable influence from Bourdieu’s theory of human action. In his perspective, the everyday activities that we all carry out are largely unconscious, and are passed down from earlier generations. This quotidian activity is termed *habitus*. Cultures have particular forms of habitus that characterize them, and are parts of individual and group identity. Even carrying out habitual activity, however, people make changes in their practices, and therefore engender change in the over-arching structures that generate habitus in the first place. Bourdieu’s and Giddens’ ideas are similar; they are subsumed under the larger rubric of practice theory, which is not confined to sociology. It has had profound influence on contemporary anthropological thought, as discussed, for example, by Sherry Orton in her 1984 article “Theory in Anthropology since the Sixties.”

Sociocultural Anthropology

Earlier, the origins of archaeology in the United States were discussed as the companion science to anthropology, both united in an evolutionary perspective that stressed unilineal change through a series of fixed stages. One of Franz Boas’ most enduring imprints on anthropology—and archaeology—was his debunking of unilineal cultural evolution and the racist tenets that the schema both deliberately and inadvertently promoted. Boas’ work did, however, show the value of the direct historical approach for understanding prehistoric Native American societies and furthered the use of ethnographic analogy as an analytical tool—that is, using data from modern people’s material culture to develop analogies about how prehistoric artifacts were used. The culture historical approach also obtained from Boas’ studies the idea of particularism, that each group has its own individualistic developmental trajectory. Although Boasian particularism did much to promote respect and understanding of different cultures, it also had the unfortunate effect of dampening comparative approaches in archaeology, except for comparison of artifacts for dating purposes. Seeing each culture as totally

unique inhibits us from seeing cross-cultural similarities; this is one of the aspects of culture history most reviled by the processual archaeologists from the 1960s through the 1980s. Whereas Boas and his students were not identical in their approaches to anthropology, the field in the United States was fairly uniform theoretically until after World War II. Developments in British anthropology, particularly the structural–functionalist approach that focused on the harmonious balance of parts within a society, and the resolution of conflicts in order to maintain that balance, had relatively little influence on American archaeologists.

After the war, several competing and quite different schools of thought emerged in the United States and across the Atlantic, all of which played a part in shaping archaeology as practiced today. The first, and for some time the most important for archaeology, was the neo-evolutionist group made up of Leslie White and Julian Steward, and slightly later including Elman Service, Marshall Sahlins, and Morton Fried. With the exception of Steward, these thinkers were interested in general evolution—that is, the changes in all of culture that took, and take, place through time; these alterations were/are largely caused by forces such as technological innovation, population growth, and conflict, in White’s version. What developed from White’s approach was a concept of stages of evolution, the now well-known bands, tribes, chiefdoms, and states of Service’s formulation, and egalitarian, ranked, stratified, and state-level cultures in Fried’s. Steward, on the other hand, believed that most cultural change was driven by adaptation to the environment. These adaptations are specific to a particular culture’s situation, rather than being the steps on a generalized path toward social complexity. The importance of the idea of adaptation to archaeological thought cannot be overstated. The evolutionary stages of Service and Fried have been operationalized and investigated, or used as heuristic devices by generations of archaeologists, but the stronger influence came from Steward and his concept of adaptation. Under the general rubric of cultural ecology, this school of thought was the basis of theory and practice in archaeology for decades. Ecological approaches were first pioneered during the 1920s and 1930s in Great Britain, but were hampered by a lack of suitable methods for recovering the necessary data. After World War II, archaeology generated a suite of methods for finding and preserving delicate floral and faunal data; in other disciplines, researchers interested in reconstructing climate also worked on these problems, with resulting interchange between them and archaeologists. Some techniques were also imported from biology, such as pollen analysis, which helps reconstruct both climate and diet. Almost no methods important to ecological reconstruction come from social sciences, but the ideas used to interpret how humans

existed in specific ecological circumstances are social theory.

A closely related offshoot of Steward and White's anthropology is cultural materialism. In distinction to cultural ecologists, who focus on how interactions between people and their environment shape culture, cultural materialists look at how specific parts of culture are developed to maintain an existing human–environmental relationship; that is, cultural ecology looks at change, whereas cultural materialism looks at balance and function, although this line of thought accommodated change when brought about from the outside (from alterations in the environment). Both intellectual strands descended from White and Steward's thinking, but also were related to functionalist anthropology, and both were central to processualist theory.

The cultural materialist concern with equilibrium is related to new archaeology's interest in culture-as-a-system. In essence, this view perceives all parts of culture as being so intimately related that a change in one (say, a new way to produce foodstuffs) will cause changes in all other segments of the system. The ecology-inclined systems archaeologist would emphasize change, while the materialist-influenced archaeologist would likely examine how a perturbed system could regain its equilibrium: a new food production technology would at first be disruptive, but a group would soon return to an essentially unchanged version of its culture that incorporated, in a nondisturbing way, the new technology. In either case, post-World War II archaeologists were better equipped intellectually than were their culture-historical predecessors to grasp both equilibrium and change or evolution.

Just as virtually no one would today claim to be a culture historian, self-identified cultural materialists or cultural ecologists are also few in the 21st century. Nonetheless, this body of theory, the methods generated to gather and interpret suitable data, and the work produced by its practitioners are central to modern archaeology. The ideas of adaptation and the significance of the environment for culture change, as well as the concept that parts of culture have specific functions in maintaining a group's existence, are now, like basic space–time systematics and the concepts of central places and peripheries, “normal science”; they are virtually unexamined parts of archaeological thinking today, via the influence of the processual archaeologists of the 1960s and 1970s. Similarly, methods developed since World War II, such as collecting soil samples (for extracting pollen and other minute remains, and studying soil composition) or screening soil and using water flotation methods (to remove soil and recover small items, such as bones, fish scales, or stone flakes from making tools), are also normal procedures today, and have been extended and refined through collaboration with natural science colleagues.

Those current practitioners who find latter-day versions of processualism congenial are in the so-called scientific subset of archaeology, whereas those who abhor positivism are today called postprocessualists or interpretive archaeologists. This latter group is not a coherent school, but rather is composed of a number of groups that may be protoschools, and they take their inspiration from very different currents in anthropology, as compared to the “scientists.” Before turning to this most recent current in anthropological archaeology, the influence of Marxist thought must first be examined, for Marxism, though often occluded due to pressures and prejudices in modern Western society, was and continues to be a highly significant force in archaeological thought.

The ideas outlined in the preceding discussion, as well as others that cannot be covered due to limitations of space, often have a Marxist subtext. Sherry Ortner suggests that the predominant strain of Marxist thought in American anthropology is structural Marxism. Structural Marxists see the determinative forces behind culture change in social relations, particularly those subsumed under “modes of production,” or those aspects of social organization that mediate the production of goods and services. Structural Marxists also emphasize ideas, which had no independent place in the processualist scheme. Ideas, or ideology, serve many purposes, such as legitimating the existing system, obscuring inequality, or providing a rationale for elite prominence. Thus, this variant of Marxism deals with materialism and ideas, a task not accomplished by processualists.

There are additional significant parts of a Marxist perspective that have attracted archaeologists because there appear to be material correlates for particular social situations or processes. The first of these is inequality, which can be marked by differential access to basic resources such as food and housing as well as to exotic materials such as imported goods, or to luxuries that define different social roles or statuses. Inequality leads to conflict; thus one of the crucial aspects of the past to examine is the degree of inequality, and the factions or groups engaged in conflict. This conflict may be overt, but can also be more subtle, a form of resistance rather than outright hostility.

A final Marxist-related concept salient for contemporary archaeology is hegemony. Two groups of researchers appear to take an interest in hegemony and possible counterhegemony, or resistance: those working with complex, hierarchically organized societies, with a clear, dominant elites, and those who find themselves in situations wherein a more complex, or so-called high, culture is in a position to influence smaller or less complexly organized neighboring peoples. Hegemony in the former situation indicates domination with control, but for cultural groups in contact, it may simply mean influence or even dominance without any specific controlling mechanism.

The most thorough current review of Marxism and archaeology is Thomas C. Patterson's *Marx's Ghost*. So, in sum, the methods archaeologists have obtained from Marxism are analytical ones, such as examining class structure, or looking for evidence of conflict among members of a society.

One critique of Marxist approaches is that, like processualist ones, they emphasize groups and large-scale social dynamics. Individual people, or even smaller groups, are not present, and humans appear to be buffeted by forces beyond their control, rather than being active agents making decisions and acting on their outcomes. For this reason, as Ortner has so cogently pointed out, anthropology has increasingly turned to practice theory; archaeologists have followed suit. Much of practice theory is derived from the works of Foucault and Bourdieu. Cultural anthropologists, to be sure, are making their own contributions to practice theory, but the foundation remains the French sociologists discussed earlier. Practice theory can present difficulties for archaeologists, because mental processes are not preserved in the archaeological record, only the material results of those processes. Any given material situation, however, can have many causes, and the difficulty for archaeologists is deciding among those causes. Here lies one of the problems with postprocessual thinking: in rejecting positivism, some archaeologists have rejected as well the possibility of testing or confirming any statement made about the past. In the extreme, this is a sort of radical relativism in which any interpretation is as good as another is. In more moderate guise, a number of competing ideas remain, and, if postprocessualists are correct, there are no means of deciding among them.

The preceding discussion has focused on how American archaeologists tend to approach theory borrowed from sociocultural anthropology. However, it should be remembered that the British and Continental views of the relationship between anthropology and sociology, on the one hand, and archaeology, on the other, may be quite different. Michael Shanks and Christopher Tilley evidence this in their book *Social Theory and Archaeology*. In addition, Ian Hodder, who has been highly influential in the United States for the development of both processual archaeology, with his work on spatial analysis, and postprocessual archaeology, comes from the British tradition. Thus, in the past two decades, American, British, and European strands of thought have become more closely knit as there is a convergence on structuration, practice theory, and Marxist approaches.

Conclusion

Postmodernism in general has taught us that knowledge is contingent; in an archaeological context, this means that what we say about the past is conditioned by our

own present, including our considered theoretical stances and our less-considered life courses. Postprocessualists are correct to remind us that there are many pasts, depending on the beholders and their contexts. Further adoptions and adaptations of social science theory by archaeologists, as well as the development of purely archaeologically based theory, will continue to expand our conceptions of the past, while reminding us that these are firmly grounded in our own present.

Quantitative and Formal Approaches to Archaeological Data Analysis

Introduction

Inferring the nature and organization of human behavior in the archaeological record often requires the use of quantitative and formal approaches to data analysis. Many such studies carried out today employ a mix of graphic imaging with a variety of formal analyses, including descriptive and probability statistics, numerical classification and scaling, and quantitative modeling. This modern approach derives from two major developments in quantitative analysis over the past century: "statistical inference," shaped largely between 1920 and 1950, and the more recent "exploratory data analysis," devised by John W. Tukey and colleagues in the 1970s and 1980s, adumbrated in works such as Tukey's 1977 *Exploratory Data Analysis*.

Statistical Inference

Statistical inference involves hypothesis testing (evaluating some idea about a population using a sample) and estimation (estimating the value or potential range of values of some characteristic of the population based on that of a sample). Archaeologists were relatively slow to realize the analytical potential of statistical theory and methods. It is only in the past 20 or 30 years that they have begun to use formal methods of data analysis regularly. Influential essays by George Cowgill (e.g., in 1970 and 1977) and others such as David Clarke (in 1962), Hodder's 1978 *Simulation Studies in Archaeology*, Orton's 1980 *Mathematics in Archaeology*, and Spaulding (in 1953) demonstrated to archaeologists that, because most of their data represent samples of larger populations, statistical methods are critical for identifying empirical patterns and for evaluating how precisely and how accurately those patterns represent "real" trends in the broader world.

In addition to basic, descriptive statistics that summarize central tendency (what is a typical case?) and dispersion (how much variation is there?) in batches

of numbers, archaeologists primarily have made use of statistical methods for sampling and for comparing data sets. For example, for nominal scale data, the chi-squared test is one of the most commonly used means of determining the probability (given relatively small sample sizes) of whether a relationship exists between cases (e.g., pottery types), although it does not inform about the strength or kind of the relationship. For interval scale or ratio scale variables, archaeologists often use tests that depend on the gaussian (“normal”) distribution, although these, too, have their problems, such as sensitivity to irregularities (“outliers”) in the data. Along these lines, linear regression, analysis of variance, and hierarchical cluster analysis have been important, especially for temporal seriation—building chronologies based on stylistic changes in material culture over time.

Exploratory Data Analysis

Exploratory data analysis is concerned with visual displays of data, rather than with summary statistics and statistical significance tests that are based on deductive reasoning; this is discussed by Tukey. The aim of this approach is purely inductive: to explore the data set for patterning (“smooth data”), as well as deviations from that patterning (“rough data”), relevant to some problem. One of the basic ways in which archaeologists have operationalized this approach for examining univariate and bivariate data is by constructing histograms and stem-and-leaf diagrams, box-and-whisker plots, frequency polygons, and cumulative curves. More complex considerations involving multivariate data include Tukey-line regression, *k*-means cluster analysis, principal components analysis, and correspondence analysis, to name a few. These graphic displays, especially when combined with computer visualization tools, such as geographic information systems, computer-aided design programs, and mapping software, have prompted archaeologists to work inductively and to become more intimately acquainted with their data. The new archaeology of the 1960s and 1970s required archaeologists to work within a hypothetico-deductive framework, with *a priori* models, theories, and assumptions, which were then evaluated with data. Today, with incredible advancements in computer-based imaging and graphic quality, research often begins with the discovery of patterns in graphically displayed data, which leads archaeologists to formulate new questions and to discover new relationships in an interactive process between hypothesis testing and graphic displays. The end result is that models of past human behavior often are built from the ground up, in contrast to “theory-down” approaches of the previous decades.

One example of the exploratory data analysis approach in archaeology is correspondence analysis. Pertinent

works are by J. M. Greenacre (*Theory and Application of Correspondence Analysis*) and J. M. Greenacre and J. Blasius (*Correspondence Analysis in the Social Sciences*). Originally developed by Jean-Paul Benzecri in the 1960s and 1970s for linguistic applications, this multivariate analytical technique is designed to analyze data consisting of frequencies of occurrence in a two-way contingency table, with the aim of showing a graphical representation of the two-dimensional relationships (viewed on a scatterplot) between cases, those between variables, and those between cases and variables. The analysis produces a graphical display of the rows and columns of the data matrix, illustrating clusters within the rows and within the columns, as well as the association between them. Here, both cases and variables are plotted together. Importantly, the analysis reduces domination by frequency counts and focuses on relationships between groups of objects and their context. This capability helps to overcome the fact that in situations in which some variables have significantly higher frequencies than others, such as in artifact assemblages representing different activity areas, the variation in the former will tend to dominate the analysis and the variation in the latter will have very little effect on it. For interpreting the plot, if two sets of cases are similar, then they will appear close to one another on the scatterplot. Likewise, if a case and a variable are similar, then these will tend to appear close to one another on the plot as well. In this way, the relationships among cases can be compared to one another, as well as their relationships to variables. Thus, this analysis can determine the relative strength of a relationship between cases as well as the ways in which the cases are similar.

Combined Approaches

One of the more influential quantitative studies that emerged in archaeology during the 1970s, based on central-place theory, combines graphic display with statistical inference. The theory, originally developed for market economies by geographers Christaller and Lösch, proposes that a regular hexagonal distribution of hierarchically ordered central places is optimal for minimizing the cost of travel and transport and for maximizing economic profits. In central-place analysis, the hierarchy of central places is established on the basis of the sizes of centers (e.g., using rank-size measures, as discussed by Haggett in *Locational Analysis in Human Geography* and in numerous articles by archaeologists). Size is assumed to correlate positively with the number of functions the center performs such that larger centers perform more functions than do smaller centers. Rank-size analysis can be used to examine the degree of socioeconomic integration of a settlement system by plotting the sizes and ranks (based on size) of all settlements on a graph. For this

study, graphic plots are produced by arranging settlement size data in descending order by size, assigning a numerical rank to each (with the largest being ranked first), and plotting size against rank using a logarithmic (base 10) scale. The idealized rank-size distribution (referred to as lognormal) is represented by a straight, negatively sloped line. Rank-size plots for particular settlement systems may approximate this line, or individual cases may lie above or below it. Distributions that lie close to the lognormal line are taken to imply a high degree of organization, cohesiveness, and interaction in a tightly integrated settlement system with a strong hierarchical structure. Deviations from the lognormal rank-size relationship (e.g., disparities in size between the first- and second-order settlements) are believed to reveal important properties of settlement structures, including the degree of centralized control or system organization.

Summary of Quantitative and Formal Approaches

In sum, quantitative and formal analyses in archaeology play an important role in evaluating patterns discovered by visual examination. As George Cowgill often has remarked, statistical analysis is not a way to arrive at certainty; rather, it is a powerful aid in discerning what the data suggest, and how strongly they suggest it. Thus, for archaeologists, quantitative methods of data analysis are often done by an estimation approach rather than by hypothesis testing. Visualization tools are essential to this effort, because simple statistics cannot convey the essence of spatial patterning in the same way that an effective graphic can. Statistical methods likewise are critical, because they provide information about the existence of tendencies or relationships (as well as the strength of those relationships) that are difficult, or even impossible, to visualize. In the future, archaeologists are likely to move beyond the statistical methods now current to nonprobabilistic methods. As their name implies, nonprobabilistic statistics are not based on probability, that is, normal distributions of data (say, random samples drawn from a known population). True archaeological populations are never knowable: no matter how thorough a surface survey, not all sites that ever existed will be found; and when working with artifacts, the sample being used consists of only those items recovered during surface collection and excavation, with the actual population remaining unknown and unknowable. Therefore, the methods discussed herein will be expanded by new approaches, ones that are relatively recent additions to the corpus of formal methods.

Glossary

definition For Aristotle, a definition is an account of the essential characteristics of the object being defined. These essential characteristics are discovered through the use of division and causal investigation. In fact, for Aristotle, to know the fundamental cause of something is critical to having a scientifically valid definition of it. Because scientific definitions identify a thing's proper kind and the fundamental ways in which it differs from other members of the kind, a scientific definition can be represented by means of a demonstration.

demonstration A form of proof that provides scientific understanding of a fact within the domain of the science. As Aristotle defines it in his *Posterior Analytics*, such understanding comes from knowing the primary causal explanation of the fact in question.

division A method for systematically examining variation, or relations of similarity and difference, within a kind. In *On the Parts of Animals* and *History of Animals*, Aristotle criticizes the *a priori* method of dichotomous division defended by his teacher, Plato, and presents an empirical method of division that permits the systematic organization of information in scientific domains in which the objects are complex and multivariate.

polis A transliteration of the Greek word for a common method of social, political, and economic organization in classical Greece. On Aristotle's account, a polis is a natural result of the development of human society.

social animal Aristotle uses the expression *politikon zōon* ("social animal") to refer to a special subclass of gregarious animals, which includes humans and the social insects. Note that *politikon* is an adjective based on "polis," but it would be very misleading to translate it as meaning "political." Aristotle discusses social animals as a group in *History of Animals*, and, in *Politics*, he discusses human social organization as a form of animal social organization, differentiated in accordance with the characteristics that distinguish humans from other social animals.

the more and less A technical expression in Aristotle's work, along with "excess and deficiency," referring to measurable

variation of a characteristic within a single kind. Forms of that kind will share all or most of the characteristics of the kind, but those characteristics will vary from one form to the next by "the more and less." Divisions within kinds will, in fact, organize information about more and less differences. Differences between kinds are, by contrast, according to analogy.

It is fair to say that Aristotle was the first person to attempt something that is recognizably a scientific study of social phenomena, certainly in the three works *Nicomachean Ethics*, *Politics*, and *Rhetoric*, but also in his zoological investigations. This is because he saw his studies of human social life as continuous in a variety of ways with his natural science, and thus, to understand his approach to the scientific study of social interaction, it is necessary to know something about his views on mankind as one among a class of "social animals." It is also interesting to explore the role of measurement in Aristotle's theory of science. He had a very clear view about the role of mathematics in the study of natural phenomena and about the limits of its uses in science. Thus, even when his scientific approach to social phenomena is very different from the modern view, his philosophical sophistication allows us to learn from those differences. It was Aristotle's view that the application of mathematics to natural phenomena was a powerful tool, but with a limited scope. He was deeply, and properly, skeptical of attempts to reduce everything to numbers, a view he saw clearly expressed by the Pythagoreans of his day.

Life and Work

Aristotle was born to Nicomachus and Phaestis of Stagira, a small town on the northern Aegean coast, in 384 BC.

Nicomachus was physician to King Amyntas of Macedon, and Phaestis was of a wealthy family from the island of Euboea. Nothing reliable is known about Aristotle's early childhood, but he was sent to Athens at the age of 17 and began a 20-year involvement with the philosophical and mathematical community gathered around Plato in the Academy. Aristotle may well have studied some medicine with his father, but there is no evidence to support this conjecture.

Aristotle's long association with Plato and the Academy ended on Plato's death in 367, by which time Aristotle had doubtless begun to develop his own distinctive philosophical ideas, including his passion for the study of nature. At the invitation of Hermias, a tyrant with connections to the Academy, Aristotle and other Academics founded a philosophical circle in Assos, a small town under Hermias' control in Asia Minor. Aristotle soon moved on to Mytilene on the island of Lesbos off the coast of Asia Minor, perhaps because he had heard of a young man with similar interests in natural science, for he there met and befriended his philosophical soul mate Theophrastus. Between the two of them, they originated the science of biology, Aristotle carrying out the first systematic scientific investigation of animals, Theophrastus doing the same for plants. This association was briefly interrupted when, in 343, Philip II of Macedon asked Aristotle to tutor his son Alexander. But by 335, Aristotle had returned to Athens, now firmly under the control of his former student. His philosophical distance from Plato was now great, and he and Theophrastus founded a rival group of scholars who spent their time in a public sanctuary known as the Lyceum. Aristotle remained at the head of this "school" until 323 BC. In that year, Alexander of Macedon died and, with anti-Macedonian feelings running high, Aristotle left Athens to live in Euboea, the birthplace of his mother. He died there in 322 BC.

The corpus of Aristotle that survives today is based primarily on manuscripts that go back only to the 10th through 14th centuries AD. There is some reason to believe that these manuscripts are based on a Roman editor's reorganization of Aristotle's writings in the 1st century BC. During the Middle Ages and Renaissance, many different manuscript editions were found, and modern printed editions are in turn based on modern editorial line-by-line choices about which of these manuscripts to trust. These works cover a remarkable range of subjects, from literary theory and rhetoric, through ethics and politics, to scientific studies of meteorology, cosmology, physics, zoology, psychology, and, finally, philosophical investigations that modern scholars classify as logic, metaphysics, and epistemology. Ancient testimony relates that Aristotle wrote a number of dialogues that rivaled Plato's, both philosophically and stylistically. Only a very few fragments of these works exist. For the most part, what survives are treatises written in a distinctively lean,

unadorned, didactic style; above all else, these treatises stress rigorous argument. They also reflect a certain view of philosophical method. Nearly all begin with serious critical discussion of previous views on the subject being investigated, followed by a fresh approach to the subject using Aristotle's own philosophical categories and methods. Aristotle was quite explicit about how different areas of science were to be related to, and distinguished from, one another and about the extent to which there was a common scientific logic and method.

Theory of Science

A group of treatises known since the Middle Ages as the *Organon* present Aristotle's views on the cognitive tools necessary for thinking clearly about any subject. Aristotle's *Categories* presents a list of types of answers to fundamental questions that can be asked about any subject, and a theory about how these questions and answers can be related to one another. At the most abstract level, the answers constitute basic categories: substance, quality, quantity, place, time, relation, and so on. But it is important to note that the Greek names for these categories are nominalized interrogatives: the what is it, the what sort, the how much, the where, the when, and so on.

Aristotle also explored the basic features of the ontology behind these categories. He argued that only individuals in the "what is it" category—primary substances, he called them—are self-subsistent; everything else is inherent in these (i.e., dispositions, qualities, sizes, and changes do not exist on their own) and/or is said of them (their species and genus names, their locations, and their relationships). This is no mere grammatical point for Aristotle. In insisting on the ontological primacy of the particular substance, he is taking a stand against Platonism in all its forms—for it was Plato who argued that things like maple trees are merely fleeting and insubstantial participants in eternal forms such as goodness, unity, or equality, thus treating the particular objects encountered with the senses as inappropriate objects of scientific investigation. By arguing that being good, or being a unit, or being equal were all dependent on the existence of particular good, singular, or equal objects, Aristotle saw himself as rescuing empirical science from the Platonists.

The *Organon* also includes a small treatise that systematically investigates the different forms of propositions and their relationships (*De Interpretatione*), a much larger treatise on methods for carrying on debates on any subject whatever (*Topics*), and four books on *Analytics*, which have traditionally been divided into two units called *Prior Analytics* and two called *Posterior Analytics*, though Aristotle makes it clear that all four books constitute a single investigation. The first two are the very first formal investigation of proof—they are part formal logic

and part philosophy of logic. Among the aims of these two books are to catalogue the various forms of valid proof, to show that these are the only valid forms, and to reduce them to a small number of basic forms. But Aristotle states in the opening sentence of this work that his ultimate aim is not a theory of valid proof, but a theory of demonstration, by which he means a causal explanation that provides scientific understanding: “We must first state what our inquiry is about and what its object is: it is about demonstration and its object is demonstrative understanding” (*Prior Analytics* Book I. §1, 24 a 10–11). (Note: the last element of the citation, 24 a 10–11, refers to the original two-column Greek text: page 24, column a, lines 10 and 11.) He immediately distinguishes his goals in the *Analytics* from those in the *Topics*. In the *Topics*, the interest is not in demonstrations of scientific truth, but rather in winning debates regardless of the truth of the starting premises. In either case, it will be valuable to determine the forms of valid argument. But for scientific demonstration, much more is required.

If to have scientific knowledge of something is what we have posited it to be, then a scientific demonstration must proceed from items that are true, primitive and immediate; moreover, they must be better known than, prior to and give the cause of the conclusions. (In this way our scientific principles will also be appropriate to what is being proved.) There can be a deduction even if these conditions are not met, but there cannot be a demonstration—for a proof without these conditions being met will not produce scientific knowledge.

[*Posterior Analytics* Book I. §2, 71b 20–26]

Each of these six additional constraints over and above logical validity deserves comment. Broadly speaking, it will be noted that the premises of a scientific demonstration have three “intrinsic” properties and three having to do with their relation to the conclusion to be demonstrated. We can go through them thinking of the following “maple tree” example (loosely based on an example in *Posterior Analytics* Book II. §16), using a standard, if anachronistic, formalization of the argument, with each subject/predicate term represented by a capital letter, and the lower case “a” representing the universal affirmative statement form:

All broad-leafed trees lose their leaves seasonally.

[A a B]

All maples are broad-leafed trees. [B a C]

All maples lose their leaves seasonally. [A a C]

The premises are true; but are they primitive and immediate? Aristotle would say no. To be primitive, a premise must have no deeper explanation. Putting aside modern evolutionary accounts, even Aristotle would want an explanation for why broad-leafed plants happen to lose their leaves seasonally, but those plants with “needles” do not.

A primitive premise would be obtained if it were true that all and only broad-leafed trees lose their leaves seasonally, and the basic causal explanation for that fact had been discovered. Aristotle, in fact, provides an example in the passage from which this sample demonstration is drawn—i.e., in all broad-leafed trees, sap coagulates seasonally, causing leaf shedding. A premise such as this would also be “immediate,” the standard translation for a Greek term that literally means “lacking a middle.” To understand this notion, look at the preceding demonstration. Notice that a term shared by both of the premises is missing in the conclusion, namely, “broad-leafed trees.” Aristotle refers to this as the “middle” term of the proof, for he tended to represent the form of an argument like this one as AB, BC, AC, where B falls between A and C, the terms in the conclusion. For a premise to “lack a middle” is for it to have no more basic explanation and thus no “middle” can be inserted between A and B. “All broad-leafed plants have seasonal coagulation of sap” is, in this example, not the conclusion of a more fundamental explanation.

From what has already been said, it can be seen that the premises are both prior to and causally explanatory of the conclusion—but what about “better known”? This idea can be explicated by reference to the other five; all Aristotle has in mind is that if only the conclusion is known, insofar as it has been demonstrated from certain premises known “in themselves,” and it is only scientific knowledge if those premises identify the causal explanation of the fact identified in the conclusion, then knowledge of the conclusion is conditional on the truth of the premises—those premises, then, are “better known.” Without going any further into the details of his theory, there are two more claims that Aristotle makes about scientifically demonstrated conclusions, which he thinks follow from the preceding conditions on the premises. Those conclusions must identify “universal, necessary truths.” That is, when a scientific demonstration shows that all broad-leafed trees lose their leaves seasonally, it is known that this is a fact about every such tree, and it is known that it could not be otherwise.

It can be seen that this is a highly demanding theory of scientific knowledge. To revert again to the example, a farmer who has noticed that olive trees lose their leaves in the winter, or a geometer who has noticed that every triangle has interior angles that add up to two right angles, is still a very long way from what Aristotle would call scientific knowledge. To know a domain of study scientifically requires penetration to a basic causal understanding of why things are so. It can also be seen that this theory of science puts a great deal of emphasis on getting the right information in the premises. Having done that, and having followed the rules of formal logic, scientific knowledge follows. It is thus frustrating that a great deal about Aristotle’s theory of science is presented in the literature as axiomatic and deductive; but very little is stressed about

his rich and complex account of establishing basic causal premises, the theory of scientific inquiry in *Posterior Analytics* Book II. Yet one of the most beautiful features of Aristotle's theory of science is his argument that there is an intimate relationship between determining the cause of the fact being investigated and discovering its underlying, essential nature. True understanding of why broad-leaved trees lose their leaves and those with needles do not, yields at once an understanding of what differentiates deciduous trees from conifers—it is known in fundamental terms what they are. If an understanding of what it is about three-sided rectilinear figures that accounts for their interior angles being equal to two right angles is attained, then the essence of triangles has been penetrated.

The Place of Measurement in Science

What role, if any, does measurement play in Aristotle's account of scientific knowledge? To answer this question, it is necessary to distinguish two fundamentally different notions of measurement in Aristotle, which may be called "ordinal" and "cardinal." Every form of measurement requires a standard. Greek mathematicians such as Archimedes or Heron wrote treatises on how to calculate the lengths, angles, volumes, or weights of various figures or entities, given certain measurements; they could compare incommensurable lengths by the use of the theory of ratios, and even incommensurable magnitudes (distances and times), by the general theory of proportions, newly discovered by Eudoxus (cf. *Posterior Analytics* Book I. §5, 74 b 18–24). Aristotle's discussion of Zeno's paradoxes shows him to have a sophisticated understanding of this area of mathematics. But he also had a sophisticated theory of ordinal measurement, for which the standard of measure is a norm of some sort or other, and items in the class are ranked in a series by reference to that norm. Without discussing the full range of Aristotle's theory and practice here, it is still possible to discuss his account of measuring degrees of sameness or likeness. His categories are sameness in number, sameness in form, sameness in kind, and sameness by analogy or proportion. The following extract from the opening page of the *History of Animals* provides an outline of Aristotle's theory of how to measure likeness. The *History of Animals* is a comprehensive application of that theory to a study of the similarities and differences of animals, which in turn is embedded in Aristotle's theory of differential division. All of this serves the goal of organizing information in the zoological domain in a form suitable for the discovery and presentation of causal explanation of these similarities and differences.

Some animals have all their parts the same as one another, some have their parts different. Some of the parts are the same in form, as the nose and eye of one human and that of another, or the flesh and bone of one in comparison with another; and the same is true of horses and of the other animals, so long as we say they are the same as one another in form—for just as the whole animal is alike to the whole, so too is each of the parts alike to each. Others—those for which the kind is the same—while the same, differ according to excess or deficiency. And by 'kind' I mean such things as bird and fish; for each of these differs according to kind, and there are many forms of fishes and birds.

Most of the parts in these animals [those that are the same in kind] differ by way of the oppositions of their characteristics, such as their color and shape, the same parts being affected in some cases to a greater and in some cases to a lesser degree, and again by being more or fewer in number, or greater and smaller in size, and generally by excess and deficiency. For some of them will have soft flesh and some hard flesh, a long beak or a short beak, many feathers or few feathers. Moreover, some differ from others in a part that belongs to one not belonging to the other, as for example some birds having spurs and others not, and some having crests and others not. But speaking generally, the majority of the parts from which the entire body is constituted are either the same, or differ by opposition, i.e. by excess and deficiency; for we may posit the more and less to be a sort of excess and deficiency.

The parts of some animals, however, are neither the same in form nor according to excess and deficiency, but are the same according to analogy, such as the way bone is characterized in comparison to fish-spine, nail in comparison to hoof, hand to claw or feather to scale; for what is feather in a bird is scale in fish.

[*History of Animals* 486 a 15–b 22]

Aristotle goes on to note (486 b 22–487 a 13) that similar differentiations can be made regarding the position of a part; the same theory of sameness and difference can be applied to the uniform parts, or tissues, generally, and indeed to all of the important characteristics of animals, their ways of life (aquatic, avian, terrestrial), their activities or functions (modes of locomotion, feeding, reproduction), and their character traits (social, predatory, aggressive). It is precisely these measurable variations in shared characteristics for which scientific explanations are sought. Here is a rather typical example, from *On the Parts of Animals*, regarding the parts of birds: "Among birds, differentiation of one from another is by means of excess and deficiency of their parts, i.e. according to the more and less. That is, some of them are long-legged, some short-legged, some have a broad tongue, others a narrow one, and likewise too with the other parts" (*On the Parts of Animals* Book IV. §12, 692 b3–6). Aristotle next notes that all birds have feathers differing by more and less, but that

these are analogous to scales in other kinds of animals. He goes on to make the same point about beaks: “Birds also have, on their head, the ‘beak’, an odd and distinctive feature in comparison with other animals; while in elephants there is a trunk in place of hands, and in some of the insects a tongue in place of a mouth, in the birds there is a bony beak in place of teeth and lips” (692 b 15–18).

Beaks differ from each other in measurable, quantitative ways, and have analogues in other animals, such as the elephant’s trunk and the insect’s proboscis. When Aristotle moves on to discuss the neck, he begins to note correlations among the variations in all of these parts, and offers a single, functional explanation for the correlated variations of parts:

Birds have a neck that is by nature stretchable, and owing to the same cause that other animals do; and in some birds it is short, in others long, generally following the legs in most cases. That is, those that are long-legged have a long neck, while those that are short-legged have a short one—setting aside those with webbed feet; for if the neck were short in those with long legs, the neck would not be of service to them for eating food off the ground; nor if it were long in those with sort legs. Again for those that eat flesh a long neck would be contrary to their way of life; while for these animals their way of life is based on overpowering prey. That is why none of the crook-taloned birds have a long neck.

[On the Parts of Animals 692 b 19–693 a 6]

They do, however, have a type of beak that is correlated with talons, and both are explained by their predatory way of life (see Figs. 1 and 2): “Their beaks too differ in accordance with their ways of life. Some have a straight beak, others a curved one; straight, those that have it for the sake of nourishment, curved, those that are carnivores; for such a beak is useful for overpowering prey.... But all birds whose way of life includes swamp-dwelling and plant-eating have a flat beak; for such a beak is useful both for digging up and cropping off their nourishment” (693 a 10–17).

Nature and Society

The biological example has provided a concrete picture of Aristotle’s notion of division within kinds by measurable differences of excess and deficiency, or “more and less.” The use of this method by Aristotle’s in his discussion of social organization is pervasive. The first point to stress is that, for Aristotle, being a *politikon zōon* (a social animal) is not something that differentiates humans from all other animals. In the *History of Animals*, Aristotle begins by distinguishing gregarious from solitary animals, and then divides gregarious animals into those that are “social” (*politikon*) and those that get together “sporadically.” He then comments on this distinction:

Social animals (politika) are those for which there is some one function or work (ergon) that is shared by all,

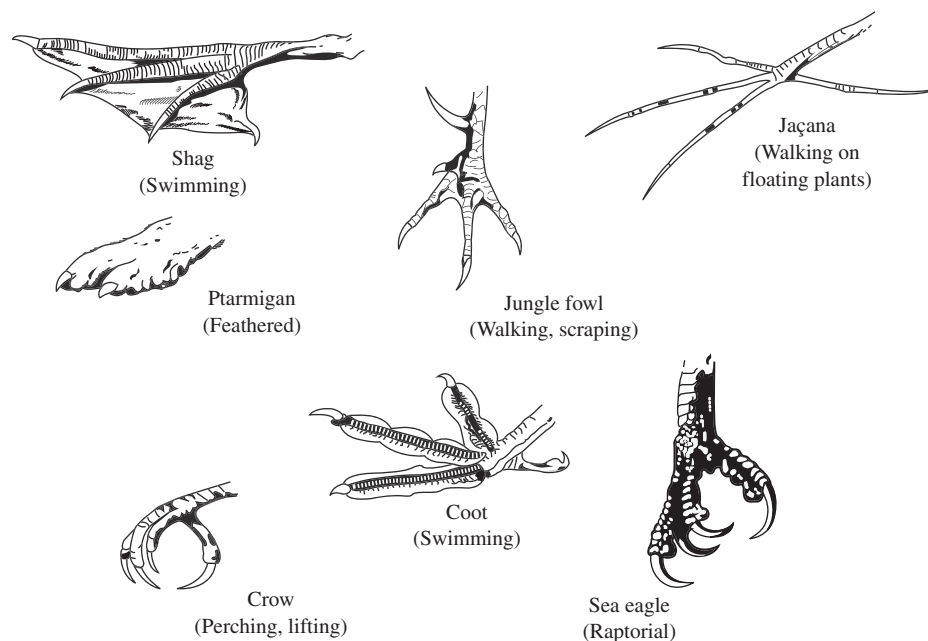

Figure 1 Kinds, forms of kinds, and the “more and the less.” Types of bird feet, indicating adaptations for locomotion and predation. Reproduced with permission from Thomson, J. A. (1970), *The Biology of Birds*, in *Encyclopedia Britannica*, 14th Ed.

something not done by all gregarious animals. Such are human kind, the bee, the wasp, the ant and the crane. And among these some live under a ruler and some do not—for example, the crane and the kind consisting of the bees live under a ruler, while ants and many other kinds do not.

[*History of Animals* Book I. §1, 488 a 8–13]

Aristotle's *Politics* opens with a reminder of this theme:

Since we observe that every polis is a sort of community, and that every community is constituted for the sake of some good (for everyone does whatever they do for the sake of what seems to be good), it is clear that while all communities aim at some good, the community that both contains and is supreme over all others does so most of all; and this is the community known as the polis or the social community (he koinōnia he politike).

[*Politics* Book I. §1, 1252 a 108]

In the *History of Animals*, Aristotle differentiates social from other gregarious animals by the fact that all of the members of the social group share a common function; he here spells this out in terms of some common good each member of the community aims for. He then goes on to say that by using his preferred method of investigation, dividing the composite into its least component parts, it will be possible to discern the differences between differently constituted social organizations (1252 a 18–23).

Lest there be any doubts about the zoological background to this discussion, he goes on:

But if we can somehow observe things that grow from their origin, it is best to study them in this manner, just as we do in other cases. And first of all it is necessary for those things that cannot exist without one another to couple, i.e. male and female, for the sake of generation (and this is not a matter of forethought—rather, just as in the other animals and plants, the impulse to leave behind another such as oneself is natural); next, it is natural for there to be a coupling of ruler and ruled, for the sake of security.

[*History of Animals* 1252 a 24–31]

In this manner, Aristotle traces the development of complex social organizations such as the Greek polis, concluding with a reminder that this development is not artificial, but natural.

The complete community formed from many villages is the polis, having, in a manner of speaking, reached the goal of complete self-sufficiency, coming to be for the sake of life, but being for the good life. For this reason every polis exists by nature—if, that is, the first communities do. For the polis is the goal of these communities, and the nature of something is its goal; that is, when the development of each thing has reached its goal, we say this is its nature, as with a human being a horse or a household. Again, that for the sake of

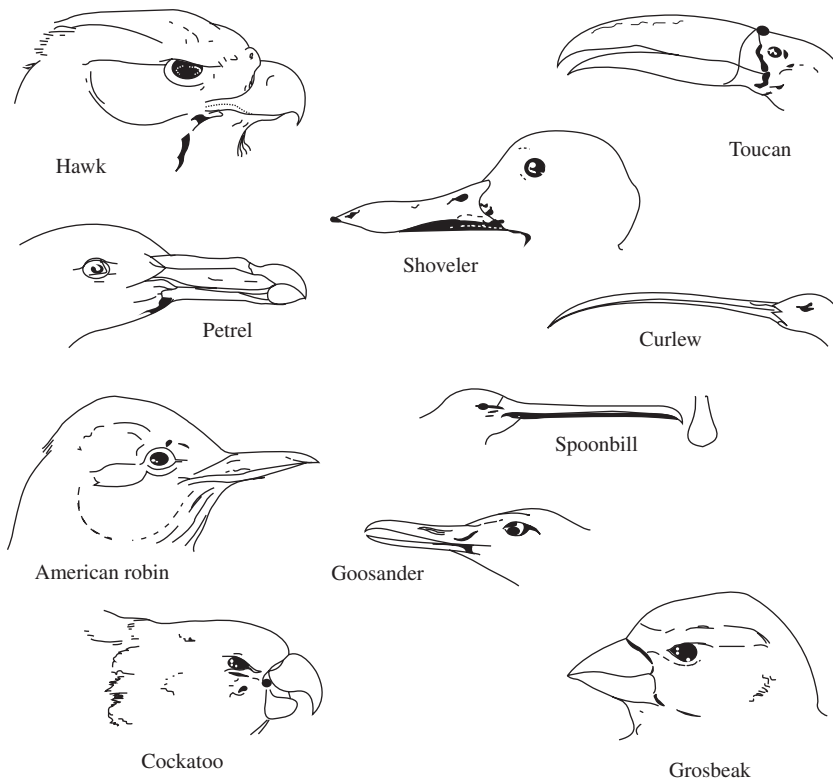

Figure 2 Matter, form, and kind. Types of bird bills, indicating adaptations for feeding. Reproduced with permission from Thomson, J. A. (1970), *The Biology of Birds*, in *Encyclopedia Britannica*, 14th Ed.

which something develops and its goal is best for it, and self-sufficiency is the goal of communities and best for them. Thus from these points it is apparent that the polis exists by nature, and that mankind is by nature a social animal.

[*History of Animals* 1252 b 28–1253 a 3]

But not only are we by nature social animals—in a conscious reminder of the discussion in the *History of Animals*, Aristotle explains why humans are the most social of animals: “The reason why mankind is a social animal more than all the bees or any of the gregarious animals is clear. Nature, as we say, does nothing in vain; and mankind is the only animal with language” (1253 a 8–10). This is not the superficial point that language is a consummately social function. In the Greek work, “language” is *logos*, and though it refers to language, it also refers to rationality. Aristotle ties the possession of language to the ability to consciously discern the differences between good and evil, justice and injustice. This is critical to the polis, for as Aristotle goes on to say, humans in the absence of law and justice are the most dangerous and savage of animals (1253 a 30–38). The remainder of the important opening chapter of the *Politics* argues for the priority of the polis over its component communities and their individuals using a biological argument—just as the parts of the whole organism exist for the sake of the organism, and in fact exist in name only unless they can serve the function of the whole organism, so too with the components of the polis (1253 a 19–29).

The Science of Political Animals

That Aristotle considers the methods of natural science to be applicable to the study of human societies should be clear by now. But does he also make use of the method of measuring similarities and differences that he so effectively deployed in biology? This can be assessed by looking at his statement in *Politics* Book IV, §4, on the proper method for investigating the similarities and differences among types of constitution:

We have noted that there are many forms of constitution (politeia) and on account of what cause; but we should add that there many more than those already mentioned, and say what they are, and why there are many, beginning by assuming what we said previously. That is, we agreed that every polis has not one part, but many. Thus, just as when we were aiming to grasp the forms of animal we would first have to determine which parts it is necessary for every animal to have (e.g., some one of the sensory organs and the parts able to take in and digest food, such as the mouth and stomach, and in addition the parts by which each of these forms of animal moves). And if there were this many necessary parts, there would be differences among them (I mean, for example, that there are many kinds of mouths,

stomachs and sense organs, and in addition locomotive parts) and the number of combinations of these will of necessity produce many kinds of animals (for it is not possible for the same animal to have many different mouths, nor likewise ears). Therefore, when the possible combinations of all these different parts are grasped they will produce the forms of animal, and there will be as many forms of animal as there are combinations of necessary parts. And the same is true of the constitutions we have discussed. For in fact the various sorts of polis are not constituted from one but from a combination of many parts, as we’ve said often.

[*Politics* Book IV, §4, 1290 b 21–39]

As a number of commentators have noted, we have here a systematic application of the theory of differential division developed in Aristotle’s biological works to the domain of the constitution of social organizations. It is applied systematically throughout the *Politics*, but this is Aristotle’s clearest theoretical defense of the method, and once again, he defends it by appeal to the similarities between the constitution of society and the organism. The method is applicable under the following conditions:

1. The objects in the domain of study are made up of many parts, without which these objects cannot exist.
2. These many necessary parts each come in a variety of different forms.
3. No object will have more than one form of these necessary parts.

Assuming these conditions are met, the method, when applied to society, consists of the following empirical steps.

1. Determine the parts that are necessary to the constitution of any polis.
2. Study the measurable variations among these necessary parts.
3. Study the ways in which these variations are combined, for this will provide an exhaustive classification of constitutions.
4. Investigate the reasons behind these variations, especially the good served by each—its function, what it is for.
5. Investigate these variations as functions of the other variations with which they are combined. Just as there is a reason why a carnivorous, soaring bird has keen eyesight, crooked talons, a hooked beak, and a short thick neck, so there are reasons for the correlations among measurable variations in the constitutions of different social organizations.

Conclusion

It would not be surprising if the reader were at this point asking the question “Where is measurement?”.

It is clear that Aristotle had a systematic interest in, a way of studying, variation among entities of the same kind in a domain, and that this was for him systematically connected to the sorts of differences for which causal explanations are sought. But at no point does he specify in numeric terms the exact range of curvature of a sparrow hawk's beak or the ideal range of citizenry for a constitutional democracy. It is thus reasonable to question the primacy of measurement. There are two responses.

The first response is a reminder of the distinction between "cardinal" and "ordinal" measurements. For every character about which Aristotle is concerned to give an account of its range of variation within a kind under investigation, he has an objective means of comparison. When he says beaks vary by "more and less," he means that every beak can be compared along the ranges long/short, wide/narrow, curved/straight, and so on. It is not that Aristotle did not have the means to apply an arbitrarily selected scale of numeric values to these things. Greek mathematics was at this point in history not very interested in mensuration, but the tools were certainly available. What interested Aristotle was (1) the mere fact that one bird would have a long, straight, and slender beak and another would have a short, curved, and thick one, (2) the more complicated fact that all birds with the latter sort of beak have a short rather than long neck, (3) and the search for a unified explanation for these correlated differences.

The second response points to the historical importance of this methodology. Aristotle's study of variations of forms by "the more and less" became, in the late Middle Ages, the calculation of the intension and remission of forms of the so-called Oxford calculators. They took from Aristotle the idea of studying differences in terms of measurable, continuous variation, and applied to it a

quasi-geometric method for representing the differences. And though this may be considered an advance, it must be said that none of these thinkers came close to Aristotle as systematic empirical investigators of nature, nor did they deploy such methods in a systematic empirical study of society.

Artificial Societies

J. Stephen Lansing

University of Arizona, Tucson, Arizona, USA

Glossary

agent-based Relying on the activities of individual agents who respond to events within the area of their local knowledge, but not necessarily to global events.

Boolean network A system of n interconnected binary elements; any element in the system can be connected to a series I of k other elements, where k (and therefore I) can vary. For each individual element, there is a logical or Boolean rule B , which computes its value based on the values of the elements connected with that particular element.

cellular automaton Usually a two-dimensional organization of simple finite-state machines where the next state of each machine depends on its own state and the states of some defined set of its neighbors.

dynamical systems theory The branch of mathematics devoted to the motions of systems that evolve according to simple rules. It was developed originally in the 17th century by Newton to model the motions of the solar system, evolving under the rules of his new theory of universal gravitation.

edge of chaos The hypothesis that in the space of dynamical systems of a given type, there will generically exist regions in which systems with simple behavior are likely to be found and other regions in which systems with chaotic behavior are to be found. Near the boundaries of these regions, more interesting behavior, neither simple nor chaotic, may be expected.

Feigenbaum's number A constant (4.6692...) that represents the rate at which new periods appear during the period-doubling route to chaos.

genetic algorithm An evolutionary algorithm that generates each individual from an encoded form known as a "chromosome" or "genome." Chromosomes are combined or mutated to breed new individuals. A genetic algorithm is useful for multidimensional optimization problems in which the chromosome can encode the values for the different variables being optimized.

nonlinearity The behavior of a circuit, particularly an amplifier, in which the output signal strength does not vary in direct proportion to the input signal strength.

object-oriented A kind of program structure in which conceptual objects are endowed with properties (data) and methods through which their data can be manipulated.

state space A mathematical space in which coordinates represent the variables needed to specify the state (or phase) of a dynamical system at any time.

As the philosopher Karl Popper cogently observed, social scientists who wish to take advantage of mathematical tools have the choice of two alternative approaches. The first is essentially Newtonian and is best represented by general equilibrium theories, for example, in economics. Such theories take the form of systems of differential equations describing the behavior of simple homogenous social actors. Change occurs as a result of perturbations and leads from one equilibrium state to another. The second type of theory is statistical. If one cannot write the equations to define a dynamical system, it may yet be possible to observe regularities in social phenomena. Both approaches have obvious weaknesses: the assumption of equilibrium is forced by the mathematics, not by the observation of social behavior, whereas sifting for patterns using statistical techniques is at best an indirect method for discovering causal relationships. In the 1990s, a third approach came into existence as powerful computational tools became available to social scientists. "Artificial societies" are computational models composed of populations of social agents that flourish in artificial environments. Although the behavior of the agents is governed by explicit rules, these rules may change in response to changes in the environment or as a consequence of learning and memory. In this way,

the behavior of agents can become heterogeneous in ways that cannot occur in conventional equilibrium models. Repeated simulations enable the investigator to study how such model societies evolve over time and to investigate their global or macroscopic properties. A burst of such models have appeared in the social and behavioral sciences.

Origins of Artificial Societies

Experiments in simulation in the social sciences began in the 1960s as computers became available for university research. Most studies concerned either discrete event simulations, such as the passage of police cars through queues, or systems dynamics, such as the Club of Rome global forecasts that used systems of difference equations to plot the trajectory of the world economy. An early “artificial societies” approach was developed by sociologist Thomas Schelling. In a classic series of papers, Schelling used very simple agents to predict patterns of racial and ethnic segregation in American neighborhoods. At approximately the same time, European sociologists developed an approach called “microsimulation,” in which samples drawn from large populations are marched forward in time (or “aged”) using vectors of transition probabilities. This approach relies on linear algebra and does not attempt to model interactions between individuals or households.

In the 1990s, the concept of artificial societies seems to have been invented independently on both sides of the Atlantic by Epstein and Axtell and by Gilbert and Conte. The timing coincided with the appearance of powerful minicomputers, but the artificial societies approach was not a simple extension of preexisting techniques for social simulations. Instead, the new approach drew on earlier theoretical work in computer science, beginning with von Neumann’s concept of self-reproducing automata. Von Neumann speculated that simple self-reproducing agents could be created as a set of instructions in a computer program. In 1953, he gave a series of lectures at Princeton University showing how this concept could be implemented in the form of a cellular automaton: a lattice of cells that follow local rules to update their state. Later, John Holland showed that such agents could be brought under the control of an evolutionary process. Holland’s “genetic algorithm” implements evolution *in silico*, representing genotypes as computer code. As the eminent evolutionary biologist W. D. Hamilton observed, “It was a very brilliant step of John Holland to realize that he could probably do something in artificial intelligence by just importing the principles of life directly.” These ideas paved the way for artificial societies models, with von Neumann agents inhabiting a lattice and evolving or interacting according to local rules. One could

argue that the artificial societies research agenda came into existence when social scientists began to see the potential of von Neumannesque models for social research. A decade later, the influence of ideas from computer science remains strong. Artificial societies researchers draw models, methods, and inspiration from research in parallel fields including cellular automata, distributed artificial intelligence, evolutionary game theory, parallel distributed cognition, artificial life, and genetic programming.

Characteristics of Artificial Societies Models

Contemporary artificial societies are a specialized type of simulation model that typically employs an object-oriented, agent-based system architecture. As Epstein and Axtell observe with regard to one of the first such models, called “Sugarscape”: “if the pure cellular automaton is a space with no agents living on it, and the pure adaptive agents model represents agent kinetics with no underlying space, then the Sugarscape model is a synthesis of these two research threads.” In models such as Sugarscape, agents are implemented as objects that are able to perceive features of their environment, which may include messages from other agents. Typically they are able to process these perceptions and make decisions about their subsequent behavior. Agents may also possess attributes of memory and a capacity for learning. These characteristics add several dimensions of novelty to artificial societies models, in comparison with conventional equilibrium models. To begin with, the architecture of these models enables the investigator to utilize dynamical systems theory in order to investigate both equilibrium and non-equilibrium conditions. In other words, the behavior of agents and societies in state space can be studied through controlled experiments in which behavioral or environmental parameters are tuned. Agents can be as heterogeneous as the investigator chooses to make them and the model environment can be arbitrarily simple or complex. Archeologists are particularly fond of very detailed environmental models based on geographic information systems. Using parameter sweeps, they can model questions such as the effects of varying rainfall on a landscape, with respect to the growth of crops and the spatial patterning of human activities. Unlike equilibrium models in economics and sociology, artificial societies models generally involve time as a critical dimension. The usual strategy is to create a landscape with agents that are instructed to follow a set of rules. Such rules might implement evolutionary dynamics, or trading rules for an artificial stock market, or kinship rules in an anthropological study. Since the behavior of each agent depends on its

local situation, in all but the simplest cases it is impossible to solve the entire system in advance. But as Stephen Wolfram observed, “One way to find out how a system behaves in particular circumstances is always to simulate each step in its evolution explicitly.”

Research Themes: Contingency

As time proceeds in simulation experiments, new patterns may emerge. This phenomenon led researchers working with the first generation of models to ponder Stephen Jay Gould’s famous question: “What if the evolutionary tape were run again?” Investigators found it easy to construct heterogeneous agents and environments and to observe their behavior over time. But the very ease with which such simulations could be performed could be worrisome: if an infinite number of such experiments could be performed, and analytical solutions are forever out of reach, is there any point to performing the calculations?

To answer this question required some new analytical tools. The most basic technique is dynamical systems theory, which provides methods to describe the global behavior of systems of differential equations. Systems of N variables are tracked in their passage through N -dimensional space, allowing the researcher to ask where the system spends most of its time and thus to assess its characteristic patterns of behavior. In continuous deterministic dynamical systems, all possible time series make up the vector field, which is represented by the system’s phase portrait, an idea first proposed by Poincaré in 1896. Analogous questions can be asked about discrete dynamical systems, such as random Boolean networks and cellular automata. Where analytical solutions cannot be found, repeated simulations can be analyzed for their statistical properties. The initial exploration of these systems was rewarded by the discovery of unsuspected patterns of simplicity and order, from Feigenbaum’s number to Langton’s “edge of chaos,” Wolfram’s Class 4 cellular automata, and Bak’s self-organized criticality. In the social sciences, political scientist Robert Axelrod reformulated the well-known “Prisoner’s Dilemma” game as an artificial society simulation with a population of agents who play a series of games with their neighbors on a lattice. This turned the game into a dynamical system evolving over time. In the original game, rational choice leads to ruin, but in the artificial society model, Axelrod found that cooperation would emerge under a wide range of conditions. In further experiments, he tested the ability of Holland’s genetic algorithm to evolve winning strategies and found that evolved strategies typically did as well or better as those created by game theorists. Axelrod concluded that the genetic algorithm proved to be “very good at what actual evolution does so well: developing highly specialized adaptations to specific environments.”

Subsequently, Kristian Lindgren embedded game-playing agents on a lattice, adding greater flexibility by making memory length an evolutionary variable. Over tens of thousands of generations, he observed the emergence of “spatial” patterns that resemble evolutionary processes and clarify preconditions for the emergence of cooperation and competition. Such simulation results have inspired behavioral ecologists to reexamine biological systems. For example, Manfred Milinski has studied stickleback fish, which enjoy “a well-earned reputation for keeping abreast of the latest trends in animal behavior.” According to Milinski, cooperation in “predator inspection” by the sticklebacks follows the dynamics of the iterated Prisoner’s Dilemma. The results of these simulations have also been used to model problems in political science and economics. There is a large literature on this topic.

However, cooperation is by no means the only emergent property investigated by social simulations. Philosopher Brian Skyrms has studied the “evolution of the social contract” by modeling it as a problem in the evolution of strategies. His most ambitious models tackle large questions such as the evolution of justice, linguistic meaning, and logical inference. Skyrms finds that “the typical case is one in which there is not a unique preordained result, but rather a profusion of possible equilibrium outcomes. The theory predicts what anthropologists have always known—that many alternative styles of social life are possible.” But this seems a bit too modest. With respect to the evolution of meaning, for example, Skyrms shows that evolutionary processes provide a plausible answer to the fundamental question, “How do the arbitrary symbols of language become associated with the elements of reality they denote?”

Research Themes: Emergence

The study of non-equilibrium economics is well under way, for example, in the simulation of stock markets, both real and imaginary. Simulation models have facilitated a shift from equilibrium models constructed with differential equations to nonlinear dynamics, as researchers recognize that economies, like ecosystems, may never settle down into an equilibrium. A clear and readable account of this change in perspective is provided by W. Brian Arthur in a 1999 *Science* article on “Complexity and the Economy.” Arthur argues that “complexity economics is not a temporary adjunct to static economic theory, but theory at a more general, out-of-equilibrium level. The approach is making itself felt in every area of economics: game theory, the theory of money and finance, learning in the economy, economic history, the evolution of trading networks, the stability of the economy, and political economy.” Biologist Stuart Kauffman draws

explicit parallels between biological and economic systems, viz., “the modern corporation is a collectively self-sustaining structure of roles and obligations that ‘lives’ in an economic world, exchanges signals and stuffs, and survives or dies in ways at least loosely analogous to those of *E. coli* . . . Both *E. coli* and IBM coevolve in their respective worlds.” Economists have followed up on this idea by investigating the “web structure” of economies, as, for example, in Schenkman’s analysis of the relationship between the diversity of sectors and the rate of economic growth in cities.

The study of the global properties of economies has been accompanied by research on the behavior of economic actors. Economist Samuel Bowles and his colleagues have begun to work with anthropologists such as Hillard Kaplan in order to investigate, as an empirical question, how social actors make decisions in game-theoretical or economic contexts. Based on these results, they propose to supplement *homo economicus* with a larger and more diverse “family of man.” Research in economics on artificial societies thus proceeds at two levels: the characteristics of individual social actors and the global dynamics of economies or societies. This research draws heavily on mathematical models of nonlinear systems; investigators keep an eye out for power-law distributions of events, such as the growth of firms or the frequency of stock market events, that may signal a system near the edge of chaos.

From Sugarscape to the Anasazi

Artificial societies research in anthropology began with George Gumerman’s pioneering collaboration with physicist Murray Gell-Mann. Gumerman became interested in Axtell and Epstein’s Sugarscape, a simulation model developed to study how sociocultural phenomena such as trade, warfare, and class structures can arise from simple interactions of adaptive agents. In Sugarscape, the “environment” is very simple, consisting of the agents themselves plus some idealized resources, such as “sugar” and “spice.” Gumerman and Jeffrey Dean wondered whether more realistic environments could be simulated, with heterogeneous agents and landscapes defined by real archaeological data, observing that “while potentially powerful, agent-based models in archaeology remain unverified until they are evaluated against real-world cases. The degree of fit between a model and real-world situation allows the model’s validity to be assessed.” They further observed that the explanatory power of mathematical models may be greatest when they fail, since such failures may expose where the researcher’s underlying conceptual model or explanation is flawed. Gumerman and Dean worked with Epstein and Axtell to apply the techniques developed for Sugarscape to create an agent-based model

of the Anasazi society of Long House Valley in northeastern Arizona from 1800 B.C. to 1300 A.D. The simple lattice environment of Sugarscape was replaced by paleoenvironmental data on a 96 km² physical landscape. The environment of “Artificial Anasazi” is populated with human households, so that spatiotemporal patterns of settlement formation and household production can be simulated and compared with the archaeological record. A similar approach was developed by Tim Kohler and Carla van West to model human settlements in Mesa Verde circa 900–1300 A.D. Such models enable their creators to test their intuitions about the complex nonlinear processes involved in human–environmental interactions. As Kohler observes, “agent-based approaches admit an important role for history and contingency (and) can also, in principle, accommodate models that invoke heterogeneity among agents, or which drive social change through shifting coalitions of agents, argued by many to be a critical social dynamic.”

Critiques and Resources

There have been several critiques of the field of artificial societies. Thus, John Maynard Smith writes in the *New York Review of Books* that he has “a general feeling of unease when contemplating complex systems dynamics. Its devotees are practising fact-free science. A fact for them is, at best, the outcome of a computer simulation; it is rarely a fact about the world.” Science writer John Horgan cautions that “as the philosopher Karl Popper pointed out, prediction is our best means of distinguishing science from pseudo-science . . . The history of 20th-century science should also make complexologists pause. Complexity is simply the latest in a long line of highly mathematical ‘theories of almost everything’ that have gripped the imaginations of scientists in this century.” (Here Horgan appears to be mostly concerned with the very general theories of emergence developed by Stuart Kauffman and Per Bak, among others.) A more ambitious critique was published by an anthropologist, Stefan Helmreich, who offers an “ethnographic” account of the researchers working at the Santa Fe Institute in the mid-1990s. In *Silicon Second Nature*, Helmreich argues that artificial societies models reflect the unconscious cultural assumptions and social prejudices of their creators: “Because Artificial Life scientists tend to see themselves as masculine gods of their cyberspace creations, as digital Darwins exploring frontiers filled with primitive creatures, their programs reflect prevalent representations of gender, kinship, and race and repeat origin stories most familiar from mythical and religious narratives.” For example, Helmreich describes Holland’s genetic algorithms as reflecting a “heterosexual” bias: “There are a number of ways we might understand the exchange

of bits between strings, but the metaphor of productive heterosex is gleefully emphasized by most authors.” Thus, for Helmreich, simulation models are like Rorschach tests, revealing the researcher’s cultural background and psychological idiosyncrasies. All statements, especially theoretical pronouncements, are taken not as statements about the world, but as evidence about the author’s beliefs and mode of thought. “That many Artificial Life practitioners are white men who grew up reading cowboy science fiction,” observes Helmreich, “is not trivial.” Simulation models may also be dangerous (as Helmreich suggests with reference to the author’s own work), urging that “the use and abuse of computer simulations bears watching—especially in situations where there is a notable power differential between those putting together the simulation and those whose lives are the subjects and objects of these simulations.”

Attrition, Mortality, and Exposure Time

Alex R. Piquero

University of Florida, Gainesville, Florida, USA

Stephanie Carmichael

University of Florida, Gainesville, Florida, USA

Glossary

attrition The loss of longitudinal study participants over time.

exposure time The temporary loss of study participants due to some type of incapacitation effect.

longitudinal data Information from research that assesses people or other units during more than one time period.

missing data Information on respondents or for variables that are lost.

mortality Death of an individual during a (long-term) research project.

The study of stability and change in the social sciences requires the use of longitudinal data. Although such data are powerful for answering how key social science phenomena change over time between and within individuals, researchers are confronted with three specific challenges: attrition, mortality, and exposure time. This article provides examples of these challenges, as well as strategies that researchers could adopt for minimizing these problems before they become insurmountable and detrimentally influence the answering of important theoretical and substantive social science questions.

Introduction

Stability and change are key themes in social research, and panel, or longitudinal, data are optimal for the study of stability and change. Cohort studies examine more specific samples (e.g., birth cohorts) as they change over time; panel studies are similar to cohort studies except

that the same sets of people are interviewed at two or more time periods. At their core, panel studies seek to measure the effect of age on the change in a particular outcome over a follow-up period of a certain length. Across several social science disciplines, the use of longitudinal panel design allows researchers to derive estimates of within- and between-individual change in key constructs of interest. For example, researchers can study how depression changes over the life course, how criminal activity varies with age, and so forth.

Although panel studies are well suited to examine issues of stability and change over time, they are also susceptible to three particular challenges. The first is attrition, or the loss of study participants over time. Attrition occurs when some participants either drop out of the study permanently or fail to participate in one or more of the follow-up assessments. The second is mortality, or the loss of participants due to death. Mortality is likely to be a salient problem when study participants enter old age and/or when a study includes individuals who exhibit some high-risk behavior (smoking, drug use, criminal activity, etc.). The third is exposure time, or the temporary loss of individuals due to some incapacitation effect. Exposure time is likely to be an important issue when studying change in criminal activity over time, because high-rate offenders are likely to experience differential (i.e., higher) incapacitation probabilities.

The following discussions address the usefulness of longitudinal data for assessing issues related to continuity and change in behavior over time; the three methodological challenges (attrition, mortality, and exposure time) are assessed, highlighting relevant research in this area, and approaches that researchers can take to minimize

these concerns are identified. Although the issues raised herein are relevant for many social science phenomena and across several social science disciplines, the focus is on two examples that are strongly associated with age: depression and criminal activity. In addition, some preliminary data are provided on attrition in two prominent longitudinal studies, the Baltimore portion of the National Collaborative Perinatal Project (NCPP), and the National Youth Survey (NYS).

Longitudinal Data

Longitudinal studies are designed to permit observations of some specific phenomena over an extended period of time. Unlike cross-sectional studies, which permit only a snapshot of individuals or constructs at a particular point in time, longitudinal studies have the key advantage in that they can provide information describing how processes remain stable and/or change over time.

There are several ways that longitudinal research can be carried out. One of the most obvious is to identify a cohort at birth and to follow that cohort prospectively for a long period of time. Though ideal for the study of within- and between-individual changes in social science phenomena over time, prospective longitudinal designs suffer from limitations, including financial costs; history, panel, and testing effects; and sample attrition. On a practical level, human life expectancies and stakes make multidecade, longitudinal projects difficult for researchers to complete and sustain, especially because such projects require significant financial resources.

Another type of longitudinal design is retrospective. This approach avoids the long delay associated with the prospective design by defining a cohort, retrospectively. In a retrospective design, the researcher defines a cohort, such as all persons born in 1970, and then retrospectively collects various pieces of information, such as offending histories. Limitations also exist with the retrospective longitudinal design. Specifically, such a design introduces potentially serious concerns over recall errors (if self-report information is gathered).

Three Specific Challenges

Because longitudinal studies are, by definition, lengthy in nature, missing data pose a particular problem. Missing data due to nonresponse pose particularly difficult challenges. Missing data cause sample sizes to decrease over time, and may also cause biased estimates of population parameters if respondents and nonrespondents differ systematically with respect to variables involved. There are three manifestations of missing data: attrition, mortality, and exposure time.

Attrition

As noted earlier, attrition occurs when some study participants either drop out of the study permanently or fail to participate in one or more of the follow-up assessments. Although attrition does not necessarily bias the results, bias does occur when changes in an outcome differ between cases that remain in the sample and cases that drop out. In particular, when change in an outcome does relate to the probability of that change being observed, the effects observed among those who continue to participate do not equal the effects in the total sample. Because the probability of remaining in a study often depends on age, and because the changes studied often seem likely to affect the probability of remaining in the sample, panel studies are susceptible to attrition bias. In sum, it is possible that individuals who drop out of a longitudinal study differ in important ways from individuals who do not. The key issue is whether the attrition is random (i.e., attrition has nothing to do with the outcome of interest) or nonrandom (i.e., attrition has something to do with the outcome of interest).

Three examples are worth pointing out here. The first concerns the relationship between age and depression, a relationship that researchers disagree on quite often. Some report a U-shaped relationship between depression and age, with middle-aged adults feeling less depressed than younger or older adults, whereas others believe that the rise of depression in old age is more myth than fact. Mirowsky and Reynolds employed data from the first two waves of the National Survey of Families and Households, a large sample of more than 13,000 respondents ages 18 and older followed over a 6-year period, from 1988/1989 to 1994/1995. These authors analyzed the impact of attrition on estimates of the age-specific changes in depression over this 6-year period. Their findings indicated that the cross-sectional relationship of baseline depression to age differs for those who later drop out, compared to those who stay in. Interestingly, once the authors controlled for health and impairment, much of the difference vanished. In sum, these authors concluded that panel models ignoring the attrition will imply that depression decreases in old age, but models that control for attrition imply that depression rises by an amount that increases with age.

The second example comes from criminology, a discipline for which the issue of sample attrition is an important concern because high-rate offenders may fall victim to attrition more so than low-rate offenders, and thus may be less likely to remain in the later waves of longitudinal studies. Brame and Piquero used the first and fifth wave of the National Youth Survey, a national probability sample based on 1725 individuals between the ages of 11 and 17 years at the first wave, to assess how sample attrition influenced estimates about the longitudinal relationship between age and crime. In particular,

Brame and Piquero were concerned with the issue of selective, or nonrandom, attrition. Their analysis of the NYS showed that modest departures from a random drop-out model could account for a substantial proportion of the within-individual decline in offending. At the same time, they also showed how researchers might be able to use the data to impose some plausible constraints on the analysis to achieve identification. Using one set of these restrictions, their analysis suggested that within-individual declines remained while explicitly adjusting for the effects of attrition.

The third example concerns the problems created by individuals who move out of jurisdiction during the follow-up period(s) of longitudinal/panel studies. Although attrition due to such movement has not been subject to intense research scrutiny, it is clear that bias may arise if the outcomes of interest (such as depression and criminal activity) are related to individuals' frequent relocations. This is probably magnified among samples of high-rate offenders who likely will wish to avoid contact with researchers and/or criminal justice officials because of their involvement in illegal activity.

Mortality

Attrition due to mortality is also a concern for researchers using panel data to study issues related to continuity and change in social science phenomena. In several panel studies, especially those studies that include high-risk individuals and/or deal with high-risk behaviors, researchers need to be aware that some individuals may not be present on key theoretical constructs because they have died.

The issue of mortality has recently been introduced as a central feature in research on criminal activity over the life course because researchers have noticed that high-rate offenders are much more likely to die earlier (within longitudinal studies and at an earlier age) compared to low-rate offenders, and that these high-rate offenders are more likely to die via a violent death (i.e., as victims of homicide). For example, before age 40, delinquent individuals are more likely to die from unnatural causes such as accidents and homicide than are nondelinquent individuals. In a follow-up study of youthful serious offenders paroled from the California Youth Authority institutions, Lattimore *et al.* found that homicide was the prevailing cause of death for the youth. The study also revealed that a higher probability of death by murder was observed for black youth, for those from Los Angeles, for those with a history of gang involvement and institutional violence, and for those with a history of drug arrests. To the extent that such individuals are assumed to have desisted from crime in longitudinal studies, then researchers will have incorrectly identified these deceased delinquents as desisted delinquents.

The same concern regarding subject mortality may be raised for researchers who study individuals who engage in high-risk behaviors (smoking, alcohol use, etc.). Because these behaviors are related to the risk of death, researchers who are tracking these individuals in a longitudinal study need to be aware that some study participants may die throughout the course of the study. In sum, efforts to collect mortality information should be a key priority for those conducting longitudinal studies, especially concerning studies that focus on high-risk populations entering adulthood. This is especially the case for high-risk offenders, who tend to create tracking and identification obstacles.

Exposure Time

The final methodological concern deals with exposure time. This challenge deals with the temporary loss of study participants to some type of incapacitation effect, such as hospitalization, jail/prison term, etc. Unlike sample attrition and subject mortality, the issue of exposure time has been relatively under-studied because of the lack of adequate data containing information on time periods (i.e., spells) associated with exposure time.

Consider a criminological example. In longitudinal studies of crime over the life course, researchers derive estimates of individuals' offending over some period of time, typically over a 6- or 12-month period. However, during these time periods, individuals may not be "free" to commit criminal acts. The calculation of "time at risk," "street time," or "free time," then, is crucial to estimating individual offending rates, because offenders cannot commit crimes on the street while incarcerated.

Estimating an individual's offending frequency without taking into consideration their exposure time assumes that he or she is completely free to commit crimes. Under this assumption, an individual's true rate of offending is likely to be miscalculated because some offenders are not completely free. Some researchers have recognized the importance of this problem and have implemented controls for street time, but many longitudinal self-report studies do not implement controls for street time. The importance of this issue was recently demonstrated by Piquero *et al.* In their study of the recidivism patterns of serious offenders paroled from the California Youth Authority, these authors found that conclusions regarding persistence/desistance were contingent on knowledge of exposure time. For example, without controlling for street time, they found that 92% of their sample desisted; however, with controls for exposure time, only 72% of the sample desisted. In sum, variations in exposure time can affect measurements of key social science phenomena and need to be considered in panel studies.

Data Examples

The methodological challenges raised herein can be illustrated with two data examples that describe follow-up activities of two important longitudinal and panel studies. First, consider the results of a follow-up survey conducted by researchers at Johns Hopkins University in Baltimore, Maryland, who were part of the National Collaborative Perinatal Project (NCPP), a large-scale medical research project initiated in the late 1950s. In the 1990s, a team from Johns Hopkins initiated a follow-up study of a sample of the original Baltimore portion of the NCPP. Of the approximately 4000 children who were initially followed in Baltimore, 2694 were eligible to take part in the follow-up study at the point in time when the individuals would have been between 27 and 33 years old. Of the eligible 2694 individuals, 17.59% ($n = 474$) were not located, leaving 82.41% ($n = 2220$) of the individuals available. For several reasons, 28 of these individuals were not fieldable, thus leaving 2192 individuals fieldable. At the end of the follow-up study, 1758, or 80%, of the fieldable individuals received a full follow-up interview. The remaining cases (1) were still in the field at the end of the follow-up period ($n = 157$), (2) refused ($n = 135$), (3) had absent subject data ($n = 71$), (4) were deceased with data ($n = 71$), (5) were deceased with no data ($n = 17$), or (6) were unavailable ($n = 11$). Thus, the final response rate for the full follow-up interview was 65.3%, or 1758 of the originally 2694 eligible sample of individuals.

Now consider the National Youth Survey (NYS), a large-scale panel study that was administered to a national probability sample of youth ranging from age 11 to age 17 in 1976. The survey also employed multistage cluster sample techniques to produce a representative sample of United States households. Respondents were then selected from sampled households and interviewed. About 27% of the 2360 individuals who were selected to participate in the study did not participate, leaving a final sample of 1725 respondents. By the fifth wave of the survey, 1485 of these individuals had been retained and the remaining 230 respondents dropped out. This produces an overall attrition rate of about 13.4% from the first to the fifth wave of the survey. Data on mortality and exposure time have not yet been made publicly available. In sum, the methodological challenges raised here are pertinent to the follow-ups of these and other important data sources. The important question for researchers is the extent to which attrition, mortality, and exposure time are random or nonrandom.

What Can Researchers Do?

As the methodological challenges have been recognized by researchers employing longitudinal and panel data,

researchers have devoted much effort to documenting their knowledge in circumventing these concerns. For example, researchers have outlined guides to detecting attrition problems and have carefully described the approaches available to finding respondents in a follow-up study. Here, the recent recommendations made by Brame and Piquero for dealing with attrition problems are underscored, and the recommended steps that researchers can take when dealing with the mortality and exposure time issues are outlined.

Regarding attrition, two practical recommendations surface. The first broad recommendation revolves around what can be done to address attrition problems in existing data sets. Currently, there are three specific strategies for handling missing data: (1) imputation of the missing values with suitable estimates, (2) analysis of incomplete data without adjustment, and (3) discarding of nonrespondents and calculation of weights for respondents to compensate for the loss of cases. The merits and demerits of these approaches must be weighed carefully before choosing which one to adopt. The second broad recommendation is the practice of partially following up on hard-to-interview respondents. For example, a researcher who has lost 150 of 1000 subjects by a later wave may wish to attempt locating all 150 missing subjects, but the outcome of this costly and time-consuming endeavor is unlikely to yield a 100% response rate. Instead, the researcher should devote resources to tracking a random sample of those 150, and then obtain valid survey-based information for those individuals. With this information, the researcher could create confidence intervals or boundaries around the estimates of interest.

With regard to mortality, perhaps the best approach is to consult the National Death Register Index, which contains information on the individual's name, date of death, and cause of death. Another approach would be to search the obituaries of newspapers. Implementation of both strategies is recommended. In terms of exposure time, two approaches are worthwhile. Regarding official data sources, researchers could obtain exposure time information regarding hospital stays and/or prison/jail stays from officially kept records at the federal, state, or local level. Because some of this information is inadequate, especially jail records, which oftentimes do not contain movement information (i.e., from jail to probation, number of days in jail, etc.), researchers could ask respondents to self-report information regarding exposure time.

Conclusion

Missing data in panel studies represent an important methodological issue that cannot be bypassed when studying continuity and change in behavior over time. The results of a recent study help to underscore the

importance of the issues raised herein. Laub, Sampson, and Eggleston sought to describe the criminal activity of over 500 men from the Boston area who were followed through their early 70s. The authors showed that the shape and size of offending trajectories in the data were highly influenced by controls for street time, length of the observation window, and mortality, thereby underscoring the importance of considering such methodological issues. Future studies should visit current data sets and revisit classic data sets and explore the extent to which attrition and mortality of data and individuals influence key theoretical and substantive findings. The discussions here have described the various methodological challenges awaiting researchers employing longitudinal data as well as approaches that researchers can consider in an effort to overcome the ill effects of such data, before the challenges and effects become insurmountable.

Glossary

audiovisual records Videotape or digital video representations of an ongoing behavioral stream.

behavior codes Operational definitions of the parameters of behaviors.

content validity The adequacy with which an observation instrument samples the behavior of interest.

continuous coding The complete and comprehensive coding of an audiovisual record.

duration The total time in which a behavior of interest occurs.

field testing The observation of behavior where it occurs and the application of a coding system for feasibility.

frequency The number of discrete times a behavior of interest occurs according to some conventional assignment of an interbehavior interval.

observation system Formalized rules for the extraction of information from a stream of behavior.

operational definitions Discrimination rules that specify target behaviors to be studied.

reactivity Atypical responses from individuals who are being observed.

sampling Behavioral coding that relies on systematic but partial coding.

This entry addresses the questions of what and how to observe about behavior. Conceptual, theoretical, practical, and ethical considerations govern the target behaviors of observation. Audiovisual record data collection procedures; coding systems, including issues related to reliability and validity; selecting and training coders; various methods of scoring observational data; and recording

technologies are reviewed and two illustrations are presented.

Introduction

The Significance of Behavioral Observation

Behavioral observation involves recording the manifest activities of individuals. Direct observation is consistent with an epistemological emphasis on overt behavior, quantification, and low levels of inference. For these reasons, observational procedures are rigorous and powerful, providing measures of both behavioral frequency and duration on the basis of their occurrence in the non-interrupted natural time flow. This approach to assessment has been called the sine qua non of social science research; that is, observation is often considered the gold standard against which other kinds of assessments should be evaluated. For these reasons, observation has been employed in the vast majority of published research.

The Challenges

Social science researchers who are interested in evaluating ongoing behavior are confronted with several methodological challenges. Salient ones concern whom to observe, when to observe, where to observe, what to observe, and how to observe. The question of *whom* to observe involves participant sampling and is central to the issue of to what population the findings will generalize. The questions of *when* and *where* to observe have to do

with time and place sampling and associated logistical issues. Scheduling observations is important to determining the overall character and quality of a research study; only observing at the right time will lead to representative data. Some settings promise ecological validity, for example, when participants are observed in surroundings where they are normally found. Less common or realistic situations may reflect less valid representations of the meaning and purpose for participants than actual life experiences. Finally, recording behaviors that are infrequent challenges the whole nature of observation.

Overview

The questions of what and how to observe are the main subjects of this entry. Determining the target behaviors of observation is governed by conceptual, theoretical, practical, and ethical considerations. We review audiovisual record data collection procedures. Coding systems are then discussed, including issues related to the reliability and validity of observational data, procedures for selecting and training coders, various methods of scoring observational data, and a brief review of recording technologies. After this, we present two illustrations.

Collecting Audiovisual Records

In naturalistic observation, participants are normally requested to behave in their usual manner, to do whatever they normally do, and to disregard the observer's presence as much as possible. Observational coding can be done in real time, or audiovisual records of behavior can be made using videotape or digital video technology. The presence of an observer-recorder (camera in hand) can be intrusive and may represent a kind of novelty that evokes atypical responses from those observed, a phenomenon termed reactivity. For example, observation may promote socially desirable or appropriate behaviors and suppress socially undesirable or inappropriate behaviors (e.g., adults may display higher than normal rates of positive interactions with children). Nonetheless, reactivity can be and often is successfully alleviated by observers' spending time in the situation with participants before recording to set participants at ease. Observers must be trained to make audiovisual records that have few (if any) breaks or gaps in the behavior stream, and conventions must be developed and adhered to for filming distances and angles that maximize the possibility of continuously and reliably coding behaviors of interest. Decisions must be made about which actor to focus on when multiple actors cannot be captured simultaneously on audiovisual records, and conventions must be developed to provide (future) coders with important off-camera information. Moreover, audiovisual records of naturally occurring behavior in

unstructured settings suffer inherent problems and limitations, and the codes that are developed to score them must take these shortcomings into account.

Coding Systems for Audiovisual Records

For any behavior, content validity is determined by the adequacy with which an observation instrument samples the behavior of interest. Three requirements must be met to establish content validity: (1) the domain of interest must be completely defined, (2) the relevant factors must be representatively or exhaustively sampled for inclusion in the observation system, and (3) the method for evaluating and combining observations to form scores must be specified. Some observation system with formalized rules must be developed to extract information from the stream of behavior. Those rules specify a set of target behaviors, how the information is to be recorded, and how the resulting data are to be combined to form analyzable scores.

The development of a coding system initially involves extensive observations and usually involves collaborative discussion. First, narrative observational accounts of behaviors of interest are made in the field. Field testing and refinement are subsequently conducted. In this way, initial, unstructured descriptive data are shaped into more structured observations and, ultimately, quantitative data. Observation target behaviors are then identified relative to the topic(s) of interest. Next, formal operational definitions of behaviors are developed; they specify the phenomena studied and facilitate coder accuracy and consistency. These definitions represent discrimination rules for coding target behaviors, and they typically possess three main characteristics: (1) they are objective and refer to directly observable target behaviors; (2) they are clear, unambiguous, and easily understood so that (experienced) coders can accurately comprehend and follow them; and (3) they require little or no inference.

The next step in coding audiovisual records involves developing formal behavior codes, often in conceptually related groups called modes. Within each mode, component codes are best operationalized so that they are mutually exclusive and exhaustive. Exclusive observation categories apply when only one act or series of acts can be scored for each time unit of observation. In exhaustive observation systems, some behavior code must be used for each observation unit. There are numerous advantages to using mutually exclusive and exhaustive coding systems.

If a rating observational coding system is used, a system is devised according to predetermined criteria for rating each target behavior. This coding system can be used to indicate the presence or absence of the target behavior

and the intensity or frequency of the target behavior. During each observational unit, a rating score is provided for each target behavior. The target behaviors rated are not necessarily mutually exclusive, which allows for the rating of more than one target behavior during each observation unit.

A target behavior may be operationally defined at different levels of abstraction. For example, a variable called “nurturant” may be globally defined at a molar level (“being attentive to a baby’s physical needs”), or it can be defined in terms of more exact target behaviors at a molecular level (“holds,” “feeds,” or “bathes” the baby). The level of abstraction is likely to affect the pattern of the findings. Single discrete behaviors and molecular codes are often influenced by immediate interactional and contextual factors; more global responses appear to be more stable and more likely to capture similarity. Moreover, molar-level behavioral definitions require more interpretation and inference on the part of observers-coders. Molecular categories code more narrowly defined and specific behaviors or sequences of behaviors. Molecular observation categories are easier for observers-coders to learn and to apply, they require less interpretation and inference, and they can later be aggregated into molar categories for summary data analyses. Although, theoretically, the number of behavior codes in an individual mode could range from two to infinity, in practice, when coding in real time, coders cannot comfortably monitor more than six to nine behavior options, including a default code “none of the above.” If rating scales are used, fewer behavior codes can be comfortably monitored in real time if the behavior modes are not mutually exclusive. To transform streams of different behaviors into appropriate quantitative data, audiovisual records are normally coded at several separate times, each time concentrating on a single behavior mode.

Reliability and Validity of Observational Data

Sampling

Before the advent of videotape and digital video technology, behavioral phenomena had to be coded in real time, and recording procedures were limited by human information-processing capacities that necessitated sampling strategies. (Indeed, even with the wider availability of new technologies and associated software, and therefore access to continuous and comprehensive coding, contemporary researchers routinely sample to make inferences to population characteristics of behavior because of the feasibility, reliability, and relative ease of sampling.) Sampling of behavior was first developed and widely applied in ethological and human developmental study.

Conventional and still popular sampling strategies include partial-interval (or time) sampling and momentary sampling. Historically, partial-interval sampling was the most common technique; an estimated one-third to three-quarters of all observational studies in psychology used partial-interval sampling. In partial-interval sampling, the observation period is divided into equal, regularly alternating observe and record periods. During each record period, the observer notes all behaviors of interest that occurred during the immediately preceding observe period. In momentary sampling, the occurrence of a behavior of interest in prespecified time slots during some or all intervals of the observation is noted. The rationale underlying these methods of data collection is that the sampling of behavior captured is a valid representation of the total behavior stream being investigated. There are many kinds of sampling measures; for example, observing and recording behaviors during alternating intervals is referred to as discontinuous partial-interval sampling; whereas observing and recording in every interval is called continuous partial-interval sampling.

Partial-interval sampling has some major advantages—for example, it permits the monitoring of a relatively large number of behaviors simultaneously. There are also, however, some major disadvantages to using partial-interval sampling. First, sampling behavior provides a valid representation of the overall phenomenon only if the behavior of interest is uniformly distributed across the observational period. Second, with partial-interval sampling, for a given observe interval, a behavior is recorded only once, regardless of whether it occurs one time, occurs many times, or extends from one interval into succeeding one(s). Thus, frequencies of behaviors are normally underestimates rather than actual counts, and these estimates vary depending on the distributional characteristics of individual behaviors. In partial-interval sampling, observers are not concerned with scoring the actual onset and offset of behaviors but more with their occurrence or nonoccurrence. In real life, all behaviors have frequencies that vary; in partial-interval sampling, all behaviors recorded in an observe interval are considered equal in terms of their quantitative and temporal characteristics. Partial-interval sampling does not yield information about duration or sequencing of behaviors. In short, using partial-interval sampling, some information about the behavior stream is lost.

By definition, sampling provides data for a subset of the population of behaviors and so is necessarily an imperfect representation of the population. All sampling methods misrepresent the source population in that sampling requires the transformation of larger numbers into smaller numbers. Because this transformation necessarily involves the loss of information, partial-interval sampling has been validly criticized for failing to accurately represent actual absolute frequency. It is fair to

observe that sampling adds noise to data and in the long run diminishes power.

Continuous Coding

Videotape and digital video technology and scoring systems based on complete audiovisual records today permit the recording, documentation, aggregation, and analysis of all (rather than sampled) ongoing behaviors. In continuous comprehensive coding, behaviors of interest from an entire observation can be quantified. This strategy serves several functions: It reduces instantaneous demands on observers, it allows focused coding, and it facilitates accurate assessments and reliability. However, the amount of time necessary for data reduction increases concomitantly.

Audiovisual records coded using computer-based coding systems are applicable to a broad spectrum of behavioral data collected in a wide variety of settings. Audiovisual records enable observers to spend their time observing and recording behavior with no distractions imposed by coding requirements; reciprocally, a computer-based coding system enables coders to spend their time coding behaviors with no distractions imposed by observation requirements. With audiovisual records in hand, it is easy to succumb to the temptation to undertake highly detailed analyses.

Coders

Coders are meant to bring objectivity to evaluations of behavior; although variation in rating behaviors should decrease with training, evaluative biases may not. Shared meaning systems serve to ensure consensus among coders, and judicious observational training helps to create and consolidate shared perceptions among coders.

Nonetheless, coders may make systematic errors in assessment and hold biases based on their information-processing limitations and expectations. Coders of behavior may miss information—the human visual and auditory senses can be insensitive or unreliable in detecting certain behaviors; coders can also suffer from information overload—when a large number of target behaviors occur rapidly or frequently within a short period of time, a coder may have difficulty detecting or recording all of the behaviors. Coders sometimes see patterns of regularity and orderliness in otherwise complex and disordered behavioral data; coders sometimes harbor or develop correct or incorrect hypotheses about the nature and purpose of an investigation, how participants should behave, or even what constitute appropriate data.

To address issues of coder bias and to maintain the accuracy of quantitative measures, it is necessary to

adhere to standardization procedures in observational coding:

1. Only trained and experienced but naive coders should be employed, and stringent training criteria instituted.

2. Coders should be trained prior to actual coding to a preestablished criterion performance of accuracy and consistency.

3. Observations should be assigned to coders randomly.

4. Coders should be cautioned about the potential negative effects of bias.

5. Coders should be oriented to the research issues, but remain naive to the specific scientific questions of the investigation.

6. To the degree possible, precise low-inference operational definitions should be used.

7. Coding drift should be corrected by means of regular reliability checks on coders.

Several statistical metrics of coder reliability can be employed. Cohen's kappa (κ) is preferable because it corrects for coder agreement due to chance.

Scoring

Computerized scores of continuous behavior streams normally yield measures of frequency, total and average duration, rate, and sequencing of component behavior codes. Frequency is the number of discrete times a behavior occurs according to some conventional assignment of an interbehavior interval (IBI). Frequencies obtained by continuous coding depend to a certain degree on arbitrary parameters; for example, in order to define two instances of a behavior (infant vocalization) as separate rather than as the same continuous vocalization, the time between the two instances must equal or exceed a specified minimum IBI. The standardized unit of frequency is the rate or relative frequency of occurrence per unit time. The duration is the total time that the behavior occurs. The standardized unit of duration, capturing the proportional nature of the measure, is prevalence per unit time. The mean duration of a behavior is its total duration divided by its frequency. These statistics summarize the nature of behavior occurrences within the real-time observation session. They describe quantitatively the various aspects of the behavior that are coded in a series of clock times. Continuous and comprehensive coding in real-time yields unbiased estimates of behavior frequency and duration.

A separate coding pass is normally made through each audiovisual record for each behavioral mode. When coding long audiovisual records, coding in shorter blocks helps coders to maintain the high level of concentration needed to score accurately without unduly prolonging

the time needed to process each audiovisual record. Many coding software programs have built-in safeguards to eliminate coding errors (e.g., codes other than those identified in the parameters of the mode being used cannot be keyed in).

Coding behavioral data in real time (online) is efficient, but also presents a number of special challenges. Coders must make instantaneous decisions about behaviors; they cannot wait to see how a behavior unfolds or whether it recurs before deciding to code it, and they cannot stop to verify whether a decision has been made correctly. Often codes cannot depend on the outcome of an action because the outcome is not known when the behavior is first observed (e.g., measures that depend, by definition, on identifying sequences of related behaviors juxtaposed in time). Particularly challenging in working with continuous coding is the task of defining when a given behavior begins and when it ends. Coding in real time also does not allow coders to decide when an action has conceptually begun and ended (e.g., a large number of short vocalizations may actually be part of a single communication). The way in which codes are operationalized for continuous coding must take these factors into account.

A system that does not allow the coder to make decisions based on the larger context in which a behavior occurs removes much (but not all) subjectivity from the coding process. However, a new problem—that of defining an action independent of the context in which it has taken place—is introduced. One part of the solution lies in the way in which operational definitions for behavior codes are written. In addition, it is possible to set objective parameters that are then used to conceptualize the data statistically. It is also possible to derive measures (for example, “responsiveness”) by examining multiple behavior streams containing the component behaviors of interest in relation to one another (that is, using “responsiveness” as an example, we define B as the response to A when B exhibits a particular distributional pattern relative to A).

Recording Technologies

Several commercially available systems for the collection, analysis, presentation, and management of observational data are now widely used to implement continuous coding of audiovisual records. The most popular include Behavioral Evaluation Strategy and Taxonomy (BEST), INTERACT, and The Observer. Ethnograph is a qualitative data version. Most programs share the same virtues. All these software packages facilitate real-time collection and analysis of real-life situations or video or multimedia recordings of observational category system data automatically. They record the start and stop times of multiple, mutually exclusive, or overlapping events. They comprehensively represent data by automatically recording

response frequency, duration, intervals, time samples, latency, interresponse time, percentage of experimental time, and discrete trials, and they represent data qualitatively (using transcription methods), quantitatively, and sequentially, as well as interfacing with other software programs to effect sophisticated graphing applications. Using these systems, it is possible to identify time-based information for each category system event, including first and last event occurrence, time spans between events, the longest and shortest event occurrences, and related means and standard deviations and to conduct a sequential analysis as well as a variety of reliability analyses. These systems permit textual annotation to events and search operations to find time codes; their behavioral codes order texts in annotations and can jump directly to associated video scenes. Time codes allow coders to identify every frame of the audiovisual records. Thus, combinations of predefined codes and free-format annotation make these programs suitable for quantitative as well as qualitative observational study. They accommodate qualitative data in the form of interview transcripts, field notes, open-ended survey responses, or other text-based documents.

Audiovisual recording is now more widely available and increasingly user friendly, but it is not accessible to all and can be intrusive, it is sometimes unnecessarily detailed, and it is time and resources consuming. In general, each researcher must choose the acceptable limits of unreliability for each study. Hoping to maximize power, the researcher must consider the effect size, the *N* available, the acceptable experimental error, and the reliability of the measures used in overall decision making.

Illustrations

Infant-Mother Interaction

It is uncommon in research for the absolute frequencies of behaviors to be of interest (e.g., whether infants vocalize 7, 10, or 15 times). Although in certain instances population base rates convey meaningful information, researchers typically use relative frequencies to compare individuals or groups (e.g., Who vocalizes more: typically developing or Down’s babies?) and to rank individuals or groups on particular variables with an eye to relating the ranks to other variables (e.g., Does infant vocalization predict child language development?). It is assumed, although not established, that continuous coding provides a more accurate reflection of reality than do sampling techniques. Do continuous recording and partial-interval sampling procedures allow investigators to reach similar conclusions regarding the relative frequency and standing of behaviors? Do partial-interval sampling procedures produce reliable estimates of actual frequencies obtained

by continuous recording? To address these questions U.S. and Japanese infant-mother dyads were compared in a 2002 methodological investigation by Bornstein that directly contrasted continuous recording, in which actual frequencies of behaviors of infants and mothers were obtained, with partial-interval sampling.

Methods and Procedures

Home observations were conducted identically in all visits. Briefly, mothers were asked to behave in their usual manner and to disregard the observer's presence insofar as possible; besides the trained observer-filmer (always a female native of the country), only the baby and mother were present; and observations took place at times of the day that were optimal in terms of babies' being in awake and alert states. After a period of acclimation, hour-long audiovisual records were made of infants and mothers in naturalistic interaction.

Four infant and four maternal activities were coded in modes (i.e., groups of mutually exclusive and exhaustive behaviors) using a computer-based coding system on four separate passes through the videotapes. Two target infant activities consisted of infant visual exploration of mother or of properties, objects, or events in the environment; blank staring and eyes closed/not looking were also coded. Two other infant activities consisted of non-distress or distress vocalization; bodily sounds and silence were also coded. Two maternal behaviors consisted of the mother's active mother-oriented or environment-oriented stimulation of the infant; not stimulating was also coded. The other two mother behaviors involved vocalization, speaking to the baby in child-directed or in adult-directed speech tones; silence was also coded. Thus, behaviors within a category were mutually exclusive, and any category of behavior could occur at any time. Coding reliabilities (κ) were all acceptable.

Data were first continuously coded. Then, partial-interval sampling data of three intervals were obtained via computer programming from the continuous data set; observe intervals selected for partial-interval sampling were 15, 30, and 45 s, a common range of durations of intervals in partial-interval sampling in the developmental science literature.

Results and Discussion

First, zero-order relations between data coded by partial-interval sampling and data coded continuously were explored. To do this, the bivariate correlations between results obtained via each method were computed. The three forms of partial-interval sampling generally preserved the relative rank obtained by continuous coding. The relation between frequencies coded by partial-interval sampling and by continuous coding was approximately linear.

Second, the possibility of estimating frequencies coded by continuous coding from frequencies coded by partial-interval sampling was examined. To this end, the regression of frequencies derived by continuous coding on frequencies derived by partial-interval sampling within one data set at one time was computed. The parameters of this regression equation were then used to estimate frequencies derived by continuous coding from frequencies derived by partial-interval sampling obtained at a second time. Altogether more than 90% of estimates of frequencies derived by continuous coding were statistically equivalent to the true frequencies, where differences occurred, the difference between the estimated and true scores was never larger than one-fifth of a standard deviation. These results indicate that frequencies derived by continuous coding at the group level can be estimated relatively accurately once the relation between sampling and frequencies derived by continuous coding has been specified. Furthermore, the results of cross-cultural comparisons of infant and maternal behaviors were largely unaffected by the use of frequencies coded by partial-interval sampling as opposed to frequencies coded by continuous coding.

Beyond the insights absolute frequency and duration data can yield about population base rates, social scientists are principally interested in the relative standing of individuals or groups for two reasons: (1) Relative standing allows comparison between individuals or groups and (2) relative standing allows for the examination of predictive validity of individual or group variation over time. In other words, researchers want to know whether or not an effect exists. Most statistical inference is based on comparisons of relative ranking rather than on actual quantity. In the final analysis, using any of the data derived by partial-interval sampling in the cross-cultural comparison produced identical results, in terms of significance, to those obtained using data derived by continuous coding.

Emotion Regulation, Parenting, and Displays of Social Reticence in Preschoolers

The substantive purpose of a 2001 investigation by Rubin, Cheah, and Fox was to determine the extent to which observed social reticence—inhibition in children could be predicted by their disregulated temperament, the observed parenting behaviors, and the interaction between temperament and parenting style. This study also illustrated the use of rating scales in encoding of audiovisual records.

Methods and Procedures

Mothers of 4-year-old children completed the Colorado Child Temperament Inventory, which comprises factors

that assess maternal perceptions of dispositional characteristics (e.g., emotionality, activity level, shyness, and soothability). Factors assessing emotionality (five items; e.g., “child often fusses and cries”) and soothability (five items; e.g., “when upset by an unexpected situation, child quickly calms down”) were composited to form an index of emotion dysregulation comprising high negative emotionality and low soothability.

Children were assigned to quartets of unfamiliar same-sex, same-age peers and observed in a small playroom filled with attractive toys. Behaviors in the peer play session were coded in 10-s intervals for social participation (unoccupied, onlooking, solitary play, parallel play, conversation, or group play) and the cognitive quality of play (functional, dramatic, and constructive play; exploration; or games-with-rules). For each coding interval, coders selected 1 of 20 possible combinations of cognitive play nested within the social participation categories. The proportion of observational intervals that included the display of anxious behaviors (e.g., digit sucking, hair pulling, or crying) was also coded. Time samples of unoccupied, onlooking, and anxious behaviors were combined to obtain an index of social reticence.

The peer quartet was followed 6–8 weeks later by a visit to the laboratory by each child and his or her mother. All children and mothers were observed in two distinct mother-child situations: During an unstructured free-play session, mother and child were told that the child was free to play with anything in the room (15 min); during a second session, the mother was asked to help guide and teach her child to create a Lego structure that matched a model on the table at which mother and child were seated (15 min). Mothers were asked not to build the model for the child and to refrain from touching the materials during this teaching task, which was thought to be challenging for a 4-year-old. A maternal behavioral rating scale measure was used to assess: (1) proximity and orientation: the parent’s physical location with reference to the child and parental nonverbal attentiveness; (2) positive affect: the positive quality of maternal emotional expressiveness toward the child; (3) hostile affect: negative instances of verbal and nonverbal behavior arising from feeling hostile toward the child; (4) negative affect: the negative quality of maternal expressiveness that reflects maternal sadness, fearfulness, and/or anxiety in response to the child’s behavior; (5) negative control: the amount of control a mother exerts over the child that is ill-timed, excessive, and inappropriately controlling relative to what the child is doing; and (6) positive control and guidance: the amount that the mother facilitates the child’s behavior or provides supportive assistance that is well-timed.

The free-play and Lego-teaching-task sessions were coded in blocks of 1 min each. For each 1-min interval, observers rated each of the maternal behaviors on a three-point scale, with higher maternal behavioral ratings

indicating greater maternal expressions of proximity and orientation, positive affect, hostile affect, negative affect, positive control, and negative control. For example, with regard to positive affect, observers gave a score of 1 if no instances of parental affection, positive feeling, or enjoyment were observed; 2 if moderate positive expression or enjoyment was observed; and 3 if the mother expressed outright physical or verbal affection or positive statements of praise for the child.

A free-play solicitous parenting aggregate was created by first standardizing and then adding the following variables: free-play proximity and orientation, free-play positive affect, free-play positive control, and free-play negative control. Lego-teaching-task maternal solicitousness was measured as in free play by standardizing and then adding the following variables: Lego proximity and orientation, Lego positive affect, Lego negative control, and Lego positive control.

Results and Discussion

Socially wary and reticent preschoolers were emotionally dysregulated; that is, they had relatively low thresholds for the evocation of negative affect and difficulty in being calmed once emotionally upset. However, emotional dysregulation was not a significant predictor of reticence, suggesting that preschool reticence is a product of factors other than dispositional characteristics. Children with mothers who are controlling and oversolicitousness during parent-child free play and emotionally dysregulated children whose mothers did not engage in such behaviors during a more stressful teaching task are thought to be more likely to display social reticence in a peer setting. Maternal oversolicitous (overprotective) behavior during the unstructured free-play situation was significantly and positively predictive of children’s socially reticent, wary, and shy behaviors—behaviors known to be associated contemporaneously and predictively with anxiety, psychological overcontrol, interpersonal problem-solving deficits, and poor peer relationships. The findings also suggest that a parenting constellation of warmth, proximity, intrusive control, and joint activity was associated with shy, reticent (and inhibited) child behavior. Taken together, these findings indicate that mothers of reticent preschool-age children do not behave in ways that allow their children to develop self-initiated coping techniques.

Another significant maternal contribution to the prediction of preschoolers’ socially reticent behavior was the moderating role played by mothers’ solicitousness during the putatively stressful, goal-oriented Lego construction task. For children whose mothers offered limited warmth, guidance, and control during the Lego task, emotional dysregulation was significantly and positively associated with the display of socially reticent behaviors among peers. The moderating role of parenting was demonstrated by the lack of a significant association between

emotional dysregulation and social reticence among preschoolers whose mothers provided appropriate control during the Lego paradigm. Thus, in structured situations in which parental goals are task oriented (such as the Lego teaching task), the display of maternal direction and guidance strategies may be normative and appropriate.

Conclusion

Computerized systems for the coding of audiovisual records of observation are comprehensive and versatile, with many potential applications in social science research. They can be used to code data collected in naturalistic as well as structured situations—at home, in the laboratory, and in clinical or educational settings; they can be adapted for actors of any age; they can be used to code behavior or to measure other dimensions of the environment; and they can be applied in real time or can be adapted for coding tasks that require a more prolonged or repetitive examination of the database. Regardless of the nature of the data collected, the recording system preserves most of the information available in the original data. Multiple behavior records can be juxtaposed, yielding new, composite behavior codes or information about the ways in which behaviors vary in relation to one another. This information can be used in the continual, iterative process of validating and revising the coding system. Data storage, retrieval, transmission, and manipulation are computer-based and therefore efficient, both in terms of time and space.

Glossary

autocorrelated errors Correlations between stochastic errors ordered over either time or space in a model, typically a linear regression model.

autoregressive process A data-generating process with “memory,” such that the value of the process at time t reflects some portion of the value of the process at time $t - i$.

common factor restriction A restriction on model parameters, produced in the context of linear regression analysis by the use of a quasi-differencing procedure as a generalized least-squares “correction” for autocorrelated errors.

fractionally integrated process A data-generating process with significant autocorrelations at long lags, such that the system has long memory and shocks erode very slowly.

integrated process An autoregressive process with perfect memory, such that shocks to the system at time t are not discounted in subsequent time periods.

minimum state variable (MSV) solution A solution procedure for rational expectations models that uses the simplest, least parameterized characterization.

near-integrated process An autoregressive process where a very large portion of the value of the process at time t carries over to time $t + 1$.

rational expectations equilibrium (REE) Citizen expectations, based on all available information (in the model), about an outcome that equals the outcome on average.

stationary A time (data) series (or model) is stationary if there is no systematic change in the mean (e.g., no trend), if there is no systematic stochastic variation, and if strict periodic variations (seasonal) are stable. Time plays no role in the sample moments.

Autocorrelation exists when successive values of a random variable, ordered over either time or across space, have nonzero covariances. A variety of data-generating processes (DGPs) may produce autocorrelation. Although interest in spatial autocorrelation has grown, most analyses of autocorrelation involve the use of time series data and, accordingly, the time series case is the focus of this article. Over the past three decades, econometricians have made major advances in the analysis of one class of such data, namely, nonstationary series produced by DGPs involving stochastic trends. Particularly important have been the development of the concept of cointegration and the explication of the relationship between this concept and the specification of error correction models for analyzing nonstationary data. Related work has led to procedures for analyzing highly autoregressive and fractionally integrated data. The former manifest very strong, but imperfect, autocorrelations across adjacent time periods; the latter have statistically significant autocorrelations at very long lags and are said to have long memory. Existing side by side with these developments are a set of procedures—some now over a half-century old—that derive from a narrow (not unimportant) concern that inferences regarding parameter estimates generated by ordinary least-squares regression analysis will be thwarted by violations of the assumption that errors are uncorrelated. We argue that these traditional procedures are potentially misleading since they ignore the possibility that autocorrelated residuals constitute evidence of model misspecification. We also contend that there is a related, larger need to develop and test theories that account for the observed autocorrelation in series of interest. The argument is illustrated

by the development of a theoretical model of macro-partisanship.

Conventional Wisdom and Conventional Practice

Historically, interest in autocorrelation (often referred to as serial correlation) has been motivated by the use of ordinary least-squares (OLS) regression to estimate the parameters of models of the form

$$Y_t = \beta_0 + \sum \beta_{1-k} X_{1-k,t} + \epsilon_t, \quad (1)$$

where Y_t is the dependent variable at time t ; $X_{1-k,t}$ are independent variables at time t ; β_0 and β_{1-k} are parameters to be estimated; and ϵ_t is the stochastic error term $\sim N(0, \sigma^2)$.

As is well known, inferences concerning OLS estimates of the parameters of this model are problematic if the stochastic errors, ϵ_t , are correlated [i.e., $\text{cov}(\epsilon_t, \epsilon_{t-1}) \neq 0$]. When errors are correlated, parameter estimates are unbiased, but standard errors are affected. Hence, t ratios (i.e., *β/s.e.*) are inflated or deflated (depending on the sign of the correlation) and the risk of making Type I or Type II errors is enhanced.

Generations of researchers have learned about this threat to inference and the advisability of conducting postestimation diagnostics to determine whether the threat obtains. Since the errors, ϵ_t , are not observed, these diagnostics are performed using the residuals from the regression analysis (i.e., $\hat{\epsilon}_t$). Proceeding in this fashion, analysts—either explicitly or, more frequently, implicitly—make the strong assumption that their model is correctly specified. If the assumption is invalid, autocorrelated residuals may be a consequence of model misspecification, rather than autocorrelated errors.

Some econometric texts have begun to emphasize this point, but many researchers still behave as if they were unaware of it. As a result, they continue to commit the fallacy of concluding that autocorrelated residuals constitute necessary and sufficient evidence of an autocorrelated error process.

Although various diagnostic procedures can be employed to detect autocorrelation in regression residuals, the standard one is the Durbin-Watson test. The Durbin-Watson test statistic is computed as:

$$d = \frac{\sum (\hat{\epsilon}_t - \hat{\epsilon}_{t-1})^2}{\sum \hat{\epsilon}_t^2}. \quad (2)$$

As its formula indicates, the Durbin-Watson test considers only first-order autocorrelation (i.e., $\hat{\epsilon}_t$ and $\hat{\epsilon}_{t-1}$). The implication is that the analyst, either explicitly

or implicitly, is entertaining the hypothesis that

$$\epsilon_t = \rho \epsilon_{t-1} + v_t, \quad (3)$$

where $v_t \sim N(0, \sigma^2)$.

Noting that $\sum \hat{\epsilon}_t^2$ and $\sum \hat{\epsilon}_{t-1}^2$ are approximately equal when N is large, the formula for d implies that $d \simeq 2(1 - \rho)$. Thus, when there is perfect positive first-order autocorrelation (i.e., $\rho = 1.0$), $d = 0$, and when there is perfect negative first-order autocorrelation (i.e., $\rho = -1.0$), $d = 4$. Critical values for d vary by the number of regressors in a model and the number of data points and are characterized by an “indeterminate zone,” where it is unclear whether the null hypothesis should be rejected.

Econometricians advise that the upper bound (d_u) of the critical values should be used in circumstances when regressors are changing slowly and caution that the test is not valid when one of the regressors is a lagged endogenous variable (e.g., Y_{t-1}). When a lagged endogenous variable is present, other tests (e.g., Durbin’s h , Durbin’s M) should be used.

If the null hypothesis of no (first-order) autocorrelation is rejected, the traditional response is to treat the autocorrelation as a technical difficulty to be “corrected,” rather than evidence of possible model misspecification. The correction is to transform the data such that the error term of the resulting modified model conforms to the OLS assumption of no autocorrelation. This generalized least-squares (GLS) transformation involves “generalized differencing” or “quasi-differencing.”

Starting with an equation such as Eq. (1), the analyst lags the equation back one period in time and multiplies it by ρ , the first-order autoregressive parameter for the errors [see Eq. (2) above]. Illustrating the procedure for a model with a single regressor, the result is

$$\rho Y_{t-1} = \rho \beta_0 + \rho \beta_1 X_{t-1} + \rho \epsilon_{t-1}. \quad (4)$$

Then, (4) is subtracted from (1) to yield

$$Y_t - \rho Y_{t-1} = \beta_0 - \rho \beta_0 + \beta_1 X_t - \rho \beta_1 X_{t-1} + \epsilon_t - \rho \epsilon_{t-1}. \quad (5)$$

This operation produces $\epsilon_t - \rho \epsilon_{t-1} = v_t$, which, by assumption, is a white-noise error process [$\sim N(0, \sigma^2)$]. The quasi-differencing operation involves computing $Y_t^* = Y_t - \rho Y_{t-1}$ and $X_t^* = X_t - \rho X_{t-1}$, and the resulting model is $Y_t^* = \beta_0 - \rho \beta_0 + \beta_1 X_t^* + v_t$, the parameters of which can be estimated by OLS.

Since the value of ρ typically is unknown, it must be estimated. Although various methods of doing so are available, the most popular (Cochrane-Orcutt) first uses OLS to estimate the parameters in model (1). The residuals then are used to estimate ρ . This $\hat{\rho}$ is used to transform Y_t and X_t to produce Y_t^* and X_t^* , respectively. The latter are then used in a second-round estimation and a new $\hat{\rho}$ is produced. This $\hat{\rho}$ then is used to transform the (original) data and another regression is performed. The process

(called feasible GLS because ρ is estimated) continues until the value of ρ converges.

Common Factors and Dynamic Misspecification

Regardless of how ρ is estimated, the quasi-differencing procedure introduces a common factor restriction. This may be seen by rewriting Eq. (5) as

$$(1 - \rho L)Y_t = (1 - \rho L)\beta_0 + (1 - \rho L)\beta_1 X_t + (1 - \rho L)\epsilon_t, \quad (6)$$

where L is the lag operator (i.e., $LY_t = Y_{t-1}$ and $L^k Y_t = Y_{t-k}$). Thus, Eq. (6)—the model implied by the conventional wisdom that first-order autoregressive residuals entail a first-order autoregressive error process—is a restricted version of an autoregressive distributed lag model. An example of such a model is

$$Y_t = \alpha_0 + \lambda_1 Y_{t-1} + \gamma_1 X_t + \gamma_2 X_{t-1} + v_t. \quad (7)$$

The requirement that $\gamma_2 = -\lambda_1 \gamma_1$ in Eq. (7) produces a common-factor (COMFAC) restriction similar to that in model (6)—the model implied by the quasi-differencing procedure typically utilized to deal with first-order autocorrelation in the residuals.

The validity of the restriction is an empirical question. Some econometricians stress the importance of COMFAC testing to help guard against misspecifying the dynamics in one's model. The test is easily implemented and can help one avoid the potentially misleading *non sequitur* of concluding that autocorrelated residuals imply autocorrelated errors.

Integrated, Near-Integrated, and Fractionally Integrated Processes

Modeling dynamic processes explicitly involves more than simply putting a lagged endogenous variable on the right-hand side of a regression equation. There are important theoretical and technical issues that should be addressed. One set of technical issues concerns the stationarity of the variables of interest. A variable Y_t is said to be (weakly) stationary if it has a constant mean [$E(Y_t) = \mu$], a constant variance [$E(Y_t - \mu)^2 = \gamma_0$], and a constant covariance [$E(Y_t - \mu)(Y_{t-k} - \mu) = \gamma_k$] at lag $t - k$ regardless of the values of t or k .

Consider the case of a simple first-order autoregressive DGP

$$Y_t = \phi_1 Y_{t-1} + \epsilon_t, \quad (8)$$

where ϵ_t is a white-noise error process and $\text{cov}(\epsilon_t, \epsilon_{t-k}) = 0$ for all t and k . If $|\phi_1| < 1.0$, the process is stationary.

However, if $\phi_1 = 1.0$, it is nonstationary. The defining characteristic of such a process, commonly called a random walk, is that it “never forgets.” Since the ϕ_1 coefficient for Y_{t-1} equals 1.0, stochastic shocks (ϵ_t) are not discounted as the process evolves; rather, they accumulate over time at their full value.

One can see this by repeated recursive substitution for Y_{t-1} in Eq. (8). Doing so shows that $Y_t = Y_0 + \sum \epsilon_i (i = 1, t)$, with Y_0 being the initial value of Y . This process has a nonconstant variance and is said to exhibit a stochastic trend. Modifying Eq. (8) by introducing a constant β_0 yields $Y_t = \beta_0 + Y_{t-1} + \epsilon_t$. Repeated recursive substitution shows that this latter model, called a random walk with drift, produces nonstationary variables. After substitution, the model contains both $\sum \epsilon_i$ and $t\beta_0$, with the latter being the “drift” component that introduces a deterministic trend.

To illustrate the behavior of these nonstationary processes, a random walk and a random walk with drift (with $\beta_0 = 0.05$) are simulated and then compared with a stationary first-order autoregression (with $\phi_1 = 0.50$). The errors for the three variables are white noise, with constant variances of 1.0. As Fig. 1 shows, the random walk and random walk with drift soon depart from their initial value (0) and never return during the 240 periods for which the data are generated. In contrast, the stationary first-order autoregressive process with an initial value of 0 repeatedly moves from positive to negative values and vice versa and shows no tendency to “trend” in any direction.

In a classic article from 1974, Granger and Newbold demonstrated that the threats to inference posed by nonstationary variables are decidedly nontrivial. Employing Monte Carlo simulation methods, they generated a large number of independent random walk variables and then performed regressions of the form $Y_t = \beta_0 + \beta_1 X_t + \mu_t$. These regressions rejected the (true) null hypothesis that $\beta_1 = 0$ at alarming rates.

Since the publication of these findings, researchers have come to appreciate the danger of such “spurious regressions.” It has become routine to use unit-root tests and other, less formal, diagnostic procedures (graphs, autocorrelation functions) to determine whether variables of interest are nonstationary.

If nonstationarity is suspected, conventional practice is to difference the variables prior to conducting regression analyses. The implicit assumption is that the data-generating process producing the nonstationarity is a random walk or a random walk with drift, rather than a deterministic trend model of the form $Y_t = \pi_0 + \pi_1 t + \eta_t$, where t is time and the π values are model parameters. If the assumption is valid, the variable is said to be integrated of order 1 [$I(1)$] because differencing it once will produce stationarity. Thus, in the random walk case, one has

$$Y_t - Y_{t-1} = 1.0Y_{t-1} - Y_{t-1} + \epsilon_t. \quad (9)$$

Figure 1 Simulated stationary first-order autoregressive, random walk, and random walk with drift processes.

The resulting variable $(1 - L)Y_t = \varepsilon_t$ is stationary. The result for a random walk with drift is similar, except that the expected value of the differenced variable is β_0 rather than zero.

Differencing nonstationary $I(1)$ variables solves the problem of spurious regressions, but does not take into account possible long-run relationships between Y_t and X_t . It is possible to study long-run relationships between nonstationary $I(1)$ variables if those variables cointegrate. For example, two nonstationary variables, Y_t and X_t , are said to cointegrate if a linear combination of the variables constitutes a stationary variable.

Cointegration cannot be assumed, but must be demonstrated empirically. In 1987, Engle and Granger proposed doing this by regressing Y_t on X_t and testing the residuals (by definition a linear combination of Y and X) for stationarity. Determining that the residuals of this “cointegrating regression” constitute a stationary series warrants the inference that Y and X cointegrate. If so, Y and X can be modeled in error correction form, with the error correction mechanism capturing the long-run relationship between them:

$$(1 - L)Y_t = \beta_0 + \beta_1(1 - L)X_t - \alpha(Y_{t-1} - cX_{t-1}) + v_t. \tag{10}$$

In this model, the expression $Y_{t-1} - cX_{t-1}$ constitutes the error correction mechanism. Given the negative feedback properties of error correction, the parameter α is expected to carry a negative sign. Its absolute value calibrates the speed with which shocks to the system are reequilibrated by the cointegrating relationship between Y and X . Rearranging terms shows that models

such as Eq. (10) are variants of the more familiar autoregressive distributed lag form. For example, Eq. (10) may be written as:

$$Y_t = \beta_0 + (1 - \alpha)Y_{t-1} + \beta_1X_t + (\alpha c - \beta_1)X_{t-1} + v_t. \tag{11}$$

Note also that since all variables in a model such as Eq. (10) are stationary, the spurious regression problem does not arise. Thus, if other conventional assumptions hold, the parameters in model (10) may be estimated via OLS. Engle and Granger suggest a two-step process, where step 1 is to regress Y on X in levels. Assuming that the residuals from this regression are stationary, step 2 is to estimate the parameters in an error correction model such as Eq. (10). Other analysts have advocated a one-step method in which all coefficients in an error correction model are estimated simultaneously. If Y and X do not cointegrate, α will not differ significantly from zero.

An error correction model specification is attractive because it enables one to study both short- and long-run relationships among nonstationary variables. However, establishing that a variable is nonstationary in the classic sense can be difficult. This is because the principal statistical tool for this purpose, unit-root tests, has low statistical power in the face of alternative DGPs that produce highly persistent data. Two such alternatives are the near-integrated and fractionally integrated cases. A near-integrated variable is the product of an autoregressive process [e.g., model (8) above], where the ϕ_1 parameter is slightly less than 1.0 (e.g., 0.95). In this case, unit-root tests are prone to fail to reject the null

hypothesis of nonstationarity, even though ϕ_1 actually is less than 1.0.

Unit-root tests also are apt to prove misleading when the DGP produces a fractionally integrated, or long-memory, variable. As its name implies, the concept of fractional integration relaxes the assumption that variables must have integer orders of integration. Rather than being integrated at orders, say 0 or 1, a variable may be generated by an autoregressive, fractionally integrated, moving average (ARFIMA) process such as:

$$(1 - L)^d Y_t = \frac{\varphi(L)}{\phi(L)} \omega_t. \quad (12)$$

This is a generalization of the familiar autoregressive, integrated, moving average (ARIMA) class of models, with ϕ and φ representing autoregressive and moving average parameters.

The fractional differencing parameter d can vary from -0.5 to 1.0 . When it is ≥ 0.5 , the series is nonstationary although, unlike a random walk, shocks do eventually decay. The simplest member of this model class is called fractional Gaussian noise [i.e., $(1 - L)^d Y_t = \omega_t$]. The left-hand side may be expanded as an (infinite) autoregression:

$$1 - dL - (1/2)d(1-d)L^2 - (1/6)d(1-d)(2-d)L^3 \\ - \dots - (1-j!)d(1-d)(2-d)\dots[(j-1) - d]L^j - \dots$$

Figure 2 presents simulated examples of near-integrated ($\phi_1 = 0.95$) and fractionally integrated ($d = 0.95$) data in comparison with the aforementioned typical first-order autoregressive series where $\phi_1 = 0.50$. Although the near-integrated and fractionally integrated series do not exhibit the obvious trending behavior of the random walk

depicted in Fig. 1, they clearly behave much differently than the garden variety AR(1), moving away from their initial value (0) for very long periods.

The persistence (memory) in the near-integrated and fractionally integrated data means that they have significant autocorrelations at very long lags. This point is illustrated clearly by calculating autocorrelation functions (ACFs) for these series (see Fig. 3). Although the ACFs for the near-integrated and fractionally integrated series decline more quickly than does the ACF for the random walk, they are very different than the ACF for the conventional AR(1) series. For these simulated data, the latter becomes statistically insignificant ($p > 0.05$) after 2 lags, whereas the near and fractionally integrated series remain significant through 18 and 15 lags, respectively.

Near-integrated variables and fractionally integrated variables with d values in the nonstationary range (i.e., > 0.5) can create threats to inference similar to those posed by random walks. In this regard, DeBoef has demonstrated that single-equation error correction models are useful for analyzing near-integrated variables. In 2003, Clarke and Lebo cited several procedures for estimating the d parameter (and associated standard error) and discussed how the ideas of cointegration and error correction may be generalized to handle the cases where variables of interest are fractionally integrated and fractionally cointegrated.

The preceding discussion has emphasized statistical issues and techniques that are relevant for the analysis of autocorrelated data. These matters are very important but, as emphasized, a crucial consideration is theoretically guided model specification. This is the topic of the next section.

Figure 2 Simulated stationary first-order autoregressive, near-integrated, and fractionally integrated processes.

Figure 3 Autocorrelation functions for simulated autoregressive, near-integrated, fractionally integrated, and random walk processes.

From Practice to Theory: A Model of Macropartisanship

Here it is demonstrated that persistence can be explained theoretically. The example given is a simple model of party identification—so-called macropartisanship. The model makes no claim to be a powerful explanation of macropartisanship. Rather, the weaker claim is made that it serves to illustrate that its highly autoregressive behavior is a matter of specification and theoretical development. Strictly mechanical approaches, which use a variety of statistical patches, fail to address these theoretical concerns.

The behavioral assumptions are primitive, but the model does have the potential to be enriched by further theoretical (formal) revisions that would incorporate findings in, for example, economics, cognitive psychology, communications, and political science. Although these modifications are welcome, the larger point is to incorporate these modifications within a framework that merges both formal and empirical analyses. When this is achieved, persistence—autocorrelation—can be identified at its source and researchers can use theory to assist in differentiating between various types of persistence (i.e., near-integrated versus fractionally integrated processes) that may characterize an empirical realization of a time series of interest.

In the model demonstrated it is assumed that political campaign advertisements influence the public. It is argued that the persistence of rival political parties’ political advisors to target and influence (through the use of political advertisement resources) rival party voters reduces the well-known persistence in macropartisanship. As a consequence, shocks to macropartisanship can either be amplified or die out quickly depending on rival political advisor behavior. Moreover, the linkage between the formal and empirical models identifies the persistence as near-integrated.

The model comprises three equations. Each citizen (i) is subject to an event (j) at time (t). The model aggregates across individuals and events so the notation will have only the subscript t . The first equation [Eq. (13)] specifies what influences aggregate party identification (M_t). The variable M_{t-1} accounts for the possibility of persistence. Citizens also have an expectation of what portion of the population will identify with the party ($E_{t-1}M_t$). It is assumed that, in forming their expectations, citizens use all available and relevant information as specified in this model (rational expectations). It is further assumed that party identification depends on how favorably a citizen views the national party (F_t). Finally, party identification can be subject to unanticipated stochastic shocks (realignments) (u_{1t}), where $u_{1t} \sim N(0, \sigma_{u_{1t}}^2)$. It is assumed the relations are positive— $a_1, a_2, a_3 \geq 0$.

Macropartisanship

$$M_t = a_1M_{t-1} + a_2E_{t-1}M_t + a_3F_t + u_{1t}. \quad (13)$$

Equation (14) represents citizens' impression ("favorability") of a political party (F_t). In this model, favorability is a linear function of the lag of favorability (F_{t-1}) and an advertising resource variable (A_t). There are many ways to measure political advertising resources. These measures include but are not limited to the total dollars spent, the dollars spent relative to a rival party (parties), the ratio of dollars spent relative to a rival party (parties), and the tone, content, timing, and geographic location of the advertisements (on a multinomial scale). Data have been collected for individual races but have the potential to be aggregated along partisan lines. For more details on measurement issues consult the Wisconsin Advertising Project Web site at: <http://www.polisci.wisc.edu/tvadvertising>. u_{2t} is a stochastic shock that represents unanticipated events (uncertainty), where $u_{2t} \sim N(0, \sigma_{u_{2t}}^2)$. The parameter $b_1 \geq 0$, while $b_2 \equiv 0$ depending on the tone and content of the advertisement.

Favorability

$$F_t = b_1F_{t-1} + b_2A_t + u_{2t}. \quad (14)$$

Equation (15) presents the contingency plan or rule that (rival) political advisors use. It is argued that political advisors track their previous period's advertising resource expenditures (A_{t-1}) and react to that period's favorability rating for the (rival) national party (F_{t-1}). Political advisors also base their current expenditure of advertisement resources on the degree to which macropartisanship (M_t) approximates a prespecified and desired target (M^*). Ideally, political advisors want $(M_t - M^*) = 0$ since it is unrealistic and far too costly to make $M_t = 0$.

It is assumed that the parameters c_1 and c_3 are positive. The parameter c_2 is countercyclical ($-1 \leq c_2 \leq 0$). This reflects political advisors' willingness to increase or conserve their advertising resources depending on whether macropartisanship is above (decrease advertising) or below (increase advertising) the target.

Rival Political Advisor

$$A_t = c_1A_{t-1} + c_2(M_t - M^*) + c_3F_{t-1}. \quad (15)$$

To obtain the reduced form for macropartisanship, substitute (15) into (14):

$$F_t = b_1F_{t-1} + b_2[c_1A_{t-1} + c_2(M_t - M^*) + c_3F_{t-1}] + u_{2t} \quad (16)$$

and

$$F_t = (b_1 + b_2c_3)F_{t-1} + b_2c_1A_{t-1} + b_2c_2(M_t - M^*) + u_{2t}. \quad (17)$$

Now substitute Eq. (17) into Eq. (13):

$$M_t = a_1M_{t-1} + a_2E_{t-1}M_t + (b_1 + b_2c_3)F_{t-1} + b_2c_1A_{t-1} + b_2c_2(M_t - M^*) + u_{2t} + u_{1t}. \quad (18)$$

Collect terms and divide through by $(1 - b_2c_2)$:

$$M_t = \frac{a_1}{(1 - b_2c_2)}M_{t-1} + \frac{a_2}{(1 - b_2c_2)}E_{t-1}M_t + \frac{b_2c_1}{(1 - b_2c_2)}A_{t-1} + \frac{(b_1 + b_2c_3)}{(1 - b_2c_2)}F_{t-1} - \frac{b_2c_1}{(1 - b_2c_2)}M^* + \frac{u_{2t} + u_{1t}}{(1 - b_2c_2)}. \quad (19)$$

Simplifying the notation shows that there is an autoregressive component in the reduced form for macropartisanship

$$M_t = \Theta_0 + \Theta_1M_{t-1} + \Theta_2E_{t-1}M_t + \Theta_3A_{t-1} + \Theta_4F_{t-1} + \varepsilon_t^*, \quad (20)$$

where $\Theta_0 = (b_2c_1Y^*)/(1 - b_2c_2)$, $\Theta_1 = a_1/(1 - b_2c_2)$, $\Theta_2 = a_2/(1 - b_2c_2)$, $\Theta_3 = b_2c_1/(1 - b_2c_2)$, $\Theta_4 = (b_1 + b_2c_3)/(1 - b_2c_2)$, and $\varepsilon_t^* = (u_{2t} + u_{1t})/(1 - b_2c_2)$.

The system is now simplified to a model of macropartisanship that depends on lagged macropartisanship and also the conditional expectation at time $t - 1$ of current macropartisanship. The prior values of advertising and favorability also have an effect.

To close the model, the rational expectations equilibrium can be solved by taking the conditional expectation at time $t - 1$ of Eq. (20) and then substituting this result back into Eq. (20)

$$M_t = \Pi_1 + \Pi_2M_{t-1} + \Pi_3A_{t-2} + \Pi_4F_{t-2} + \xi_t', \quad (21)$$

where

$$\Pi_1 = \left[\frac{\Theta_0}{1 - \Theta_2} - \left(\frac{\Theta_3}{1 - \Theta_2} - \frac{\Theta_4}{1 - \Theta_2}b_2 \right) c_2 Y^* \right],$$

$$\Pi_2 = \left[\frac{\Theta_1}{1 - \Theta_2} + \left(\frac{\Theta_3}{1 - \Theta_2} + \frac{\Theta_4}{1 - \Theta_2}b_2 \right) c_2 \right],$$

$$\Pi_3 = \left[\left(\frac{\Theta_3}{1 - \Theta_2} + \frac{\Theta_4}{1 - \Theta_2}b_2 \right) c_1 \right],$$

$$\Pi_4 = \left[\frac{\Theta_3}{1 - \Theta_2}c_3 + \frac{\Theta_4}{1 - \Theta_2}(b_1 + b_2c_3) \right],$$

and

$$\xi_t' = \left(\frac{\Theta_4}{1 - \Theta_2}u_{2t} + \varepsilon_t^* \right).$$

Equation (21) is the minimum state variable solution for macropartisanship. Macropartisanship (M_t) depends, in part, on the lag of macropartisanship (M_{t-1}). More importantly, the persistence of macropartisanship (Π_2) is now shown to depend on the persistence and willingness of rival political advisors to maintain a rival macropartisanship target (c_2).

This can be shown by examining the reduced form AR(1) coefficient expression Π_2 :

$$\Pi_2 = \frac{a_1 + b_2c_2(c_1 + b_1 + b_2c_3)}{1 - b_2c_2 - a_2}. \quad (22)$$

The derivative of Eq. (22) with respect to (c_2) is taken and the following relationship is obtained:

$$\frac{\partial \Pi_2}{\partial c_2} = \frac{b_2[a_1(-1 + a_2)(b_1 + c_1 + b_2c_3)]}{(-1 + a_2 + b_2c_2)^2}. \quad (23)$$

The denominator is always positive since it is squared. Given the assumptions about the signs of the coefficients in the model, the numerator is positive as long as $a_2 < 1$. Therefore, under these conditions, it is known that the relationship is positive ($\partial \Pi_2 / \partial c_2 > 0$).

The final step is to determine whether the model reaches an equilibrium when it starts from a point of reference that contains nonequilibrium values. Because the model presented has a first-order autoregressive component, the result is straightforward. The stability condition is summarized in the following proposition:

PROPOSITION 1. *Equation (21) is a uniquely stationary MSV solution if $|\Pi_2| < 1$.*

The relationship between c_2 and Π_2 is demonstrated in Fig. 4. The following values are used for Eq. (22): $a_1 = a_2 = b_1 = b_2 = c_1 = c_3 = 0.5$. The parameter c_2 ranges from 0.0 to -1.0 . As the value of c_2 is varied between 0.0 and -1.0 , it is found that the persistence

Figure 4 The relationship between Π_2 and c_2 .

(autocorrelation) in macropartisanship (Π_2)—all things being equal—is zero when $c_2 = -0.5$. On the other hand, macropartisanship becomes highly autoregressive ($\Pi_2 \rightarrow 1.0$) when rival political advisors fail to react ($c_2 \rightarrow 0.0$) to deviations from their prespecified target. The conclusion from this model is that negative advertisements from rival political parties can influence the persistence of their opponent’s national party identification.

An Agenda for Future Research

Social scientists’ interest in autocorrelation is longstanding. This interest reflects a scientifically unassailable concern to make sound inferences regarding forces driving the dynamics of a variable of interest. As discussed above, researchers historically have interpreted the remit implied by this concern very narrowly, focusing their attention exclusively on autocorrelation in the residuals of an OLS regression analysis. Construed so narrowly, autocorrelation is—to use Hendry’s characterization—a “nuisance,” with traditional “corrections” constituting possibly unwarranted and misleading model simplifications.

Since the early 1990s, advances in the analysis of integrated, near-integrated, and fractionally integrated data have helped to relieve this situation by explicitly articulating technical concerns with the diagnosis of various forms of autocorrelation and the implications thereof for successful inference to questions of model specification. Although these developments constitute a major step in the right direction, the analytic stance remains highly reactive. Model specification is governed by *ad hoc* inferences regarding characteristics of the data and relatively little attention is given to the theoretical foundations of the model. Above it is argued that it is desirable to redress the balance, by giving greater priority to the development of theoretical models that can generate various forms of autoregressive behavior in a variable being studied.

The argument has been illustrated by developing a small theoretical model of macropartisanship—a topic traditionally of great concern to students of voting, elections, and the stability of democratic political systems—and demonstrating how it implies autoregressive, quite possibly highly autoregressive, behavior in observed time series data. Following Granger, this model could be elaborated in various ways, for example, by specifying autoregressive heterogeneity in the electorate as a means of generating the nonstationary fractional dynamics observed in macropartisanship in mature democracies. The general point is that various forms of autocorrelation can and should be seen as empirical implications of theoretical models. Developing and testing such models constitutes a challenging agenda for future research.

Basic vs. Applied Social Science Research

Scott Greer

*University of Prince Edward Island,
Charlottetown, Prince Edward Island, Canada*

Glossary

applied research Concerned with practical knowledge; outcome focused rather than theory focused, and involving the application of existing knowledge to solve problems.

applied science Knowledge directed toward producing a product for public interest, and perhaps developing its commercial value.

basic research Involves questions and investigative practices that are focused on discovering or formulating fundamental principles; generally inspired by scientific curiosity rather than by the need to solve a particular problem.

basic science Involves theories about the world that are considered foundational to human understanding.

human science Includes methods and theories based on the idea that human beings are fundamentally unlike other components of the natural world, and that methods and assumptions different from those applied to the natural sciences are necessary to understand human conduct.

ideographic research The study of a single individual case (e.g., a case study); contrasted with nomothetic research.

natural science Includes methods and theories devoted to understanding the natural world through the measurement of systematic and controlled observations.

nomothetic research The study of groups of individuals, and the search for universal generalizable laws of behavior.

paradigm A broad set of assumptions that works as a framework of knowledge.

social science The study of individual human behavior as individuals and in groups.

Although the concepts of basic and applied social sciences originated during the mid-19th century, the modern understanding of these disciplines emerged only after World War II. Basic social science research involves questions and investigative practices that are focused on discovering or formulating fundamental principles of human

behavior, and are generally inspired by the scientist's curiosity rather than by an attempt to solve a particular problem. Applied social science research, by contrast, is more pragmatic and goal oriented, focusing more on practical concerns than on theory, and involves the application of existing knowledge to solve problems.

Introduction

Basic social science research involves questions and investigative practices that are focussed on discovering or formulating fundamental principles of human behavior, and is generally inspired by the scientist's curiosity rather than an attempt to solve a particular problem. Applied social science research, driven more by practicality, is outcome focused rather than theory focused. Basic research answers questions relating to the "whys" and "hows" of human behavior, and does not typically result in a product or technology. Applied research, on the other hand, is directed toward producing an improved product, or toward finding ways of making the use and delivery of the product better and easier. In short, basic research tends to improve our understanding of the world, and applied research tends to improve our ability to function and interact with it. To fully understand this distinction, however, it is important to realize that basic and applied research are sets of practices that are based on two differing conceptions of science, with differing professional interests. As a result, the relationships between them are dynamic, highly complex, and often quite ambiguous.

Although the distinction between basic science and applied science had existed in various forms since the 19th century, contemporary understanding of these terms is based on the effects of World War II, and the changes it brought about in the ways science operates

within society. There is no one single definition that would be historically accurate to differentiate these approaches or the activities of social scientists, although there are some broad commonalities that serve to distinguish “basic” from “applied” science and research. It should be remembered that the definitions of and relationship between basic and applied research approaches are not static, and must be understood within their historical and social context.

Basic Science Research

Basic research refers to the activities of scientists who are investigating theoretical questions for the sake of building knowledge. Basic research is constituted by the types of investigative practices that both inform and reflect the current understanding of “basic science.” These forms of research practice and scientific knowledge form a reciprocal relationship, in that knowledge informs the basis of research methods, and these methods in turn shape the questions and even the findings of scientists. Basic science involves theories about the world—and indeed the universe—that are considered foundational to human understanding. Basic social science, then, refers to the knowledge that scientists use in formulating questions and research strategies to better understand human behavior. It also involves the means by which scientists carry out these investigations, and the knowledge that is produced as a result. In the social sciences, basic science theories typically describe the essential factors believed to be involved in human behavior, and provide some explanations about the relationship of these factors to each other and to the world. Basic science therefore strives to be (1) explanatory, by developing causal theories about relationships among events in the social world, and (2) descriptive, by presenting an accurate and comprehensive portrayal of fundamental processes and structures. Ideally, basic science would be articulated in terms of causal relationships about the social world and social behavior, and these relationships would be thought of as scientific laws (or at least lawful).

Applied Science Research

Applied social science has interests that are often quite disparate from basic or pure scientific questions. As already noted, applied science is about producing a product for public interest, and perhaps developing its commercial value, whereas basic researchers are drawn to more purely theoretical questions about advancing the current state of knowledge. Applied researchers evaluate their work more in terms of its utility and public appeal, and may create instruments or measures for specific users and situations. Accordingly, applied social researchers use less technical language, and often frames

their approach with a specific problem or task already in mind. A major step in the evolution of applied social science was the professionalization of applied disciplines. This development has created a much more complex picture in understanding the relationship between basic and applied social research, adding numerous other goals and interests. For example, clinical psychologists (who are specialists in psychological treatment and testing) want to maintain standards of training, restricting the job of administering mental tests only to those with the proper qualifications. Psychologists and other mental health professionals want similar standards of practice, and issues such as licensure, liability, and insurance all become highly salient and often contentious. Professional social science concerns are often economic in nature, and include ways of expanding professional horizons to include other practices and clientele (e.g., the issue of whether psychologists should be allowed to prescribe drugs). In order to accommodate the incredible proliferation of professional psychologists, the American Psychological Association (APA) was reorganized in 1945, and even altered its mission statement to reflect the presence of professional psychology. Today, over half of the psychologists in the world work in the United States, and half of American psychologists are professional, mainly clinical, practitioners.

Before addressing the relationship between basic and applied social science research, and the professionalization of social science practices, it is important to recognize there are different types of basic and applied sciences, including natural science, social science, and human science.

Types of Science: Natural Science, Social Science, and Human Science

Following the earlier writings of Vico (among others), it was typical in Germany during the 19th century to distinguish between natural scientific theories (*Naturwissenschaften*) and human scientific theories (*Geisteswissenschaften*). Natural science theories were mainly developed during the historical period known as the Enlightenment, and sought to understand the laws of nature through experimental methods. Though it has assumed many forms, the experimental method has historically emphasized objectivity, measurement, and a self-verifying cycle of deductive and inductive logical analysis: ideas (theories) yield hypotheses that are tested under controlled conditions. Measurements are taken, results are recorded, and the initial hypothesis is either supported or rejected as a possible explanation for the observed relationship.

By contrast, human science theories originated from the notion that human beings are fundamentally unlike

other components of the natural world, and, although the exact nature of this difference varies and has evolved over time, different methods and assumptions are necessary to understand human conduct. Nevertheless, the principal differences between natural and human science theories revolve around the idea that human conduct is based on meaning and intentionality, factors that do not have physical referents, are not amenable to objective experimental analysis, and do not appear to follow causal laws. Where natural science theories see causal scientific laws as their essential feature, human science tends to see understanding (or *Verstand*, in the original German) as its central feature. The concept of understanding is based on the abilities of human beings to engage the world in a unique way; for instance, empathy, or the ability to understand another's point of view, is a capacity that is not found in other living things (to the best of our knowledge). Human science theories do not involve what would normally be regarded as scientific or experimental methods, but instead favor approaches that are more interpretive and discursive, emphasizing the roles of empathy, interpretation, and intentionality in framing human conduct.

The social sciences are a blend of the natural and human science orientations, although different disciplines have emphasized one over the other at various points in time. Most social sciences began during the 19th century, a time when experimental research was at its peak and widely received by both professionals and the public as unlocking the secrets of the universe. Soaring urban populations, the Industrial Revolution, and the rise of the middle class were also factors that led to new types of questions concerning the individual and the causes and processes of human behavior. Following philosophers such as John Stuart Mill, many believed it was not only possible but quite desirable to apply the highly successful experimental methods of the natural sciences to human behavior, and these burgeoning social sciences (including psychology, sociology, and economics) were founded on the natural science paradigm. Psychology, for instance, was initially conceived by its recognized founder, the German physiologist Wilhelm Wundt (1832–1920), to be a combination of natural and human sciences. However, the idea of a natural science of human behavior was eagerly embraced by North American psychologists (and the North American public) for a variety of practical and economic reasons, and “psychology” was transformed from this dual perspective into a largely singular focus on experimental approaches.

Unlike natural science theories, social science theories take human behavior as their primary object of investigation, although there are many clear links between social and natural science theories (e.g., neuroscience, physiology). The social sciences are not generally recognized as having the same type of laws as the natural

sciences, principally because their subject matter is of a different nature. Nevertheless, most social scientists believe the methods of experimental analysis are an essential component of basic science knowledge. With some variation and to different degrees, the social sciences have continued to emulate the natural science method of investigation. The social sciences have developed an array of their own methodologies as well, although these are all based on the assumptions of either a natural science or a human science paradigm.

Similarly, applied social science research involves a reciprocal set of practices that are connected to the foundations of basic science on the one hand, and the practical needs and problems of society on the other. Ideally, the applied social scientist looks to the principles and advancements of basic science to meet the demands of consumers of technology and technological services. Most researchers in the social sciences, like their counterparts in the natural sciences, have assumed that there needs to be some fundamental, basic knowledge in place before progress can be made; basic research, in other words, lays the foundation for what follows. The idea that basic science necessarily precedes applied science has been traditionally accepted as the logic of scientific progress, but closer examination of the social sciences show that this is far from a set formula.

At the most fundamental level, the distinction between basic and applied social science research revolves around the purposes for which the research question is directed, not which type of knowledge was the basis for the other. In other words, knowledge itself is not essentially either basic or applied; the decisive issue concerns the context in which the research was conducted, and the ends toward which such knowledge was initially directed. It is also clear that there have been and continues to be considerable tensions between basic and applied forms of research. Examples of this complex relationship among society and basic and applied research are readily available in the social sciences: intelligence, race, genetics, abnormal behavior, and psychotherapy are but a few of the instances in which the concerns of applied research have conflicted with (and, some may argue, superseded) the foundational science of basic research.

The Case of Psychology: Basic Science, Applied Science, and Professionalization

The APA was founded in 1892, and the preamble to their bylaws stated that their mission was to “advance psychology as a science.” When the APA was reorganized in 1945, the mission statement was modified to “advance psychology as a science, a profession, and as a means of

promoting human welfare.” This revision reflects some important and fundamental developments in the field—namely, the emergence of applied and professional psychology as dominant interests. This was, however, a complete turnaround from the notion behind the founding of psychology as a scientific discipline devoted to discovering the laws of behavior (i.e., a basic science).

Psychology as a scientific endeavor began in Germany in the late 19th century. On the heels of significant advances in physiology (e.g., Helmholtz’s measurement of the speed of nerve impulses), the experimental analysis of physical movement and functioning led to attempts to measure mental functioning as well. Although there had been a long tradition of believing that mental events could not be measured, and that a scientific psychology was therefore untenable, the development of fields such as psychophysics, which looked at the relationship between changes in physical stimuli and perception, began to show that measurements of mental phenomena were indeed possible. Scientific psychology was thus dependent on the objective, experimental measurements of mental phenomena and their relationship to the world; this would be the basic science of psychology. Most German scholars in this new field would have scoffed at the idea of an “applied psychology” or any form of applied social science research—there had to be a basic set of fundamental principles in place before the practical questions of application could even be asked. Although never actually professionally aligned with psychology, Sigmund Freud started as a medical doctor, practising various treatments for hysteria. Freud wanted very much to bring relief to his neurotic patients, but he also wanted to create a new science of the mind, called “psychoanalysis,” just as badly. Moreover, social sciences in Germany were relative newcomers to academic institutional stalwarts such as philosophy, physiology, and the experimental sciences. This meant that they needed first to prove themselves as bona fide disciplines, which meant creating a foundation of basic science principles.

Although generally much more practical and public oriented, some early North American psychologists also saw themselves as basic scientists. Edward Titchener and his “structuralism,” for instance, sought to establish the foundational elements of conscious experience. In the long run, however, this type of psychology in North America proved to be the exception. Reflecting the American *Zeitgeist* (spirit of the times), most American psychologies would have a largely pragmatic philosophy of science, one that would result in a psychology of everyday life rather than a pure science. William James, one of the founders of North American psychology, noted that “the kind of psychology which could cure a case of melancholy, or charm a chronic insane delusion away, ought certainly to be preferred to the most seraphic insight into the nature of the soul.” Right from the very beginnings of the field

in the early 1890s, James understood that there was a great need for a practical social science, and not more grand philosophizing about the human condition, nor a purely laboratory (and thus somewhat artificial) basic science of behavior. James’ *Principles of Psychology* (1890), the first American psychology text, was similarly geared toward areas of social importance and relevance, but presented itself as also dealing with scientific “principles.” Similarly, John Dewey, one of the cofounders of (philosophical) pragmatism along with James, urged psychologists in the early 20th century to investigate phenomena in learning and education, areas in which basic science was needed in order to formulate new methods of application. Like Dewey and James, many early North American social scientists were trying to achieve a balance between a scientific and a public-friendly discourse. As APA’s mission statement illustrates, once psychology achieved recognition as a scientific discipline, the shift toward applied psychology, and the professionalization of psychological practice, became much more pronounced and varied.

From Pseudoscience to Social Science

Early Approaches to Applied Knowledge

A variety of applied social science practices existed long before the formal disciplines were founded. One could argue that the assessment and treatment of individuals, whether for abnormal behavior or other reasons, are as old as recorded history. The witch doctor, priest, and shaman are all practitioners of assessment and intervention on the individual and society, although the means of establishing credibility and training have evolved considerably, as have the forms of treatment. Prior to the emergence of the social sciences, there were other forms of social and psychological “measurement” that would be regarded today as pseudoscience, in that they appeared to be based on empirical observation and measurement, but they often relied on untenable assumptions or failed to demonstrate a set of testable principles. Some of these included phrenology, which claimed that bumps and indentations on the skull were indications of character and aptitudes; physiognomy, which proposed that the face and facial expressions revealed the person’s character and intellect; and animal magnetism, the idea that mental and physical pathologies were a result of the body’s magnetic fields being out of alignment. This latter theory proposed that magnets could be applied to the body to realign the errant fields. Franz Mesmer made this treatment famous in the late 18th century, claiming that his hands alone possessed enough animal magnetism to “cure” his patients. Mesmer would pass his hands over his patients in a dramatic fashion, telling them what they would experience, and

inducing a trancelike state to affect a cure. Mesmer's work is generally regarded as the beginning of modern hypnosis, a practice that has little theoretical or scientific justification, but nevertheless has maintained its presence in some therapeutic treatment.

What can be seen from such examples is that the social sciences, and the distinctions between basic and applied social science and research, evolved from earlier practices of social assessment and treatment. These early practices were a kind of applied social science, although the assessment of the individual had not yet evolved into measurement, and the forms of treatment often reflected a belief system that was a combination of the "high" (physics) and "low" (alchemy) sciences. With the emergence of psychology, anthropology, sociology, and other social sciences, the more empirical aspects of human conduct became the focus, and experimental methods became the means by which new disciplinary identities were created. For the social sciences, these new identities were formed around (1) behavior, (2) a codified set of testing and measurement practices, and (3) a new scientific vocabulary, created by and for each discipline that articulated its own perspective and findings. In other words, the role of a specialist for social assessment and intervention did not begin with the social sciences, but rather the social sciences took over existing forms of practice and transformed them. Although the social sciences were new as academic entities, they were not new in terms of their presence as specialists, now turned measurement-oriented professionals, of social assessment and intervention.

The Rise of Social Science

Social science, then, is the application of the methods originating in the natural sciences to the individual and to society. In Western thought, until the 19th century, the individual had been seen as qualitatively different from the rest of the natural world, as divine and as having a soul, thus making scientific analysis of the mind not only inappropriate but somewhat heretical. In light of Darwin and the theory of evolution through natural selection, human beings became "naturalized," or understood as just another aspect of the natural world, no different in their origins and development than any other species. Thus, the emergence of the social sciences is partly predicated on the impact of Darwin's theory on the way humans perceived themselves. This paradigm shift was also made possible by other social and economic developments during the 19th century.

In 1795, astronomer Nevil Maskelyne and his assistant David Kinnebrook were setting ships' clocks by astronomical observation: when a particular star crossed the hairline of a telescope, the time would be set. Maskelyne noticed that Kinnebrook's measurements were usually about half a second slower than his. He reprimanded

Kinnebrook for sloppiness, but that only made the discrepancy greater. As a result, Kinnebrook was fired for incompetence, although as Friedrich Bessel was to discover, it was through no fault of his own. Some 20 years later, Bessel discovered what he called "personal equations": corrections to individual systematic differences in reaction time among observers. Bessel found, in other words, that such differences were a normal part of astronomical measurements, and could be adjusted by adding to or subtracting from individual measurements. A thorough understanding of the implications of this pointed to some key changes in the way we understood scientific knowledge: (1) the observer influences the observation, (2) the need to understand how the physical world was represented through human sensation and perception, and (3) the gradual realization that knowledge about the natural world deals less with certainty and more with probability (i.e., the likelihood of a particular value being true or accurate).

The Naturalistic and Probabilistic Turns

The question of how the mind works is, of course, one of the oldest questions of civilization, and theories on this topic stretch as far back as recorded history. This age-old question took on a new meaning after observations (e.g., Bessel) had revealed that mental processes take a measurable amount of time, and that the interval for these operations differed across people. The concept of "reaction time" thus provided a way to measure the mind, to compare these measurements across a population, and then to apply these findings to the calculation of scientific observations. As human behavior became increasingly connected to technology (e.g., a telescope), the differences among the users of these technologies were becoming increasingly clear; something that had not yet been salient until this point in history. However, it was becoming quite apparent that similar types of knowledge about the individual were vital to science and society. The Industrial Revolution transformed Europe in the 19th century from an agrarian society to one of urban factories and industries. The population in Europe more than doubled, from 205 million in 1800 to 414 million in 1900. Government grew even faster, with an estimated 99,000 government officials in Great Britain in 1800 to an incredible 395,000 in 1900. Growing cities and the rise of the middle class were all responses to the Industrial Revolution. This, in turn, put enormous pressure on government to manage the exploding population and the commerce of international industry. Politicians and various social leaders turned to the social sciences as a means of gaining and maintaining control. Creating personal equations out of reaction times was now replayed on the grandest scale: the need to predict and understand the behavior of populations became of paramount

importance. Moreover, the individual was no longer separate from the world, but had become interwoven with not only how society functions, but with the very possibility of knowledge about the world.

The 19th century would bring great advances in the biological sciences, and the research that would figure prominently in the origins of the social sciences would be that which addressed the discrepancy between objective and subjective reality. One of the earliest research areas in psychology was the area known as “psychophysics,” which was defined as the experimental investigation of the relationship between changes in the physical environment and changes in the perception of the environment. Hermann von Helmholtz, among others, laid the foundation for such research in demonstrating that nerve impulses move at a measurable rate, and in proposing a theory of color vision (known as the Young–Helmholtz theory) that shows the perception of all color is based on three types of color receptors in the body, corresponding to the primary colors of red, green, and blue-violet. In each case, it can be seen that perception is far from just a mirror of reality, but is constructed through the physiological processing of sensation and learned inferences from our environment; physical reality is not the same as psychological reality. The case of reaction times is but one example; visual perception is another. According to Helmholtz, visual perception involves “unconscious inferences” about distance and size (e.g., the image on our retina “sees” the railroad tracks converge in the distance, but the tracks are perceived as parallel).

The problems facing scientists were thus both basic and applied: how do we perceive reality (basic) and how do we address the problems arising from human–technology interactions (applied)? These questions were both pursued, initially, as essentially the same question. However, they have become differentiated over time, and scientists with interests in discovery are drawn toward basic research, and those interested in applications work in the field of applied research. In Germany, where a number of classic studies in physiology were carried out during the 19th century, there was a clear focus on basic physiological research, with the notion of applications to a market secondary. Of course, at the time, there was not the enormous complex of industry and business that there is today, nor the multitudes of professional and scientific interests that they bring.

The Language of Science and the Scientific World View

The rise of the social sciences in the 19th century resulted not only in new fields of scientific study, but also in new social roles, jobs, and forms of social behavior (e.g., filling out a questionnaire). Perhaps more than anything else, the

dawn of social science, in both its basic and applied forms, entailed a new language for understanding human conduct. For example, the notion of human “behavior,” now a commonplace term, was not present before the more empirical disciplinary language of social science. The concept of behavior replaced the more general notion of “conduct,” because not only is it a much more discrete and measurable unit of analysis, but also because it does not deal with the moral quality of an act (something unobservable). It was for many of the same reasons that the concept of “personality” replaced the notion of “character”: personality could be broken down into “traits,” or predictable predispositions of behavioral consistency, and it eschewed the thorny moral implications of “character.”

This shift in language and social practice represents a complex transition from prescientific language to scientific discourse. The practices of basic and applied science and research are a product of earlier attempts to perform similar functions in society—namely, the quest for knowledge about the world and the ability to apply that knowledge to people and society. Compared to earlier approaches, the scientific method emphasizes objectivity, systematic observation, and controlled conditions, allowing the experimenter to measure accurately the effects of manipulating the independent variable (i.e., the environment). The transition to the scientific method therefore shows a concern with establishing an objective way of investigating questions about the way the world works, and, at the same time, a practical concern for the ability to control and perhaps apply these observations in everyday life. We see ample evidence of this from the early experimental scientists of the Enlightenment, such as Galileo and Newton. Both were concerned with establishing the laws of nature, but both were also interested in how these laws might work for practical use, or perhaps be brought under some form of control. The telescope, for instance, not only told us about the heavens and the moons around Jupiter, but it also enabled us to see ships coming into port much more quickly and allowed for better navigation at sea. So, in other words, science, from the beginning, had this dual purpose of providing both basic and practical knowledge. These purposes were carried over and transformed from earlier prescientific theories, and part of this transformation process involved creating specialized languages about observations. It is through examining these new forms of discourse about the world that we can more fully understand the relationship between basic and applied social science research. It is here, in the language of social science, that we discover the meaning of “science” for a particular society—how scientists frame the questions and methods of their field, the process by which questions are identified, and the context in which investigations are interpreted. We also see how the professionalization of scientific interests transformed social practices that, yet again, relate to

this underlying desire to know the world and to help improve our place in it.

Consider now a specific example of the ways in which applied social science differs from basic science, looking in particular at the way knowledge is transformed as it evolves from basic theoretical issues to issues of application and social practice.

The Self in Psychology: Basic vs. Applied Research

The Self and the Dawn of Psychological Testing

Among the many theories of self in the history of psychology, a distinction can be made between theories of self, addressing the person holistically (e.g., Maslow), and theories that are more fragmentary, viewing the person in terms of specific personality traits or constructs (e.g., the individual differences approach). The general trend in “self” research, since the 1950s, has been away from the holistic view of the self and toward a multidimensional perspective, which is more concretely tied to predicting specific behaviors. During and after World War II, the psychological test emerged as an important tool for both the military and the industrial and governmental complexes of North America. With the war, there were enormous numbers of decisions to be made regarding personnel: the military needed a way to screen and select soldiers for various duties, and, in the private sector, companies and industries needed to replace workers going to war. Thus, there was a tremendous need for scientifically designed tests that could be administered to large numbers of people, to determine factors such as intelligence, aptitudes, and personality traits. With regard to the self (and the person in general), prediction and application were the keys, so psychological tests defined these concepts in more objective and behavior-oriented terms to allow for better prediction. In the history of self research, then, there was a shift from theories of a single self or ego to multiple or “possible selves,” as the science of the self became increasingly applied. An important part of this shift has entailed changes in the language of self research, as the theoretical self or ego became displaced by terminology with closer connections to behavior, such as is seen in the concepts of “self-concept” (“I am good at math”) and “self-esteem” (“I am better looking than most of my friends”).

Following World War II, the use of paper-and-pencil tests to tap such “self-report behavior” became the primary means of collecting data about the individual. The demand for psychological research on the self increased, and because large numbers of people were usually involved, it was in the form of aggregate (or group) data

that information about the self was collected and disseminated. The idea that psychological tests could render mental attitudes, beliefs, and abilities in objective terms was found to be incredibly useful, and psychological research entered into the era of the questionnaire.

A central theme in our understanding of basic and applied social science research has been language and the purposes for which research is carried out; here we see that the shift toward applied research involves changes not only in how the concept is used, but in how it is defined and understood at a basic level. This difference is far from simply semantics, but represents a conceptual evolution in the meanings of scientific constructs. Similar changes were made with other personality measures during the 1940s and 1950s. For example, the early predecessors of contemporary personality testing were the projective tests, such as the Thematic Apperception Test and the Rorschach Inkblot Test. These tests purport to tap into the preconscious and unconscious forces at work within the person. Earlier examples of this same general idea resided in physiognomy, or the analysis of handwriting or other forms of personal expression. These early personality tests were based on the same basic idea: that we project parts of who we are into verbal and physical expressions, and these can be interpreted to give us insight about hidden parts of our personality. However, as psychology began to strive for more measurable and quantifiable means of measuring the person, these subjective methods fell out of favor (but by no means completely), and were replaced by more quantitative approaches.

The Self in Transition

Another clear example of the transition the self underwent as it became part of the world of applied research and testing involves the early self-concept research of Victor Raimy. For his doctoral dissertation in 1943, Raimy devised a “checklist” for describing the self-concept. As a therapist, Raimy conceived of this measure for a clinical context, and this is actually one of the early attempts to do so. To tap the self-concept, the person was asked to rate a list of self-referential statements. These were then classified by judges into one of three categories: approval of self, disapproval of self, or ambivalence toward self.

Raimy’s study was groundbreaking in that it represents one of the first modern self measures in psychology. Although it drew on phenomenological theory as a conceptual basis for the self, it is also significant that it operationalized the “self-concept” into self-referential statements (i.e., behavior). This rendering of a holistic, experiential notion of self into an empirical methodological context helped bring about, and could be seen as a signal of, the rise of self-concept testing. Further efforts to understand the self along these lines soon followed

with the development of the Q-sort by William Stephenson in 1953, which was quickly picked up and elaborated by Rogers and Dymond in 1954. Almost immediately afterward, there was a flash flood of self-rating methods in the early and mid-1950s, most using an adjective checklist or self-rating scale. Clearly, there was a vast and diverse audience for such a technology in schools, industry, companies, and government; the psychology questionnaire had found its place in psychology and society.

What is rather remarkable, and also quite telling about the relationship between basic and applied social science research, is that the first step toward measuring the self as a set of quantifiable component parts was made by the clinicians themselves, who at the time generally maintained a holistic and experiential understanding of the self. However, it was clear to clinicians and other mental health professionals that knowledge about the person, outside of a therapeutic context, was crucial and much needed. So, even though a fragmented, behaviorally oriented view of the self was contrary to the theoretical models they held, the decision to address applied questions substantially changed the theory of the self. In other words, issues involving the prediction of behavior are paramount in applied research, and the theory of self that emerged from these concerns represented a radical departure from the more basic question of “what is the self?” Furthermore, as the trend toward psychological testing and other applied self research grew, the self was no longer just interpreted in a clinical context by therapists who viewed the person as an organized whole. Instead, these measures became tools for more widespread consumption and application, whereby they would be increasingly used by researchers with more specific and practical questions and problems. This process proved truly transformative: self research began to be carried out within the pragmatic perspective of North American culture, and the science of the self now turned on the applied axis of psychological testing. This transformative process was thus twofold: the redefinition of self into the more behavior-focused concepts of self-concept and self-esteem, and the change in interpretative contexts from a more theoretical and clinical focus to an applied and experimental one.

Conclusion—The Future of Basic and Applied Social Science Research

The distinction between basic and applied social science is based on an evolving relationship between different forms of scientific and social practice. Basic social science, on the one hand, seeks to discover the fundamental principles of human behavior, whereas applied social science attempts to create and improve technologies that

assist in the prediction, assessment, and description of behavior as it exists in society. There are numerous clashes between these perspectives, and these are also found in the natural sciences as well. Many, and perhaps most, of these conflicts have an economic basis: scientific projects with commercial value and practical utility receive a great deal more funding, and remain much more likely to be funded, than do projects that lack a commercial payoff. Today, major funding comes from public and private sources such as government agencies, universities, corporations, and industries. As a result, there is a substantial and rather lopsided monetary emphasis on applied social science research. Researchers who are interested in basic science questions are often faced with difficulties in securing funding, and may have to prove that their research has some perhaps indirect application or other economic potential. Basic social science also has as its task the rather considerable job of illustrating what the basic principles of human behavior are; as of yet, no tangible “laws of behavior” have emerged. However, the recent ascendancy of neuroscience may rejuvenate the languishing social scientist with aspirations of creating a new basic science of human behavior.

Bayes, Thomas

Andrew I. Dale

University of KwaZulu-Natal, Durban, South Africa

Glossary

Act of Uniformity An act, passed by the anti-Puritan parliament after the Restoration, decreeing that all ministers who were not episcopally ordained or who refused to conform were to be deprived of their livings.

Bayes's Theorem A formula that allows the determination of the posterior probabilities $P[C_i | E]$ of the (possible) causes C_i , given the occurrence of an event E , in terms of the prior probabilities $P[C_i]$ (determined anterior to the conducting of the current investigation) and the likelihoods $P[E | C_i]$ of the event, given the causes C_i .

Bayesian statistics That branch of modern statistics in which Bayes' Theorem plays a fundamental role in the incorporation of past experience into the making of decisions, statistical analyses, and predictions.

fluxionary calculus Newton's development of the calculus, concerned with problems of tangency and quadrature.

prime and ultimate ratios Introduced by Newton as a rigorous justification of the methods of his fluxionary calculus, these ratios, analogous to the modern right- and left-hand limits, are concerned with the ratios of magnitudes as generated by motion.

Thomas Bayes, by profession a Presbyterian minister, presented a result in a posthumously published essay on "chances"; this work has come to play an important role in modern statistical theory and practice.

Genealogy

The family of which Thomas Bayes was a member can be traced back to the early 17th century. The city of Sheffield, in Yorkshire, England, has long been known for the manufacture of steel, iron, and brassware, and Thomas's

forebears were of considerable importance in the Company of Cutlers of Hallamshire; for instance, one Richard Bayes was Master of the Company in 1643, as was his son Joshua in 1679. But the Bayes family was known not only in business circles. The 17th and 18th centuries were times during which Nonconformity and Dissent became both of importance and of concern to the Established Church, and Richard's second son, Samuel, having studied at Trinity College, Cambridge, was among those ejected in 1662 from his living because of his refusal to accept in full the doctrines of the Established Church and to take the oaths demanded of her clergy. Samuel moved to the village of Grendon St. Mary, near Wellingborough in the county of Northamptonshire, where he probably remained for some years before moving to Sankey in Lancashire.

Samuel's younger brother, Joshua, rose in the ranks of the Sheffield cutlery industry. He married Sarah Pearson on 28 May 1667, seven children issuing from this union. Ruth, Joshua and Sarah's eldest daughter, married Elias Wordsworth (who became a Town Burgess in Joshua's place on the latter's death in 1703); another daughter, Elizabeth, married John de la Rose, minister of the Nether Chapel in Sheffield. Joshua and Sarah's eldest son, Joshua, baptized on 10 February 1670 (old style), married Anne Carpenter.

The younger Joshua entered Richard Frankland's Academy at Rathmell, in Yorkshire, in 1686. Frankland, a dissenting minister, having been ejected from his living, had started the first Nonconformist academy in that town in 1669. The various laws and regulations aimed at oppressing the Nonconformists resulted in the academy having to move several times, before it ended up once again at Rathmell. Although the training provided by such dissenting academies was not restricted to those who felt they had a vocation, Joshua must have attended this academy with at least some interest in making the

Nonconformist ministry his profession, for, in 1694, he was ordained with six other candidates for the ministry. This ordination (lasting from before 10 o'clock in the morning to past 6 o'clock in the evening) was celebrated in London at the meetinghouse of Dr. Samuel Annesley and was important in being the first public ceremony of that nature held in that city after the passing of the Act of Uniformity.

Soon after his ordination, Joshua must have moved to Box Lane, Bovingdon, Hertfordshire. His signature as "clerk" is found on the trust deed by which the Bovingdon Nonconformist Chapel was entrusted by the proprietors to 12 trustees in 1697, and in 1702 he certified that the chapel was used for worship. Suitable records of that time are few and often in conflict. However, the information derived from the trust deed is probably reliable, and it may be concluded that Joshua and Anne's eldest child, Thomas, was born in Bovingdon, Hertfordshire. In all, Joshua and Ann had seven children, the others being Mary, John, Anne, Samuel, Rebecca, and Nathaniel.

In 1707, Joshua moved to London and took up a position as assistant to John Sheffield at St. Thomas's, Southwark. During this time, Joshua also became assistant to Christopher Taylor at the Presbyterian Chapel in Leather Lane, moving into a full-time position there on Taylor's death. On 24 April 1746, Joshua died, after a ministry in which he earned the respect and admiration of the London Nonconformists. He was interred in the family vault in Bunhill Fields, near Moorgate, this vault later being the repository of the remains of several of his children.

Youth and Education

Though it may thus be relatively confidently claimed that Thomas Bayes was born in Hertfordshire, the year of his birth is uncertain. It is usually derived by the subtraction of his age at death from the year of his death (both these figures being recorded on the family vault), and it would appear that he was born either in 1701 or 1702 [the doubt arises from whether dates are given in old style (o.s.) or new style]. What is clear, however, is that Thomas would have received his early education in London, though once again there is no certainty as to which school or academy he might have attended.

The British Library contains in its manuscript collection copies of letters written both from and to John Ward. One of these letters, written in 1720, is directed to Thomas, and the contents suggest that the latter had been a pupil of Ward's. Further opinion on Thomas's schooling is perhaps received from the fact that one of his sponsors for election to the Royal Society in 1742 was John Eames, who is known to have kept a school in London. There is no certainty about any of this, however, and it is possible only

to attach a nonzero probability to the suggestion that Thomas had some educational connection with Eames and Ward. However, it is certain that Thomas studied later at Edinburgh University—something that makes perfect sense when it is remembered that the universities in England were closed to Nonconformists. Thomas's name is recorded in various manuscripts, still fortunately extant, showing that he was admitted to the college in 1720 on the recommendation of "Mr Bayes" (presumably his father).

Though Thomas appears to have studied both logic and theology at Edinburgh, there is no evidence of any mathematical studies; that he had perhaps some acquaintance, albeit slight, with the Scottish mathematician James Gregory is shown by the fact that the latter signed the certificate giving Thomas access to the university library in 1719 (o.s.). On completion of his theological studies, Thomas was licensed as a preacher (though not ordained), and he presumably then returned to England.

Thomas Bayes and Tunbridge Wells

Thomas's whereabouts for the years immediately following the completion of his studies in Edinburgh are uncertain. It is probable that he spent a few years in London, for his name appears in a *List of Approved Ministers of the Presbyterian Denomination* drawn up by John Evans in 1727, and he was also appointed to the Leather Lane Chapel in 1728, presumably as assistant to his father. In the early 1730s, though, we find Thomas installed as minister of the (English) Presbyterian Chapel in Tunbridge Wells, Kent. It is uncertain as to when he took up this position: the general opinion is that it was in 1730 on the resignation of John Archer, who died in 1733, but it has been suggested by Bailey and Bailey that Thomas left Tunbridge Wells in 1728 and returned in 1731. It is certainly true that the Presbyterian Chapel in Tunbridge Wells frequently enjoyed the services of visiting clergy, and Thomas could well have been of this number until his permanent appointment.

Although Presbyterianism had been supported, at first more or less covertly, in Tunbridge Wells from the late years of the 17th century, the New Chapel, with Archer as its minister, was not opened until 1720. The chapel was situated on Mount Sion, one of the hills on and around which Tunbridge Wells nestles. The salubrious air and elevation made the site most enviable, and the congregation seems to have prospered for a number of years. However, it slowly began to decline, and indeed decay set in among the Nonconformist persuasions in Tunbridge Wells in general. The Presbyterian Chapel was closed in 1814, and although the building became more and more dilapidated, it was fortunately saved

from demolition and remains today as a simple but elegant secular memorial.

In the 18th century, Tunbridge Wells was regarded as one of the prime resorts for those wishing to “take the waters.” The chalybeate springs were supposedly possessed of medicinal and curative powers—even the ability to cure barrenness—and royalty visited there on occasions. The Presbyterian Meetinghouse and its incumbent were as important to the Nonconformists who lived and visited there as were the Established Church’s Chapel and its clergy to the orthodox; the more frivolous aspects of life were catered for by the numerous balls, card evenings, etc. organized by the Master of Ceremonies (at one time the social dandy, Richard “Beau” Nash). Visitors included members of the nobility, the clergy, and the scientific and literary community, as well, no doubt, as those of lesser ranks. Some of these visitors were certainly acquainted with Bayes. William Whiston, for instance, records that he breakfasted with Thomas on St. Bartholomew’s Day in 1746, and it is also recorded (though perhaps the accuracy of the story may be doubted) that distinguished visitors from the East visited Tunbridge Wells and were introduced to Bayes, who provided them with “much useful and valuable information.”

In 1752, Bayes retired. Although no longer active in the ministry, he remained in Tunbridge Wells until his death some 9 years later, his remains being taken to Founders’ Hall, London, before interment in the family vault.

Bayes’s Works

Tract on Divine Benevolence

In 1731, an anonymously published tract appeared. Entitled *Divine Benevolence, or, an attempt to prove that the principal end of the divine providence and government is the happiness of his creatures*, this tract, now known to be by Thomas Bayes, was a rebuttal to an earlier one by John Balguy entitled *Divine Rectitude*, and was in turn followed by Henry Grove’s *Wisdom, the first Spring of Action in the Deity*. All three authors were trying in these works to find a single principle to which God’s moral principles could be ascribed. Whereas Balguy maintained that God’s moral attributes, such as truth, justice, and mercy, were modifications of His rectitude, Bayes found the fundamental principle to be benevolence, that is, God’s “kind affection towards his creatures,” leading to the conferring on the universe of “the greatest happiness of which it is capable.” Bayes’s argument is closely reasoned and wide ranging (the tract is some 75 pages long), critical of Balguy in some places and in agreement with him in others, but there is perhaps room for doubt as to whether it is entirely convincing.

Tract on Fluxions

Bayes’s second printed work, *An Introduction to the Doctrine of Fluxions*, was also published anonymously. Its attribution to Bayes is made on the authority of the 19th-century mathematician and bibliophile Augustus de Morgan, who is most reliable in such matters. Writing in response to Bishop George Berkeley’s *The Analyst*, Bayes was concerned more with the logical theory of Isaac Newton’s prime and ultimate ratios than with either moments or the methods of the fluxionary calculus. Though he in general approved of the bishop’s attention to fluxionary matters, Bayes could not agree with the incorporation of religious aspects, and indeed he declared in his introduction to the tract that he would restrict his attention to an “endeavour to shew that the method of Fluxions is founded upon clear and substantial principles.” To this end, he set down postulates, definitions, axioms, propositions, and corollaries. The propositions are carefully proved (though the proofs may sometimes seem slightly deficient), and Bayes’s defense of Newton against Berkeley seems unobjectionable. The paper shows a logical mind with concern for mathematical rigor, and the arguments adduced, without the use of limit theory and nonstandard analysis, are perhaps as sound as was possible at that time.

A Semiconvergent Series

Within a few years of Bayes’s death, three posthumous papers under his name and communicated to the Royal Society by Richard Price appeared in the *Philosophical Transactions*. The first of these was little more than a note on some aspects of series, the most important being concerned with the well-known Stirling-de Moivre expansion of the series for $\log z!$ as

$$\begin{aligned} (1/2)\log(2\pi) + [z + (1/2)]\log z - [z - (1/12z) \\ + (1/360z^3) - (1/1260z^5) + \dots]. \end{aligned}$$

Bayes showed that the series actually failed to converge in general, a fact that he was apparently the first to note (though Leonhard Euler, some 6 years before the death of Bayes, had noted the failure for the special case $z = 1$). Comments are also found here on the divergence of similar series for $\log(2z - 1)!!$ [with $n!! = n(n - 2)!!$ and $n!! = 1$ for $n = 0$ or 1] and $\sum_n (k/n^r)$.

Papers on Chance

The second posthumously published paper by Bayes is the important *An Essay towards Solving a Problem in the Doctrine of Chances*. Here Bayes provided the seeds of the modern ideas of inverse, prior, and posterior probabilities, and indeed the whole theory of Bayesian

statistics has its roots in this paper. The problem with which Bayes concerned himself was as follows:

Given the number of times in which an unknown event has happened and failed: required the chance that the probability of its happening in a single trial lies somewhere between any two degrees of probability that can be named.

The *Essay* is set out in a way that would be quite acceptable to a modern mathematician. The given question is answered, though its solution requires the acceptance of an assumption that has generated a considerable amount of controversy since its publication—that is, in essence and perhaps somewhat crudely, the assumption of a uniform distribution as a prior when one is in a state of ignorance.

Three rules are presented for the obtaining of bounds to the exact probability required (Bayes's solution is effectively given as an infinite series), and proofs of these rules were given in a supplement to the *Essay* in a subsequent issue of the *Philosophical Transactions*, with improvements, obtained by Price, of Bayes's bounds. Price also added an appendix to the *Essay*, in which he explored the use of Bayes' results in a prospective sense. He developed a Rule of Succession (e.g., if an event is known to have occurred m times in n trials, what is the probability that it will occur on the next trial?), and discussed the place of Bayes's results in induction.

The importance of these posthumous papers on probability cannot be denied, and though it is not expedient to speculate here on the reason for Bayes not having published his results, it might be noted that this is sometimes assumed to flow from his suggested modesty.

Miscellaneous Scientific Work

Although Bayes is known mainly for his work on chances, it is clear that he enjoyed no mean reputation among the mathematical community of his time. Despite the slightness of his published work, he was elected a Fellow of the Royal Society in 1742, his proposers being men of considerable scientific weight, and including people such as Martin Folkes, John Eames, and Philip, Earl Stanhope.

David Bellhouse has recently discovered a number of manuscript papers by Bayes, in the Stanhope of Chevening papers in the Kent County archives in Maidstone, England. From certain letters in the same collection, Bellhouse has deduced that Bayes was in a sense a "referee" for mathematical papers, being consulted by Stanhope on mathematical matters. There remains to this day a notebook in Bayes's hand, now in the possession of the Equitable Life Assurance Society in London. This is a curious collection clearly kept over a number of years, with mathematical results appearing cheek by jowl with, among others, excerpts on a miracle (the cure, by the touching of a relic to the affected area,

of a lachrymal fistula suffered by Blaise Pascal's niece) and from John Greaves's writings on the Great Pyramid of Cheops.

The Royal Society in London has in its possession a manuscript by Bayes on a book on electricity by Benjamin Hoadly and Benjamin Wilson. Also to be found there is a letter from Bayes to John Canton commenting on Thomas Simpson's recommendation that the error in astronomical observations could be reduced by the reliance on several measurements rather than just one. Bayes's point was that this would not do if the measuring instrument were inaccurate—and he was also unhappy with the suggestion that errors in excess, as in defect, should be taken as equiprobable.

Death and Burial

Bunhill Fields Burial Ground, the great Nonconformist cemetery, was opened in the 1660s. By 1852, more than 120,000 burials had taken place there, and the ground was then closed. It was, however, preserved as a public space, and despite its having been considerably reduced in size over the years, the visitor today can take comfort in knowing that he will find, in addition to the Bayes family vault, memorials to the Nonconformists John Bunyan, Daniel Defoe, John Eames, and Richard Price, among others. The Bayes vault has been restored a number of times over the years. Some of the original inscriptions have disappeared altogether, whereas others, presumably as a result of such restoration, have been changed. Not all these changes, however, have been for the worse: for instance, in place of the original "The Rev. Thomas Bayes, son of the said Joshua, died April 7th, 1761, aged 59 years," the vault now carries the information that it was restored "In recognition of Thomas Bayes's important work in probability . . . in 1969 with contributions received from statisticians throughout the world."

As might be expected, in view of his family's commercial success, Joshua Bayes left his family well provided for. Thomas, as the eldest child, perhaps inherited the most, and his will in turn, though showing him to be not of the wealth of his father, nevertheless proved him to have been of considerable means. His siblings were the main inheritors, though some remembrance was taken of one Sarah Jeffrey, living at the corner of Jourdans Lane in Tunbridge Wells. Roger Farthing, a modern historian of that city, has made the reasonable suggestion that Bayes, as a bachelor, might well have boarded at that address (where it is known that there was a lodging house), and might well have wished to benefit the daughter of the house in that way.

The Bayes vault had been built in 1733 (o.s.). As they in turn died, the members of the family were buried there, such burials often being of the simplest kind. The deceased having stipulated in their wills that their

interment be as frugal as possible, there would have been no “singing boys” and no funeral sermon would have been preached. Thomas, too, made such a request in his will, a reflection of the modest way in which he had probably lived his life.

Glossary

conditional probability density function A density for a random variable that is the ratio of a joint density for two random variables to the marginal density for one. For example, $f(A | B) = f(A, B)/f(B)$. Often simply called conditional density.

joint probability density function A probability density function that assigns probabilities to a set of random variables (see probability density function).

marginal probability density function A density for a random variable in which all other random variables have been integrated out. For example, $f(A) = \int \dots \int f(A, B, C, \dots) dB dC \dots$. Often called a marginal density or marginal pdf.

normalizing constant A constant that ensures that a probability density function is proper, that is, that it integrates to 1.

probability density function (pdf) A function that assigns probabilities to random variables in a continuous parameter space. A function that assigns probabilities on a discrete parameter space is called a probability mass function, but many use pdf for both types of spaces. In both cases, the function must integrate/sum to unity to be a proper density. The pdf is often referred to as simply a density, and the term is also synonymous with distribution.

sampling density The joint probability density for a set of observations. A normalizing constant is required to make it proper (i.e., a true density). Expressing an unnormalized sampling density as a function of the parameters rather than the data yields a likelihood function.

Bayesian statistics is an approach to statistics that considers probability as the key language for representing uncertainty, including uncertainty about parameters for which inference is to be made. The Bayesian approach to statistics differs fundamentally from the classical

approach, although results obtained via Bayesian and classical approaches are often numerically similar, differing only in interpretation.

Bayes's Theorem

In 1763, Reverend Thomas Bayes introduced a theorem for calculating conditional probabilities that ultimately provides a recipe for updating prior uncertainty about parameters of distributions using observed data. Bayes's theorem is simply a double application of the well-known conditional probability rule, and the mathematical basis for the theorem is thus beyond dispute. The theorem states:

$$p(B | A) = \frac{p(A | B)p(B)}{p(A)} \quad (1)$$

Proof of Bayes's Theorem and Its Extension

Bayes's Theorem is easily proven by observing that:

$$p(A | B) = \frac{p(A, B)}{p(B)} \quad (2)$$

Rearranging this yields:

$$p(A | B)p(B) = P(A, B) \quad (3)$$

Similarly,

$$p(B | A) = \frac{p(B, A)}{p(A)} \quad (4)$$

and

$$p(B | A)p(A) = P(B, A) \quad (5)$$

Given that $p(A, B)$ is equivalent to $p(B, A)$, the left-hand sides of Eqs. (3) and (5) can be set equal, and we obtain:

$$p(B|A)p(A) = P(A|B)p(B) \tag{6}$$

Dividing both sides by $p(A)$ yields Bayes's theorem. In this representation the theorem is unquestionable. However, Bayesian statisticians replace B with "parameter" or "hypothesis" and A with "data" so that the theorem appears as:

$$p(\text{parameter} | \text{data}) = \frac{p(\text{data} | \text{parameter})p(\text{parameter})}{p(\text{data})} \tag{7}$$

The denominator of the right-hand side of this equation is the marginal probability of the data (often called a normalizing constant), which is an average of the probability of the data under all possible parameter values (θ). In a continuous parameter space (S):

$$p(\text{data}) = \int_{\theta \in S} p(\text{data} | \theta)p(\theta) d\theta \tag{8}$$

In a discrete parameter space, the marginal probability of the data is:

$$p(\text{data}) = \sum_{\theta \in S} p(\text{data} | \theta)p(\theta) \tag{9}$$

Since the denominator typically does not provide us with any information about the parameter, Bayes's theorem is often reduced to:

$$p(\text{parameter} | \text{data}) \propto p(\text{data} | \text{parameter})p(\text{parameter}) \tag{10}$$

In Bayesian language, this expression says that the posterior probability for a parameter is proportional to the likelihood function for the data (or the sampling density for the data) multiplied by the prior probability for the parameter. The posterior is so called because it is our estimate of the probability for the parameter after having observed additional data; the prior is so called because it represents our belief about the probability for the parameter before observing data.

To provide an example of the applicability of Bayes's theorem, I demonstrate the theorem on data about prostate cancer. Suppose a 30-year-old male tests positive on the standard test for prostate cancer. Suppose also that the test has a 90% accuracy rate for people in that age group, meaning that it will give a positive test result to positive cases 90% of the time. Suppose, however, the test also produces false positive results 10% of the time; that is, among noncases 10% will receive a positive test. Obviously, the question of interest is whether, given the positive test result, the individual in fact has prostate cancer, which can be expressed as $p(\text{p.c.} | \text{test+})$. However, we know $p(\text{test+} | \text{p.c.})$, and we can obtain prostate cancer incidence rates for age 30, $p(\text{p.c.})$

(here, I use an approximate rate for people under 45). We can substitute the known information into Bayes's formula:

$$p(\text{p.c.} | \text{test+}) = \frac{p(\text{test+} | \text{p.c.})p(\text{p.c.})}{p(\text{test+} | \text{p.c.})p(\text{p.c.}) + p(\text{test+} | \text{no p.c.})p(\text{no p.c.})} \tag{11}$$

In this case, we have the following:

$$p(\text{p.c.} | \text{test+}) = \frac{(0.90)(0.00001)}{(0.90)(0.00001) + (0.10)(0.99999)}$$

Simplifying reveals that the actual (posterior) probability of having cancer at age 30, given a positive test, is 0.0001. Certainly our posterior probability for having cancer is greater than our prior probability, but this posterior probability is still quite small, revealing the shortcoming of a test with a modest false positive rate applied to a low-risk population.

Philosophical Foundation of Bayesian Statistics

Many researchers use Bayes's theorem for probability problems, such as the one about prostate cancer, in which the parameter values are known quantities. However, historically non-Bayesians have frowned on the use of Bayes's formula when it involves parameters whose true values are unknown. This disdain for the formula arises from the competition between two key philosophical understandings of probability. One understanding of probability defines probability in terms of the relative frequency of an event in a long series of trials. For example, the "frequentist" justification for believing that the probability of obtaining heads on a single coin flip is 0.5 is that in a long series of trials, we expect to see heads approximately 50% of the time.

The frequentist perspective grounds the classical approach to understanding probability. For virtually any statistical problem, a classical statistician will develop a likelihood function, which represents the relative frequency of a particular set of data under a particular parameter. For example, suppose a classical statistician is interested in estimating a population mean from a sample of n independently and identically distributed (i.i.d.) observations. If the statistician supposes that the data arises from a normal distribution with mean μ and variance σ^2 , then the likelihood function (or sampling density) for n observations will be:

$$p(Y | \mu, \sigma) \propto L(\mu, \sigma | Y) = \prod_{i=1}^n \frac{1}{\sigma\sqrt{2\pi}} \exp\left\{-\frac{(y_i - \mu)^2}{2\sigma^2}\right\} \tag{12}$$

Notice that this equation presents us with the relative frequency of the data *given* a particular set of values for μ and σ . The classical statistician, interested in μ and σ , uses the notation $L(\mu, \sigma | Y)$ to denote that we are interested in determining the values of μ and σ that make the data *most likely* to have occurred. The classical statistician uses this likelihood notation (L) to clarify that, from his or her perspective, the data are still considered random and the parameter is assumed to be fixed. From a classical standpoint, the only random quantities in the equation are the data themselves. The parameter is fixed but unknown, and inference regarding the parameter proceeds under the assumption that $\hat{\mu}$, the estimate for μ , is a random quantity that varies if repeated samples are taken from the original probability density thought to generate the data. Classical confidence intervals around $\hat{\mu}$ are interpreted in this light, leading to expressions such as “95% of all samples drawn from this distribution would contain μ in the confidence interval around $\hat{\mu}$.”

A Bayesian approach to this problem, on the other hand, begins by treating the parameters of interest as random quantities. From a Bayesian perspective, the parameter may well be a fixed quantity, but our uncertainty about the parameter’s true values allows us to use the language of probability to express this uncertainty. A Bayesian approach requires us to specify a prior for the parameter, that is, a distribution representing our belief regarding the true values of the parameters (either based on prior research or prior ignorance). A Bayesian then specifies the model as:

$$p(\mu, \sigma | Y) \propto p(Y | \mu, \sigma) \times p(\mu, \sigma) \quad (13)$$

The first expression on the right-hand side of the equation is identical to the likelihood function shown before, although the Bayesian uses the sampling density notation rather than the likelihood notation. The second term is the joint prior distribution assigned to represent our prior uncertainty about the parameter, and the left-hand side of the equation is our posterior probability distribution for the parameter after having observed the data. From this equation, it should be apparent that the posterior probability is our prior distribution updated with the new data. This posterior distribution can then be used as the prior distribution for a subsequent analysis.

Critique of Bayesian Paradigm and Responses

The classical critique of the Bayesian approach consists of two arguments: (1) treating the parameter as a random quantity is inappropriate and (2) the use of a prior distribution injects too much subjectivity into the modeling process. The first argument against the Bayesian approach

is a philosophical critique with no correct answer. The classical approach is grounded in the philosophy that parameters are fixed entities, and thus attaching probability distributions to them, essentially giving them the same status as random variables, is simply wrong. [It is easy to see how the Bayesian approach gives parameters and random variables the same status. If Eq. 7 is not normalized by dividing by $p(y)$, then the left-hand side is equivalent to the joint density for both the parameters and the data: $p(\text{parameters}, \text{data})$.] The Bayesian response to this argument is multifaceted. Bayesians argue that probability is the natural language for representing uncertainty and, given that we do not know the true value of parameters, it is perfectly appropriate to make probabilistic statements about them. Bayesians also argue that this subjective view of probability resonates better with lay understandings of probability and thus provides for a better lay understanding of scientific analyses. Bayesians also argue (pragmatically) that the Bayesian approach works in many settings in which the classical approach does not or is philosophically unsatisfactory. For example, it is difficult to apply a frequentist approach to statements about whether a particular candidate who has never run for office will win or whether there will be a nuclear war this year, given that it is virtually impossible to conceive of these events as being part of a long series of trials. Yet laypeople always discuss these sorts of events using the language of probability. Finally, the Bayesian argues that many researchers misinterpret classical confidence intervals anyway, giving them a Bayesian interpretation, which is inappropriate under the classical paradigm.

The second argument against the Bayesian approach may seem more compelling because it implies that two researchers using the same data but different priors could draw different conclusions, something that should not occur in an objective science. However, the Bayesian has numerous responses to this criticism. First, a Bayesian points out that the entire process of statistical modeling and making inferences about parameters contains numerous subjective decisions regardless of which approach is used. We must first establish a model, which is ultimately a subjective decision. One researcher, for example, when faced with an ordinal outcome variable may specify a normal linear model, whereas another may specify a generalized linear model (GLM). Two researchers using a GLM may specify different types of GLMs—for example, an ordered logit or an ordered probit. Beyond establishing a model, researchers use subjective criteria to make inferences. The classical p value is the perfect example: the decision to declare a result statistically significant based on a p value is purely subjective. Why should $p < 0.05$ be the criterion? Is a result really less significant if $p = 0.0501$ than if $p = 0.0499$, especially if the sample sizes vary across the data sets used to obtain these p values? Finally, a Bayesian may argue that, because

statistical significance and substantive significance are not equivalent, subjective criteria must ultimately be brought to bear on interpreting results in any analysis. The danger of supposing that the classical approach is objective is that we are misled into ignoring the subjective nature of the entire enterprise of statistical analysis.

As a second response to the subjectivity criticism, Bayesians argue that prior distributions can be noninformative (often called vague or diffuse priors). For example, in the normal distribution example previously discussed, we can establish independent uniform prior distributions for μ and σ over a broad enough interval (in some cases, the entire real line) that no particular value for the parameters is favored *a priori*:

$$p(\mu, \sigma) = p(\mu)p(\sigma) \propto c \times d \propto 1$$

with c and d each equal to $1/(U_{\theta_i} - L_{\theta_i})$, where L_{θ_i} and U_{θ_i} are the lower and upper bounds of the parameter space in which μ and σ (θ_1 and θ_2 , respectively) can possibly lie. The use of this type of prior yields a posterior density that is equivalent to the likelihood function, and thus the results obtained under a Bayesian analysis are often equivalent to those obtained using a classical approach. For example, given that the maximum likelihood estimate (MLE), the standard estimate used by classical statisticians, is nothing more than the parameter value at the mode of the likelihood function, the mode of the posterior distribution (the maximum *a posteriori* estimate) under uniform priors is exactly equal to the MLE.

A third response is that prior distributions are often asymptotically irrelevant. The prior enters into a model only once, whereas the likelihood portion of the model contains n terms. With enough data, the prior may have little influence on the model results.

A fourth response is that priors can be made to be quite conservative in order to provide for conservative tests of hypotheses. In other words, we can establish a prior that assigns high probability to particular parameter values and see if the data are strong enough to overturn this prior expectation. Similarly, we can conduct models with different priors to determine the sensitivity of an analysis to a particular prior.

Fifth, the Bayesian approach allows for the coherent progression of science. The classical approach to hypothesis testing ultimately involves testing the same hypothesis over and over (e.g., that a particular parameter equals 0) without making any progress toward determining the true value of a parameter. The Bayesian approach readily allows us to incorporate the findings of previous studies into the current one. This approach may thus prevent us from publishing counterintuitive findings when we obtain a data set that produces such results (something that theoretically should occur on occasion).

Finally, as alluded to in some of the previous responses, a Bayesian argues that models should always be tested for sensitivity and for their fit to the data. When we assume our models are objectively based, we may be more inclined to ignore this aspect of the modeling process. Ultimately, the best test of a model's worth is how well it actually fits the data at hand—but how many classical analyses do not investigate this issue because the modeling process is assumed to be objective?

Bayesian Estimation

For decades, the two arguments against Bayesian statistics, coupled with the computational intensity required to conduct a Bayesian analysis, made Bayesian analyses of marginal use in social science. However, the recent explosion in computing capabilities, coupled with the growth in hierarchical modeling (for which the Bayesian approach is very well suited) has led to an explosion in the use of Bayesian techniques. In this section, I discuss the estimation of Bayesian models, primarily focusing on the contemporary approaches that have made Bayesian analyses more popular in the social sciences over the last decade.

Specifying a Model with a Prior Distribution

Whereas classical approaches to modeling often allow the development of canned statistical routines for particular models (e.g., multiple regression and logit models), the use of a prior distribution for parameters in a Bayesian analysis makes each modeling exercise unique. Often Bayesians use conjugate priors—priors that yield posterior distributions that have the same distributional form as the prior distribution. For example, in modeling a set of J Bernoulli outcomes, an appropriate sampling density would be a binomial density with parameters $n = 1$ and p , so that the likelihood function is a product of binomial densities:

$$p(Y | n = 1, p) \propto \prod_{i=1}^J \binom{1}{y_i} p^{y_i} (1-p)^{1-y_i} \quad (14)$$

Simplifying this expression yields:

$$p(Y | n = 1, p) \propto p^{\sum_{i=1}^J y_i} (1-p)^{J - \sum_{i=1}^J y_i} \quad (15)$$

A conjugate prior density for this sampling density is a beta density with parameters α and β :

$$p(p) \propto p^{\alpha-1} (1-p)^{\beta-1} \quad (16)$$

This density has a mean of $\alpha/(\alpha + \beta)$, a variance of $(\alpha\beta)/((\alpha + \beta)^2(\alpha + \beta + 1))$, and a mode of $(\alpha - 1)/(\alpha + \beta - 2)$. For a moment, suppose we leave α and β

unspecified. Because the posterior is proportional to the multiple of the prior and the likelihood, the posterior is:

$$p(p | Y) \propto p^{\alpha + (\sum_{i=1}^J y_i) - 1} (1 - p)^{\beta + J - (\sum_{i=1}^J y_i) - 1} \quad (17)$$

which is again a beta density with parameters $\alpha + \sum y_i$ and $\beta + J - \sum y_i$. In other words, our prior density is of such a form that the posterior and prior densities are the same type of density. What remains is to specify the parameters of the prior density. For the beta distribution, the parameters can be thought of as prior pieces of information. If we expect that our prior mean probability of a success on any given trial is 0.5, but we are not very certain about this, we can simply choose $\alpha + \beta$ to be small (representing a small number of prior observations) and allow $\alpha = \beta$ to represent a prior mean of 0.5. Suppose, for example, we choose $\alpha = 1$ and $\beta = 1$. In this case, our prior mean is 0.5 and the prior variance is 1/12. This yields a standard deviation of 1/3.46, which means (assuming approximate normality of the distribution, an incorrect assumption here) that the parameter p is expected to fall in the interval:

$$\left[0.5 - 2 \times \frac{1}{3.46}, 0.5 + 2 \times \frac{1}{3.46} \right] = [-0.078, 1.078]$$

with probability 0.95. This distribution is a very vague prior under the assumption of approximate normality because it says we cannot rule out any value for p within the range of $[0, 1]$. If we examine the density with these parameter values, it is apparent that this distribution is actually a uniform density—and hence not normal—because the exponent of p and $1 - p$ is 0 and, hence, the density is flat:

$$p(p) \propto p^0 (1 - p)^0 = 1$$

This result demonstrates the principle that prior densities can often degenerate to a uniform density, implying that a prior density may contribute little or no information to the posterior.

In this example, the posterior mean for this distribution is $(1 + \sum y_i) / (2 + J)$, and the posterior mode is $\sum y_i / J$. Notice that the posterior mode in this case is identical to the MLE for a proportion. Furthermore, the posterior mean approaches the posterior mode as $J \rightarrow \infty$ because the 1 in the numerator and 2 in the denominator become asymptotically irrelevant.

In our example, we chose a prior distribution that was conjugate for the sampling density and were able to specify a closed-form solution for the mean, variance, and mode because the beta density is analytically tractable. In other words, we were able to directly compute the integrals for the mean:

$$\mu = \int_{\theta \in S} \theta p(\theta) d\theta$$

and the variance:

$$\sigma^2 = \int_{\theta \in S} (\theta - \mu)^2 p(\theta) d\theta$$

where $p(\theta)$ represents the density of interest. Often Bayesians work with prior distributions that are not conjugate, or they otherwise obtain posterior distributions that do not have analytically tractable forms. With nonconjugate prior densities or with complex multivariate posterior distributions, these integrals, which are fundamental to Bayesian inference, may be impossible to compute analytically. Also, even given any particular likelihood function, the use of different priors between researchers will lead to different values of these integrals. For these reasons, Bayesians need to use alternative methods to evaluate these functions.

Historical Approaches to Estimation

Historically, Bayesians used a number of techniques to compute such integrals or to approximate posterior distributions using known distributions, including quadrature methods (a technique for numerically integrating a density using weighted points on a grid), normal approximations based on Taylor series expansions about the mode of the posterior distribution (a technique for approximating an integral by appealing to a Bayesian Central Limit theorem regarding the normality of most posterior distributions), and other techniques (e.g., weighted normal mixture distributions for multimodal densities). These methods are computationally difficult and mathematically complex, limiting their use in mainstream social science research.

Contemporary Approaches to Estimation

Over the last decade, new methods of estimation—Markov chain Monte Carlo methods—have become popular. These methods have the advantage of being able to handle high-dimensional parameters (something that quadrature methods cannot) and being theoretically exact (something that approximation methods, by definition, are not). I focus extensively on these methods because they hold the most promise for making Bayesian analyses more accessible to social scientists.

The name Markov chain Monte Carlo (MCMC) derives from the nature of the techniques; the methods produce simulated parameter values (hence Monte Carlo), with each sampled parameter being simulated based only on the immediately prior value of the parameter (hence Markov chain). In plain English, these techniques produce sequences of random, but not independent, samples of parameters from their posterior distributions.

In order to understand the usefulness of simulated parameter values, we must discuss the linkage of a collection of random quantities to the integrals previously discussed. If we are unable to integrate a density analytically, we can simulate a large number of draws from the density and then use discrete formulas to compute summary statistics of interest, such as the mean, median, variance, and so on (this is called Monte Carlo integration). For example, suppose we are unable to integrate a normal density with mean μ and variance σ^2 . We can simulate $n = 1000$ random draws $y_i, i = 1, \dots, n$, from this density using very basic simulation algorithms. We can then compute the mean of this distribution as:

$$\hat{\mu} = \frac{\sum y_i}{1000}$$

We could also compute the variance as:

$$\hat{\sigma}^2 = \frac{\sum (y_i - \mu)^2}{n - 1}$$

For that matter, we can compute any other integral value we like. For instance, the median (M) of a distribution is defined as the value that divides the distribution in half such that one-half of the values fall below the median and one-half above, that is, it satisfies:

$$\int_{-\infty}^M p(\theta) d\theta = 0.05$$

With a large sample from the distribution, the median of the sample estimates the median of the underlying distribution. We can obtain other quantiles of interest in this fashion as well.

The Metropolis-Hastings Algorithm

With simple distributions, routines are generally available that allow us to simulate random samples directly. With complex distributions, there generally are not simple routines for generating samples. MCMC methods are techniques that enable us to conduct such simulation so that these various quantities of interest can be calculated from the iterates, thereby avoiding the necessity of analytical computation. The most basic MCMC methods are the Metropolis-Hastings (MH) algorithm and the Gibbs sampler (a special case of MH). An MH algorithm consists of the following steps, which are explained in depth later:

1. Establish starting values for the parameter $\theta^{j=0}$ (possibly at maximum likelihood estimates).
2. Sample a candidate parameter θ^c from a proposal distribution $\alpha(\theta)$.
3. Evaluate the posterior density, $p(\theta)$, at the candidate point and previous point and form the ratio $R = (p(\theta^c)\alpha(\theta^{j-1} | \theta^c)) / (p(\theta^{j-1})\alpha(\theta^c | \theta^{j-1}))$. The $\alpha(a | b)$ terms represent the probability that a will be proposed as a candidate, given the chain is currently in state b , providing a way to compensate for

asymmetric proposal densities. If the proposal density is symmetric, these terms drop from the ratio.

4. Accept the candidate parameter with probability $\min(1, R)$ by drawing a random variable $u \sim U(0, 1)$ and comparing to R . If $R > u$, then accept the candidate (set $\theta^j = \theta^c$); otherwise reject it (set $\theta^j = \theta^{j-1}$).
5. Set $j = j + 1$ and return to step 2.

As written, the parameter of interest is contained in the vector θ , and $p(\theta)$ is the density of interest (hereafter referred to as a posterior density). In step 1, we provide starting values for the parameter. These starting values could be MLEs, guesses, or some other value (e.g., for a regression model, we may choose to start all regression parameters at 0). In step 2, we simulate a candidate value for the parameter from a proposal density. This value is called a candidate because it is not automatically accepted as having come from the posterior density; it is merely a trial value. The proposal density is so called because it is any density that is easy to simulate from. The proposal need not be identical to the posterior distribution because the next steps determine whether the candidate is to be considered a draw from the posterior. In step 3, we compute R , which is a ratio of the (possibly unnormalized) posterior density evaluated at the candidate value to the (possibly unnormalized) posterior density evaluated at the previous value of the parameter, with an adjustment that accounts for possible asymmetry in the proposal density from which the candidate was drawn. We also simulate a random draw (u) from the uniform distribution on the interval $[0, 1]$. If the value of the ratio R is greater than the value of u , then we treat the candidate value as having come from the posterior distribution of interest and we update the parameter accordingly. If not, we set the current values of the parameters to the previous values. The algorithm then returns to step 2 and continues iterating until enough unique iterates have been obtained so that we can summarize the posterior density with our sampled parameters.

A few notes are in order about the algorithm. First, the ratio R obviates the need for computing the normalizing constant, often a complex integral, because the constant is contained in both the numerator and denominator. Second, the ratio R actually consists of two ratios. The first ratio, as discussed, is simply the ratio of the posterior density evaluated at the candidate versus previous values. The second ratio compensates for asymmetry in the proposal density. Often we use symmetric densities, for example, a normal proposal density with variance C centered on the previous value of the parameters; that is, $N(0, C)$. In this case, the first ratio will not oversample one value of the parameter over another (i.e., candidate versus previous) simply as a virtue of a greater probability of proposing one value over another. The probability of

proposing θ^a when the previous value is θ^b will not be greater than the probability of proposing θ^b when the previous value is θ^a . To make this idea concrete, suppose we are sampling the variance parameter, σ^2 , from a normal model. If we use a $U(-0.5, 0.5)$ density (centered over the previous parameter value) as our proposal density, subject to the constraint that all candidates must be greater than 0 (because variances cannot be negative), we will tend to oversample values away from 0 because whenever the previous parameter value is less than 0.5, we will automatically reject any candidate proposed below 0 for violating the boundary constraint. Over the long run, this will make the algorithm more likely to propose (and thus accept) values away from 0 out of proportion to their actual probability. The second part of the ratio compensates for this problem. Notice that in this case, the second half of the ratio will be greater than 1, boosting the overall ratio and lending a little greater probability that we may accept values closer to the boundary. In practice, with very narrow proposal densities, peaked posterior densities, or a posterior centered away from a boundary, the bounding issue is not much of a problem.

The Gibbs Sampler

In some cases, we may be able to derive the full conditional distributions for each parameter in the posterior distribution. In those cases, rather than drawing candidate parameters from proposal distributions, we can draw them from their full conditional distributions. When that occurs, the ratio R always equals 1 and every draw is accepted. This algorithm is called a Gibbs sampler. A generic Gibbs sampling algorithm with k parameters can be specified as follows:

1. Establish starting values for $\theta_2, \dots, \theta_k$.
2. Sample $[\theta_1^{(j)} | \theta_2^{(j-1)}, \theta_3^{(j-1)}, \dots, \theta_k^{(j-1)}]$
3. Sample $[\theta_2^{(j)} | \theta_1^{(j)}, \theta_3^{(j-1)}, \dots, \theta_k^{(j-1)}]$
4. Sample $[\theta_3^{(j)} | \theta_1^{(j)}, \theta_2^{(j)}, \dots, \theta_k^{(j-1)}]$
- \vdots
- k . Sample $[\theta_k^{(j)} | \theta_1^{(j)}, \theta_2^{(j)}, \dots, \theta_{k-1}^{(j)}]$
- $k + 1$. Set $j = j + 1$ and return to step 1.

This specification says that we sample the first parameter from its full conditional distribution, conditional on the previous values of the other parameters. As we work our way through the steps, we use the updated values of the parameters in drawing subsequent parameters from their conditional distributions. Because the Gibbs sampler accepts every draw, it is much more efficient than the MH algorithm. However, the price to be paid for efficiency is that we must be able to derive the full conditionals for each parameter and they must take on known forms. Otherwise, we must use some other method for simulating from the conditional distribution, including possibly using an MH step.

Fine-Tuning Markov Chain Monte Carlo Algorithms

Theory indicates that, *in the limit*, the stationary distribution of the Markov chain of iterates produced by an MH algorithm will be the distribution of interest, and so the MH algorithm and Gibbs samplers produce a random walk over the appropriate parameter space. However, convergence to this distribution is not immediate; thus, early iterations of the algorithm should be discarded (called a burn-in period). In general, checking convergence to the appropriate stationary distribution should be a primary concern when using these algorithms, and several methods for evaluating the success of an algorithm have been suggested. Some have suggested that a very long single run of the algorithm may be best. Others have suggested that several runs of the algorithm using widely dispersed starting values provide the best evidence of convergence. Diagnostic tests on the iterates from these multiple chains can help determine whether convergence has been obtained, essentially by examining the extent of the total variance in the iterates that is between-chain variance versus within-chain variance. To date, however, perhaps the most commonly used test of convergence is the ocular test—we can simply examine a trace plot of the iterates to see whether any trending exists. If so, then the algorithm has not converged; if not, then the algorithm *may* have converged.

Another key concern when using these algorithms is the acceptance rate. We have already mentioned that the acceptance rate for a Gibbs sampler is 1 because every draw is accepted. The acceptance rate for an MH algorithm, however, depends on several things. First, if the proposal density is too wide relative to the posterior density, then the algorithm tends to propose candidates that are outside the main support of the posterior. In those cases, the rejection rate will be quite high, and the Markov chain will remain in one place for a long time and will not converge rapidly. On the other hand, if the proposal density is too narrow, the acceptance rate may be quite high, but the algorithm will not explore the entire posterior density very quickly because it cannot move very far at each iteration. Obviously, a delicate balance must be reached between proposals that are too narrow or too wide, so that the algorithm mixes well. Research suggests that an acceptance rate in the range of 15% to 85% is acceptable, although most suggests a narrower range.

In high-dimensional models, establishing appropriate proposal densities becomes more difficult. For example, suppose our density of interest is a bivariate normal density with a very high correlation. In that case, the contours of the density will be a very narrow, tilted ellipse. If our proposal density is a bivariate normal with 0 correlation, most of the candidates will be drawn from regions outside the densest regions of the density. We may correct for this problem in several ways. First, we may transform the

model parameters to a parameterization in which the distribution does not evidence such a high correlation. Second, we may alter our proposal density to attempt to match the relative shape of the distribution. In our example, we could, for instance, use a bivariate normal distribution with a high correlation as our proposal. These two approaches are equivalent. Third, we may update parameters one at a time rather than jointly. In high-dimensional models it is often very difficult or impossible to obtain reasonable acceptance rates without doing this. If we update parameters independently, then we have a tremendous amount of flexibility in specifying appropriate proposals for each parameter. Indeed, we can even sample some parameters from their full conditionals, yielding an algorithm that is a hybrid of Gibbs sampling and MH.

Bayesian Inference

We have already discussed some aspects of Bayesian inference, including estimating the mean, median, mode, and variance. Using simulated samples from the posterior distribution is easy, and there is virtually no limit to the statistics that we can use. For much of Bayesian inference, the variance of the posterior distribution is important. Credible intervals (the Bayesian version of confidence intervals) can be constructed based on the variance of the marginal posterior distribution for a parameter, or we can simply use the sampled iterates themselves to construct empirical intervals. That is, for a $100 \times (1 - \alpha)\%$ interval for a parameter, we can simply order the simulated sample of iterates from smallest to largest and take the $n(\alpha/2)$ th and $n(1 - \alpha/2)$ th iterates as the bounds of the interval. The interpretation of such an interval differs from the interpretation of a classical interval. From a Bayesian perspective, we simply say that the probability the parameter fell in the interval is $1 - \alpha$.

The Bayesian approach also directly allows inferences for parameters that are not in the model but are functions of the parameters that are in the model. For example, suppose our MCMC algorithm generates samples from the distribution for θ , $p(\theta | y)$. If we are interested in making inferences for a parameter $\delta = f(\theta)$, we simply compute $\delta^j = f(\theta^j)$, $\forall j$ and use the collection of δ as a sample from $p(\delta | y)$. We then proceed with inferential computations as previously discussed.

Model Evaluation and Comparison

As with any statistical modeling process, after a model is estimated, we should determine whether the model

actually fits the data. In addition, we may also be interested in comparing multiple models. The Bayesian approach has very flexible methods for model evaluation and comparison.

Posterior Predictive Distributions

For evaluating the fit of a model, perhaps the most flexible approach is to examine the Bayesian posterior predictive distribution. The posterior predictive distribution is the distribution of future observable data, based on the posterior distribution. It is defined as:

$$p(y^{\text{rep}} | y) = \int p(y^{\text{rep}} | \theta)p(y | \theta)p(\theta) d\theta \quad (18)$$

In this equation, y^{rep} is future data that could be drawn from the posterior distribution, y is the current data, and θ is the model parameter. Notice that the last two terms (prior to $d\theta$) are the posterior density for the parameter. The first term is the sampling density for future data, conditional on the parameter. This equation simply specifies a form for the distribution of future data, given the model parameter and data. If a model fits the current data well, then we expect that simulated future data should look much like the current data. Thus, we can simulate data from the posterior predictive distribution, compare it to the observed data, and determine whether the model has an appropriate fit. More formally, we can conduct statistical tests that indicate a level of fit. If we define $T(y)$ to be a function of the data (a test statistic) and $T(y^{\text{rep}})$ to be the same function applied to the replicated data, then we can compute a Bayesian p value as:

$$p \text{ value} = p(T(y^{\text{rep}}) \geq T(y) | y) \quad (19)$$

This value can be calculated by simply computing the proportion of replicated data sets whose function values exceed that of the function applied to the original data. For example, $T(y)$ can be $T(y) = y_{\text{max}}$, that is, the maximum observed y . If we simulate 10,000 replicated data sets (of size n , where n is the original sample size) from the posterior predictive distribution, and the maximum y^{rep} value exceeds the maximum observed y value in 3500 of the replicated data sets, then the p value is 0.35. In that case, the replicated data appear consistent with the observed data.

The interpretation of tests based on the posterior predictive distribution is straightforward. It represents the probability that a future observation will exceed the existing data, given the model. An extreme p value, therefore, implies poor model fit. In addition to constructing tests that are solely functions of data, we can compute discrepancy statistics that are functions of both data and parameters.

From this brief discussion, it should be apparent that the posterior predictive distribution provides a very flexible approach to examining model fit. There is virtually no limit to the statistics that can be examined to evaluate any aspect of model fit. Furthermore, from a Bayesian perspective, this approach is more reasonable than the classical approach because it considers not only sampling variability but also parametric uncertainty, something the classical approach ignores. That is, most model fit statistics in a classical setting are predicated on the assumption that the model parameter estimates are the true values; Bayesian posterior predictive checks average over parametric uncertainty, as evidenced by Eq. (18).

Bayes Factors

Of interest for many statisticians is the comparison of multiple models that are thought to capture the processes that generate the data. Often, competing theories imply different models. The classical approach to statistics is limited to comparing nested models, but models often are not nested. A Bayesian approach to comparing non-nested discrete sets of models is based on the Bayes factor. If we have two models, M_1 and M_2 , each with parameters θ , then Bayes's theorem gives the posterior probability for each model and a ratio of these probabilities can be formed:

$$\text{Posterior odds} = \frac{p(M_1 | y)}{p(M_2 | y)} \tag{20}$$

Both the numerator and denominator can be broken into their constituent parts, the Bayes factor and the prior odds for model 1 versus model 2:

$$\text{Posterior odds} = \frac{p(y | \theta_{M_1})p(\theta_{M_1})}{p(y | \theta_{M_2})p(\theta_{M_2})} \tag{21}$$

The former ratio is simply the ratio of the marginal likelihoods and is called the Bayes factor; the latter ratio is the ratio of the prior odds for the two models. The marginal likelihoods are so called because they represent the integral of the posterior density over the parameter space S_i for each model M_i (essentially averaging out parametric uncertainty within each model; notice that this is nothing more than the inverse of the normalizing constant required to make a posterior density proper):

$$p(y | M_i) = \int_{\theta_i \in S_i} p(y | \theta_i)p(\theta_i) d\theta_i \tag{22}$$

or, with the model explicit:

$$p(y | M_i) = \int_{\theta_i \in S_i} p(y | \theta_i, M_i)p(\theta_i | M_i) d\theta_i \tag{23}$$

The prior odds in Eq. (21) are usually set to 1. If both models are assumed to have equal prior probability, the posterior odds are equivalent to the Bayes factor. Thus, a value of 1 for the Bayes factor indicates equal support for both models, whereas a ratio greater than 1 favors model 1 and a ratio less than 1 favors model 2.

The integration required is one limitation to the use of Bayes factors; the integration is difficult. However, in 1995 Raftery proposed an approximation, termed the Bayesian Information Criterion (BIC), that can be fairly easily computed using standard output from most software packages. Perhaps a more difficult issue is that the Bayes factor is quite sensitive to the choice of priors used for parameters in each model.

Bayesian Model Averaging

Rather than comparing a discrete set of models, the researcher may be interested in making inferences about a parameter using all models in a particular class of models. Bayesian model averaging extends the notion of model uncertainty alluded to in the discussion of Bayes factors. When we conduct statistical analyses, we typically construct a single model. This approach, however, ignores model uncertainty; that is, it ignores the fact that we may not have chosen the appropriate model. Model averaging is nothing more than constructing a marginal posterior distribution for a parameter, averaging across all models in a class:

$$p(\theta | y) = \sum_{j=1}^J p(\theta | M_j, y)p(M_j | y) \tag{24}$$

The first term on the right-hand side of Eq. (24) is simply the posterior distribution for the parameter under a specific model. The second term is the posterior probability for the model. This term is the numerator of the posterior odds presented in Eq. (20). From this equation, then, it should be clear that the posterior distribution for a parameter under Bayesian model averaging is simply a weighted mixture of the probabilities under each model.

Model averaging is tricky for two reasons. First, we must assign prior distributions for each model in the model space we are examining. An obvious choice of prior may be one that assigns equal prior weight to all models, but this approach may ultimately favor models that are very similar to one another, giving them high posterior weight. Second, model averaging is computationally intensive. For example, in a normal linear regression model with J covariates there are 2^J possible models that must be examined. To date, two primary approaches to dealing with this problem have been advanced. One is to exclude models if they have low posterior probability relative to another well-fitting model

using a decision rule called Occam's window. Under this approach, we can also exclude models that are supersets of better-fitting smaller models. The second approach is to sample from the posterior for all models using MCMC methods. The benefit of the first method is that it typically reduces the model space to fewer than 100 models, making Eq. (24) easier to compute; the downside is that it only provides an approximation to the true posterior probability for a parameter because numerous models are excluded. The benefit of the MCMC method is that it provides the correct posterior probability; the downside is that it is difficult to obtain convergence and that it is incredibly time intensive.

Behavioral Economics: The Carnegie School

Mie Augier

Stanford University, Stanford, California, USA

Glossary

bounded rationality A phrase coined by Herbert Simon; used to describe an approach to economics that is more realistic than that of neoclassical economics.

maximization One of the assumptions of neoclassical economics and rational choice theory, assuming that all agents maximize expected utility (or profit) of all possible outcomes.

neoclassical economics A branch of economics building on very strict assumptions about economic behavior as optimizing behavior.

satisficing The idea that economic agents (and organizations) do not maximize (due to cognitive limitations and bounded rationality) but search for an outcome that is “good enough.”

theory of the firm A field of economics and organization theory centered around questions relating to the existence, boundaries, and internal organization and activities of the business firm.

Behavioral economics aims at broadening the behavioral and psychological foundations of economics in order to explain phenomena, such as the firm, that are not adequately addressed in neoclassical economics. By incorporating ideas such as bounded rationality and satisficing into economic analysis, behavioral economics provides a more realistic perspective on individual and organizational decision making than does mainstream economics. Many ideas in behavioral economics began in the 1950s and 1960s around a group of researchers at Carnegie Mellon University. Herbert Simon (one of the three key figures at Carnegie in the early development of behavioral economics) won the Nobel Prize in economics in 1978. Modern developments in behavioral economics include much of the research on judgment and

heuristics by Daniel Kahneman and Amos Tversky, which led to the Nobel Prize in economics in 2002. Key ideas in behavioral economics are also embedded in traditions such as transaction cost economics and evolutionary economics. Here the focus is mostly on the early development of the tradition.

History and Scope

An important part of behavioral economics is often identified with the pioneering work done by Herbert Simon, James G. March, and Richard Cyert in the 1950s and 1960s at Carnegie Mellon University. The Carnegie behavioralists are known for their interest in understanding how individuals and organizations act and make decisions in the real world, and their challenges to the neoclassical theory of optimization and maximization in decision making and organizations. Behavioral economics developed concepts such as bounded rationality and satisficing to describe individuals and organizations acting in the face of “the uncertainties and ambiguities of life.” Many of these concepts were first discussed in the book *Organizations*, and none of them has lost currency. They prove their usefulness whenever actual behavior departs from the tenets of rationality (for instance, when action is rule based rather than consequence based, or when it conflicts with statistically informed strategies, as described in the prospect theory of Tversky and Kahneman).

Behavioral economics also stood out early in its aim to be interdisciplinary. Whereas mainstream economics stays within the discipline of economics to analyze behavior and decision making, behavioral economics draws on other traditions, such as political science, sociology, organization theory, and psychology, to obtain a broader understanding of human behavior and decision making.

In particular, because there are limits to rational behavior, we must deal with the psychological elements of human decision making.

The background for the Carnegie School was the Ford Foundation's mission to establish a broad and interdisciplinary behavioral social science in the late 1940s and early 1950s, and much of the efforts were directed at supporting the early setup of the Graduate School of Industrial Administration at Carnegie Mellon University (originally Carnegie Institute of Technology), where Simon, March, and Cyert worked. The Carnegie Institute of Technology had been founded in 1912 by Andrew Carnegie and had established itself as one of the best engineering schools in the country. The early president, Robert Doherty, who had come from Yale, wanted Carnegie Tech to be a leader in research and, hence, to break with the traditional mechanical engineering view of business education and include broader, social and interdisciplinary, aspects. As a result of Doherty's ambitions, the first dean of what came to be known as the Graduate School of Industrial Administration (GSIA), George Leland Bach, was hired. Bach wanted to staff his department with economists who combined intellectual skills and experience in applying theory to real-world situations and he wanted to put Carnegie at the forefront of U.S. business schools. Simon, March, and Cyert all came to Carnegie to help develop this view.

Business education at that time was not much oriented toward research, but was more focused on case studies. But Simon, Cyert, and March wanted to be different. They wanted to do research. They wanted their research to be relevant for business leaders, while at the same time emphasizing the tools of good science. Early core courses in the program included "quantitative control and business" (consisting of basically accounting and statistics), a sequence of micro- and macroeconomics, and organization theory. The vision they had was reflected in an emphasis on creating a new behavioral science that was broad enough to accommodate disciplines such as economics, sociology, and social psychology, yet precise enough to reflect the rigor and technical sophistication of mathematical models. In the end, their implementation of this vision produced significant contributions to areas such as behavioral economics, operations research, experimental economics, and theories of the firm. It also created a model for business schools that was widely adopted across the United States and (later) Europe.

The behavioral group at Carnegie was embedded in a larger group of scholars, which included innovative economists such as Franco Modigliani, John Muth, Charles Holt, and Merton Miller. The spirit at Carnegie was that everybody interacted with everybody else; discussed each other's research, and discussed science, so collaborative teams worked together as well as across each other's projects. Consisting of different people with

different interests, these teams always worked together in a friendly way, despite different disciplines and despite varying degrees of admiration for the idea of rationality. It was an environment in which people were united by their deep and intense interest for doing science. And it was a unique environment where joy from work was present more than anywhere else. Several Nobel Prize winners were fostered during the golden years at Carnegie, including Robert Lucas, Franco Modigliani, Merton Miller, and Herbert Simon, and Carnegie had outstanding records on other accounts as well.

The Carnegie school tried to develop the rudiments of process-oriented understandings of how economic organization and decision making take place. They did so in an interdisciplinary way, linking economics to organization theory, cognitive science, sociology, and psychology, and centering around concepts such as uncertainty, ambiguity, norms, routines, learning, and satisficing. They used ideas from social science more broadly to advance understanding of economics and, in the process, contributed to the strands that came to be called behavioral economics. The ideas initiated by the Carnegie School helped to establish a foundation for modern ideas on bounded rationality; adaptive, behavioral, and evolutionary economics; and transaction cost theory.

Key Ideas and Theories

The behavioral research of Simon, Cyert, and March aimed at making understandable how individuals make decisions and behave in the real world. They found that neoclassical economics gave too little attention to the institutional and cognitive constraints on economic and organizational behavior and on individual decisions, and allowed too little room for human mistakes, foolishness, the complications of limited attention, and other results of bounded rationality. As a result, they proposed to include the whole range of limitations on human knowledge and human computation that prevents organizations and individuals in the real world from behaving in ways that approximate the predictions of neoclassical theory. For example, decision makers are sometimes confronted by the need to optimize several, sometimes incommensurable, goals. Furthermore, instead of assuming a fixed set of alternatives among which a decision maker chooses, the Carnegie School postulated a process for generating search and alternatives and analyzing decision processes through the idea of aspiration levels, a process that is regulated in part by variations in organizational slack. Finally, individuals and organizations often rely on routines or rules of thumb learned from experience or from others, rather than seek to calculate the consequences of alternatives.

Underlying these ideas is the emphasis on bounded rationality, bringing in a more psychological and realistic assumption to the analysis. As Simon noted early on, “the first principle of bounded rationality is that the intended rationality of an actor requires him to construct a simplified model of the real situation in order to deal with it. He behaves rationally with respect to this model, and such behavior is not even approximately optimal with respect to the real world. To predict his behavior, we must understand the way in which this simplified model is constructed, and its construction will certainly be related to his psychological properties as a perceiving, thinking, and learning animal.”

The twin idea of bounded rationality is satisficing. Satisficing is the idea that decision makers interpret outcomes as either satisfactory or unsatisfactory, with an aspiration level constituting the boundary between the two. Whereas decision makers in neoclassical rational choice theory would list all possible outcomes, evaluated in terms of their expected utilities, and then choose the one that is rational and maximizes utility, decision makers in the behavioral model face only two possible outcomes, and look for a satisfying solution, continuing to search only until they have found a solution that is good enough.

Both satisficing and bounded rationality were introduced in 1955, when Herbert Simon published a paper that provided the foundation for a behavioral perspective on human decision making and introduced the ideas of satisficing and bounded rationality. The paper provided a critique of the assumption in economics of perfect information and unlimited computational capability, and replaced the assumption of global rationality with one that was more in correspondence with how humans (and other choosing organisms) made decisions, their computational limitations, and how they accessed information in their current environments. In Simon’s illustration of the problem, the influence of his early ideas outlined in *Administrative Behavior* is clear, echoing the view that decisions are reasoned and intendedly rational, yet limited. He first suggests a simple and very general model of behavioral choice that analyzes choosing organisms (such as humans) in terms of basic properties to understand what is meant by rational behavior. He introduces the simplifying assumptions (such as the choice alternatives, the payoff function, possible future states, and the subset of choice alternatives considered, as well as the information about the probability that a particular outcome will lead to a particular choice). But immediately afterward, he turns to the simplifications of this model, stressing that, on careful examination, “we see immediately what severe demands they make upon the choosing organism.” Whereas in models of rational choice, the organism must be able to “attach definite payoffs (or at least a definite range of payoffs) to each possible outcome,” Simon suggests that “there is

a complete lack of evidence that, in actual human choice situations of any complexity, these computations can be, or are in fact, performed.” As a consequence of the lack of computational power, decision makers have to simplify the structure of their decisions (and thus satisfice), one of the most important lessons of bounded rationality. This idea later became important to the work on organizational behavior and decision making done by Simon and March. In addition, the idea of satisficing has been used by evolutionary and adaptive economics (such as that of Richard Nelson and Sidney Winter).

Major Early Works

One of the first major results of the Carnegie School’s work was a propositional inventory of organization theory, involving Herbert Simon, James March, and Harold Guetzkow; this led to the book *Organizations*. The book was intended to provide the inventory of knowledge of the (then almost nonexistent) field of organization theory, and also a more proactive role in defining the field. Results and insights from studies of organizations in political science, sociology, economics, and social psychology were summarized and codified. The book expanded and elaborated ideas on behavioral decision making, search, and aspiration levels, and elaborated the idea on the significance of organizations as social institutions in society. “The basic features of organization structure and function,” March and Simon wrote, “derive from the characteristics of rational human choice. Because of the limits of human intellectual capacities in comparison with the complexities of the problems that individuals and organizations face, rational behavior calls for simplified models that capture the main features of a problem without capturing all its complexities.” March and Simon also wanted to unite empirical data-gathering research with rigorous theorizing in order to create a rigorous empirical theory that could organize and so give meaning to empirical facts with legitimate theory. Science, they believed, was the product of the organization of empirical facts into conceptual schemes, and the progress of science was based on the development of more sophisticated and elegant theoretical systems, but not necessarily the discovery of new facts.

The Ford Foundation also supported a larger project on behavioral theories of organizations; this was carried out by Richard Cyert and James March (along with their students, including Julian Feldman, Edward Feigenbaum, William Starbuck, and Oliver Williamson). The project originated in the works of Cyert and March to develop improved models of oligopoly pricing by using organization theory. The research on the behavioral theory of the firm aimed at investigating how the characteristics of business firms, as organizations, affect important

business decisions. Integrating theories of organizations with existing (mostly economic) theories of the firm, they developed an empirical theory rather than a normative one, and focused on classical problems in economics (such as pricing, resource allocation, and capital investment) to deal with the processes for making decisions in organizations.

The behavioral theory of the firm is built around a political conception of organizational goals, a bounded rationality conception of expectations, an adaptive conception of rules and aspirations, and a set of ideas about how the interactions among these factors affect decisions in a firm. Whereas goals in neoclassical theory are pictured as given alternatives, each with a set of consequences attached, goals within behavioral theory are pictured as reflecting the demands of a political coalition, changing as the composition of that coalition changes. Said Cyert and March: "Since the existence of unresolved conflict is a conspicuous feature of organizations, it is exceedingly difficult to construct a useful positive theory of organizational decision-making if we insist on internal goal consistency. As a result, recent theories of organizational objectives describe goals as the result of a continuous bargaining-learning process. Such a process will not necessarily produce consistent goals." Thus, the theory treats the demands of shareholders, managers, workers, customers, suppliers, and creditors as components of the operational goals of a firm. In the behavioral view, agents have only limited rationality, meaning that behavior in organizations is intendedly rational, neither emotive nor aimless. Because firms are seen as heterogeneous, boundedly rational entities that have to search for relevant information, expectations in the behavioral theory are portrayed as the result of making inferences from available information, involving both the process by which information is made available and the processes of drawing inferences. Because information is costly, it is generated by search activity. The intensity of search depends on the performance of the organization relative to aspirations and the amount of organizational slack. The direction of search is affected by the location (in the organization) or search activity and the definition of the problem stimulating the activity. Thus, the search activity of the organization furthers both the generation of new alternative strategies, and facilitates the anticipation of uncertain futures.

Decision making in the behavioral theory is seen as taking place in response to a problem, through the use of standard operating procedures and other routines, and also through search for an alternative that is acceptable from the point of view of current aspiration levels for evoked goals. Choice is affected, therefore, by the definition of a problem, by existing rules (which reflect past learning by the organization), by the order in which alternatives are considered (which reflects the location of

decision making in the organization and past experience), and by anything that affects aspirations and attention. Within this framework, four concepts were developed. The first is the quasi-resolution of conflict, the idea that firms function with considerable latent conflict of interests but do not necessarily resolve that conflict explicitly. The second is uncertainty avoidance. Although firms try to anticipate an unpredictable future insofar as they can, they also try to restructure their worlds in order to minimize their dependence on anticipation of the highly uncertain future. The third concept is problemistic search, the idea that search within a firm is stimulated primarily by problems and directed to solving those problems. The fourth concept is organizational learning. The theory assumes that firms learn from their own experiences and the experiences of others.

This view of the firm was important to modern developments such as evolutionary theory and transaction cost economics, which both bear intellectual debts to the ideas in the behavioral theory of the firm. For example, the ideas of bounded rationality and conflict of interest are now standard in the transaction cost theory of especially Oliver Williamson, and the view of the firm as a system of rules that adapt to its changing environment is important in the evolutionary theory put forward by Richard Nelson and Sidney Winter. The transactions cost approach is widely accepted as a framework for understanding economic organization. This perspective sees markets and hierarchies as alternative mechanisms for organizing transactions. In order to economize on transaction costs, production is frequently required to be organized in firms. Transaction cost economics builds on the assumptions of bounded rationality and opportunism. In the evolutionary view, the firm is seen as a profit-seeking entity, the primary activities of which are to build (through organizational learning processes) and exploit valuable knowledge assets. Firms in this view also come with "routines" or "competencies," which are recurrent patterns of action that may change through search and learning. Routines will seldom be "optimal" and will differ among agents, and behaviors cannot be deduced from simply observing the environmental signals (such as prices) to which agents are exposed. This variety drives the evolutionary process because firms articulate rent-seeking strategies on the basis of their routines and competencies, and competition in the product market constitutes an important part of the selection environment of confronting firms.

Another modern development within behavioral economics comes from the work of Daniel Kahneman and Amos Tversky. Drawing heavily on experimental psychology, they showed how rational choice theory cannot be applied to the real world and they investigated the influence of a number of human factors. One such factor is heuristics. Heuristics "reduce the complex tasks of assessing probabilities and predicting values to simpler

judgmental operations.” Thus, heuristics economize the limited cognitive resources of decision makers, which allows decisions to be made, but introduces errors and biases. Kahneman and Tversky’s work on heuristics led them to a model of choice called prospect theory. One of the key assumptions in this model is that people’s probability judgments are not attached to events but to the descriptions of events. When choices are irreversible and outcomes are time lagged, uncertainty will prevail. No objective facts will figure in the forecasts of decision makers, merely their perception of such facts. Decision making thus depends on the framing of the problem, which shapes perceptions and thus influences choices.

Closing

An important branch of behavioral economics was conceived at Carnegie Mellon University during the 1950s and early 1960s around the work of Herbert Simon, Richard Cyert, and James March. For these scholars, behavioral economics meant doing science in an interdisciplinary way, linking economics to organization theory, cognitive science, sociology, and psychology, and centering around concepts such as uncertainty, ambiguity, norms, routines, learning, and satisficing. Emphasizing the concern with the empirical validity of assumptions, Simon thus wrote that “behavioral economics is best characterized not as a single specific theory but as a commitment to empirical testing of the neoclassical assumptions of human behavior and to modifying economic theory on the basis of what is found in the testing process.” He included in the behavioral economics different approaches, such as new institutional economics, transaction cost economics, evolutionary economics, and the literature on heuristics coming from Kahneman and Tversky.

Glossary

avoidance conditioning A procedure in which a particular response during a conditional stimulus prevents the occurrence of an aversive event.

conditional stimulus A stimulus that elicits a conditional response after being paired with an unconditional stimulus.

extinction In Pavlovian conditioning, when a conditional stimulus is no longer followed by an unconditional stimulus, the conditional response will return to its preconditioning level. In operant conditioning, withholding a positive reinforcer after a response it normally followed will cause the response to return to its preconditioning level.

functional relationship A description, often summarized in a graph, that shows how one variable (the independent variable) is related to another variable (the dependent variable). Knowledge of the functional relationship and of the value of the independent variable allows one to predict the value of the dependent variable.

habituation The waning of a response elicited by a usually harmless stimulus because of repeated presentations of that stimulus.

hypothetical construct Unobserved entities purported to mediate an environment–behavior relationship.

operant conditioning The procedure in which behavior is modified by its consequences.

Pavlovian conditioning The procedure in which a stimulus comes to elicit a new response after being paired with a stimulus that elicits a similar or related response.

positive reinforcer A stimulus whose occurrence after a response increases the likelihood of that response recurring.

punisher A stimulus whose occurrence after a response decreases the likelihood of that response recurring.

unconditional stimulus A stimulus that reliably and persistently elicits behavior that is resistant to habituation.

Behavioral psychology is a subdivision of psychology and an approach to the study of behavior that relates what people and animals do to the stimulus conditions

before, during, and after behavior. In other words, behavioral psychology is concerned with understanding environment–behavior relationships.

Foundations of Behavioral Psychology

Historically, behavioral psychology was incorrectly identified with “rat psychology” because, at one time, its primary data were collected using laboratory rats as the subjects. It was thus assumed that its theories were most appropriate to rats and other laboratory animals. In terms of its application to humans, behavioral psychology was considered most useful for populations with developmental disabilities, autism, and the seriously and persistently mentally ill. For many critics, to modify someone’s behavior is tantamount to “mind control” and evokes disturbing images from Orwell’s *1984*, Huxley’s *Brave New World*, and Burgess’s *A Clockwork Orange*. But behavioral psychology resembles none of these any more than nuclear medicine resembles atomic bombs, meltdowns, and genetic mutations. In this section, the scope and origins of behavioral psychology are presented.

Scope

There are no restrictions on what behavioral psychologists study, as long as it is something that people and animals do. Crying during a movie, reading a book, writing a poem, counting to 10, speaking to a teacher, playing a guitar, thinking silently, feeling pain, solving a puzzle, using a tool, remembering a quote, and loving a child are examples of actions that behavioral psychologists can study, as are capturing food, attracting a mate, eluding predators, avoiding poisons, and seeking shelter. Topics

such as stress, personality, learning, intelligence, creativity, and consciousness are also studied by behavioral psychologists.

There are also no restrictions on where these actions are studied. Behavior can be studied by unobtrusive observations in the natural environment, such as when a teacher observes children playing during recess or a naturalist studies ants carrying food to their nest. Behavior can also be studied by experimentation in the natural environment, such as when a coach compares the effectiveness of relaxation techniques to alleviate a tennis player's anxiety before big matches or a biologist removes pine cones and stones near the entrance of a wasp's burrow to see how this affects the insect's ability to find its home. Finally, behavior can be studied experimentally in a clinic or laboratory, such as when a therapist measures the nonverbal behavior of a married couple and then implements a counseling program to reduce their negative body language or when a psychologist presents a rat with tones of different durations to study its timing abilities.

Philosophical Origins

The origins of studying environment–behavior relationships are as old as humans themselves, for humans' earliest ancestors must have tried to understand the relationship between a season and the migration of animals, the behavior of prey animals and the noises made by those who hunt them, the ingestion of a mushroom and bodily sensations, and so on. Somewhere in the history of humans, these informal observations and understandings evolved into explicit and written musings about behavior. The intellectual roots of behavioral psychology can be traced to several sources: Francis Bacon (1561–1626), who urged an inductive approach to science; John Locke (1632–1704), who emphasized the role of experiences in the formation of knowledge; Julien de la Mettrie (1709–1751), who believed that humans and animals were machines that differed by degree and not kind; David Hume (1711–1776), who postulated several laws of association; Auguste Comte (1798–1857), who insisted that the data of science be publicly observed; Charles Darwin (1809–1882), who argued that living creatures evolved by natural selection; and many other philosophers and scientists of the late 19th and early 20th centuries who were a part of the philosophical movements known as functionalism, logical positivism, and behaviorism.

Despite these early influences and that ethologists in Europe were also studying the relationship among animals' behavior and their environments, the birth of behavioral psychology is most often attributed to Russian physiologist Ivan Pavlov (1849–1936) and American psychologists Edward Thorndike (1874–1949), John Watson (1878–1958), and B. F. Skinner (1904–1990).

It was these scientists who argued most strongly that an understanding of people's and animals' actions requires discovering functional relationships between the environment and behavior. However, it is important to note that behavioral psychology is no more like associationism, positivism, or Watsonian behaviorism than modern humans are like Neanderthals. Just as humans and other species continue to evolve, behavioral psychology continues to evolve. Although once erroneously associated with stimulus–response psychology, the view that a response would reflexively occur in the presence of a particular stimulus context, contemporary behavioral psychology seeks to discover and understand several types of functional relationships between environmental conditions and behavior, such as the properties of operant and Pavlovian conditioning.

A Natural Science of Behavior: Distinguishing Features of Behavioral Psychology

Behavioral psychology is not only a subdivision of psychology it is also an approach to the study of environment–behavior relationships. There are two challenges to specifying the defining features of behavioral psychology. The first is that there is no single characteristic that distinguishes behavioral psychology from other areas of psychology. The second challenge is that there are two related but separate traditions within behavioral psychology, each with its own characteristics: laboratory research of basic mechanisms and processes in humans and other animals (termed the experimental analysis of behavior) and applied research directed toward improving people's and animals' lives (termed applied behavior analysis, behavior therapy, or behavior modification). Despite these challenges, there are features that when considered together distinguish behavioral psychology from other areas. These are described next.

Hypothetical Constructs

Hypothetical constructs are unobserved entities purported to mediate an environment–behavior relationship. Behavioral psychologists avoid the use of hypothetical constructs because these are easily misused and, hence, can hinder the scientific study of behavior. One reason for this misuse is that it is often unclear whether these constructs are real, metaphorical, or promissory notes for something that might be observed in the future. For example, it has been said that a rat navigates a maze by scanning with its mind's eye a stored cognitive map of the maze. However, proponents of this type of explanation also say that there is no actual mind's eye, no

actual action of scanning, and no actual map. Behavioral psychologists, who eschew these types of explanations, then ask: If these entities and actions are not real, then how does the account explain the rat's behavior of navigating a maze? A second reason for the misuse of hypothetical constructs is that the attributes imputed to them are often poorly defined, proliferate unnecessarily, and their interconnections are unspecified. For example, "attention" can be shared, transferred, conditioned, focused or unfocused, divided or undivided, increased or decreased, conscious or unconscious, and central or peripheral. Exactly what these attributes are, how they differ, and how they relate to one another is unclear.

It is important to note that it does not follow from the information above that behavioral psychologists believe that people and animals are "black boxes" or that it is inappropriate to postulate and use hypothetical constructs. These are used in behavioral psychology and are most likely to be used when several independent and dependent variables are involved. For example, the independent variables "hours of water deprivation," "eating dry food," and "receiving a saline injection" all cause an increase in the dependent variables "lever-pressing for water," "drinking water," and "quinine tolerance." In this circumstance, some behavioral psychologists would say that an increase in thirst (the hypothetical construct) causes an increase in drinking, actions that lead to drinking, and a tolerance for unpleasant tastes in water.

Theories

Theories fall along a continuum, ranging from a set of loosely interconnected observations to precise mathematical formulations. Behavioral psychology is not atheoretical, though its practitioners believe that the best theories are those that organize facts at the same level that those facts were collected. This means that if someone has determined the functional relationship between certain environmental conditions and behavior, then it is unnecessary to appeal to physiological mechanisms or processes that were never manipulated or measured or whose own relationships to behavior are poorly understood.

Theories can also be distinguished on the basis of their use of hypothetical constructs. For behavioral psychologists, a theory with too many hypothetical constructs is sloppy because it has too many degrees of freedom. A theory that can explain everything explains nothing.

Finally, theories in behavioral psychology differ from those in other areas by using behavioral primitives—basic terms and relationships that serve as pillars of theory and therefore do not require further explanation—and then coordinating and integrating these to explain more complex behavior (see Operant–Pavlovian Interactions for an example). In the process of integration, behavioral

theories stress the context of behavior and the history of experiences and iterative causes in the shaping of behavior.

Dependent Variables (Effects or Measures)

Like most areas of psychology, behavioral psychology uses behavioral dependent measures. However, unlike other areas, behavior is studied as an end in itself in behavioral psychology. It is generally not used as a means of studying other phenomena such as the brain or self-esteem. For these other areas, behavior is measured as a means toward an end: the study of something that intervenes or mediates an environment–behavior relationship.

A related difference between how the same dependent measure is used differently in behavioral psychology versus many other areas is that, for behavioral psychologists, behavior is not something apart from that which it assays. The following example clarifies the distinction. For some psychologists, low self-esteem causes people to make frequent negative self-statements (e.g., "I'm too stupid to succeed in college."). Self-esteem is a hypothetical construct. However, for behavioral psychologists, these statements express low self-esteem. That is, low self-esteem is partly defined by the behavior of making negative self-statements in specific contexts rather than resulting from low self-esteem. Viewed in this manner, self-esteem is not a hypothetical construct; it does not mediate an environment–behavior relationship because it is behavior.

Independent Variables (Causes or Treatments)

The ways in which psychologists conceive of the action of independent variables is yet another feature that helps distinguish behavioral psychology from other areas. Behavioral psychologists study independent variables that are lawfully related to behavior and which can be broadly categorized as ways of changing a person's environment. The rationale for this approach is that if the environment is altered, then behavior is likely to be altered. In contrast, most other areas of psychology infer that changes in an independent variable cause changes in a hypothetical construct, which then produces changes in behavior.

This is a subtle but important difference between behavioral psychology and other areas, for how psychologists conceive of the action of independent variables influences the independent variables that they use and study. Consider how a behavioral versus a cognitive sports psychologist might try to help a baseball player who is in a batting slump. Although there are many similarities between the two psychologists, the cognitive psychologist

would probably attribute the player's poor batting performance to a decline in his confidence; for the behavioral psychologist, the player's slump is likely the result of poor batting mechanics and responses that interfere with batting (e.g., intrusive thoughts, tensed muscles). To help the struggling batter, the cognitive psychologist focuses on changing the player's cognitions and feelings. Thus, this psychologist might help the athlete focus on the positive ("Hey, you're swinging the bat well and making good contact!"), lower his goals ("Hitting 1 out of 4 at-bats is okay."), and challenge unrealistic statements ("You're not going to be demoted to the minor leagues because of a batting slump."). The goal is to impact the player's confidence, which will then presumably raise his batting average. In contrast, although there is nothing that prevents a behavioral psychologist from trying to change the player's confidence, this psychologist focuses on video analysis, modeling, and corrective feedback to show the player how he is gripping the bat too rigidly, dropping his right shoulder too soon, as well as how he can shorten his swing, how to steady his head, and the like. Following this instruction, the player will practice batting with these new mechanics. The goal is to change the player's batting behavior directly rather than change a hypothetical construct (e.g., confidence) that might lead to a change in batting performance.

Research Designs and Data Analysis

The research designs used in most areas of psychology are known as between-groups or large-*N* designs. In their simplest form, these designs consist of randomly assigning individuals to different groups that receive different levels of the independent variable. To assess differences in the average level of the dependent measure between the groups, researchers use inferential statistics, which are data analysis techniques rooted in probability theory that help them determine the likelihood that any differences between groups are caused by differences in the independent variable. Confidence in the differences between groups is gained by using large numbers of participants in each group. In applied settings, the dependent variable is typically measured once before and after treatment or, less desirably, once after treatment. Understanding individual differences among participants is not of particular interest; the group's mean and variance are what is important.

In contrast, the research designs favored by behavioral psychologists are known as within-subject, small-*N*, single-organism, or single-subject designs, even though studies in behavioral psychology almost always use more than one person or animal. In contrast to group designs, within-subject designs rely on measuring subjects' behavior frequently. Typically, the data are plotted in graphs that show how the dependent variable changed across

time. Confidence in the effect of the independent variable relies on replicating the effects within a subject or across subjects, settings, or responses. Data from all individuals are analyzed and used to determine the effect of the independent variable.

Behavioral psychologists are interested in independent variables that consistently produce large effects relative to the amount of variation in an individual's behavior. This reduces the need for inferential statistics, for if changes in an individual's behavior are not detectable by visually inspecting the graphed data, then there was too much variation or noise in the subject's behavior and/or the effect of the independent variable was weak to nil. If the independent variable affected behavior, then the effects will be obvious. When the independent variable has not affected all individuals' behavior, behavioral psychologists try to understand this variation rather than accept it as "unexplained error."

Changing Environment—Behavior Relationships

Although there are many ways of changing environment—behavior relationships, most of these ways can be categorized into three types of procedures: habituation, Pavlovian conditioning, and operant conditioning. Whether these three procedures represent three distinct phenomena is controversial; each procedure seems to contain elements of the others. In this section, each procedure is summarized along with a few of its major properties. An understanding of these properties gives behavioral psychologists the foundation for changing environment—behavior relationships.

Habituation

If a usually harmless stimulus occurs repeatedly and there are no other events associated with it, then behavior elicited by that stimulus will diminish. This is habituation, one of the simplest ways to change behavior. By repeatedly presenting some stimuli (the environmental cause), people and animals stop responding to those stimuli (the behavioral effect). Habituation is one of the reasons that listening to the same song causes someone to lose interest in that song and a roller coaster becomes uninteresting after a few rides.

To illustrate some of the features of habituation, consider an example of a person staying in a downtown Chicago hotel along the city's famous elevated train line. Initially, trains rumbling down the track and screeching to a stop (the stimuli) elicit responses such as waking up, covering one's ears, and a set of sensations, emotions, and thoughts that collectively might be called

“annoyance.” However, as these trains continue to pass, say, every 20 min, these responses decline. Eventually, the trains are ignored in the sense that the person continues to sleep and is generally not bothered when the trains pass or stop.

Besides being an important phenomenon in itself, a discussion of habituation is also a starting point to introduce some features common to many environment–behavior relationships. For example, spontaneous recovery refers to the reoccurrence of a previously habituated response after the passage of time since the last stimulus presentation. If the train stops passing for a period of time (e.g., 24 h) after a person has habituated to it, a subsequent presentation of that stimulus will again elicit covering one’s ears, waking up, and the like. Habituation itself wanes when the stimulus that produced it stops occurring.

Habituation also helps one to appreciate the role of a stimulus’ intensity in controlling behavior. Even after a response has habituated, a more intense stimulus will elicit the (previously) habituated responses. Also, responses habituate more slowly to intense stimuli. In the preceding example, it will take longer to habituate to two loud trains stopping at the same time and the occurrence of this stimulus will again startle and annoy the guest whose behavior had habituated to the sounds of a single train.

Just as the role of time is important for spontaneous recovery, time is also a determinant of the rate of habituation. In general, habituation occurs more quickly when stimuli occur closer in time than when they are farther apart. Stimuli presented closely together also require a shorter period of nonoccurrence for spontaneous recovery than stimuli presented farther apart.

As a general rule, behavioral adaptation occurs more rapidly each time a person or animal readapts to changes in its environment. Imagine that the number of times the above hotel guest awoke during the first night she was in Chicago was recorded and it was noted that she woke up less and less as 20 trains passed during the night. Her response was habituating to the sound of the train. Then, on the second night, it was noted that she awoke only during the first 8 trains; on the third night, only the first 2 trains awoke her. These results indicate that the rate of habituation is faster each time a person or animal is presented with the stimulus series. In other words, relearning to habituate to a stimulus is quicker than learning to habituate it.

The last major feature of habituation is that a response not only habituates to the stimulus that was presented repeatedly, but also to similar stimuli. For example, once habituated to the sound of the train, a large garbage truck picking up a dumpster is also ignored. This is stimulus generalization. However, the sound of a car accident (e.g., screeching tires, crashing metal) elicits

a startle response. This is stimulus discrimination. Habituation to one stimulus might (generalization) or might not (discrimination) extend to other stimuli.

Pavlovian Conditioning

If a “neutral” stimulus (e.g., a bell) reliably precedes, usually in close temporal proximity, a stimulus that reliably and persistently elicits behavior (e.g., food in the mouth), then people and animals begin reacting during the neutral stimulus (e.g., by salivating) in way that prepares them for the impending stimulus. Although few if any stimuli are neutral in the sense that they do not elicit any behavior, behavioral psychologists consider a stimulus to be neutral when any behavior it elicits readily wanes with repeated presentations of the stimulus (i.e., responding habituates). A ringing bell, for example, might initially elicit an orienting response directed toward the sound, but this action will disappear with repeated ringing.

A stimulus that comes to elicit behavior after being paired with the stimulus that elicits behavior is a conditional stimulus (CS). A stimulus that reliably and persistently elicits behavior resistant to habituation is an unconditional stimulus (US). The responses elicited by the CS and the US are the conditional response (CR) and the unconditional response (UR), respectively. The procedure for changing behavior when two or more stimuli are paired is Pavlovian, classical, or respondent conditioning.

Although many examples of Pavlovian conditioning involve biologically significant USs such as food or water, the US does not have to be biologically significant. For example, imagine that when Jane’s grandparents visit each week, they give her \$20 when they arrive. After several pairings between these relatives and the money, how will Jane react when her grandparents visit? She will probably be happy and expecting money at the sight of her grandparents at the door because her grandparents (CS) precede the occurrence of money (US), which normally elicits a constellation of positive emotional responses (URs) when she receives it. By reliably giving Jane \$20 when they arrive, the grandparents come to elicit a set of similar responses (CRs). However, if these relatives stop giving Jane the \$20 gift when they visit, then she will become less happy and less likely to expect money when she sees them. That is, when the CS no longer predicts the US, the CR weakens and might eventually disappear. Presenting a CS without the US is termed extinction.

But just as the passage of time without a stimulus causes the spontaneous recovery of a habituated response, so too does a period of time following the extinction of a CR cause spontaneous recovery of that response. If Jane’s grandparents stop visiting for a few weeks after

extinction had occurred, and then following this break they show up again at Jane's door, their arrival might once again elicit positive emotional responses. Extinction itself wanes when the CS on which it is based stops occurring.

Stimulus generalization and discrimination also affect Pavlovian conditioned behavior. Generalization would be evident if Jane was happy to see her grandmother when she visited without her husband. If visits by the grandmother alone did not elicit positive responses, then stimulus discrimination had occurred. Thus, a CR elicited by a CS might also be elicited by other stimuli. The more similar a stimulus is to the CS, the more likely it will elicit a strong CR; the more a stimulus differs from the CS, the weaker the CR it elicits. Explicit stimulus discrimination training could also occur when visits by Jane's grandparents together predicted a gift of \$20, but visits by either the grandmother or grandfather alone were never followed by a gift. The presence of either grandparent alone would not elicit as strong a reaction as when they visited together. A stimulus that is never followed by a US becomes an inhibitory CS or CS⁻, a stimulus that suppresses behavior. Differential stimulus training is yet another way in which stimuli come to control behavior.

Not only is the correlation between the CS and US important, humans' and other animals' evolutionary histories predispose them to learn some stimulus associations differently from other associations. Perhaps the most well known example is taste or flavor aversion. Flavor aversion learning occurs when people and animals avoid gustatory and olfactory cues associated with gastrointestinal illness. There are two interesting facts about flavor aversions: (1) the flavor elicits illness and avoidance of the flavor after just a single pairing and (2) flavor aversion occurs even when the flavor is separated from the illness by many hours. In most circumstances, Pavlovian conditioning works best when the neutral stimulus repeatedly precedes the US by just a few seconds. The unique characteristics of flavor aversion probably evolved because most gastrointestinal illnesses are caused by the ingestion of toxins, some of which are life-threatening and have effects that might not be experienced for several hours. An organism that could associate a flavor with illness even if many hours separate this pairing has the advantage of not repeating its mistake. In this manner, natural selection could have favored organisms that learned flavor–illness associations after a single trial and when the flavor and illness were separated by many hours.

Operant Conditioning

Habituation deals with how a person or an animal's behavior is changed by repeated presentations of single stimuli. Pavlovian conditioning focuses on how someone's behavior is changed by a particular relationship among

two or more stimuli. During operant conditioning, a person or animal's behavior causes a change in the environment and this change then causes subsequent changes in the organism's actions. For example, immediately after a pack of wolves kills a moose, the low-ranking (omega) wolf tries to eat but is attacked by the high-ranking (alpha) wolf. However, if the omega wolf waits until higher ranking wolves have finished eating, it will then be allowed to eat. In the future, the omega wolf is less likely to try to eat before other wolves do and is more likely to eat after other wolves have finished. Behavior that produces a consequence and is affected by that consequence is operant or instrumental behavior.

In the preceding example, the operant response produced different consequences. Behavioral psychologists classify these consequences by their effect on behavior. Consequences of an action that increase the likelihood of that action recurring are reinforcers—positive reinforcers if the consequence is the occurrence of a stimulus (e.g., allowing the omega wolf to eat) and negative reinforcers if the consequence is the cessation or avoidance of a stimulus (e.g., stopping the attack on the omega wolf). Consequences of an action that decrease the probability of that action recurring are punishers (e.g., the attack suffered by the omega wolf).

The more closely in time a consequence follows a response, the more likely that response will be affected by that consequence. Increasingly delayed consequences are relatively ineffective reinforcers and punishers. However, operant conditioning may fail to occur even when the interval between a response and a consequence is short if the correlation between the response and the consequence is low. For example, a child who is paid for completing daily chores will probably stop engaging in this behavior if she is paid once every 3 months. Similarly, a child who is paid daily regardless of whether she does any chores is also likely to stop engaging in this behavior. In both examples, the response–consequence correlation is considerably less than +1.

As with habituation and Pavlovian conditioning, changes in behavior resulting from operant conditioning are not necessarily permanent. When a response that was followed by a reinforcer is no longer followed by it, that response undergoes extinction. How quickly extinction occurs depends on how often a response was reinforced. The less often a response is reinforced relative to the number of times it occurs, the more it will persist when reinforcement no longer occurs; however, a particular behavior will cease to occur if reinforcement for that action falls below a critical value. Thus, intermittent reinforcement can increase persistence, but insufficient reinforcement will cause the response to extinguish.

The rules that specify when a response will be reinforced are termed schedules of reinforcement. Two major classes of reinforcement schedules are ratio schedules

and interval schedules. In ratio schedules, the reinforcer depends solely on the occurrence of a response (e.g., a quarterback's contract that contains incentive clauses stating that he will receive a bonus each time he passes for a touchdown). In interval schedules, the reinforcer depends on the occurrence of a response and the passage of time. For example, assuming that mail is delivered at the same time daily, a person will be reinforced for checking his mailbox if he waited at least 24 h since the mail was delivered. Checking the mailbox during the 24 h period will not be reinforced because the mail will not yet have arrived.

Typically, ratio schedules support higher rates of behavior than comparable interval schedules. To see why, consider a ratio schedule in which two responses produce one reinforcer. In this schedule, how often reinforcers occur depends exclusively on how rapidly the person responds. The rate of reinforcement will always equal one-half the rate of behavior. But now consider an interval schedule in which a response is reinforced if it occurs at least 10 s since the previous reinforcer. In this situation, a person can never earn more than six reinforcers per minute regardless of how fast he or she responds. Because interval schedules have a built-in cap on the amount of reinforcement that can be earned over a period of time, people and animals generally respond slower during interval schedules than comparable ratio schedules.

Of course, all response–consequence relationships occur in a stimulus context. Just as different CSs differentially paired with a US will acquire different capacities to elicit or inhibit responding, so too do stimuli present during a response–consequence relationship come to control the operant response. Behavioral psychologists refer to this relationship among the antecedent context, behavior, and its consequences as the A-B-C of behavioral control. For example, in the presence of a red traffic light, a driver will depress the brake, stopping the car. However, once the light turns green, the driver releases the brake pedal and depresses the accelerator, moving the car forward. The color of the light (red or green) controls different actions (depressing the brake versus the accelerator) because each response is associated with different consequences (stopping versus moving the car). A stimulus in the presence of which a particular response is reinforced is an S^D (pronounced S-dee) or $S+$; a stimulus in the presence of which a particular response is not reinforced is an S^A (pronounced S-delta) or $S-$. Stimulus generalization occurs when a response is more likely in the presence of other, usually similar, stimuli; stimulus discrimination occurs when the response is less likely in the presence of other, usually dissimilar, stimuli. For instance, a dolphin reinforced with a fish for jumping over a red rope might also jump over a blue, yellow, or green rope, but not over a thick ribbon of any color. Which dimensions of a stimulus control

behavior depends on the history of reinforcement in the presence of these dimensions (e.g., a whale that is never reinforced for splashing people in the pool, but is routinely reinforced for splashing people outside of the pool), evolutionary biases (e.g., a falcon is more likely to associate the sight than sound of a rodent with food), perceptual capabilities (e.g., a bass that is more likely to strike at silvery shad than reddish crayfish in murky water), and the like.

Operant–Pavlovian Interactions

Although habituation, operant conditioning, and Pavlovian conditioning are often discussed separately, the three procedures are almost always involved in varying proportions in learned behavior. For example, in most Pavlovian conditioning situations, the neutral stimulus usually elicits a response that undergoes habituation as this stimulus is increasingly paired with a US.

Some of the clearest examples of operant–Pavlovian interactions involve situations where people and animals avoid aversive events. A man who is afraid to speak in public will not wait to see how his audience reacts; on being asked to give a speech, he will decline the request or make an excuse. A woman who fears that an elevator she rides aboard might crash will not ride the elevator to see what will happen; she will use the stairs instead. A gang member hears gunshots and ducks for cover. In these examples, being asked to give a speech, the sight of the elevator, and the sound of gunfire predict possible aversive outcomes (e.g., an unresponsive audience, a crashing elevator, being shot) unless an avoidance response occurs (e.g., declining to give a speech, taking the stairs, diving to the ground). In these circumstances, there is a Pavlovian and an operant component that controls behavior. The Pavlovian component is the relationship between a signal and an aversive event. The operant component is the response–consequence relationship involving the avoidance response and the consequent absence of the aversive event. If someone makes a particular response during the signal that predicts the aversive event, then this event will not occur and the avoidance response is negatively reinforced.

It is worth noting that, for many people, the aversive event does not have to be probable, only possible. The probability that an elevator will crash is low. Despite this, modifying avoidance behavior is difficult. In the example of the woman who is afraid to ride in elevators, it is unlikely that this fear will disappear because she will never sample the real contingencies of safely riding in an elevator. The fear elicited by the CS (sight of the elevator) causes her to make a response (climbing the stairs) that prevents her from discovering that her fear (an elevator she rides aboard will crash) is unrealistic. To eliminate avoidance behavior related to unrealistic anxiety or fear,

people must first be exposed to the fear-eliciting stimulus and prevented from making the avoidance response.

Bentham, Jeremy

Gilbert Geis

University of California, Irvine, Irvine, California, USA

Glossary

felicity calculus The process by which the balance of pleasures and pains is measured; sometimes called hedonistic or hedonic calculus.

happiness For Bentham, a state measured in terms of whether an action adds to an individual's pleasure or diminishes the sum total of his or her pain. The term is generally used by Bentham to refer to the aggregate of a person's pleasures over pains.

paraphrasis Bentham's coined term for the process of demystifying words such as "liberty," by breaking them down into their constituent elements. If such a definitional breakdown is not possible, it demonstrates that the term is a "fiction," unrelated to any real thing.

pleasure and pain Bentham maintains that "nature has placed mankind under the governance of two sovereign masters, pleasure and pain." The difference between happiness and pleasure lies in the fact that the former "is not susceptible of division, but pleasure is."

utility For Bentham, the principle of utility approves or disapproves of every action whatsoever according to its tendency to augment or diminish the happiness of the party whose interest is in question.

Jeremy Bentham (1748–1832) is generally regarded as the founder of the utilitarian school, an approach still vibrant in economic and philosophical thought. Bentham was the first thinker to provide a barrage of information as well as insights and analyses that sought to make utilitarian thought approximate as closely as possible the mathematical exactitude of natural science scholarship as well as its classificatory sophistication. Bentham applied his principle of utility to ethical, legal, and constitutional issues, but, as Tom Warke observes, only after more than a century of adaptation did it become the

dominant explanation within economic theory for consumer behavior and the basis for contemporary rational choice theory.

Biographical Notes

Jeremy Bentham was an eccentric, reclusive intellectual who spent the better part of his life writing tracts that sought to enlighten his fellow humans about the paths of proper thought and persuading persons with power to support the kinds of programs he believed would improve the human condition. The son and grandson of successful London lawyers, Bentham was an exceptionally precocious child. He became a boarder at the fashionable Westminster School at the age of 7 years and enrolled at Queen's College, Oxford University, when he was not yet 13. He later studied law and clerked at Lincoln's Inn, developing a deep disdain for both lawyers and lawyering, regarding the latter as a pursuit built on fictions and marked by the use of terms and concepts that only initiates could comprehend, all this being so in order to enrich practitioners and keep laymen from knowing what was going on. "Lawyers feed upon untruth, as Turks feed upon opium," was one of Bentham's caustic jabs. On his father's death in 1792, Bentham inherited a sizable fortune, realized from property investments, that allowed him the leisure to spend his days putting together a monumental outpouring of ideas that reflected his utilitarian views.

Bentham wrote tirelessly for all his adult life. James Steintrager insists that to read all that Bentham wrote would take a lifetime longer than Bentham's 84 years. Besides, Bentham's prose at times can be virtually impenetrable. The essayist William Hazlitt sarcastically observed that "his works have been translated into French—they ought to be translated into English."

Bentham's Utilitarianism

Of Pleasures and Pains

Jeremy Bentham is regarded as the father of the utilitarian school of thought that seeks to analyze human and social actions in terms of their consequences for well being. Many writers before Bentham had employed the term and some of the ideas of utilitarianism, but in a much looser sense than Bentham proposed. Bentham advocated that human action and public policy should seek to create “the greatest happiness for the greatest number.” This concept, as Robert Shackleton’s adroit detective work has demonstrated, was taken verbatim from Cesare Beccaria’s *Dei delitti e delle pene* (1764; translated into English as *An Essay on Crimes and Punishments*). Later, Bentham would truncate the goal to “the greatest happiness,” a move Mary Mack regards as mere definitional “housekeeping,” though it more likely was prompted by Bentham’s recognition that, from a mathematical perspective, the original definition contained one too many “greatests.” Bentham finally settled on the term “the felicity maximizing principle” to describe the ideal that characterized his recommendations. Bentham also was deeply concerned not to ignore the needs of persons in the minority. This is reflected in his system of weighting, in which everyone was to count for one and no one for more than one. In modern economic welfare theory, this equal weighting defines a utilitarian principle as being specifically “Benthamite.”

For Bentham, the wellsprings of human behavior reside totally in attempts to gain pleasure and to avoid pain. He maintained that “men calculate [pleasure and pain], some with less exactness, indeed, some with more; but all men calculate. And all humans voluntarily act in regard to their personal pleasure.” It is difficult, Bentham granted, to prove enjoyment in the case of, say, a Japanese man who commits *hari kari*; but, nonetheless, the pursuit of pleasure was his goal. Bentham believed that self-interest, if enlightened, would produce socially desirable results, though he was aware that individuals at times fail to appreciate what will bring them pleasure rather than pain, in part because they cannot adequately anticipate the future.

For Bentham, present and future consequences of actions could be estimated in terms of seven considerations: (1) intensity, (2) duration, (3) certainty, (4) propinquity, (5) fecundity, (6) purity, and (7) extent, this last referring to the number of individuals affected. Bentham conceded that intensity was not measurable, but maintained that the other outcomes might be calibrated. Pleasures and pains were of various kinds, 13 of which Bentham, an inveterate maker of lists that sought to embrace comprehensively all possible ramifications of a subject, spelled out: (1) pleasures and pains of sense, (2) pleasures of wealth, with the corresponding pains of deprivation, (3) pleasures of skill and

pains of awkwardness, (4) pleasures of amity and pains of enmity, (5) pleasures of good reputation and pains of ill-repute, (6) pleasures of power, (7) pleasures of piety, (8) pleasures and pains of sympathy and benevolence, (9) pleasures and pains of malevolence, (10) pleasures and pains of memory, (11) pleasures and pains of imagination, (12) pleasures and pains of expectation, and (13) pleasures and pains of association.

Bentham’s aim was to teach moral agents (that is, humans) a proper arithmetic, to lay before them a satisfactory estimate of pain and pleasure—“a budget of receipt and disbursement, out of every operation of which [they are] to draw a balance of good.” Vice then would be a miscalculation of pleasures and pains. Thus, “there are few moral questions which may not be resolved with an accuracy and a certainty not far removed from mathematical demonstration.”

The Legislator's Task

It becomes the duty of legislators to create conditions that offer the widest potential for the personal pursuit of pleasure, so long as that pursuit does not interfere with a similar mission by others. The legislator also was to remove circumstances that would create conflicts in self-interested pursuits. Those legislating must take a scientific view of all human endeavor. Legislation was to be judged in terms of its impact on four conditions related to pleasure and pain: (1) security, (2) subsistence, (3) abundance, and (4) equality. Bentham granted that “this division has not all the exactness which might be desired” because “the limits which separate these objectives are not always easy to be determined.”

A difficulty that increasingly bedeviled Bentham’s blueprint concerned the question of how to reconcile the self-interest, that is, the quest for their own happiness, of those in power with his demand that they govern so as to ensure the greatest happiness of their subjects. During the latter part of his life, Bentham began to advocate widespread popular democracy so that people could seek to maximize their happiness by selecting leaders who would help them in this quest. His hope was to educate and train the citizens so that they would be better able to determine which leaders would act to increase constituent happiness.

Critiques of Bentham

Bentham’s appeal was to rational argument and to what James E. Crimmins calls “consequentialist calculation.” His aim was “to extend the physical branch [of science] to the moral,” but it must be stressed that he was well aware that his measuring formula inevitably would provide an inexact answer: his was a roadmap without any precise

mileage measurements. As Mack indicates, “the truth is that Bentham did not offer a systematic theory of ethics based on exact calculation, but a series of prudential rules . . . based on a new vocabulary and a new logic.”

A Bentham scholar has pointed out that only a single dimension can be employed to measure utility as Bentham defined it because, as Warke notes, “no unique and continuous ordering exists for a multi-dimensional entity except in trivial cases where all dimensions save one remain constant or where all dimensions vary in the same proportion.” Bentham’s utility construct was irreducibly multidimensional, with a distinct dimension for each type of pleasure and pain. Warke further points out that faced with two outcomes, a person is likely to have a continuum of responses because preference sets tend to be fuzzy and agents often dither. Therefore, mathematical precision is likely to be elusive, if not impossible to attain: Bentham’s tactics were of necessity coarse-grained; he was interested in “approximation” and in the way that the “preponderance” (two words Bentham much favored) of evidence tilted rather than in exactitude. Utility, as Mack maintains, represents in Bentham’s work not a formula but an attitude.

Bentham’s concept of happiness was a blunt measuring instrument. He recognized this in an early example:

Call the species of misery produced by any one action in a single person, x [say, a threat of injury], and that produced by another, y [say, loss of property]. Now whether x or y be the greater, is a matter of conjecture and opinion, but that x + y is greater than either x or y alone, is a matter of demonstration In this manner it is a matter of demonstration that Robbery is worse than Theft [since it includes both x and y while Theft includes only y].

Bentham granted that more finite distinctions were out of the question and that it was only the first principles of mathematics that have anything to do with such a calculation. Therefore, whereas it is possible to rank order robbery and theft for a given loss of property, it is problematic to rank order a \$100 petty theft and a \$20 armed robbery.

John Plamenatz (1958) sagely notes that Bentham “often talks as if he were advising legislators and judges how to make calculations which it is plainly impossible to make. But all the misleading language can be ignored,” Plamenatz adds, “and Bentham’s rules can be treated as if they were rules for making possible calculations. Once this is done it is easy to see how much is really valuable.”

Further Utilitarian Considerations

Motives, Punishment, and Paraphrasis

For Bentham, the motives (or “springs of action,” as he labeled them) for human behavior were beside the point.

There is no such thing for him as a bad motive; it is only the consequences, the pain and the pleasure created, that are significant. A man may want to eat. To satisfy his hunger he can go to a restaurant, get food at home, or steal: the motive remains the same, the behavior and its consequences are quite different.

Punishments were to be established to convince real and potential wrongdoers—that is, those who pursue pleasures by means such as stealing, acts that produce pain for others—to choose more positive paths. But the punishments should be only of such magnitude as to achieve satisfactory deterrence; harsher inflictions add an unacceptable dosage to individual and possibly to social pain. As Bentham expressed the matter, “never use a preventive means of a nature to do more evil than the offense to be prevented.”

Bentham urged analysts to engage in what he called paraphrasis, that is, to tie real meanings to words that represent unanchored ideas, terms such as “natural law,” “justice,” “power,” “duty,” and “liberty.” In Bentham’s work, an act, once its ingredients are clearly defined, meets the standard of utility “if it tends to produce benefit, advantage, good or happiness (all this in the present case comes to the same thing) or (which again comes to the same thing) to prevent the happening of mischief, pain, evil or unhappiness to the party whose interest is considered.”

Felicity Calculus

To measure the “goodness” or “badness” of an act, Bentham introduces the pseudomathematical concept of what he calls felicity calculus. Bentham offers the following vignette to illustrate how a situation might be looked at:

[I]f having a crown in my pocket and not being thirsty, I hesitate whether I should buy a bottle of claret with it for my own drinking or lay it out in providing sustenance for a family . . . it is plain that so long as I continued hesitating the two pleasures of sensuality in the one case, of sympathy in the other, were exactly . . . equal.

The illustration, however, is not as straightforward as Bentham indicates, because it involves determination of the “goodness” of family considerations in contrast to that of claret. And the matter becomes a great deal more complicated if the need is to predict, as social scientists attempt to do, which of the two alternatives any given individual will adopt or, for that matter, which alternative a person will choose each time the same choice is presented.

And how are 5 minutes of exquisite pleasure to be measured against 10 minutes of routine pain? For Bentham, pains carried greater weight than did pleasures on the scale of values, and the miseries of loss outweighed those of acquisition. Despite such evaluative hurdles, Bentham

pressed onward, as a further illustration demonstrates: writing about heavy gambling, he pointed out that if a person has 1000 pounds and the stake is 500, the odds are always unfavorable in regard to pleasure, even if the game is fair, because if the gambler loses, his fortune is diminished by one-half, whereas winning increases it only by a third. Besides, Bentham notes that when sums and circumstances are equal, the enjoyment produced by gain is never equal to the suffering produced by loss.

Bentham also appreciated that wealth could not be equated systematically with degrees of happiness, as the following illustration shows:

Put on one side a thousand farmers, having enough to live upon, and a little more. Put on the other side . . . a prince . . . , himself as rich as all the farmers taken together. It is probable, I say, that his happiness is greater than the average happiness of the thousand farmers; but it is by no means probable that it is equal to the sum total of their happiness, or, what amounts to the same thing, a thousand times greater than the average happiness of one of them. It would be remarkable if the happiness were ten times, or even five times greater.

The problem of assigning satisfactory weights to different pleasures (any one of which will also vary for different persons) was overwhelming: all Bentham really asked was that responsible people ought to take the utilitarian approach as a valuable tool for directing and evaluating behaviors and public policies.

John Stuart Mill, a Bentham disciple with ambivalent views about his mentor, put the matter particularly well: "He [Bentham] introduced into morals and politics those habits of thoughts and modes of investigation, which are essential to the idea of science; and the absence of which made those departments of inquiry, as physics had been before Bacon, a field of interminable discussion, leading to no result. It was . . . his 'method' that constituted the novelty and the value of what he did, a value beyond all price . . ." (Mill, 1769/1838).

The issue of slavery offers a good example of Benthamite thought. Having slaves might create a good deal of happiness in those who possess them and a good deal of wretchedness in those who are enslaved. But rather than attempting to measure these consequences, Bentham points out that he knows of nobody who would voluntarily prefer to be a slave; therefore, it is apparent that the unattractiveness of the status and the pain associated with it overwhelm any advantage slavery might offer to those who benefit from it.

Bentham's felicity calculus, given his dogged analytical attempts to pin down all possible consequences of an action, usually is up to the task of differentiating what most of us would consider the "good" from the "bad," or "pleasure" from "pain." He offers, for instance, a situation of an employee of a medical research center

who grabs off the street almost at random a person whose body parts are to be used to save the lives of those in need of such reinforcements. A superficial utilitarian conclusion might be that the act is commendable because, though it inflicts devastating pain on a single victim, it produces great pleasure in a number of persons whose well being is saved or improved by the transplants. But Bentham points out that the alarm created among the citizenry, that any of them might be the next person snatched off the streets by the medical team, is so painful that the act clearly falls beyond the pale of utilitarian approval. Bentham's examples often are reasonable enough, but they do not go very far toward persuading a reader that what he proposes can truly be applied to measure complex psychological phenomena mathematically. Here is another Bentham's illustration:

You tell me that St. Paul's is bigger than the Pantheon. I agree with you that it is so. This agreement does not hinder our ideas of the proportion of those two bodies from being very different. You may think St. Paul's ten times as big as the other building. I may think it not more than half as big again.

The disagreement, Bentham observes, can readily be settled by obtaining a measuring stick, the accuracy of which both parties concede. The same process, Bentham maintains, can be carried out in regard to disagreements about happiness. But he never truly found an adequate measuring rod. At one point, in fact, in a not uncharacteristic manner, Bentham observed that the single honk of a goose some thousands of years earlier undoubtedly has influenced many aspects of contemporary life, and he sought to enumerate some of these consequences. His was an indefatigable pursuit of a detailed inventory of the consequences of events and actions, so that all of us could be better informed and thereby persuaded to make wiser choices.

Money as a Measure of Pleasure

Money became for Bentham one of the more readily measurable items in his felicity calculus, because its possession strongly correlates with happiness. He was well aware of what later came to be called the Law of Diminishing Marginal Utility, that is, that the more wealth an individual possesses the less total happiness an increment is likely to bring. A multimillionaire would hardly be moved greatly by the addition of \$100,000 to his fortune, but a poor person undoubtedly would derive great pleasure obtaining this amount of money. Though Bentham might not be able to calculate precisely the quantities of pleasure involved in such a situation, he was able to use it to advocate public policies favoring more equitable distribution of wealth, basing his advocacy on utilitarian principles.

Conclusion

In a long life dedicated to interminable written analyses and exhortations, Bentham attempted to translate his premises regarding happiness into formulas that offered an opportunity to determine pain and pleasure. He inevitably failed by a wide margin to approximate exactitude in a mathematical sense. Nonetheless, relying on utilitarian doctrine and formulas, Bentham had remarkable success in bringing about significant number of political reforms, particularly in criminal law and in regard to the punishment of offenders. He typically did so by specifying with striking perceptiveness and in excruciating detail the consequences of the old ways and the advantages of his recommendations for creating a fairer and a happier society. In addition, Bentham's utilitarianism, scoffed at and caricatured for decades, later regained favor in the social sciences, particularly in economics, and today forms the intellectual skeleton that is being fleshed out by sophisticated analytical and empirical formulations.

Auto-Icon

Bentham's skeleton, stuffed with padding to fill it out, and seated in his favorite chair and dressed in his own clothes, is displayed in the South Cloister at University College, University of London. His head did not preserve well, so a wax replica sits atop the body (see Fig. 1). He requested in his will that his body be so preserved, but only after it furnished final utility for medical science by means of a public dissection.

A Bibliographic Note

Bentham produced a torrent of written material, much of it still unpublished. His method of work was highly disorganized. As Shackleton notes, "drafts succeeded drafts, abridgments and expansions followed each other, manuscripts were often dismantled and physically incorporated in others." Bentham's correspondence alone now occupies 11 large volumes that have been published as part of a project to move all of his manuscript material into print. Three more volumes are in process, with a possible fourth to include material that has come to light since the project began. Bentham characteristically enlisted aides to edit his material and they often took considerable liberties reorganizing and rewriting what they regarded as a sometimes impenetrable thicket of words. The best guide to the quality and reliability of Bentham's work is provided by Ross Harrison in *Bentham* (pages ix–xxiv).

The Bentham Project, housed at University College, University of London, offers a website (available at <http://www.ucl.ac.uk>) with up-to-date information on the

progress being made toward shepherding into print all of Bentham's works. The project, described by Gertrude Himmelfarb as perhaps the most ambitious publishing venture of its kind ever to be undertaken in England, is contemplated to result in at least 38 volumes. In addition, Bhikhu Parekh has edited four volumes that reprint 143 of the most important assessments of Bentham's work. Volume II is made up of pieces that focus on Bentham's ideas regarding measurement.

Glossary

Bernoulli's measure of probability A measure of probability derived from the transformation of Huygens's value of expectation into a quantifiable concept. There are two ways of determining this measure of probability: (1) (*a priori*) for an equipossibility of the outcomes of a finite number of mutually exclusive elementary events, such as drawing a ball of a certain color out of an urn filled with balls of different colors, by the ratio of the number of cases favorable for the event to the total number of cases; (2) (*a posteriori*) for events such as a person of known age's dying after 5 years, by the relative frequency of "the frequently observed event in similar examples."

law of large numbers The theorem that the estimates of unknown probabilities of events based on observed relative frequencies of such events become the more reliable the more observations are made (also called Bernoulli's golden theorem). More precisely, Bernoulli proved that the relative frequency h_n of an event with probability p in n independent trials converges in probability to p or that for any given small positive number ε and any given large natural number c , for sufficiently large n , the inequality:

$$\frac{P(|h_n - p| \leq \varepsilon)}{P(|h_n - p| > \varepsilon)} > c$$

holds, which is equivalent to $P(|h_n - p| \leq \varepsilon) > 1 - 1/c + 1$.

mortality The quantification of human mortality.

probability The degree of certainty based either on belief depending on testimony or on evidence derived from the frequency of occurrence of an event. This is a change from earlier ideas held by Aristotle and his followers that probability was what was common opinion of most or of the majority of the best informed or what would happen "in most cases." Bernoulli's concept of probability, degree of certainty, showed at the same time subjective or epistemic and frequentist or aleatory aspects.

value of expectation According to Huygens, the payoff table in a game with a finite number of outcomes. The value of an

expectation is determined the weighted average of the payoffs in terms of money.

Jakob Bernoulli (1655–1705), one of the leading mathematicians of his time with important contributions to infinitesimal calculus, is the father of a mathematical theory of probability. His posthumously published *Ars Conjectandi* influenced the development of probability theory in the 18th century up to Laplace. The basic concept in Bernoulli's art of conjecturing became probability, the classical measure of which he had derived from a transformation of Huygens' value of expectation. *Ars Conjectandi* should be applied to what we call now the social domain and what Bernoulli described as the domain of civil, moral, and economic affairs. Bernoulli distinguishes two ways of determining, exactly or approximately, the classical measure of probability. The first, called *a priori* presupposes the equipossibility of the outcomes of certain elementary events and allows us to relate the number of cases favorable for an event to all possible cases. The second, called *a posteriori*, is for the determination of the probability of an event for which there are no equipossible cases that we can count (e.g., mortality). For these cases, we can inductively, by experiments, get as close as we desire to the true measure the probability by estimating it by the relative frequency of the outcome of this event in a series of supposedly independent trials. This he justifies by his *theorem aureum*, which was called later by Poisson Bernoulli's law of large numbers.

The Role of Jakob Bernoulli in the Development of a Mathematical Probability Theory and Statistics

Jakob Bernoulli brought together in his work culminating in the *Ars Conjectandi* two hitherto largely separated

domains: the calculus of games of chance as codified by Christiaan Huygens in his tract *De Ratiociniis in Ludo Aleae* and the domain of application of the word “probability” as used in the language of everyday life. By this he created a new mathematical subject that he called the “art of conjecturing” and that in the hands of his successors became the calculus or the mathematical theory of probability. The central idea in Bernoulli’s art of conjecturing was the transformation of Huygens’s concept of expectation into a quantifiable concept of probability applicable to what we call now the social domain and what Bernoulli described as the domain of civil, moral, and economic affairs. Bernoulli tried to justify the application of his concept of probability to the social domain by using his principal theorem, later called the law of large numbers. The problem of how to gain reliable estimates for unknown probabilities from a finite set of data became a main concern of mathematical statistics, which originated only with the biometric activities of Francis Galton in the 19th century.

Jakob Bernoulli’s Scientific Career

Jakob Bernoulli, born in 1655 in Basel, came from a family of merchants. His father, Nikolaus Bernoulli, took over the drug business from his father and became a member of the town council in Basel. Jakob Bernoulli and later members of the Bernoulli family became the most prominent family in the history of mathematics, producing four generations of outstanding mathematicians.

After finishing a master’s degree in 1671, Jakob Bernoulli studied theology until 1676, when he received the licentiate in theology; at the same time he studied mathematics and astronomy secretly, against his father’s will. After 1676, he left Basel to work as a tutor for 4 years, which he spent in Geneva and France. In France and during a second journey in 1681 and 1682 to the Netherlands, England, and Germany, he became a Cartesian. During his second journey he also met the mathematicians Jan Hudde, John Wallis, and Isaac Barrow and natural philosophers such as Robert Boyle, Robert Hooke, and John Flamsteed. His first publication (1681) dealt with comets, based on his observations of the comet of 1680. He predicted the reappearance of this comet in the year 1719 and stated that comets belong to the solar system and reappear after a certain period.

After his return to Basel he began to give private lectures, especially on the mechanics of solid and liquid bodies. He read the mathematical works of Wallis and Barrow and the second Latin edition of Descartes’s *Géométrie* with the commentaries by Frans van Schooten and his students. He became interested in problems concerning algebra and infinitesimal analysis. In 1684 Leibniz published in the *Acta Eruditorum* (founded in

1682) a short presentation of differential calculus in algorithmic form, and in 1686 he published some remarks concerning the fundamental ideas of integral calculus. These papers occupied the interest of Jakob Bernoulli and his younger brother Johann (1667–1748). Jakob tried to get further information from Leibniz in 1687, but Leibniz could answer Bernoulli’s questions only 3 years later because of a diplomatic mission he had to undertake. At that time, Jakob and Johann had not only mastered the Leibnizian calculus, but also had added so considerably to it that Leibniz in a letter of 1694 remarked that infinitesimal calculus owed as much to the Bernoulli brothers as to himself. Jakob cultivated the theory of infinite series on the basis of preliminary work done by Nikolaus Mercator, James Gregory, Newton, and Leibniz. He published five dissertations on series between 1689 and 1704. He considered series to be the universal means to integrate arbitrary functions, to square and rectify curves. In 1690, Jakob had introduced the term “integral” in his solution to the problem of determining the curve of constant descent.

In the 1690s, the relationship between Jakob and Johann deteriorated and led to bitter quarrels. In 1687, Jakob had become professor of mathematics at the University of Basel, in which position he remained until his death in 1705. He was honored by the memberships of the Academies of Sciences in Paris (1699) and in Berlin (1701). He had a daughter and a son from Judith Stupan, whom he had married in 1684.

Early Work on Problems of Games of Chance and Mortality

Jakob Bernoulli’s interest in stochastics began in the 1680s. His first publication on the calculus of chance dates from 1685. The development of Bernoulli’s ideas leading to his art of conjecturing can be traced, at least in part, in the *Meditationes*, his scientific diary that he began in 1677. In it we can distinguish three periods in which Bernoulli worked on problems concerning games of chance and probability: (1) 1684–1687, in which he was engaged in the solution of problems of games of chance; (2) in which he extended the methods for the solution of games of chance to the solution of problems concerning decisions in everyday life; and (3) approximately 1687–1689, in which he was concerned with the proof of his main theorem, the law of large numbers.

In the first period Jakob Bernoulli began with the solution of the five problems Huygens had proposed to his readers at the end of his tract *De Ratiociniis in Ludo Aleae* from 1657.

In the second period, crucial for Bernoulli’s transformation of Huygens’s concept of expectation to a quantifiable concept of probability was the juridical problem of

a marriage contract, on which Bernoulli worked in 1685–1686. Bernoulli was concerned with a passage of the contract proposed by the groom in which it was assumed that the couple would be blessed with children and that the wife, Caja, would die before her husband, Titius, and the children; in this situation the passage governs the division of the couple's common property between the father and the children. A distinction is made among the possibilities that neither, one, or both of the fathers of the bridal couple, who were alive at the time of the conclusion of the contract, die and leave their heritage to their children. Only property that had become the common property of the couple was to be regulated, and so such distinctions needed to be drawn. The portion of the groom would be larger if he had already entered into his inheritance and smaller if not, unless both fathers die. The bride's father objected to Titius's initial proposal; this induced Titius to make a second proposal, according to which he would receive the same portion of the common property regardless of what happened to the fathers.

Here Bernoulli posed the question: Which suggestion would be more favorable for the children? To this end he had to make assumptions about the possible order of death of the three people involved, the two fathers and the bride. He first assumed that all six possible orders have equal weight. But this assumption did not satisfy him because the youth of the bride had not been taken into account. Thus, he assumes that for every two instances (e.g., diseases, symptoms, or events) that might bring about the death of either father, there is only one that would threaten Caja with death. There are thus five cases in all, each equally likely to take its victim first. Because Caja would be affected by only one of these, whereas the two fathers would be affected by four, her situation is evaluated as one-fifth of certainty of her being first to die, that is, "one probability, five of which make the entire certainty."

Here Bernoulli used the plural "probabilities," where these are equated with the no more precisely distinguished individual cases; this use does not permit the conception of probability as "degree of certainty," which is observed in the next stage. Aided by Huygens's formula for determining expectation, Bernoulli then derived a certainty of $4/15$, written $4/15c$ (where c stands for *certitudo*), or 4 probabilities out of 15 that Caja would die second and finally $8/15c$ that she would die third. Bernoulli first generalized this approach to the problem and added two different models that he employed to weigh the various orders of death. In the second model, the chances of Caja dying in first, second, and third place were 2:5:11; in the third, they were 4:8:12. So each model gave different chances for Caja to survive none, one, or both fathers.

Therefore, at the end of his treatment of the marriage contract between Titius and Caja Bernoulli proposed

extensive investigations into human mortality. Here he introduced the concept of a quantifiable probability with a view to making probability the main concept of the calculus of chance, extended to what we call now the social domain:

This we have to understand generally in civil and moral affairs, in which we of course know that one thing is more probable, better or more advisable than another; but by what degree of probability or goodness they exceed others we determine only according to probability, not exactly. The surest way of estimating probabilities in these cases is not a priori, that is by cause, but a posteriori, that is, from the frequently observed event in similar examples.

A series of further problems underline this procedure for estimating probabilities *a posteriori*, in Bernoulli's sense of taking the average of frequently observed data as in the prediction of the number of births and deaths in a certain city in the next year or the appearance of the next epidemic. Bernoulli even wanted to determine a man's reliability from the number of times he told the truth or lied or the outcome of *jeu de paume*, a predecessor of lawn tennis, depending on estimates of the skills of the players involved. On the same basis, Bernoulli tried to solve other problems, such as whether to accept an offer for 80 bottles of light wine. In all these cases, we can find marginal notes indicating that the estimates are more reliable if based on more observations.

Bernoulli carried out the determination of probabilities *a posteriori* by adopting relative frequencies determined through observation as estimates of probabilities that could not be given *a priori*. He felt justified in proceeding in this form because of his main theorem, which at the same time served as the essential foundation of his program to extend the realm of application of numerically determinable probabilities.

In a preliminary version of the theorem, Bernoulli tried to show by induction that in a game with equal chances of winning or losing, as in the toss of a coin, the probabilities of winning more often than $2n$ times in $3n$ trials is not greater than:

$$\frac{1}{8} \left(\frac{7}{8} \right)^n$$

which tends to become smaller than any assignable small quantity for increasing n . So the probability of winning more often than $2n$ times in $3n$ trials and for reasons of symmetry the probability of winning less often than n times in $3n$ trials approaches 0 with increasing n . Accordingly, the probability of winning a number of times between n and $2n$ in $3n$ trials approaches 1 with increasing n .

After the treatment of the special case of equal chances winning or losing, Bernoulli proved in the *Meditationes* generally the equivalent of the following proposition: It is

possible to make so many observations that it becomes arbitrarily much more probable that the ratio of the number of games that are won by one or the other player falls between any given narrow limits around the expected value than outside. At the end of his proof Bernoulli remarked that he valued this proposition higher than the quadrature of the circle, which even when found would be of little use.

Correspondence with Leibniz Concerning the Art of Conjecturing

Johann Bernoulli had informed Leibniz in a letter dated February 16, 1697, that his brother Jakob had been busy for many years on a work that he called art of conjecturing, that would not only treat mathematically all kinds of games but also subject to calculus probabilities in all situations of daily life. However, Johann did not know in 1697 whether Jakob was still working on the manuscript or had given up this task. Leibniz himself had developed similar ideas independently of Jakob Bernoulli. He was interested in the creation of a doctrine or a logic of degrees of probabilities motivated by the hope of quantifying things such as conditional rights. In contrast to Jakob Bernoulli, Leibniz never worked out his ideas in this field. He left only a series of partly redundant drafts and manuscripts, but no publication offering an outline of the new doctrine. He had hoped that somebody, preferably a mathematician, would indulge in the creation of this new theory of probability.

Presumably because of the many projects he was involved in, his numerous obligations, and his enormous correspondence, Leibniz took up Johann Bernoulli's information only 6 years later, when he asked Jakob Bernoulli in a letter of April 1703 to inform him about his activities concerning a theory of probability estimates. Jakob Bernoulli answered in a letter dated October 3, 1703, that he had nearly finished a book dealing with estimates of probabilities, but that it still lacked the most important part: the application to the social domain. However, he had already solved the crucial problem for such an application 12 years before; he then described his main theorem, the law of large numbers, according to which the estimates of unknown probabilities of events based on observed relative frequencies of such events become more reliable the more observations are made.

To Bernoulli's astonishment Leibniz reacted very critically. Instead of the possibility of attaining a better approximation to a sought after probability with an increasing number of observations, Leibniz suggested that the probability of contingent events, by him identified

with dependence on infinitely many conditions, could not be determined by a finite number of observations. The path of a celestial body such as a comet could be determined by a finite number of observations only if we assumed that the path is a conic; otherwise infinitely many different curves could fit the finite number of observed positions of the moving body. This infinity of different curves would correspond to infinitely many estimates of probability in the same way as the finite number of observed positions would correspond to a finite number of observed outcomes of the event. In addition, the appearance of new circumstances could change the probability of an event; so the appearance of new diseases would diminish the probability of survival of a person of a certain age.

In his answer, Bernoulli attempted to clarify his main theorem, using the example of an urn containing white and black stones in the ratio of 2:1. In this example, Bernoulli claimed to be able to determine exactly the number of draws (with replacement) for which it would be 10 times, 100 times, 1000 times, and so on more probable that the ratio of white to black stones found by drawing would fall inside rather than outside a given interval about the true value, for example (199/100, 201/100). Although Bernoulli could only prove this assertion for probabilities *a priori*, as in the urn model, he was convinced that he had also shown with his main theorem the solubility of the reverse problem, namely, the determination of unknown, *a posteriori* probabilities. This conclusion becomes understandable through Bernoulli's belief that it would make no difference for the behavior of the observed ratio whether the person drawing the stones knew the true ratio or not. The possibility that two urns containing different ratios of white to black stones would yield the same ratio for an equal number of draws, appeared conceivable to Bernoulli only for a small number of draws; for a large number, such a result would be excluded by the "moral certainty" secured through the main theorem. In this way, Bernoulli saw no problem with applying the urn model to human mortality, with the stones corresponding to diseases with which a person could be taken ill, and so to approach by a finite number of observations the probability of dying within a certain period as close to the true value as practice affords.

Bernoulli knew of Leibniz's activities in the field and hoped that Leibniz could provide him with material relevant for the application of *a posteriori*-determined probabilities, as in certain areas of jurisprudence, or with appropriate data. Bernoulli had read of the *Waerdye*, an assessment of Jan de Witt, raadspensionaris of Holland, in which the advantage of buying and selling life annuities was determined on the basis of hypotheses about life expectations at different ages. Because Leibniz was one of the few who owned a copy of the *Waerdye*, Bernoulli

asked him to send him his copy for a while. In his following letters, Leibniz disappointed Bernoulli, claiming to be unable to find the *Waerdye* or relevant papers of his own. Instead he declared that in the area of jurisprudence and politics, which seemed so important for Bernoulli's program, no such extended calculations were usually required because an enumeration of the relevant conditions would suffice. In his last letter to Bernoulli, of April 1705, Leibniz explained that the *Waerdye* contained nothing Bernoulli could not find in Pascal's *Triangle Arithmétique* or in Huygens' *De Rationciniis in Ludo Aleae*, namely to take the arithmetical mean between equally uncertain things as is done by farmers or revenue officers when estimating the value of real estate or the average income. Bernoulli, who died the following August, seemed to have ignored Leibniz's hint about Pascal's *Triangle Arithmétique*, which was not mentioned in the *Ars Conjectandi*. Astoundingly, Leibniz did not mention Edmund Halley's work on human mortality in the *Philosophical Transactions*, which was based on data from the city of Breslau that Leibniz had helped to make available to the Royal Society. The only relevant work Bernoulli mentioned in his manuscripts was John Graunt's *Natural and Political Observations* from 1662, a German translation of which appeared in 1702. However, Bernoulli took Leibniz's objections, especially those against the significance of his law of large numbers, as representative of a critical reader and tried to refute them in Part IV of the *Ars Conjectandi*.

The *Ars Conjectandi*

According to his brother's and his own statements Jakob Bernoulli had begun work on the manuscript of the *Ars Conjectandi* in the 1690s and had resumed work after some interruptions in the last 2 years of his life. When he died in 1705, the book was not finished, especially lacking good examples for the applications of his art of conjecturing to civil and moral affairs. Opinions about the time it would have needed to complete it differ from a few weeks to quite a few years, depending on assumptions about Bernoulli's own understanding of completeness. Jakob Bernoulli's heirs did not want Johann Bernoulli, the leading mathematician in Europe at this time, to complete and edit the manuscript, fearing that Johann would exploit his brother's work. Only after Pierre Rémond de Montmort, himself a pioneer of the theory of probability, offered to print the manuscript at his own expense in 1709 and after some admonitions that the *Ars Conjectandi*, if not published soon, would become obsolete did Bernoulli's son, a painter, agree to have the unaltered manuscript printed. It appeared in August 1713 together with a letter in French on the *jeu de paume* and a short preface by Nikolaus Bernoulli, Jakob's nephew. Nikolaus, who had read the manuscript when his uncle

was still alive, had made considerable use of it in his thesis of 1709 and in his correspondence with Montmort. However, when asked to complete the manuscript, he declared himself to be too inexperienced.

The *Ars Conjectandi* consists of four parts. The first is a reprint of Huygens's *De Rationciniis in Ludo Aleae*, which was published as an appendix to van Schooten's *Exercitationes Mathematicae* in 1657. Jakob Bernoulli complemented this reprint with extensive annotations that contain important modifications and generalizations. For example, in his annotations to Huygens's proposition IV, Jakob Bernoulli generalized Huygens's concept of expectation. Huygens had introduced this concept in this form:

that in gambling the expectation or share that somebody can claim for something is to be estimated as much as that with which, having it, he can arrive at the same expectation or share in a fair game.

It is clear that this expectation, like the shares, is measured in terms of money. Bernoulli wanted to extend the meaning of share to include "some kind of prize, laurels, victory, social status of a person or thing, public office, some kind of work, life or death." Also, by generalizing Huygens's proposition XII, Jakob Bernoulli arrived at the binomial distribution.

In the second part of *Ars Conjectandi*, Bernoulli dealt with combinatorial analysis, based on contributions of van Schooten, Leibniz, Wallis, Johannes Faulhaber, and Jean Prestet. This part consists of nine chapters dealing with permutations, variations with and without repetitions, combinations with and without repetitions, and figurate numbers and their properties. It is probable that he did not know Pascal's *Triangle Arithmétique*, although Leibniz had referred to it in his last letter to Bernoulli. At any rate Bernoulli did not mention Pascal in the list of authors he had consulted concerning combinatorial analysis. He did repeat results already published by Pascal, among them the multiplicative rule for binomial coefficients, for which he claimed the first proof to be his own; Bernoulli's arrangement differed completely from that of Pascal and went in several instances beyond Pascal. An important result in this part is the general formula for the sums of powers of natural numbers:

$$\sum_{v=1}^n v^c$$

where c is a given natural number in the form of a polynomial in n of degree $c + 1$, the coefficients of which were constructed with the help of certain constants, later called Bernoullian numbers. This formula played an important role in the demonstration of de Moivre's form of the central limit theorem.

In the third part of *Ars Conjectandi*, Bernoulli gave 24 problems concerning the determination of the modified Huygenian concept of expectation in various games. He solved these problems mainly by combinatorial methods, as introduced in part II, and by recursion.

The fourth part of *Ars Conjectandi* is the most interesting and original; it is also the part that Bernoulli was not able to complete. In the first three of its five chapters, it deals with the new central concept of the art of conjecturing, probability; its relation to certainty, necessity, and chance; and ways of estimating and measuring probability. Bernoulli stated on that, the one hand, at least for God, chance and with it objective probabilities do not exist in a world the functioning of which in the past, present, and future is completely known to him down to its smallest entities. Through a more precise knowledge of the parameters affecting the motion of a die, for instance, it would be possible even for humans to specify in advance the result of the throw. Chance, in his view and later in the view of Laplace, is reduced to a subjective lack of information. Thus, depending on the state of their information, an event may be described by one person as chance and by another as necessary. The entire realm of events that are described in daily life as uncertain or contingent in their outcome is such, he claimed, merely because of incomplete information; nevertheless, these too are covered by his concept of probability. However, the only way to check that the probabilities estimated *a posteriori* (in Bernoulli's sense) are reliable in practice is to make sufficiently many observations and calculate the relative frequencies of the outcome of the event in question. So the denial of objective chance and probabilities does not prevent Bernoulli's concept of probability, defined as degree of certainty, from showing at the same time subjective or epistemic and frequentist or aleatory aspects.

For the mathematical part of the *Ars Conjectandi*, this ambiguity in Bernoulli's concept of probability does not matter because the numerical value of a probability is a real (in Bernoulli's case a rational) number between 0 and 1, no matter how it is conceived. For practical applications, Bernoulli introduced the concept of moral certainty of events, "whose probability nearly equals the whole of certainty."

In chapter 3 of the fourth part, "About various kinds of arguments and how their weights are estimated for quantifying the probabilities of things," the realm of nonadditive probabilities is touched upon. In chapter 4, Bernoulli distinguished two ways of determining, exactly or approximately, the classical measure of probability. The first presupposes the equipossibility of the outcomes of certain elementary events such as drawing any 1 of n balls numbered from 1 to n out of an urn. So the probability of drawing a ball of a certain color out of an urn filled with balls of different colors is determined *a priori*

by the ratio of the number of balls of this special color to the number of all balls in the urn. The second is for determining the probability of an event for which the reduction to a number of equipossible cases that are favorable or unfavorable for the event is impossible, such as a certain person's dying within the next 10 years. According to Bernoulli, we can inductively, by experiments or *a posteriori*, get as close as we desire to the true measure of such a probability. The possibility of estimating the unknown probability of such an event by the relative frequency of the outcome of the event in a series of supposedly independent trials is secured, according to Bernoulli, by his *theorema aureum*, which was called later by Poisson Bernoulli's law of large numbers. The proof of this theorem is contained in chapter 5. In it he showed that the relative frequency h_n of an event with probability p in n independent trials converges in probability to p . More precisely, he showed that, for any given small positive number ε and any given large natural number c , for sufficiently large n , the inequality:

$$\frac{P(|h_n - p| \leq \varepsilon)}{P(|h_n - p| > \varepsilon)} > c$$

holds, which is equivalent to:

$$P(|h_n - p| \leq \varepsilon) > 1 - \frac{1}{c + 1}$$

This, again, is now called Bernoulli's weak law of large numbers. In an appendix to *Ars Conjectandi*, Bernoulli treats *jeu de paume* as a game of chance by taking the relative frequency of winning as a measure of the probability of winning.

The title *Ars Conjectandi* was suggested by the *Ars Cogitandi*, better known as the *Logic of Port Royal*, in the very last chapter of which the chances for future contingent events are equated with the ratios of the associated degrees of probability. We can see how Bernoulli, beginning from this notion, developed the classical concept of probability and how he became the first to set down the prerequisites for consciously formulating a program for the mathematization of all the fields of application subject to *probabilis*. The fact that he had no time to illustrate how this program could be realized with examples from the social domain was a stimulus for his successors.

The Impact of the *Ars Conjectandi*

Jakob Hermann, a student of Jakob Bernoulli who was trusted by the family, informed the authors of eulogies that appeared in honor of Jakob Bernoulli of the content of the *Ars Conjectandi* and especially the law of large numbers. It can be shown that the rather short pieces of information contained in these eulogies influenced Montmort, who

learned from them that the main concept around which the new doctrine of chance should be built was probability. Nikolaus Bernoulli, Jakob's nephew, had tried to apply the findings of his uncle to a series of concrete problems in law in his dissertation *De Usu Artis Conjectandi in Jure*, published in 1709. Montmort included part of his extensive correspondence with Nikolaus Bernoulli on the new field in the second edition of his *Essay d'Analyse sur les Jeux des Hazard*, which appeared late in 1713. Both agreed in their judgment that the *Ars Conjectandi* had appeared too late to offer anything new for specialists, understandably in light of their own efforts to develop the subject. Their judgment has been interpreted as proof of the lack of impact of Jakob Bernoulli's work, even though both had been beneficiaries of Bernoulli's results in the *Ars Conjectandi*. Bernoulli's main theorem, the law of large numbers, stimulated Abraham de Moivre, who late in his life found the first form of the central limit theorem, which allows the approximation of the binomial by the normal distribution. Bernoulli's program to mathematize the realm of the probable, including the social domain, occupied mathematicians throughout the 18th and 19th centuries until the advent of mathematical statistics. The peak of this development was reached in late enlightenment when Condorcet and Laplace held the

view that the science of the probable is the only reliable guide to deciding questions for which we have no certain knowledge, such as those concerning human mortality or the reliability of witnesses.

Glossary

arithmetic average A term Bertillon borrowed from Laplace and Quetelet to describe an average calculated on the basis of qualitatively different types of objects. A famous example of an arithmetic average is the average height of houses on a street. As this example suggests, arithmetic averages do not give any information about the individual observations that make up the population or about the population as a whole.

demography The science of population statistics. In the 19th century, this included the study of all those features of a population that could be quantified, including measures of population size and growth such as births, deaths, and marriages, physiological measures such as height and weight, environmental measures such as the type of housing and climate, and social measures such as income and level of education.

natural averages Averages taken on (relatively more) homogeneous populations, such as a racial or socioeconomic group. In contrast to arithmetic averages, natural averages were seen to provide valuable information about the characteristics of the observed population.

special rates A term coined by Bertillon to refer to what are now called “age-specific rates.” They measure the likelihood of a particular event affecting a population of a particular age, generally between ages x and $x + 1$. In the case of mortality, the special rate for the population of age 20 would be the number of people between ages 20 and 21 dying in the course of a year divided by the number of people aged 20 alive at the beginning of the year.

statistical laws A term used by 19th century statisticians to refer to statistical regularities. By using the term “law,” they indicated their belief that this regularity pointed to the existence of an underlying cause or force that influenced all individuals in the observed population with the same force, thus accounting for the presumed stability of the phenomena.

Louis Adolphe Bertillon (1821–1883) was one of the leading French social statisticians of the Second Empire and early Third Republic. He was highly respected internationally, in particular by administrative statisticians. He published hundreds of pages on statistical methodology, demography, and anthropological topics, such as “acclimation” and anthropometric measurement, many of which served as standard statistical textbooks for decades thereafter. At his death, Luigi Bodio, the head of the Italian national bureau of statistics, placed Bertillon’s name alongside that of Adolphe Quetelet as the two leading statisticians of the century. Bertillon’s contributions to the history of social measurement can be found in his continuation of Quetelet’s concern to combine mathematical and administrative statistics. More significantly, he played a major role in the education of French administrative statisticians and medical men in what he called the “correct” statistical method, moving them beyond simple forms of enumeration and sums to the construction of probabilistic rates and the use of mortality tables in the analysis of population statistics.

Bertillon and the History of Social Measurement: Primary Contributions

Historians of statistics generally focus on the development of new concepts and techniques; Bertillon’s contributions, however, lie in the promotion and diffusion of what he referred to as a more “scientific” use of statistical methods among practicing statisticians. It is difficult for observers today to fully appreciate the counterintuitive character of statistical reasoning at the time and the long

period of informal education necessary to transform this new way of thinking into a taken-for-granted aspect of political, administrative, and medical thinking. As Alain Desrosières has shown, statistical reasoning assumes the existence of statistical populations constituted by homogeneous individuals. The concept was particularly difficult for French statisticians to accept, especially with regard to their own national population. Bertillon was a central figure in the diffusion of this new abstract concept of population and in the education of his colleagues in the use and interpretation of different statistical measures.

At a time when administrative statistics involved simple enumerations and general averages, Bertillon campaigned for a more sophisticated and rigorous understanding of the significance of different measures. He insisted on the use of what he referred to as “special rates,” involving the number of occurrences of an event over the population at risk, rather than the general population, and on the use of serial comparisons, rather than simple averages, to identify laws and causes. Finally, he was the first French scholar to construct a mortality table combining civil registration and census data.

Whereas his methodological work focused primarily on the measurement of mortality, his empirical work laid out the contours of a new science of demography. Contemporary notions of a demographic population and the basic model of population as constituted by the entry and exit of individuals, modeled in terms of the force of natality, mortality, nuptiality, and migration, can all be traced to Bertillon’s writings. At the time Bertillon wrote, the dominant national administrative statistical tradition in France treated the statistical population as an aggregate of discrete individuals, subject to the vicissitudes of history (famines, wars, epidemics) and divided along territorial lines. Bertillon, in contrast, promoted a more abstract concept of population as a collective entity (social fact) shaped by both internal and external forces, subject to discernible laws.

As this brief description of Bertillon’s approach and work suggests, he was one of a group of scholars committed to using the numerical method to develop a new type of social science, one that was simultaneously empirical and devoted to the identification of an otherwise invisible, underlying reality, constitutive of the human collective. The task of statistical analysis was, first, to identify the natural laws governing society, as evidenced by statistical regularities, and second, to explain those laws by examining the parallel development of different variables two at a time. In contrast to his counterparts in England or to mathematicians engaged in the analysis of social statistics, Bertillon made no attempt to use probability calculus to measure the certainty of his statistical measures or to establish the relation between variables. For Bertillon, the innovation in his project came from its strict insistence on observation over logic or reason and

in the search for constant causes or laws. In contrast with the dominant administrative tradition of the time, Bertillon called for the calculation of rates, the critique and correction of official data, the identification of statistical regularities and laws, and the search for causes.

Bertillon as Professional Methodologist

Public Hygiene and the Measure of Well-Being

Louis Adolphe Bertillon was born in Paris on April 2, 1821. Little is known about his parents, except that his mother died of cholera in 1832 and that his father subsequently placed him in a boarding school where he was destined for a career in business. Against his father’s wishes, Bertillon went on to study medicine. He attended the School of Medicine in Paris, where he enthusiastically embraced the new experimental medicine, inserting himself in scientific laboratories (generally restricted to professors) and eventually gaining a position as an assistant (*préparateur*). While at the School of Medicine, Bertillon also attended the public lectures of Jules Michelet and became a devotee of the Republican historian. His Republicanism combined a strong belief in liberty—especially freedom of expression—with a socialist support of workers’ associations and mutual aid societies and a strong anti-clericalism. Although Bertillon opposed capitalism, he did not favor state intervention or revolutionary action. Instead, he believed that society had to be allowed to develop naturally according to its internal logic.

Bertillon’s political views developed in the years leading up to the 1848 Revolution. It was during one of his many visits to political clubs that had sprung up all over Paris that he first met Achille Guillard, his future father-in-law and cofounder of demography as a discipline. These activities brought Bertillon to the attention of the authorities and he was arrested and imprisoned a number of times in the conservative backlash that followed the 1848 Revolution and the military coup of 1851. Bertillon’s early political activities also introduced him to the medical researcher Paul Broca, with whom he later founded the Anthropological Society.

Arithmetic versus Physiological Averages

In 1852, Bertillon completed his medical studies with a doctoral thesis entitled *De quelques éléments de l’hygiène dans leur rapport avec la durée de la vie*. The thesis began from the classical public hygiene problem of how to measure well-being or, in this case, national prosperity. The text involves a discussion of the most commonly used measure, the average age of death. Bertillon groups the

average age of death with Quetelet's search for the "average man" and criticizes both measures for failing to pay attention to the distribution around the mean. More damning, for Bertillon, is the practice of combining qualitatively distinct individuals and subgroups in the same measure. Bertillon uses the example of average age at death to expound on the difference between what he refers to as arithmetic averages and natural, physiological averages. The concept of arithmetic averages was taken from Laplace and Quetelet; it refers to an average taken on a heterogeneous population, with no natural referent, and thus no meaning or sense. In contrast, physiological averages are based on data from an existing homogeneous population. They refer to real entities and thus provide valid knowledge.

The point Bertillon wishes to make is twofold. First, following Quetelet, he acknowledges cases where an arithmetic average—for example, of the heights of a group of conscripts—proves to be a physiological average as well. In this case, the average signals the fact that the different observations were taken from a single homogeneous race or type. Second, in opposition to Quetelet, he warns against the tendency to treat arithmetic averages as physiological averages. His examples come from attempts to characterize the French population as a whole. National averages, Bertillon explains, combine infants and adults of all ages. Far from being probable, such measures are highly improbable; in other words, they rarely correspond to real-life individuals.

The interesting point in this exposition, from the perspective of the history of social measurement, involves the deep ambivalence that French statisticians displayed toward abstract or "improbable" statistical measures. In contrast to their English counterparts, they began from a realist approach to statistics, such that statistical indices were valid only if they corresponded to real ("natural") entities and they struggled with the assumption of homogeneity built into averages and statistical rates. This was particularly important given their insistence on statistics as certain knowledge, thereby precluding the use of hypotheses or arithmetic averages to model society. Practically, the problem was one of identifying legitimate classifications and subclassifications. This dilemma was a major subtheme in Bertillon's work throughout his career and his ability to negotiate the dilemma was one of his major contributions to the art of social measurement. Many of his methodological prescriptions—such as the use of special rates and parallel series—were directed at controlling for this problem, either by explicating the meaning of different measures or by privileging specific indices and tools. Whereas, in 1853, he focused on the different weights that infants, middle-aged, and elderly populations brought to national mortality rates, later in his career his attention shifted to the differences among single, married, and widowed persons.

The second half of the thesis reviewed different explanations for variations in longevity. This separation of the identification of statistical regularities and their explanation was characteristic of Bertillon's work throughout his life. His studies began with a documentation of statistical phenomena—either a stable trend or parallel in the development of two variables over time—and were followed by a more speculative, qualitative discussion of different types of explanation. Statistical data were sometimes used to support or discount particular trends, but no attempt was made to measure the stability of the observed trend (degree of certainty) or to discriminate between different causes. In the case of his thesis, Bertillon considered various classical public hygiene explanations, including the influence of climate, temperature, latitude, urban living, race, and profession on longevity. He concluded by supporting the well-known public hygienist, Louis René Villermé, in his then-novel arguments concerning the (nonmathematical) association of poverty with above-average death rates.

Mortality Differentials

Bertillon's political activism brought him under the suspicion of the authorities in the early years of the Second Republic. To avoid arrest, Bertillon moved his family to Montmercy, a town outside of Paris, where he practiced medicine. It was during this period that Dr. Malgaigne, a member of the Academy of Medicine and Faculty of Medicine where Bertillon had studied, asked Bertillon to participate in an ongoing debate on the efficacy of the vaccine. Bertillon intervened in the discussion as a statistical expert. The invitation led him to a study of mortality differentials in France by age and region and a first major publication entitled *Conclusions statistiques contre les détracteurs de la vaccine: essai sur la méthode statistique appliquée à l'étude de l'homme* (1857). The book was basically a methodological treatise on the construction of mortality rates in terms of the population at risk and the effect of age structure on mortality statistics, illustrated with a systematic study of mortality trends in France in the 18th and 19th centuries. In contrast to public officials who claimed that the increase in the absolute number of deaths among 20- to 30-year-olds pointed to a worsening in the health of the population, Bertillon argued the reverse. His evaluation rested on an increase in the absolute size of the cohort owing to a decline in infant mortality. The memoir received a number of prizes from the Academies of Sciences and Medicine.

This systematic study led Bertillon to the identification of an unusually high rate of infant mortality in the departments surrounding Paris. His study was the first to signal the effects of the practice of wet-nursing on infant mortality. Bertillon first submitted a report on the problem to the Academy of Medicine in 1858 in a paper entitled "*Mortalité des nouveau-nés*," but the problem was

ignored. It was only a couple of years later, when other public hygienists again called attention to the phenomenon, that Bertillon's report was revived and he was credited with the discovery. Bertillon's data and testimony were subsequently used in 1874 in parliamentary hearings held on the topic and led to the passage of the *Loi Roussel* regulating the practice of wet-nursing.

Another topical issue that Bertillon's systematic study of mortality led him to address concerned the impact of Hausman's reconstruction of Paris on the well-being of the Parisian population (1869). In contrast to official claims that the public health (*salubrité*) of the city had improved, Bertillon argued that it had declined, at least for certain segments of the population. In studying the differential mortality rates within Paris, Bertillon distinguished between the mortality of the new sections of the city (where many paupers were sent to hospitals to die) and the old. In old Paris, he documented an overall increase in mortality, especially for the very young. In the new sections of the city, he found a slight decline in mortality for the very young and an overall increase for the adult and elderly population. Moreover, he demonstrated that the mortality in Paris was higher than in the rest of the country for every age. Bertillon's paper points to the central role of classification in statistical inquiry. As for the earlier public hygienists, the art of social statistics lay in the classification of the population into subgroups and the use of creative comparisons.

Bertillon's Turn to Social Science

Anthropology and Liberal Economy

In 1859, the government began to relax its strictures against public assembly and free speech. This change opened the way for the revival of scientific activity that had been suppressed in the repressive decade of the 1850s. The impact was especially striking in the moral and human sciences. In the following years, numerous new scientific societies were launched. Two, in particular, transformed Bertillon's career. The first was the Society of Anthropology. In 1859, Bertillon returned to Paris and, together with 18 other medical doctors, helped his friend Paul Broca to found the new society. Although Bertillon knew little about anthropology, he attended classes at the Natural History Museum and actively entered into the ongoing debates over monogenism versus polygenism. Bertillon's contribution lay in the application of the statistical method to anthropology. Together with Broca, he worked to develop a system for the study of skulls and skeletons and for the comparison of anthropometric characteristics. One of his most influential articles of the period was an essay entitled "*De la méthode statistique dans l'anthropologie*," which he originally presented as a memoir in 1863. The article was written in the context of ongoing debates over the influence of *milieux* on skin

coloration; Bertillon used the problem to reiterate his usual insistence on the empirical method and on the need to use series of observations. This anthropological work was also the occasion for his first and only attempt to follow up on Quetelet's suggestions that the error curve could be used to establish whether a set of observations belonged to a homogenous population—in this case a single race—or not (see below).

The second society that Bertillon helped to found was the Statistical Society of Paris (1860), which brought together liberal economists and administrative statisticians. The society provided Bertillon entry into the world of quasi-official social statistics. One of his most influential papers in the Society's journal was a paper entitled "*Des diverses manières de mesurer la durée de la vie humaine*" (1866). The article had an enormous impact. It established Bertillon as a statistical expert and remained required reading for two generations of administrative statisticians, in France and abroad.

The 1866 article reviewed the 11 different measures of mortality in use by administrators at the time, discussed their construction, their significance (the phenomena they were actually measuring), and the types of problems for which they were appropriate. In terms of the history of statistical methods, the article made a strong bid for the use of age-specific rates and mortality tables as the only way to establish the "true" sanitary condition of human collectives. It also reviewed the different ways of constructing mortality tables, distinguishing between population lists (taken directly from observations) and population tables (which separated out the influence of historical causes, focusing exclusively on the effect of mortality as a force). Finally, the article provided administrators and statisticians with a manual on how to produce correct mortality tables by first using civil registration data and other comparisons to correct census data and then constructing population lists (of the mortality at each age) and finally using these lists to calculate a mortality table.

As both Michel Dupâquier and Bernard Lécuyer have noted, most of Bertillon's technical points were taken from his reading of the work of the British statistician and administrator William Farr. In contrast to Farr and in keeping with the French administrative tradition, Bertillon insisted on the total empirical grounding of his numbers at the expense of any type of hypothesis. Thus, in the conclusion to his presentation, Bertillon noted that the advantage of his procedures is that "the mortality thus determined does not depend on hypotheses of any kind; it provides the average of a *collective fact* which rests wholly on the exactitude of the empirical record" (Bertillon, 1866, p. 54). Although scholars today will quickly recognize the role of hypotheses both in the construction of Bertillon's data sets and in his qualitative explanations, Bertillon's insistence to the contrary points to the role of "reality" in the authorization of statistical

claims in France at the time. This insistence on the reality of the ontological referent of statistical measures may also explain why Bertillon, and the French administrative statisticians more generally, failed to follow their English counterparts in the age standardization of mortality rates. In England, statisticians such as Neison and Farr systematically calculated the mortality of one city were it to have the age structure of another in order to assess the relative health of the two locales. In France, statisticians lacked the epistemic warrant for this type of statistical manipulation.

The Dictionnaire Encyclopédique des Sciences Médicales

Although the Society of Anthropology and the Statistical Society of Paris provided Bertillon with two distinct scientific communities, the bulk of his scientific production occurred in the context of his work for Amedée Dechambre, the editor of the *Dictionnaire Encyclopédique des Sciences Médicales*. The Encyclopedia was published between 1864 and 1889 and included over 100 large volumes. In preparing the Encyclopedia, Dechambre deliberately set out to cultivate new sciences relevant to medicine and he included demography in the list. At Dechambre's instigation, Bertillon was led to expand his statistical investigations beyond the classical public hygiene problem of mortality as a measure of well-being. Between 1864 and his death in 1878, Bertillon researched and published a series of lengthy monographs, ranging from 30 to 150 pages, on different aspects of what was to become demography. These included (1) articles on births, deaths, marriages, natality, mortality, nuptiality, migration, and population; (2) country studies, such as Austria, Bavaria, Bade, Belgium, Great Britain and her colonies; and (3) methodological entries on averages, statistics, average life, probable life, and demography. The two best known articles, which helped to make his national reputation, were the essays on France, which provided a statistical review of the state and movement of the French population (constituted as a demographic object), and his article on averages from which the Statistical Society article was taken.

In 1866, Bertillon's wife died, leaving him to raise their three sons, two of whom were to become well-known statisticians in their own right. Jacques Bertillon later took over from his father as head of the Municipal Bureau of Statistics in Paris and authored one of the leading treatises on administrative statistics and Alphonse Bertillon moved to England, where he developed the use of anthropometric measures to identify criminals. The loss of his wife affected Louis Adolphe Bertillon deeply; it also influenced his political and intellectual positions. Politically, Bertillon evoked the wrath of the religious authorities when he insisted on providing his wife with a civil burial. According to the family biography,

this move led to his ostracism from a number of political and scientific societies. The attacks would also seem to have hardened his anti-clerical stance. Intellectually, they contributed to his turn to scientific materialism and his participation in the Society of Mutual Autopsy.

The personal loss also coincided with his preparation for an article on marriage—a topic that he had ignored prior to Dechambre's request. The result was a shift in his basic model of population and a new conviction that the experience of single life, marriage, and widowhood constituted one of the deepest divides structuring social life and an ontological obstacle to the construction and thus scientific legitimacy of national statistical rates. As Bertillon noted in his article on marriage, the experience of marriage creates three distinct social groups, "...which work, suffer, pleasure...live and die differently" (1872, p. 7). This concern for the differential experiences of the unmarried, married, and widowed only intensified Bertillon's already strong concern over the heterogeneity of the French population and the consequent artificiality of national population statistics.

The Promotion of Demography as a Discipline

Bertillon's reputation as a leading scientific figure only really took off in France after the fall of the Second Empire and the establishment of the Third Republic in 1871. During the siege of Paris by the Prussians in 1870, Bertillon served as mayor of the Fifth Arrondissement of Paris. He held the post until the establishment of the Republic, at which time he returned to scholarly work. The Third Republic provided a number of professional opportunities for Bertillon. In the early 1870s, the problem of depopulation was a growing concern. The decline of the French birth rate had been identified by French statisticians as early as 1857, but it was only in the last years of the Second Empire that liberal economists and administrators began to view the development with alarm; prior to that they had taken it as evidence of the Malthusian mechanism of foresight and the diffusion of civilization to the middle and lower classes. After the war, the new, Republican government actively set out to explain the defeat of France to Prussia to the French public. A slower birth rate and a lack of investment in science were presented as important causes of France's defeat. Bertillon was one of the few statisticians with the skills and data to address the problem. In 1873, he gave the opening speech at the annual meeting of the newly founded French Association for the Promotion of Science, in which he made a strong bid for the gravity of the problem of depopulation and the ability of demography, a new science devoted to the statistical study of human collectives, to address it.

For the first time in his career, Bertillon actively engaged in institution-building directed at establishing demography as a distinct discipline. In 1876, he was given a new chair of demography and medical geography in the School of Anthropology. In 1877, he launched the first specialized journal in demography, entitled *Les Annales Internationales de Démographie*, and in 1878, he organized the first International Congress of Demography in conjunction with the Universal Exposition of 1878. In 1883, Bertillon was appointed the head of the newly created statistical bureau for the city of Paris. The move was important both practically and symbolically. On a practical level, the Municipal Bureau provided Bertillon with an opportunity to shape the production of official data to suit the requisites of his new science. On a symbolic plane, the Municipal Bureau marked Bertillon's role as the carrier of Villermé and Quetelet's projects into the second half of the 19th century. The series of volumes produced by the original Municipal Bureau of Statistics for the City of Paris in the 1820s had provided both Villermé and Quetelet with the data necessary to engage in their projects. Whereas Joseph Fourier, the original director, had far more mathematical expertise than Bertillon, the two men shared with Villermé and Quetelet a commitment to overcome the strong gap between mathematical and administrative statistics.

Bertillon's project for demography can be found in his articles for Dechambre's dictionary, in his lectures at the School of Anthropology, in his contributions to *Les Annales Internationales*, and in his speeches at the first meetings of the International Congress of Demography. As the above review of his work indicates, Bertillon envisaged demography as a systematic endeavor focused on producing a demographic profile of a population, rather than a problem-oriented discipline. Most of his topical studies, such as his work on the impact of wet-nursing or on Hausman's reconstruction of Paris, emerged from his attempt to map out the differential mortality of the French nation according to a number of predefined variables. His country studies in Dechambre's dictionary were all modeled along the same grid. Each was divided into two sections: the state of the population and population dynamics, corresponding to the anatomy and physiology of the population under investigation. The first relied largely on census data to trace out the composition of the population by age, sex, language, habitat, civil state, and profession, whereas the latter mined the registration of births, deaths, and marriages for annual movements of the population. The physiology of the population was decomposed into four principal movements by which the population increases and declines: natality, matrimoniality, mortality, and the intensity of migratory movements. As this article indicates, Bertillon's approach was ultimately empiricist. The different elements of a demographic study were not tied together by any

overarching theory, but instead related to one another ontologically, by their contribution to the constitution of population viewed as an abstract statistical object.

The new scientific community constituted around demography combined the earlier base of positivist Republican medical men and municipal administrators with the support of national administrators from foreign countries. For much of the second half of the 19th century, demography was treated as the applied branch of statistics. Leading statistical manuals such as the *Traité théorique et pratique de statistique* (1886) by Maurice Block and the *Cours élémentaire de statistique administrative* (1895) by Bertillon's son, Jacques, included a separate section on demography that reported on the key findings of the discipline. The term "statistics" was thus used to refer to the method (administrative or mathematics), whereas the term "demography" referred to the application of that method to population defined as an abstract statistical object. It was only after Bertillon's death in 1883 that his version of demography came to be adopted by liberal economists and mainstream statisticians and that his vision was institutionalized in national administrative bureaus.

Bertillon passed away in 1883. At the time of his death, he had the satisfaction of seeing his project for demography institutionalized in a number of specialized organizations. Although few of them survived the decade after his death, his intellectual and institutional work did contribute significantly to the "scientization" of French administrative statistics. This success was symbolized in 1885 by the creation of the *Conseil Supérieure de Statistique*, an advisory committee within the administration that brought together scholars and administrators to improve the quality of official data.

Bertillon and Quetelet

One of the main themes in the little scholarly work that has been done on Louis Adolphe Bertillon concerns the relationship between his work and that of Adolphe Quetelet. The comparison is illuminating, as Bernard Pierre Lécuyer has suggested, in that it provides a vehicle to assess the impact of Quetelet's social physics on French administrative and social scientific thought. It also serves to summarize the specificity of Bertillon's own contribution to the development of social statistics in general and demography in particular. On a very general level, Bertillon took from Quetelet and others his belief that society was governed by natural laws and his faith that statistics could be used to identify them. He also shared with Quetelet the Laplacian distinction between constant and accidental causes and the association of statistical regularities with constant causes.

Problems with the Average Man

In his doctoral thesis, Bertillon refers positively to Quetelet's project to use averages to establish the characteristics of a race and to trace the (civilizational) development of the population. At the same time, he criticizes Quetelet's notion of the average man on realist grounds. In his thesis, Bertillon objects to the notion of the average man on the grounds that it is an arithmetic mean that combines values from individuals of vastly different ages or races. To illustrate his point, he considers the average height of French conscripts by combining the heights of Frenchmen in the Doubs (the department with the tallest conscripts) with those in the Corrèze and Pyrénées-Orientales (the departments with the shortest conscripts). The result, he explains, is an arithmetic mean combining individuals of different races. In contrast, the heights of conscripts from a single department tended to cluster around the departmental average in a form resembling the error curve or binomial distribution. In this case, the arithmetic mean might also be the most probable height, such that one could use a series of average heights, taken over a century, to determine the progress or decay of the population. In 1852, Bertillon failed to provide a statistical means of distinguishing between physiological and arithmetic averages. It was not until the mid-1870s that he returned to the problem.

In his course at the School of Anthropology, Bertillon explicitly distinguished his project for demography from Quetelet's social physics. According to Bertillon, Quetelet was driven by an interest in universals. His work was shaped by an *a priori* perspective directed at the identification of the average man, which he regarded as an ideal. Bertillon, in contrast, was concerned with the natural history of actual human collectivities. In his 1876 article on the theory of averages, Bertillon further developed his criticism of the average man by pointing to the failure of different average measures to adjust among themselves. The point had been made by Cournot and was supported by Bertillon's own attempts to identify the average primitive man on the basis of the collection of skulls stored at the Anthropological Society. For many years, he and Broca sought to order the collection according to multiple criteria. The attempt failed. There was no systematic relation between the five or six different measures that anthropologists used to characterize skulls.

Using the Error Curve

Although Bertillon rejected the scientific value of the concept of the average man, he accepted Quetelet's analysis of the similarities in the distribution of values around natural physiological means and certain arithmetic averages. In his article on methodology in anthropology, Bertillon returned to Quetelet's suggestion that one

could use the shape of the error curve to establish the homogeneity of the population. The context for his analysis was a debate at the Society of Anthropology. The question on the table was whether climatic conditions could lead to the birth of new human species or races. More specifically, the Society was embroiled in a discussion over whether the white skin of Europeans could, over time, be transformed into the black skin of the Negro, the chocolate skin of the Ethiopian, the red skin of the Iroquois and under what influence. Underlying the discussion was a broader intellectual debate concerning the single versus the multiple origins of the human species. Bertillon and Broca were strong supporters of the polygenist position.

To counter the arguments of monogenists, Bertillon challenged the use of simple averages to establish the presence or absence of a single race. Instead he proposed that anthropologists follow Quetelet in his analysis of the circumference of the chests of conscripts in the Scottish regiment. To illustrate the value of this approach, Bertillon examined the distribution of the heights of conscripts in different departments. In the case of the Doubs, he found that the heights of 9002 conscripts, measured between 1851 and 1860, failed to cluster symmetrically around the average height. Instead, they displayed a camel-shaped distribution (see Fig. 1). According to Bertillon, this curve could be explained only by the presence of two distinct human types, with different average heights. The camel-shaped curve was the result of the superposition of two binomial distributions, corresponding to the two racial types present in the population. The absence of a binomial distribution discounted the racial homogeneity of the population.

Thirty years later, the Italian statistician Rudolfo Livi reexamined Bertillon's data and found that the observed distribution was the result of the particular way that Bertillon had converted his data from centimeters to inches. At the time, however, Bertillon used it to make his usual case for the need to move beyond simple averages to an analysis of distributions. Although this study is often cited as evidence of the connection between Quetelet and Bertillon, the study of the distribution of the heights in the Doubs was the only time that Bertillon ever attempted an analysis of this type. As such, it cannot be taken as indicative of his methodological or theoretical position.

The Theory of Averages Revisited

Bertillon did, however, use the analysis later in his career as an illustration in his article on the theory of averages. Once again, his primary focus in this article concerned the ontological referent or reality associated with a statistical measure. Whereas in 1853 Bertillon had focused on the distinction between natural physiological averages and arithmetic averages, in 1876 he refined his analysis by

Figure 1 Camel-shaped distribution.

carving out a special conceptual space for the category of averages that were simultaneously natural and arithmetic. His point was twofold: first, to emphasize the need to move beyond simple averages to an examination of the distribution of values around the mean (what he called *mise en série*) and second, to distinguish between measures of “real” objects that could be used by scientists and artificial measures that could not. The problem, as before, concerned the reality of statistical objects or social facts.

The article on the theory of averages distinguishes between three types of averages: objective, subjective, and, within the category of subjective averages, typical and indexical. An objective average rested on a determinate (real) object, such as the series of observations taken on the same star or copies of a gladiator statue. A subjective average, in contrast, involved a summary measure of actual individual variations. It refers to an “imaginary abstraction, created by our spirit (*esprit*) to synthesize these impressions (of individual variations) and thereby direct our memory, attention and investigations” (Bertillon, 1876, p. 267). Subjective averages, he explains, were

similar to the type of common-sense categories that people make every day to negotiate the complexities of social life. Within the category of subjective averages, Bertillon distinguishes between typical averages, where the individual observations were all variations of a single type or race, and indexical averages, where they rested on a purely “fortuitous and factitious agglomerations,” such as the average height of houses on a street (Herschel’s example) or the average height of the conscripts in the Doubs.

The challenge for statisticians was to distinguish between typical and indexical averages, the first being of scientific value, the latter not. The value of the error curve (or curve of probability as Bertillon referred to it) was that it provided a means to empirically distinguish between these types of averages. If the different values displayed a symmetrical distribution about the mean according to the binomial distribution, then the average was either objective or a typical subjective average; if not, then it was an indexical subjective average and of dubious scientific value. Bertillon’s 1876 discussion suggests that, although he himself did not use the error curve to

establish homogeneity (with the exception of the one above-mentioned instance), he was still attached to the prospect of a technical solution to the problem of homogeneity. Moreover, his personal reluctance to use Quetelet's method would seem to have been linked to its association with the notion of the average man.

Historians of statistics argue that Quetelet's notion of average man was essential for the conceptual slippage between a subjectivist and a frequentist interpretation of probability and thus for his entire intellectual project. To be more specific, Quetelet's social physics rested on an analogy between the distribution of observations taken from a single object, such as the copies of a single statue of a gladiator or a number of observations taken on the same star, and the distribution of a set of observations taken on different entities, such as the height of Scottish conscripts. Both the observations taken on a single real entity and the distribution of individual values taken on a group of real entities follow the binomial distribution. The concept of the average man constituted Quetelet's answer to this question of the ontological referent of a statistical series. The fact that the set of observed values clustered symmetrically about the mean was taken as evidence that the distribution was like a set of errors that converged on the true, or in this case, ideal value. The average man was the ideal type around which the characteristics of a given population tended to converge.

Bertillon recognized the explanatory work that the concept of average man accomplished in Quetelet's theory and he explicitly criticized Quetelet for using it. Instead, Bertillon appealed to the constancy of causes such as heredity and milieu over more diverse, contradictory influences belonging to subpopulations and individuals. In the case of typical subjective means, he explained, the constant causes associated with race increasingly dictated the shape of the distribution the greater the number of observations taken on the population. Like Quetelet, Bertillon argued that the sources of diversity acted like errors, balancing one another out, such that the larger the number of cases, the closer the convergence around the mean. In contrast to Quetelet, he refused to abandon

a physiological notion of mechanical determinism of different types of causes for a "mystical" explanation.

Binet, Alfred

Dolph Kohnstamm

Emeritus, Leiden University, Leiden, The Netherlands

Glossary

cephalometry Methods and scientific motives to measure the size and form of the head of individuals in order to find characteristics of specific groups of human beings, e.g., of gifted children, early forms of mankind (in evolution), criminals, and people belonging to different races. Discredited because of Nazi theories and practice. In modern times, replaced by measures of brain volume using magnetic resonance imaging scans.

conservation Jean Piaget's term for the ability of the child to recognize that certain properties of objects (e.g., mass, volume, and number) do not change despite transformations in the spatial appearance of the objects.

mental age Stage and level in cognitive (mental) development that are typical for children of a given age, as determined in large and representative samples of children in a given population.

pedagogy From the Greek words *pais* (boy; child) and *ago* (to lead), thus the art and science of educating children. The concept currently comprises more than school education alone. It also encompasses the guidance parents give to their children, in all respects, not only their cognitive development.

suggestibility A personality trait indicating the degree to which a child or adult is susceptible to suggestions made by other children or adults.

Alfred Binet (1857–1911) found his true vocation in the new science of psychology after some years in law school and medical school. Driven by an extremely inquisitive mind, he first studied psychopathology and suggestibility before settling on experimental psychology. A warm interest in the mentally retarded led him to the invention of a wide range of tasks to test individual differences in mental capacities between retarded and normal

individuals, both adults and children. Commissioned by the ministry of education to devise selection criteria for schools of special education, and assisted by his young co-worker Théodore Simon, he developed the series of tasks that became known as the Binet–Simon scales for the measurement of intelligence. This invention of a practical method brought him international fame. Founder, in 1894, and long-term editor of *l'Année Psychologique*, Binet published articles and books on an unbelievably wide range of subjects. His seminal work in education bears witness to his dedication to individual differences and their standardized assessment.

Youth of Alfred Binet

Born in Nice in 1857, Alfred Binet was the only child of a physician and his wife, an amateur painter. Binet's father was not the first physician in the family: he was son of one, and so was the grandfather of his mother. The latter, Mr. Jordan, served also as mayor of Marseilles.

Little is known of Binet's childhood and adolescence. It is a pity that this great child psychologist never took the time to commit his own childhood memories to paper. Was it his characteristic modesty that prevented him from doing so? Were his memories too painful to pass on to strangers? Or did he postpone this task too long and did his deathly illness come too soon? It is known that the marriage of his parents was unhappy and that after a few years at high school in Nice, his mother took him, at age 15, to Paris for further education. There, Alfred first attended a famous lycée (Louis le Grand) before entering law school, obtaining his license degree at age 21. Dissatisfied with the prospect of a career in law or public affairs, he switched for a while to medical school. This may not have been a good choice for such an extremely inquisitive and original mind. After a year or so, he embarked on

a self-study of psychology at the national library, the famous Bibliothèque Nationale, soon finding his vocation in that discipline, so new that it was not yet a field of study at the university. Binet's first enthusiasm was stirred by the then dominant current in cognitive psychology, associationism. Only 1 year later, in 1880, his first paper, on the fusion of resemblant sensations, was published in the *Revue Philosophique*.

Early Career

In 1882, a former schoolmate of Binet, the neurologist Joseph Babinski, introduced him to the psychiatrists of the famous hospital, La Salpêtrière, and Binet began work in the clinic of Professor Charcot, where hysterical patients were treated with hypnosis. Only 3 years later, young Freud came from Vienna to study Charcot's methods in this same clinic. Binet published about a dozen papers on this subject over the next 7 years, most of them in the *Revue Philosophique*. At the same time, he continued his work in cognitive psychology and published his first book, *La Psychologie du Raisonnement*, in 1886, based strictly on the premises of association psychology.

With John Stuart Mill as his "hero," the young Binet had to mitigate his extremely environmentalist beliefs that were influenced by his father-in-law, E. G. Balbiani, a professor in embryology at the Collège de France. Binet adapted his lectures on heredity for publication. All this time, Binet had no paid appointment. He must have had sufficient access to the family capital, being the only child of a wealthy father. This allowed him excursions into another new field, zoology. Studying and dissecting insects in a laboratory led him to write a doctoral thesis, entitled "A Contribution to the Study of the Subintestinal Nervous System of Insects," defended in 1894. Meanwhile, he had made yet another move by asking for and obtaining a nonpaid appointment at the Laboratory of Physiological Psychology at the Sorbonne. Being accepted as a staff member by its director, Henri Beaunis, in 1891, he was to succeed him 3 years later, when Beaunis retired. In that same year, which also brought him his doctor's title, he and Beaunis founded the first psychological journal in France, *l'Année Psychologique*, of which Binet was to remain the editor until his death, 17 years later. But that was not all. Two of his books went to print in that fruitful year, an introduction to experimental psychology and a study on the psychology of chess players and master calculators. Also, his first article on experimental child development appeared, in collaboration with his co-worker Victor Henri, foretelling what was to become the focus of his studies in child intelligence and education.

With this solid and impressive academic record, it is amazing that Binet was never offered a chair in the French

universities. Notwithstanding his international recognition, even long before his scales of mental tests brought him international fame. A course of 12 lectures he gave at the University of Bucharest, in 1895, progressed so well that the number of students, professors, and interested citizens increased to the point that the course had to be continued in a larger audience hall. Also, a year before, he had been appointed member of the editorial board of the new *Psychological Review*, at a time when only American psychologists were appointed. One can imagine Binet's great disappointment about not being given a chair in Paris.

A Father Becomes a Child Psychologist

In 1884, Binet had married Laure Balbiani, daughter of an embryologist, and in 1885 and 1887, two children were born, Madeleine and Alice. The father began to observe the behavior of his little daughters, just as Piaget would do some 20 years later. Binet was struck by the differences in behavior patterns the two girls showed, especially their different styles of "voluntary attention." Madeleine always concentrated firmly on whatever she was doing, whereas Alice was impulsive. He took notes and began writing reports on his observations, using the pseudonyms Marguerite for Madeleine and Armande for Alice. He published three of these reports in the *Revue Philosophique*, when his eldest daughter was 5 years old. The following quotation from the first report (1890) described motoric behavior: "When M. was learning to walk she did not leave one support until she had discovered another near at hand to which she could direct herself. . . . while A., in contrast, progressed into empty space without any attention to the consequences (of falling)." On their temperamental differences, Binet noted that M. was "silent, cool, concentrated, while A. was a laughter, gay, thoughtless, frivolous, and turbulent. . . . Now, [at their present age] the psychological differences. . . have not disappeared. On the contrary, they have disclosed a very clear character to their whole mental development."

In child psychology of the past century, long after Binet's time, people have tried to explain such individual differences between two sisters or brothers as resulting from their difference in birth order. The characteristic differences between Binet's two daughters echo the typical differences found in some of those studies between first- and second-born children. But this research has practically come to a halt because wide-scale confirmation has failed to materialize. In Binet's days, this was not yet a hypothesis known to be reckoned with and neither had Freudian psychoanalytic thinking colonized the minds of

child psychologists. The explanation that Madeleine was the first to establish an oedipal relation with her father, and might be suffering from anxiety for fear of the punishment from her mother, was not yet formulated. So here we see a still-innocent investigator of child behavior, a confirmed environmentalist in his student years, who is impressed by the individual differences in personality characteristics as seen in the behavior patterns of his own children. Convinced that he and his wife had provided both girls with about the same environment and comparable experiences, no other conclusion could be inferred in these pre-Freudian decades, than differences in genetic predispositions. This unmistakable truth came to the father's mind in the same period that he edited the lectures on heredity by his father-in-law. Binet's great interest in the development of individual differences was born. So impressed was he by the differences in approaching tasks by the two girls that it seems as if he initially failed to discern the important maturational differences between young children almost 2 years apart. This amazing conclusion was derived by Binet's biographer, Theta H. Wolf, in her admirable book on Binet's professional development. This article owes much to her fine study.

Assessment of Individual Differences in Cognitive Functioning

Binet tried many cognitive tasks on his two daughters. Several tests of memory were devised, from remembering colors seen to recalling sentences spoken. Other tasks included interpreting simulated emotions in expressions (using Darwin's original pictures) asking for word definitions ("What is it? Tell me what it is?"). With answers by his daughters such as "a snail is to step on" or "a dog bites," Binet was amazed to see how "utilitarian" children are. He made discoveries that nowadays are textbook knowledge in child development. He touched on these insights in his articles, but he did not bring them into a systematic framework, e.g., by writing a book on language development or the development of memory. In this respect, he differed from other child psychologists who came after him. For example, Binet touched on the problems young children have in distinguishing between what looks like "more" and what is "more." He arranged beads of different colors or sizes on the table and asked his daughters to make judgments on quantity, much as Piaget would do two decades later with his children. But Piaget, who must have known Binet's publications, did not stop there, and devised many different tasks on number "conservation," describing meticulously how children of different ages reacted to these tasks, embedding the

results in an elaborate and complex theory on the growth of logical thought.

An important change in Binet's thinking came when he and his co-worker, Victor Henri, gave cognitive tasks to school children differing much more in age than his two daughters differed. For example, he discovered how 12-year-old children could resist false suggestions made by the experimenter, as to what would be the right answer to a problem of perception, whereas most 7-year-old children could not resist. The misleading questions Binet and Henri presented to the children are similar to the tricks played by Piaget in his conservation tasks. Binet came to see the growth of children's faculty of attention, judgment, and criticism as essential in their development of intelligence. He and Henri published a book on suggestibility in 1900. In this book, they warn the reader how susceptible children are to suggestions, true or false, and that in many experimental situations, insufficient attention is given to implicit suggestions caused by the experimenter's words or acts, by the way the materials are arranged or by the behavior of other children present in the situation. This warning has not been heard or taken seriously by many researchers in cognitive development in the century following this publication. Even Piaget did not show sufficient caution against the use of "misleading" questions in the cognitive problems that he arranged for his subjects. Only since the 1980s has the suggestibility of young children come to be extensively researched, out of concern for the reliability of children's testimony in court cases.

From his earlier publications on his work in the Salpêtrière hospital, Binet was widely known as a staunch supporter of hypnosis as a method to learn more about unconscious motives and thoughts. When publishing the book on his suggestibility experiments with children, headmasters of schools in Paris closed their doors to him, fearing he was bringing their pupils under hypnosis during his experiments. Binet's pioneering work on suggestibility was seen by him as essential for the psychology of court testimony. He even saw a wider application in the courtrooms, because also the judges were subject to suggestions and let their judgments be influenced by them. Thus Binet proposed the formulation of a psychojudicial science, and if he had continued on this road he might now have been regarded as the founder of experimental forensic psychology—in particular, the validity of eyewitness testimony.

It is impossible in a short text to give a complete overview of the great variety of studies Binet undertook; among the many interests of Binet was the study of creative imagination in novelists and playwrights. In interviews and questionnaires, numerous famous authors, among whom were Edmond de Goncourt and Alexander Dumas, told Binet how inspiration appeared to come to them. Especially the "spontaneous inspirations"

produced by the mind during sleep fascinated Binet. Later in his life, Binet would become an author of fiction, writing plays for the theater; one of his plays saw 30 performances in succession at the famous Sarah Bernhardt theater in Paris.

Assessment of Intelligence in Groups of Children and Mentally Retarded Adults

Not in the position to offer students grades and diplomas, nor to offer co-workers a salary, Binet was totally dependent on the enthusiasm of one or two volunteer assistants. Therefore, Theodore Simon was just the person he needed. Simon worked in a colony for retarded children and adolescents, all boys, and had permission to use them as subjects in tests. Binet first tested Simon, for his competence, persistence, and good faith, as he used to do with prospective co-workers. Luckily, Simon passed the high standards Binet had in mind for his assistants. A very fruitful period followed. Both the differences in age and the differences in mental capacities in the population of retarded children and adolescents yielded a mass of differential data on the many cognitive tasks Binet and Simon invented for them. Together with his co-worker Victor Henri, Binet joined other European investigators in studying mental fatigue in school children. The introduction of compulsory education for all children, including those from the working classes, caused concern about their endurance during long days of mental exertion. With another co-worker, Nicholas Vaschide, Binet set out to measure physical, physiological, and anatomical characteristics of the boys, to study individual differences in physique and physical force. In order to find meaningful relations between the many different measures, he invented a crude measure of correlation, using rank differences. It is fair to note that this research was met with devastating criticism, also in the *Psychological Review*, because of its many flaws in computations and the doubtful reliability of the measures used. A few years later, Binet and Simon made extensive studies of the relation between certain measures of intelligence and head size. Cephalometry was very common in those days, in psychology as well as in criminology. Both men hoped to find significant correlations between head size and intelligence. But after many years of data collection and publications, among which was Simon's doctoral thesis on mentally retarded boys, they gave up, because in the normal ranges of intelligence the correlations were too small. It is only now, with the more precise magnetic resonance imaging scans of brain volume, that some psychologists have returned to this old hypothesis. For Binet and his co-workers, it was because of their interest in the distinction

between mentally retarded, normal, and gifted children that they had spent so much time on the assessment of physical and anatomical measures. When they left this track, it was because obtaining reliable measures from children was so difficult, not because they no longer believed in the relatedness of the physical measures to cognitive capacities.

One other association they saw clearly was the relatedness between intelligence and success at school, notably in reading and arithmetic. From studying cognitive development in his own two daughters, Binet was dedicated to the study of cognitive growth and to the necessity of a match between what teachers should expect from pupils and the students' developmental level. It was in fact his concern about such mismatches observed in schools Binet visited that first motivated him to create a series of age-appropriate cognitive tasks. Such an instrument would allow teachers to assess the cognitive level of each individual child and then to adapt their educational goals for each child, or group of children, according to the level of development.

A second motivation to set out on this expedition was an invitation by the French Ministry of Education to devise a test to detect those children who were too retarded to profit from ordinary schooling. For this goal, a "Ministerial Commission for the Abnormal" was appointed in 1904. Binet and Simon began to devise series of six small cognitive tasks for each age, from age 3 onward. For example, a task for a 3-year-old child was to provide the proper reaction to "show me where is your nose, your mouth, your eye," the task thus serving as a simple test of vocabulary development. Or the children were asked to copy squares and triangles, setting criteria for pass or fail. Tasks were seen as age appropriate when 75% of a given age group passed the criteria set and 25% failed. Binet framed the issue in levels of cognitive development for each individual child and in standards for groups of a given age. Thus a child of age 5 who passed all six tasks for age 5 and also three of the tasks for age 6 was deemed to have a mental level of 5 and a half years. Such knowledge would help the teacher to adapt his or her expectations for that child and to set the proper educational goals for that child accordingly. Children 2 or more years behind the standard levels for their age should be given special education in classes for the retarded. In 1905, Binet and Simon published their scales for the first time, and the title of the publication referred to the usefulness of the scales to distinguish between children of "normal" and "abnormal" intellectual level. In subsequent revisions of these scales, this "commissioned" goal was pushed into the background, as can be inferred from the change in titles, from "the development of intelligence in children" (1908) to "the measurement of intellectual level in school children" (1911).

Although Binet's first concern was with retarded children, deaf mutes, and the visually handicapped, he was probably the first to ask special attention for the gifted child, suggesting the organization of special classes for the "above-averaged." He argued that it is "through the elite, and not through the efforts of the average that humanity invents and makes progress." Though many of those who later promoted the Binet–Simon scales, such as Goddard and Terman in the United States, were ardent hereditarians, Binet held a more balanced view. As Siegler has documented in his fine biographical article, Binet strongly believed in the potential of education for increasing intelligence.

Other Offices Held in Education

In 1899, Binet was asked to become an adviser of La Société Libre pour l'Etude Psychologique de l'Enfant, a society just established by Ferdinand Buisson, occupant of the chair of the science of education at the Sorbonne University, at the request of his students, who were teachers and professors attending his courses. These students had read about child study associations abroad, notably those initiated in the United States by G. Stanley Hall. In 1901, Binet became vice-president of this society and a year later he succeeded Buisson as president. He remained president until his death. Six years later the society was renamed in La Société Alfred Binet, and after Simon's death, in 1961, it was again renamed, this time adding the name of Binet's closest ally and successor, Théodore Simon. This society exists to the present day, and publishes a bulletin that has covered more than a century in child psychology and education, under different names. The present name of the bulletin is *Eduquer. Revue de la Société Binet–Simon*, published under the direction of Bernard Andrieu of the University of Nancy.

In 1909, 2 years before his death, Binet presided over the first international pedagogical congress, held in Liège (Belgium). He was then asked to chair an international commission studying pedagogical trends in different countries.

Reception of the Binet–Simon Intelligence Scales

Both in Europe and the United States, the publication of the Binet–Simon scales in *l'Année Psychologique* did not go unnoticed. To the contrary, it was as if the profession had been waiting for this invention. All over Europe, psychologists and educators began to translate and adopt the scales. To mention only the best known

names, these scholars included Alice Descoedres in Geneva, Otto Bobertag in Breslau, and Ovide Decroly in Brussels. It was William Stern, Bobertag's colleague in Breslau, who in 1911 coined the concept "mental age" and proposed to compute an intelligence quotient (IQ) by comparing mental age and chronological age. The IQ was thus born, albeit still without the multiplication by 100. Thus, a child in those days could obtain an IQ of 0.75!

Nowhere was the reception of the 1908 revision of the scales to measure intelligence so enthusiastic as in the United States. In that same year, Henry H. Goddard of the Training School at Vineland, New Jersey, introduced to the new scales by Ovide Decroly, took them back to the States, where he published his adaptation in 1911. He was so enthusiastic about the discovery he made in old Europe that he compared the importance of the scales with Darwin's theory of evolution and Mendel's law of inheritance. The most widely known American revision became the one developed by Lewis Terman, published in 1916 and standardized on about 2000 children. This test, known as the Stanford–Binet, later revised by Terman and Merrill in 1937, used the factor 100 as a multiplier. Terman's standardization brought the normal distribution and standard deviation into Binet's invention.

Binet's biographer, Theta H. Wolf, quoted John E. Anderson when she wrote that "it is impossible, unless we lived through the period, to recapture the enthusiasm, discussion, and controversy that the Binet tests started. Clearly [Binet's work] substituted for the onus of moral blame, a measurable phenomenon within the child's resources that [was] to be studied henceforth in its own right." Wolf added that "these tests made it possible to show that measurable differences in mental levels, rather than voluntary and thus punishable 'moral weakness', could be responsible for children's [below standard] school achievement." Not everyone in the United States was charmed by the triumphal progress of the intelligence scales. Kuhlman was among the first to criticize the scales for their flaws. William Stern reported to have read in American publications about "binetists" who tried to "binetize" children and adults. Especially in France the reception of the Binet–Simon scales was met with reservation and disregard. Binet had no easy character and had been frank with many of his academic colleagues in giving his opinion on their work. After Binet's death in 1911, Simon became the director of their now world-famous laboratory. When at the end of the First World War the young biologist Jean Piaget, aged 22, came to Paris to study at Bleuler's psychiatric clinic and at the Sorbonne, Simon offered him the opportunity to work in the laboratory. Simon asked Piaget to standardize Cyril Burt's reasoning test on Parisian children. Although Piaget undertook this project without much enthusiasm, his interest grew when he began the actual testing.

He found himself increasingly fascinated with the thought processes by which the child came to his answers—in particular, the incorrect ones. Several years later, when his own children were born, he followed his predecessor Binet in probing their cognitive development by confronting them with simple problems and misleading questions. Although Piaget in his publications never explicitly recognized that he was influenced and inspired by Binet, both Wolf and Siegler concluded that circumstantial evidence clearly shows this so.

Over the next few decades, Piaget's compatriots also grew convinced of the seminal importance of Binet's work. In the early 1960s, René Zazzo and his collaborators published a new scale to measure intelligence in children. As Theta Wolf has described and explained, Zazzo discovered that Binet had never used the concept "mental age" and actually found it an inadequate notion, preferring "mental level" instead.

Glossary

biomedical model Based on the dominant natural science paradigm that guides the research and practice activities of the medical enterprise.

coping with disease and treatment Viewed as either a stable coping style, reflecting a personality trait, or as a flexible, context-specific behavioral process in which an individual appraises and copes with illness.

health, disease, illness, sickness Health is as much a social and cultural as a biological issue; health standards change over time and across cultures. Disease refers to the medical practitioner's perspective as summarized in an official diagnosis. Illness is a subjective experience referring to how sick persons perceive, live with, and respond to symptoms and disability. Sickness underlines the role of the person who is ill and refers to the social aspects of illness and its consequences for wider social networks and macrosystems.

health-related locus of control A personality construct referring to an individual's perception of the locus of events as determined internally by his/her own belief that his/her outcome is directly the result of his/her behavior. This contrasts with the perception in this regard of external circumstances, the control of powerful others (doctors), or the vagaries of fate, luck, or chance.

health-related quality of life Relates both to the adequacy of material circumstances and to people's feelings about these circumstances, including feelings about how actual circumstances compare with the ideal. Quality of life is seen today as an ultimate outcome of health care and so is used for assessing the consequences of specific diseases, for characterizing the needs of those living with specific chronic conditions, or as an additional result of the evaluation of specific treatments.

holistic care Relating to or concerned with complete systems rather than with parts. Treat focuses on both the mind and the body, expanding to include the many personal, familial, social, and environmental factors that promote health, prevent illness, and encourage healing.

impairment, disability, handicap In the context of the health experience, impairment is any loss or abnormality of psychological, physiological, or anatomical structure or function. Disability is the restriction of performance of any activity within the range considered normal for a human being. A handicap is a disadvantage that limits or prevents the fulfillment of a role that is normal for a specific individual.

psychometrics The use of psychophysics methods to measure subjective judgments of psychosocial phenomena and health qualities.

reductionism Usually refers to attempts to explain all biological process by the same mechanisms (such as physical laws) that chemists and physicists use to interpret inanimate matter. Biological reductionism in the social sciences refers to interpretations that link all human phenomena exclusively to biological concepts.

the sick role Relates to the structural constraints that define the expected behavior of a sick person, transcending personalities and attitudes.

Social scientists have made very important contributions to studies of health, medicine, and the health care system. Social theorizing has elucidated some of the outer trappings of biomedicine, such as the power of the profession, its increasing impact on society, the social values often encoded in medical/scientific knowledge, and the cognitive basis of biomedicine. These perspectives are underpinned by viewing biomedicine as historically and culturally located, and afford a simple way of modeling illness. Reflecting the postmodern turn in late 20th-century thought, illness has become the object of social theorizing. However, almost all theoretic contributions have been external, independent glimpses by "outsiders," and their impact on the medical milieu has so far been minimal. This article focused on social theory rooted in the social sciences has served as conceptual support for

medical enterprise, methods, specific means of measurement, and approaches that have already been incorporated and are almost integral to medical discourse.

Historical Perspective

In the conceptual relationship between social science and medicine, four important periods can be identified: the Greek and Roman holistic approach to health and disease, the “enlightenment legacy” and development of the biomedical model, the development and consequences of the epidemiological approach, and the postmodern reactions to biomedical orthodoxy.

The Greek and Roman Holistic Approach to Health and Disease

In writings as far back as Hippocrates, the father of Western medicine, health is seen as a function of a mind–body/nature equilibrium, i.e., a psychophysiological–environmental balance or harmony. The concept of fusion of psychosocial and biological factors in medicine is very old. The association of personality types with particular diseases can be found as early as the 2nd-century CE in Galen’s observation that depressed women were more likely to get cancer than were happy women. Diagnoses of behavioral and biological factors interactively suggest an ongoing interest in a holistic or biobehavioral approach to medicine.

The humoral theory of disease, derived from the traditions of Hippocrates, Empedocles, and Galen, conceived the world in terms of four basic elements (fire, water, air, and earth), four qualities (hot, cold, dry, and damp), four humors (blood, phlegm, yellow bile, and black bile), and four personality types (sanguine, phlegmatic, choleric, and melancholic). In this theory, the body could be imagined as a hydraulic system in which illness represented a lack of balance. For instance, melancholia was a consequence of an excess of black bile. Greek therapeutics consisted of bloodletting, diet, exercise, and bed rest, which were designed to restore the equilibrium of the system. Medical prescriptions for good living covered a variety of activities, including leisure, nutrition, lifestyle, and sex.

The “Enlightenment Legacy” and the Development of the Biomedical Model

Two 17th-century ideas had a decisive influence on scientific thought, up to the end of the 19th century. One concept, initiated by Descartes, posited a fundamental division of reality into two separate independent realms, that of mind and that of body or matter. The other idea,

converging with a manifest disjunction of mind and matter, was a novel conception of the universe stemming from Newton’s *Mathematical Principles of the Natural World*. Newtonian mechanics sanctioned the idea of organized complexity, like that found in biological systems, as, in principle, reducible to the interaction of its physical parts. The influential ideas of this physical paradigm, which begot the Age of Enlightenment, had a decisive influence on the life sciences and a revolutionary impact on medical thinking. The body came to be viewed as a machine, independent of psychological and environmental factors. As such, disease, like malfunctioning in a machine, suggested the need for repair. Two defining characteristics of the Enlightenment period have had an ongoing influence to the present day, particularly on the medical sciences. These are faith in science and a belief in the human ability to exercise control over that which is understood scientifically. Both notions derive from the idea of progress. Embracing the natural science paradigm provided the foundation for the rise of biomedicine. By the mid-19th century, medicine was infused by a physicalist approach. Most notable during this period was the recognition that certain organic entities (e.g., bacteria) caused certain diseases, and their pathogenic effect could be avoided or reversed by certain substances (e.g., antitoxins and vaccines). The concepts that are at the foundation of the biomedical model surface as arguments concerning what is medically relevant. Most members of the medical profession delineate their field and their responsibility by those elements of disease that can be explained in the language of physiology, biology, and, ultimately, biochemistry and physics. They prefer not to concern themselves with psychosocial issues that lie outside medicine’s responsibilities and authority. By the mid-20th century, the underlying premises of medicine were that the body can be separately considered from the mind (dualism) and that understanding the body can proceed from knowledge of its parts and how they interrelate (reductionism).

Development and Consequences of the Epidemiological Approach

Evidence of systematic epidemiological analysis can be found dating back to the 18th century. Edward Jenner, through his systematic observations during smallpox outbreaks in the 1760s through the 1780s, developed the idea of a vaccine and administered the first vaccination in 1789. John Snow, in his epidemiological work in 19th-century London, discovered that contaminated water was associated with cholera. Epidemiology as a science thus developed through studies of how disease is distributed in populations and the factors that influence or determine this distribution. A major goal of epidemiology is to

identify subgroups in the population that are at high risk for disease. Most of the variables used in defining these subgroups have biological as well as social significance (for the most part, not clearly defined conceptually), such as age, sex, gender, ethnicity, or race. In fact, all early epidemiologists were at first physicians, but worked very closely with statisticians and demographers. To define population subgroups, they applied social variables, including education, occupation, socioeconomic status, religion and level of religiosity, and urban-dwelling or rural, far more so than biological parameters. Epidemiology aspires to identify the etiology or the cause of a disease and the risk factors, which are those factors that increase a person's risk for a disease. The physical and social environment to which a person is exposed determines much of his/her risk level. A person's lifestyle (residence and work environment, diet, sexual life) can determine his/her exposure to etiological factors.

After the germ theory of disease and epidemiological concepts were firmly accepted, and as countries became industrialized, changes in morbidity and mortality occurred. Medicine then had to deal with diseases characterized by multiple-causal etiology, including many psychosocial factors. Thomas McKeown's thesis led the way in demonstrating the importance of environmental and social factors in the decline of mortality rates. Social inequality and poverty are now regarded as major determinants of individual health; major differences in morbidity and mortality among social classes were demonstrated in Britain with the 1982 publication of the Black Report. Identifying the etiological or causal factors for disease allows the potential reduction or elimination of exposure to those factors through the development of prevention programs. Many public health interventions comprise changes in behavior and lifestyle, and this is the obvious territory of psychosocial disciplines.

Reactions to Biomedical Orthodoxy

Critics both within and outside the medical community have expressed concern that biomedicine is too narrowly focused in its research and practice. They charge that because biomedicine is guided by a logic that requires all meaningful data to be, in principle, reducible to a single-level physicalist vocabulary, a part of medicine will always be beyond the reach of its scientific capabilities. To recognize, for example, the placebo effect as being psychoactive, as opposed to biochemical, would violate foundational premises that recognize the primacy of the body to the exclusion of mind. Western medicine is often referred to as one of humankind's most outstanding contemporary achievements. But in the midst of success, there is the unsettling sense of "crisis." This tension is nowhere more evident than in the distinctions made between the science of medicine and the art of medicine.

From the critic's point of view, the art of medicine—a euphemistic way of saying that successes cannot be explained in biomedical terms—starts where the science of medicine begins to show its limitations. Patient dissatisfaction has become an inescapable consequence of medical practice and the concept of the physician as healer has gone progressively into decline. As a result, a wide variety of health alternative approaches, cults, and sects flourish, including naturopathy, homeopathy, chiropractic, acupuncture, nutritional medicine, psychic healing, and Christian Science approaches. Common to all is an effort to meet the perceived needs of patients who feel neglected by "scientific medicine."

The marketplace has played an enormous part in the rise and fall of the popularity of alternative medicine. A strong medical counterculture emerged in the mid-1960s, debunking science and technocratic solutions to problems and exploring alternative lifestyles. There was increasing awareness of the limits to orthodox biomedicine in terms of safety and efficacy and a desire by consumers to gain greater control over their own health care and well being, especially when orthodoxy had failed to produce results for them individually. Proponents of holistic medicine argue that the proper scope of medicine is not just the "diseased body," as biomedical practitioners would propose, but rather the "sick person." Holistic proponents encourage researchers and practitioners to pursue alternative avenues, especially those involving extrasomatic, caring qualities. In particular, the holistic practitioner encourages the patient to get involved in the healing process. Holistic health recognizes the impact that attitudes and emotions can have on physiological states. Patients are appreciated as mental, emotional, social, spiritual, and physical beings.

Another counterstrategy is behavioral medicine. This movement's most basic assumption is that there is an interrelationship between the immune system, the central nervous system, and the endocrine system. The core of basic research in this field is an attempt to locate the specific neurochemical mechanisms by which subjective states, specifically those associated with emotional stress, lead to disease, by integrating biological and behavioral knowledge in a multidisciplinary approach. One conclusion is that the "insurgents" (the behavioral medicine specialists, disciplines, interest groups, and countermovements) fail to provide the medical enterprise with an alternative to the biomedical model. Unpacking the common features of the insurgents makes it clear that the philosophical and scientific foundations of contemporary (bio)medicine go unchallenged. Despite their rather pointed criticisms, they seek only to build on the biomedical edifice. The insurgents do not follow the implications of their arguments to their logical conclusion. If they did, they would provide the basis for alternative medical foundations. Others will claim that biomedicine's

success in dominating the health care field is so remarkable that its paradigm has attained virtually unique legitimacy.

In sum, medicine can be seen as a specific culture with its peculiar and distinctive perspective, concepts, rituals, and rhetoric. Medicine provides a context in which public consciousness about health and illness and about the role of medicine in society is generated.

What Methods Used in Biomedicine Can Be Ascribed to the Social Sciences?

Theoretical Recognition of Psychosocial Sciences

Biology and the social sciences have a common focal point, the human being, which gives the biologic and social sciences much common ground and differentiates them from the natural or exact sciences. August Comte (1798–1857), the creator of the first major sociological synthesis, in his theory of the hierarchy of the sciences, sees the social sciences as the most complex and the most dependent for their emergence on the development of all the other sciences. Although sociology has special methodological characteristics that distinguish it from its predecessors in the hierarchy, it is also dependent on them, especially on biology, the science that stands nearest to it in the hierarchy. The early classic sociological theories of August Comte, Herbert Spencer, and Emile Durkheim resorted many times to biological analogies, to the parallels between organic and social evolution, and to similarities in the structure and evolution of organic and social units, such as the idea of the primacy of the living entity over any particular element. This approach was to guide the functional analysis that came to dominate British anthropology under the impact of Alfred Radcliffe-Brown and Bronislaw Malinowski, and which led, somewhat later, to American functionalism in sociology under Talcott Parsons and Robert K. Merton. On the other hand, biomedicine, today's scientific medicine, has long recognized that for understanding and explaining some of its topics, it has to turn to the behavioral and social sciences, especially when trying to apply biological and other scientific knowledge to human beings. The reductionist argument claims that levels of organization do not involve ontologically new entities beyond the elements of which they are composed. As a theoretical system, pure biologism is a method that constantly and exclusively interprets all human phenomena through biological concepts; this allows no breakthrough into its preserve, no access to causal factors external to its layout causality. This theory can be found only at the margins of biomedicine. The recognition

that the human is not only physiological processes, that most human behavior cannot be explained in biophysiological concepts, and that social reality cannot be wholly reduced to biology is today widely recognized in biomedicine. Emile Durkheim (1858–1917) presented a definitive critique of the reductionist explanation of social behavior. Social phenomena are “social facts” and these are the subject matter of sociology. They have, according to Durkheim, distinctive social characteristics and determinants that are not amenable to explanations on the biological or psychological level. They are external to any particular individual considered as a biological entity. Any effort to explain a physiological phenomenon such as urination in biological terms alone will never be able to succeed, because most persons can restrict urination to socially defined situations.

Despite this entire line of reasoning, the reductionist argument is still alive, receiving encouragement from sporadic discoveries of enzymes, hormones, and genes explaining some human behavior. Biology and medicine as autonomous disciplines employing *sui generis* modes of explanation will prove, in the fullness of time, that human feelings, attitudes, and states of mind are fully explicable in physiological, or even physicochemical, terms.

Concepts Based on Social Theories

Numerous biomedical concepts have strong roots in the social sciences; they are not exotic or strange to medical discourse and are routinely discussed in the professional medical literature and other contexts.

Objective and Subjective States

Health caregivers have always been interested in what patients think, know, perceive, and feel, and the meaning they attach to their own behavior. Of equal interest are issues concerning why and when people ask for care; their compliance with treatment, prevention, and health promotion directives; and the influence of feelings and attitudes on the etiology and development of disease. Ruth Wallace and Alison Wolf, in their book *Contemporary Sociological Theory*, used the words of Max Weber (1864–1920), one of the most influential and fecund masters of the art and science of social analysis:

Sociology is a science which attempts the interpretive understanding of social action in order thereby to arrive at a causal explanation of its course and effects. In “action” is included all human behavior when and insofar as the acting individual attaches a subjective meaning to it. Action in this sense may be either overt or purely inward or subjective; it may consist of positive intervention in a situation, or of deliberately refraining from such intervention in a passively acquiescing in the situation. Action is social insofar as by virtue of the subjective meaning attached to it by the acting individual (or individuals)

it takes account of the behavior of others and is thereby oriented in its course. [Wallace and Wolf, 1991: 238]

Many of the attempts to understand subjective meanings in the health arena are based on a social–psychological perspective; the focus is primarily on the individual (“self”) and on the interaction between a person’s internal thoughts and emotions and his or her social behavior. Individuals, viewed as active constructors of their own conduct, interpret, evaluate, define, and map out their own action.

Health, Disease, Illness, Sickness

Health is a broad concept that can embody an enormous range of meanings, from the narrowly technical to the all-embracing moral or philosophical. Even today there is no clear and common definition among professionals, and social scientists have assumed a central role in challenging medical thinking, contributing additional dimensions to the phenomena, and pushing for a more systematic conceptual distinction between different states of health. Disease is what is detected as a pathology or abnormality in the body or in physiological functions. Diseases are defined medically by being included in the International Classification of Disease (ICD). Illness is the subjective experience of harm, pain, or loss of function, usually couched in terms of symptoms. Sickness is reported illness, as revealed when a person seeks care or help. Health care providers are apprised of only a fraction of illnesses, because people treat themselves, ask advice from friends, or just put up with feeling ill.

The “Sick Role”

The “sick role” relates to structural constraints that define the expected behavior of a sick person, transcending personalities and attitudes. Role expectations are at the heart of what was once the most influential schema in the sociology of medicine, that of Talcott Parsons. According to Parsons, the social structure of medical practice can be defined by the shared expectations about the “sick role” and the role of the doctor. On the one hand, the sick are exempt from normal obligations, they are not held responsible for their illness, they must try to get well, and they must seek competent help. On the other hand, the physician is expected to be “universalistic,” “functionally specific,” “affectively neutral,” and “collectivity oriented.” These complementary normative rules have a functional relation to the therapeutic process and the larger society. Critics of Parsons rejected his narrow formulation regarding the sick role and the doctor–patient relationship, as well as his assumptions of body and society as perfectly balanced harmonic systems. Parsons’ sick role formulation seems to be an ideal type construct, which does not necessarily match the empirical variations of illness behaviors and doctor–patient interactions. Most

sociologists have developed a more systematic and neutral typology of doctor–patient relationship based on the degree of the correspondence between the doctor’s and the patient’s assertion of illness. Parsons’ sick role refers to only one of the many possible situations when there is an agreement between the patient’s and the doctor’s perception of the illness. Another major criticism of Parsons’ model states that going to see the doctor is not the only component in the complex system of help-seeking behavior, so a distinction should be made between the sick role and the patient role. A large body of sociological research has demonstrated that actual doctor–patient relations can vary and do not always match the Parsonian model. Most sociologists see Parsons’ model as much too oriented by the ideological claims and viewpoints of the profession. Yet, probably precisely for that reason, the concept has become bound up in the medical discourse.

Impairment, Disability, Handicap

The International Classification of Impairments, Disabilities, and Handicaps (ICIDH), developed in the 1970s, was issued by the World Health Organization in 1980 as a tool for the classification of the consequences of disease and of their implications for the lives of individuals. This categorization is based on a totally different approach to disease, departing from all other medical classifications, and is conceptually much more psychosocially oriented. Sickness is seen as an interference with the individual’s ability to perform his/her accustomed social role and the functions and obligations that are expected of him/her. The sequence underlying illness-related phenomena can be extended as shown in Fig. 1. According to the World Health Organization, impairment from disease or injury is defined as any loss or abnormality of psychological, physiological, or anatomical structure or function. The resultant disability is any restriction or lack of ability to perform an activity in the manner or within the range considered normal for a human being. A handicap is a disadvantage for a given individual, resulting from an impairment or a disability, that limits or prevents the fulfillment of a role that is normal (depending on age, sex, and social, and cultural factors) for that individual. A handicap may result from impairment without the mediation of a state of disability (e.g., a disfigurement). On the other hand, someone with a serious disability may be living a fairly normal life without being handicapped.

Figure 1 The extended sequence underlying illness-related phenomena.

Social, Cultural, and Personal Resources

Studies of social causes of health and illness deal with the association between stressful socioenvironmental contexts and the resources mobilized by individuals to mitigate the threats of stressful experience. Resources are classified into two broad categories: external (material or interpersonal and cultural) and internal (personal traits, skills, etc.). Resources are assumed to moderate the stressor–strain relationship (the pathogenic or salutogenic components of the stress process). Some theories emphasize the cumulative effects on health produced by the presence of social stressors and limited external or internal resources (or the presence of distinct vulnerability factors), pointing to “cycles of disadvantage” that precipitate a susceptibility to illness and adaptive breakdown.

Life Events

Illness or disability is a social experience that should be examined in the context of the life course. Critical life events can affect the etiology of illness, disease development, and personal experience with illness. Life events requiring readaptation, whether perceived culturally as “good” or “bad,” increase psychological stress and can even cause acute physical symptoms and constrain daily activity. Among the most frequent stressful life events are retirement, bereavement, and severe disease of significant others.

Stigma and Labeling

The concepts of stigma and social “labeling” are well known among contemporary medical professionals and researchers. There has been much research and theory development of labeling in sociology and social psychology. Every society establishes criteria for categorizing persons, stating what the “normal” attributes are of each of the social categories. Cultural assumptions define what is normal or natural in every social situation or human condition. Sometimes individuals, or even entire social groups, possess attributes that do not match the socially defined natural states. Looking “different,” or “strange” may “reduce” an individual to the single discrepant stigmatizing attribute. Sick or disabled people are often subjected to this kind of stigmatization.

In cultures with a tendency to regard the states of health and youth as normal conditions, stigmatizing and labeling are common. Health conditions differ in their capacity to be used as deeply discrediting attributes; physical abnormalities, for example, that are visible are likely to lead to labeling. Some people with evident physical “differences” may turn to plastic surgeries or other medical interventions to avoid labeling. Another factor is the social image and etiology of a disease. Health conditions may be seen as a serious cause for stigma because of their seemingly psychological and nonobjective nature.

Individuals with some illnesses (e.g., sexually transmitted diseases, cancers, mental illnesses) are especially vulnerable to labeling. The sick person is often viewed as blameworthy for his or her illness. For example, people with AIDS are often assumed to have engaged in deviant and promiscuous sexual behavior. These people, who are already suffering physiological and psychological distress, have to cope with additional tensions caused by accusations, rejection, and labeling by society. Even the diagnosis process of certain diseases can unintentionally become a labeling process. In the course of the disease, the patient may internalize a label imposed by society (the “looking-glass self”) and adopt behaviors and self-perceptions that match this label. This phenomenon has the nature of a self-fulfilling prophecy. In the present era of increasing medicalization (wherein social and psychological phenomena tend to be seen as primarily medical), it is especially important for medical professionals to be aware of the implications their care can have for labeling patients.

Psychosocial Measures or Indices

An influential arsenal of psychosocial measures and instruments is now widely used as health indicators of populations, as etiological factors of diseases, as interventions in disease development, as assessors of the consequences of health conditions, as estimates of the outcomes of care, as evaluators of health services, and as factors influencing the effect of treatments. This development probably has to do with the shift away from viewing health in terms of survival, toward defining it in terms of freedom from disease, and therefore to an emphasis on the individual’s ability to perform his or her daily activities. The current emphasis is on positive themes of happiness, social and emotional well-being, and quality of life.

Health-Related Quality of Life

Quality of life has been studied and used from the perspectives of a variety of disciplines. Medical interest in the quality of life has been stimulated largely by modern skill and success in prolonging life, and by the growing realization that this may be a mixed blessing: patients want to live, not merely to survive. The theme, of course, is not new; what is new is the development of formal ways to measure quality of life and their application in evaluating medical outcomes. We have become bold to the point that the idea of measuring such an abstract and complex theme as quality of life no longer seems presumptuous. Although concern over quality of life in the health field is comparatively new, the social sciences have long evinced interest in measuring the quality of life in the general population. Though conceptual distinctions may be drawn among themes such as life satisfaction, happiness, morale, and anomie, progress in developing separate measurements

for these concepts lags far behind. The current medical literature commonly reports the use of different quality-of-life instruments as one of the parameters for assessing the consequences of specific diseases, characterizing the needs of those living with specific chronic conditions, or as an additional result of the evaluation of specific treatments. Another use is in the estimate of medical services cost–benefit assessments.

The Quality-of-Life Index The quality-of-life instrument measures the general well-being of patients with cancer and other chronic diseases. It is intended to evaluate the effects of treatment and supportive programs such as palliative care. A measurement of quality of life considers physical, social, and emotional function; attitudes to illness; the adequacy of family interactions; and the cost of illness to the individual. The emphasis in the quality-of-life scale is on practicality: it is brief and easy to administer and yet broad in scope. It has proved acceptable to clinicians and so may come to replace the use of older and less well-validated scales.

SF-36 Health Survey The SF-36 Health Survey is probably the most extensively used tool to measure health-related quality of life. The 36-item short-form (SF-36) survey was constructed to provide a comprehensive assessment of physical, mental, and social components of health status. This tool, translated into many languages, is widely used to measure quality of life in patients with specific diseases or disabilities such as cancer, heart diseases, and diabetes, in patients in orthopedic or cardiac rehabilitation programs, and in patients after specific surgical treatments. Together with other measurements, it provides a medical tool to assess the quality of treatments or the efficiency of health services. The instrument generates a health profile consisting of 36 questions in eight subscales and two summary measures for physical and emotional well-being. Shorter versions of the tool have also been developed.

Personality Measures/Characteristics

A number of psychological instruments are used in medical research to find risk factors for disease and to classify different patient coping modes or health-related behaviors. One of the best known correlations is found between Type A personality and heart disease. Among the most widely used instruments are the Minnesota Multiphasic Personality Interview-2, the COPE Inventory, and the Health Locus of Control.

Locus of Control The “locus of control” is a personality construct referring to an individual’s perception of the locus of events as determined internally by his/her belief that an outcome is directly the result of his/her behavior. This contrasts with the perception of external

circumstances, by which control is in the hands of powerful others (doctors), or outcomes are due to the vagaries of fate, luck, or chance. Some research suggests that what underlies the internal locus of control is the concept of “self as agent.” This means that our thoughts control our actions, and that when we apply this executive function of thinking, we can positively affect our beliefs, motivation, and performance. We can control our own destinies and we are more effective in influencing our environments in a wide variety of situations.

A health-related Locus of Control Inventory developed in the mid-1970s was derived from social learning theory. This tool was a one-dimensional scale containing a series of statements of people’s beliefs that their health was or was not determined by their own behavior. A further development was the three 8-item Likert-type “internal, powerful others, chance” (IPC) scales, which predicted that the construct could be better understood by studying fate and chance expectations separately from external control by powerful others. The locus of control and IPC approaches were combined to develop the Multidimensional Health Locus of Control (MHLC) Scale. The MHLC Scale consists of three 6-item scales also using the Likert format. This tool is used to measure quality of life in patients with diseases or disabilities such as breast cancer, irritable bowel syndrome, chronic leg ulcer, and traumatic spinal cord injury. The second aspect is medical outcomes as assessment for quality of treatments (for example, for cervicogenic headache, after cardiac surgery; treatment outcome in subgroups of uncooperative child dental patients; outcomes of parent–child interaction therapy). The last aspect is efficiency of health services or planning a new service. Examples of application include prediagnostic decision-making styles among Australian women, relating to treatment choices for early breast cancer, intention to breast feed, and other important health-related behaviors and beliefs during pregnancy; predicting the ability of lower limb amputees to learn to use a prosthesis; and planning a program of awareness in early-stage Alzheimer’s disease.

Sense of Coherence Sense of coherence (SOC) is a global construct expressing the degree to which a person has a pervasive and dynamic, but lasting, feeling that the internal and external stimuli and stressors in his/her environment are (a) comprehensible, i.e., predictable, structured, and explicable, (b) manageable, i.e., there are resources available to meet the demands of these stimuli, and (c) meaningful, i.e., the demands are challenges worthy of engagement and coping. It has been proposed that a strong SOC would help to mediate and ameliorate stresses by influencing coping efforts. This concept is the basis of the “salutogenetic model,” i.e., explaining how people cope with stressors such as illness and how

people remain in reasonably good physical and emotional health despite the stressors and environmental “insults.” To explore this dimension and to explain a person’s position or change on a health-disease continuum, health sociologist Aaron Antonovsky developed a 29-question self-rating scale that has been widely employed in research. Primary research dealt with the feasibility, reliability, and validity of the SOC scale in a variety of countries and settings, and then employed it as a measure of both independent and dependent (outcome) variables.

Although the SOC scale was first developed some 25 years ago, it is in wide use in a broad range of health research. A PubMed search for literature since 2000 turned up over 140 publications using this concept/instrument. These research efforts include studies on (1) general health, quality of life, and subjective well being, (2) adjustment to natural life changes such as menopause and old age, (3) coping/adjustment to illness such as chronic heart failure, stem-cell transplantation, and orthopedic injury, (4) coping with trauma such as post-traumatic stress disorder, (5) dealing with illness of a family member and/or the stress of caretaking, and (6) assessing intervention programs.

Emotional States

Psychological tests are widely used in medical research and even in medical practice to characterize states that influence the development of disease or the impact of treatment. Instruments used in medical research and settings include the Center for Epidemiological Studies Depression Scale, the Beck Depression Inventory, and the Spielberger State–Trait Anxiety Scale. Interestingly, although these instruments are decades old, they have stood the test of time and are still used extensively.

Subjective Health Requesting individuals to evaluate their general health status has become a widespread practice in health research, especially because of the correlation of subjective health status with mortality. However, conceptual/theoretical work is still needed in order to further benefit from this simple and promising parameter.

Social Measures

A person’s immediate environment often has a strong impact on his/her degree of resilience or vulnerability to stresses. Examples of instruments used to measure these factors are the Multidimensional Perceived Social Support Scale and the Family Assessment Device.

Socioeconomic Status Inequalities in health are a major challenge for society and the health care system. The socioeconomic status of the individual, a central feature of the social structure of any society, is a major determinant of inequalities in health, and strong

evidence exists for the association between health and socioeconomic status. The most common way to measure socioeconomic status (SES) is by education, occupation, and income, but the conceptual construction is still weak. The wide use of the indicator is almost disconnected from the large amount of theoretical work that has developed in the social sciences. Conceptualizing and measuring social status is one of the most difficult and controversial subjects in social research. The statistical findings are poorly interpreted and there is not yet a clear understanding of how education, occupation, and income influence health.

Social Support Many studies in the field of social epidemiology and gerontology have highlighted the importance of social support in attenuating the effects of stressful events and thereby reducing the incidence of disease. In addition, social support contributes to positive adjustment. Social support is generally defined in terms of the availability to the individual of trusted people, i.e., those on whom an individual can rely and who make him/her feel cared for and valued as a person. The measure of social support has become an important index and an area of growth in sociomedical studies.

Social Science Methodologies

The historical development of American social sciences led to the assiduous dedication of sociologists and social psychologists to the development and refining of their research methods. Many sociologists will claim that this investment was at the expense of the theoretical advance of the discipline. In any case, there has been a meaningful contribution by social scientists to the development and improvement of study designs, data collection methods, and statistical techniques, much of which has been adopted by other disciplines.

Survey Techniques

The collection of data through questioning people is integral to the work of clinicians, but it has largely been social scientists who have developed the query technique into a systematic survey of populations and a scientifically valid data collection method. Epidemiological surveys borrow most of their methods from the social sciences. The interview and the questionnaire methods of collecting data depend on the verbal performance of populations; what people say or write in response to stimuli presented to them is recorded by the researcher. There are different types of verbal information:

1. Statements or testimonies; these consist of “external/objective facts” known to the person being interviewed (e.g., “Have you visited a physician in the last three months?”).

2. The interviewee's perceptions or comprehension of certain actions/occurrences/events/objects (e.g., "How do most parents you know react to their children's sickness?"); these perceptions can be in the form of conjectures/explanations of the interviewee's behavior or of some social event, or his/her expectations for future occurrences.

3. Attitudes, or the interviewee's evaluation or judgmental position (e.g., "Do you think it is good or bad that...?").

A distinctive feature of the measurement of subjective states (people's knowledge and perceptions, their feelings, and their judgments) is that there are, in fact, no right or wrong answers to questions. No objective criterion against which to evaluate answers exists. Although the consistency of answers with other information can be assessed, there is no direct way to know about a person's subjective states independently of what he/she says. Survey techniques have developed significantly, especially in question design, methods for question evaluation, and the study of cognitive processes and social factors that influence the way people capture/interpret/recall information, form their judgment, and respond to different types of questions. However, an unresolved problem with the questionnaire technique is that people with all manner of backgrounds, and no special training, design and administer survey questions.

Qualitative Methods

Qualitative methods are becoming more evident in health research, especially in nurses' studies. Semistructured in-depth interviews (including personal narratives of illness) explore what people say in as much detail as possible, exploring personal meaning and uncovering unanticipated data. Another widely used technique is the focus group, a kind of group interview that capitalizes on communication among the research participants. The idea behind the method is that group processes can help people explore and clarify their views in ways that would be less easily likely in a one-to-one interview. Focus groups are a popular method for assessing health education messages and examining public understanding of illness-related behaviors. In addition, the method has proved an effective technique for evaluating health services and exploring attitudes, needs, and experiences of health care users and health providers. Other qualitative methods include observation, which can supply data on what people actually do (as opposed to what they say), and consensus methods, the Delphi process and the nominal group technique, which attempt to assess the extent of agreement and to resolve disagreement by having experts (or credible lay persons) consider a problem through a self-administered mailed questionnaire (the Delphi process) or through structured meetings (nominal

group). The Delphi process has been used widely in health research within the field of technology assessment, choosing outcomes for clinical trials, identifying priorities in care, developing clinical guidelines, and planning and forecasting the organization of services.

Cost–Benefit Analysis

An influential contribution of health economics has been to relate the evaluation of health treatments, services, or programs to cost accounting. In assessing benefits relative to costs, economists have succeeded in compelling the medical system to identify and systematically specify non-marketed commodities. They have developed techniques (in many cases rather controversial) to draw inferences from market data and from behavior they have observed in other contexts, as well as methods to estimate the value of life, as distasteful as such a calculation may seem. An alternative procedure widely employed is cost-effectiveness analysis, which determines the most effective way to achieve an objective.

Psychometrics

The arguments for considering subjective judgments as a valid approach to measurement derived ultimately from the field of psychophysics. Basic to the development of these techniques is the recognition that humans can make consistent, numerical estimates of sensory stimuli. The exact form of the relationship between stimulus and subjective response varies from one sensation to another. This holds important ramifications for health measurement: people can make subjective judgments in a remarkably internally consistent manner, even when asked to make abstract comparisons. Much work has been done in adapting psychophysical methods for use in measuring qualities for which there is no physical scale. Psychologists are working on applying knowledge from other psychological measurements to subjective health information.

Psychosocial Professional Partnerships in Different Areas of the Medical System

Today's complex health care system employs psychosocial professionals as members of the caregiver staff; as members of planning, priority-setting, or evaluation teams; as partners in research projects; and as consultants in many areas.

Service Delivery, Organization of Care, Organization of the Medical System

Medicine had been transformed into an industry, with a growing role of corporations and the state. Governments

are assuming a major (perhaps the dominant) role in the organization of medical care. Decisions that once were exclusively professional are now often subject to public debate, and some become political issues. Whoever provides medical care or pays the cost of illness stands to win the gratitude and goodwill of the sick and their families, as well as that of the healthy public, who recognize the possibility that care may be needed in the future. Employers, unions, and insurance companies all stand to derive some advantage of goodwill, power, or profit from serving as a financial intermediary in health care. Even with wide regulatory differences between countries, physicians generally try to escape from corporate and bureaucratic control over their private practices and to channel the development of hospitals, health insurance, and other medical institutions into forms that do not intrude on the autonomy of the physician. The late 20th century, however, was a time of diminishing resources and autonomy for most physicians, hospitals, and medical schools. There is a rapidly increasing supply of physicians and a continued search by government for control over the growth of medical expenditures. These developments create severe strains throughout the medical system. Sociologist Paul Starr predicted in 1982 that these developments would lead to the rise of corporate enterprise in health services, and supply and demand are indeed already having a profound impact on the ethos and politics of medical care as well as its institutions. Emerging developments now jeopardize the medical professional's control of markets, organizations, and standards of judgment. The medical profession has benefited from state protection and political accommodation of its interests, but government is no longer so sympathetic and physicians are no longer the single, dominant claimant in the medical industry. Private corporations are gaining a more powerful position in American medicine; it has become more necessary to understand medicine as a business as well as a cultural phenomenon, and perhaps most important, to understand the relation between the two. Because medical care has become tightly arranged in bureaucratic organizations, professionals from different disciplines dealing with organizational issues have become part of the scene.

In managerial terms, the chief characteristic of most health organizations is their status as nonprofit organizations providing services. The term "service" is a vaguer, less measurable concept than "profit," and performance is even more difficult to measure. It is also more difficult to make clear-cut choices among alternative courses of action in such organizations, because the relationships between costs and benefits, and even the amount of benefits, are difficult to measure. However, the distinction between for-profit and nonprofit organizations is not black and white, and any criterion used for the distinction is certain to have gray areas, such as the sources and uses

of funds, the types of services provided, or the proprietary nature of the entity. A company that manufactures and sells tangible goods has certain advantages, from a control standpoint, that a service organization does not have. Services cannot be stored; if the facilities and personnel available to provide a service today are not used today, the potential revenue from that capability is lost forever. Service organizations tend to be labor intensive, requiring relatively little capital per unit of output. It is not easy to measure the quantity of many services, and their quality cannot be inspected in advance. Medical institutions are run today like any other institution, with significant representation of organizational psychology, sociology, and economics, together with management and administration, quality control, technology assessment, marketing, jobs and production engineering.

Program/Project Evaluation

Because the delivery of health care is a social intervention, many of the approaches and methodologies used are adaptations of techniques developed in other social areas. Program evaluation is a collection of methods, skills, and sensitivities necessary to determine whether a human service is needed and is likely to be used, whether it is sufficiently intense to meet all the unmet needs identified, whether the service is offered as planned, and whether the human service actually does help people in need at a reasonable cost and without undesirable side effects. Through these activities, evaluators seek to help improve programs, utilizing concepts from psychology, sociology, administrative and policy sciences, economics, and education.

Coping with Disease and Treatment

Experiencing serious or chronic illness means much more than a feeling of physical distress, acknowledging symptoms, needing care, and confronting the inevitability of death. It also includes modifying daily routines, role changes, social status, questions of identity, the searching for new meaning, moral judgments, and ethical dilemmas. Studies have indicated that the way a person perceives his/her illness, his/her personal and social resources, and his/her coping strategy can predict his/her well being more than his/her illness and treatment. There is growing recognition in the medical field that coping is an integral part of the curative process (especially in serious illnesses), and extensive research is focused on the area. Studies have indicated that problem-focused and approach-seeking strategies (e.g., for information or social support) prove to be the best predictors for optimal management and control of the illness, whereas avoidance strategy is associated with less positive outcomes (except at certain stages of the illness). Intervention programs,

such as education, behavioral training, individual psychotherapy, and group interventions, are developed and operated by health professionals to improve the health/illness outcomes. Social workers are an integral part of the hospital care team. Considering the social consequences of the patient's illness, they have acquired a major role in discharge planning and in helping the patient to cope better with the illness situation (e.g., utilizing community services, special devices, legal rights, and home care). However, there is still a need for more theoretical and methodological development of the concept of coping and its extensive application in the medical field.

Professional/Patient Communication and Relationships

Clinical work is a practice of responding to the experience of illness, and, as such, its context is a relational encounter between persons. Though the general parameters of the doctor-patient relationship have been constant throughout history, important elements vary in time and place: patient characteristics, the modes of organizing practice, and the social and economic context within which the relationship exists. With the breakdown of the paternalistic model of medical care, there is growing awareness of the importance of effective communication between the caregiver and the patient and his/her family. Obtaining the patient's compliance with medical treatment, or with instructions and recommendations given to him/her by the medical staff, has become much more difficult. The expansion of consumerism into health care, relating to the patients as "clients," has also had a strong influence. Efforts are being made to develop appropriate techniques among medical personnel, and in some cases new mediator roles have been created. There is a growing interest in better understanding patient perceptions and in techniques to manipulate patient behaviors.

Prevention, Health Promotion, Early Detection of Disease

Prevention, health promotion, and early detection of disease, or risk-factors, constitute a psychosocial arena par excellence, dealing with perceptions, motivations, persuasion, behavioral change, and lifestyle. Here psychosocial knowledge is used, and in many cases psychosocial professionals are those in charge of the programs.

Lay Perspective View

Frequently, social scientists are those responsible for presenting to the medical system the lay perspective. Social scientists are providers of feedback from clients, such as

their satisfaction with services, as well as opinions relevant to health policy issues.

Research

Psychosocial variables are frequent in medical research; they take the form of independent variables in the etiology of disease or in the use of health services, of dependent variables in evaluating treatments and consequences of disease, and of intervening variables in understanding the development of disease or in the impact of treatment. Many difficulties are encountered when the premises of biomedicine attempt to explain psychosocial factors in disease causation. These premises are, in principle, if not always in practice, reductionist and dualist. The significance of these difficulties is heightened as psychosocial factors increasingly emerge as factors in today's disease burden ("afflictions of civilization"). However, social scientists are much more frequently becoming partners in health research, rising to the great challenge of influencing medical knowledge.

Psychosocial Health Specialization

The need for special expertise when dealing with psychosocial aspects of health and illness has led to the development of medical school subspecialties such as behavioral medicine and behavioral pediatrics. Conversely, most psychosocial professions have developed specializations in health, such as health psychology, health social workers, or medical sociology/sociology of health.

Critiques on the Current Situation

Quality of the Dialogue between Medicine and Social Sciences

In many cases, medicine embraces very superficially the concepts and variables from psychosocial sciences. During the absorption of these concepts into the medical professional discourse, much of their original meaning, depth, and comprehensiveness is lost. As a simple example, recall the uses of social variables in epidemiology. The associations of education or socioeconomic status with health measurements are frequently analyzed, but the impression is of a "fishing expedition," with no clear or focused hypothesis behind the effort. Explanations of the findings are usually *post factum* and superficial. Even the common characterization of population groups by ethnic origin lacks a clear and consistent rationale. Is ethnicity being used to categorize genetics, or socioeconomic or cultural groups? Considerable theoretical work done by social scientists on these issues is totally unknown to epidemiologists and other health professionals. On the

other hand, social scientists are accustomed to refer exclusively to their professional colleagues, with no genuine attempt to reach other audiences. Both sides need to change their attitudes in order to improve the dialogue, not just as individuals but as a true interdisciplinary operation.

Social Scientists as Insiders or Outsiders

There are two clear positions about social scientists whose main focus of interest is health and medicine. At one extreme are those social scientists who strongly believe that in order to be a real sociologist, anthropologist, or economist, they have to be “outsiders,” totally independent, autonomous academic professional intellectuals. The tenet for this is that the best and most significant research questions have to be strongly grounded in theory and must contribute directly to theory development. The main critique leveled at this position is that social scientists become a closed sect, talking only to themselves, frequently taking a one-sided critical and even scornful position. The other position is a parallel tradition of social scientists aspiring to change, improve, and in some sense modulate social reality. A modest group in this tradition consists of those social scientists who see their work as applying their perspective and knowledge to real social problems. They prefer, then, to be “insiders,” in order to better identify and understand what really burdens people and social organizations, and to be able to contribute directly to social change. The major criticism brought against this position is lack of perspective, because the social scientist, like any human being, is strongly influenced by the social milieu in which he/she lives. Applied social science usually finds it far more difficult to liberate itself from the point of view and the ideology of the medical profession, and its practitioners are then criticized by colleagues for being too conformist and not critical enough in their conclusions.

Theory-Grounded Research

The development of social science as an occupation, especially in American society, carries with it some distancing from theory and submersion in survey opinion polls and experiments with strong emphasis on strict and polished techniques and methodologies. In many cases, this aspect of the social scientist's work focuses only in providing very specific data commissioned by employers or clients, with almost no significance for the broader theoretical perspective. Statistical data, even social measurements, will not “become” sociology or economics or social psychology until they are interpreted and slotted into a theoretical reference framework. Practical problems have to be translated into clear conceptual definitions, and hypotheses have to be derived strictly from theories

so that when they are verified or refuted, the explanation and significance of the findings can be grounded in theory. This theoretical emphasis is not just to defend the research before academic colleagues, but to ensure in a multidisciplinary problem-solving process that the social scientist has contributed a unique point of view and body of knowledge. Social scientists, even with a strong applied or policy-oriented approach, have to always remember who they are and from where they come.

Built Environment

Karen A. Franck

New Jersey Institute of Technology, Newark, New Jersey, USA

Glossary

architectural programming The information-gathering phase that precedes architectural or interior design decisions; may include behavioral research to determine organizational goals and user needs.

behavior mapping An observational method for recording details of ongoing activities in specific locations.

behavior setting A concept referring to the regularly occurring combinations of physical features and patterns of use and meaning that constitute everyday environments.

cognitive map An internal spatial representation of the environment that takes the form of a schematic map.

participatory design A process of designing or planning an environment to be built (or modified) that includes future occupants in decision making.

personal space The zone around the body that a person, and others, recognize as that person's space; zone size varies according to activity, context, culture.

post-occupancy evaluation Research conducted in a recently built (or renovated) environment to determine how well user needs have been met.

Sanborn maps Detailed maps of cities, showing land subdivision, building forms, construction, uses, and street widths; used primarily by city governments.

spatial syntax A technique for graphically representing structure of circulation in or around the interior or exterior of a built environment.

The built environment has been the subject of social science research in the United States since the 1950s and 1960s. With the twin aims of filling a gap in the social sciences, which traditionally ignored relationships between the physical environment and human behavior and experience, and of improving the quality of built environments for occupants, members of a variety of disciplines have pursued diverse research approaches and

topics, employing a variety of methods. The sources of information frequently used include occupants, environments, records and archives, architects, and building professionals. The “built environment” is understood to include buildings and interiors as well as designed open spaces such as streets and plazas, neighborhoods, communities, and cities.

Introduction

When and Why the Built Environment

Social scientists in the United States started to study the built environment and its relationship to human behavior and experience in the 1950s and 1960s. In response to inquiries from psychiatrists and architects about how to improve the design of mental wards, psychologists Humphrey Osmond and Robert Sommer in Canada, and Harold Proshansky and his colleagues William Ittelson and Leanne Rivlin in New York, began to explore how the design of these settings influences patient behavior. Psychologist Roger Barker had already been documenting the precise location, content, and sequence of everyday activities of children in small towns in the Midwest. As interest in the built environment grew among psychologists, concepts of privacy, personal space, and territoriality became useful, as evident in the research of Irwin Altman. Following earlier traditions in their discipline, sociologists, including Lee Rainwater and Herbert Gans, studied the experiences of residents in public housing, urban neighborhoods, and suburban communities. Because social scientists traditionally focus on people and their experiences, much of the research treated the built environment as the independent variable, or as context. One researcher who treated the environment as a dependent variable early on—that is, as the product of human actions—was an architect. Amos

Rapoport adopted an anthropological perspective to investigate variations in house forms resulting from differences in cultures and climates.

During the 1960s and 1970s, within the general climate of concern over solving social problems and improving urban life, architects, planners, and urban designers became aware that many of the modernist tenets of city and building design were creating serious problems for daily life; this encouraged building professionals to gain a greater understanding of human responses to the designed environment, for which they turned to social scientists and their research methods. Social science methods provided design professionals with a more systematic, empirically based and verifiable means of gaining information to make design decisions, as compared to the more personal, subjective, and anecdotal means traditionally employed in design fields.

Architects and urban designers, along with social scientists, were greatly affected by Jane Jacobs' 1961 book *Death and Life of Great American Cities* and by the 1972 demolition of the Pruitt Igoe public housing project in St. Louis. Architects and social scientists of this period began to collaborate in various ways. Professional organizations were formed, including the Environmental Design Research Association (EDRA) in the United States, the International Association of Person–Environment Studies (IAPS) in Europe, the Pacific Association for People–Environment Relations (PAPER) in Australia, and the Man–Environment Relations Association (MERA) in Japan. Over the years, journals were established (*Environment and Behavior*, *Journal of Environmental Psychology*, *Journal of Architectural and Planning Research* and *Architecture and Compartment/Architecture and Behavior*) and books and book series were published. Architecture programs hired social scientists to teach; and Ph.D. degree-granting programs were started.

Various descriptive names emerged to delineate the field, some indicating disciplinary connections, some more inclusive: environmental psychology, ecological psychology, environmental sociology, environmental anthropology, human ecology, social ecology, man–environment (and then person–environment) studies, environment behavior studies, and environmental design research. A goal among many researchers was, and continues to be, both to fill a gap in social science knowledge about the built environment, as context and as outcome, and to provide information that will improve the quality of the built environments for occupants. To do either, within a social science framework, requires the development of conceptual approaches and the invention of appropriate methods. It is clear that the foundation of this field lies in social science, not in the design disciplines. Not surprisingly then, although architects and designers have sought out, and continue to seek, education in social science

disciplines, there has not been the same movement of social scientists into design.

Characteristics of Research

Research in this field is typically conducted in real-world settings and not in laboratories. Although “field research” is common in anthropology and sociology, for psychologists it was initially a disciplinary and methodological departure, which followed the legacy of Kurt Lewin's action research. Researchers may also explore people's responses to graphic representations of actual or ideal environments or may use simulated environments. These include physical models, full-scale constructions of rooms or entire buildings, and, more recently, digital modeling and virtual reality models. Studies may also be longitudinal, looking at situations before and after physical interventions have been made or before and after people move, and comparative between different kinds of environments.

Researchers acknowledge that the built environment and human behavior and experience affect each other—that the environment does not determine human behavior and experience, and that what influence it does have is very likely modified by a host of other factors. The built environment is recognized to be adaptable, to change over time, and to have both fixed and semifixed and movable features. Thus, even though any given research endeavor must, necessarily, focus on a few aspects of environment and people and often looks primarily at the environment as an independent variable (context of human action) or as a dependent variable (product of human action), the true complexity of the situation has been a key concern in the development of theories and methods. One concept that addresses this complexity, originally proposed and used by Roger Barker and further developed by Allan Wicker, is the “behavior setting.” This refers to the combination of a particular type of built environment and its use, thus encompassing the regularly occurring combination of physical features, furniture and objects, patterns of use, kinds of users, and related rules of a small-scale environment. For instance, an elementary school classroom or a dentist's office is a behavior setting. Further development of this concept has emphasized the importance of meaning and cultural variations in behavior settings and the linking of both settings and activities into systems.

Both built and natural environments are subjects of study in this field, although studies of the latter are not discussed here. Research has covered all kinds of built environments (houses, housing complexes, day care centers, offices, markets, malls, schools, prisons, hospitals, post offices, courthouses, museums, zoos, parks, streets and plazas, and environments for particular groups, including housing for the elderly or those with dementia) at different scales, ranging from individual rooms or

outdoor spaces to buildings to communities, neighborhoods, and entire cities. There is a strong empirical tradition in the field, and in some cases, it is possible to make quite well-controlled comparisons between environments that are similar except in only a few key respects (or even one). For the most part, however, such control is not possible. Nonetheless, a breaking down of environment and behavior/experience into discrete and measurable, or at least discernible, components is common. An alternative perspective on research in this field is found in phenomenological approaches used by David Seamon, Robert Mugerauer, and Louise Chawla.

The choice of what environments, what aspects of them, what aspects of human behavior and experience to study, and how to do so depend on the particular interests and disciplinary background and predilection of the researcher, as well as on requests for information that arise from design and planning projects. For these reasons, the kinds of research questions pursued, the conceptual approaches adopted, the methods used, the research findings, and the format and location of presentation are highly varied (and dispersed). The result is a rich array of methods, information, and insight, not a cohesive, well-structured, and centralized body of knowledge.

Research and Design

The goal of providing findings that will help to improve the built environment proves to be difficult to achieve, given the differences between the requirements and expectations of social science and those of the design professions. Designers need very specific information, quickly, regarding particular kinds of building occupants in particular kinds of buildings, in a format that allows them to make design decisions. Social scientists, however, generally conduct studies over a longer time period and generate findings that do not indicate the value of highly specific design features. For instance, a social science study of productivity in office environments may show that chairs and lighting quality are important influences on the level of productivity or worker satisfaction. On hearing this, a designer may ask “What kinds of chairs?” or even “What brand of chairs?” This degree of specificity about environmental features may well not have been recorded.

To address the differing requirements of social science research and the design process, researchers have sought, in different ways, to conduct studies that are directly addressed to contributing information that will be useful in making design decisions. One way is to use the results of research to develop guidelines, in book form, for the design and furnishing of particular types of environments, such as housing for the elderly, public plazas, or correctional facilities. Guidelines are not as specific as recommending brands of chairs, but they do contain functional

information to guide design decisions (e.g., chairs with certain kinds of features, such as wheels, or with arms and a high back, that allow the elderly to use them easily). Guidelines are also likely to present examples of different design solutions, such as the size, function, and arrangement of rooms, indicating the behavioral advantages or disadvantages of the choices.

Researchers also conduct analyses of organizational goals and user needs during the information-gathering phase that precedes design; architects and interior designers call this “architectural programming.” In behaviorally based programming, researchers systematically interview and observe the future occupants of the new building (possibly in their present one) and/or the occupants of similar buildings, to determine the user needs that will inform design decisions. Or the process may involve working closely with the client and the building’s future occupants, including those who will manage and maintain it, to discover needs and aspirations through in-depth discussions, focus groups, and community meetings, as Henry Sanoff, Lynda Schneekloth, and Robert Shibley have done, facilitating a programming or a participatory design process.

Another form of research directly connected to design is the study of an environment after it has been built and occupied to determine how well, and in what ways, it does (and does not) fulfill the architect’s intentions regarding its use and how it meets the needs of its occupants. This kind of research, often called “post-occupancy evaluation,” usually takes place at least two years after the building is first occupied. The intention is that findings from the study may be used to adapt the building (or the way it is used) to make it more responsive to needs and, as importantly, to provide information for the future design of similar types of buildings. Starting with the founding in the 1970s of the Buffalo Organization for Social and Technological Innovation (BOSTI) by Mike Brill, private firms have offered research-based organizational analysis, architectural programming, and postoccupancy evaluation services to paying clients. Academics may do similar kinds of work as consultants.

Occupants

For social scientists studying the built environment, the most immediate and possibly the most obvious sources of information are the present, past, or future occupants. In contrast, given their training, designers and other building-related professionals would be more likely to look to the environments first. This was a key contribution social science made to the design disciplines early on: the recommendation to look at how environments are actually used and to talk to the occupants.

With their interest in naturally occurring behavior in everyday environments, researchers often employ

methods of behavioral observation. These observations may take the form of walk-throughs of the environment being studied, possibly with the architect, staff, or occupants, during which observations may be recorded on plans, as a way to connect the observed behavior with a specific location, or with photographs or videotape. In other cases, more systematic and possibly repeated techniques may be adopted in which observers use precoded categories to record, at specific periods of the day and week, types of activities, number, and kinds of participants in each activity, location, and use of physical props. Given this noting of behaviors located in particular spaces, the technique has been called “behavior mapping.” Time-lapse filming has been used as a means of recording behavior, notably by William H. Whyte in his study of public plazas in New York, work that led to revising the zoning code in New York to increase the number and quality of such places. In this type of place-centered mapping, the unit that is being observed is a given space or spaces, whereas in person-centered mapping, what is being observed is a person or group of people as they move from one space to another, a technique often used in way-finding research. Various electronic devices can now be used, by the observer and/or by the people being observed, to increase the ease and efficiency of both types of behavior mapping.

Focused interviews with individuals and groups of people and standardized questionnaires containing fixed-choice and open-ended questions are common instruments. Questions may cover environmental preferences, perceptions, and evaluations of experienced or hypothetical environments or specific features of them, uses of and experiences in given environments, adaptations of environments, and other aspects of life (such as friendships, socializing, desire to move, etc.) that the researcher may be studying in relation to the environment. Those responsible for the management, maintenance, security, or programs and activities within environments are also approached for information and insight to understand the functioning of particular buildings or outdoor spaces or of that type of environment.

Because built environments are places (actual and imagined), visual images are used in a wide variety of ways. The interviewer may present a map of a neighborhood or a simple plan of a building and ask for answers to be made on it (e.g., “Where do you feel most safe?” or “Where do you spend most of your time?” or “What route do you take to get to your house?”). This technique is often used in participatory planning and design projects. Respondents may be asked to rate photographs or drawings according to preference or other criteria, or to sort them into categories. This method has been used in studies of people’s perceptions and evaluations of urban environments. In some studies, people were given cameras to take their choice of pictures of particular kinds of

places, such as favorite places in their neighborhoods. Researchers have also asked respondents to give answers in the form of maps or drawings that they draw themselves. Kevin Lynch’s method, described in *Image of the City*, of asking people to draw a quick sketch map as they might to describe their city to a stranger, helped initiate widespread adoption of this technique of cognitive mapping, including in way-finding research and in Donald Appleyard’s planning of a planned city in Venezuela.

Environmental simulations are also used as a research method. The simulated environment may be physical (a small-scale model or a full-size mock-up of a setting) or, using computer technology, a virtual three-dimensional model that allows the participant to “move” through the simulated spaces. Whether physical or virtual, simulations are useful for getting people’s feedback on environments that have not yet been built. Methods can also involve lengthier and possibly more intimate activities, such as keeping daily diaries, or writing environmental autobiographies to describe the places lived and the memorable experiences and feelings related to those places. To explore people’s deepest feelings about their homes, Clare Cooper Marcus developed a role-playing method whereby respondents draw symbols to represent their homes and then speak to the drawings, as if speaking to the home. They then adopt the role of the home, speaking back.

Environments

Built environments, regardless of the presence of people, are key sources of information. One common and very useful technique is to observe environments for visual, auditory, and olfactory evidence of current or past use and for adaptations that occupants have made. With drawings, cameras, video cameras, plans of the environment, or precoded checklists, observers record the conditions of settings and a variety of physical traces. As John Zeisel has listed them, traces could include by-products of use (erosions, leftovers, missing traces), adaptations for use (props, separations, connections), displays of self (personalization, identification, group membership), and public messages (official, unofficial, and illegitimate signs). Leftovers can include items left outdoors, such as toys or lawn furniture; erosion might be shown in the way a path has been worn through the grass, and an adaptation might be the hole made in a fence.

To understand how interior space is used, and what problems may arise with the size and relationships of rooms, researchers will record on floor plans (and through photographs) the location, type, and size of furniture and other belongings, as Sandra Howell did in an early study of housing for the elderly, resulting in design guidelines for future buildings. This kind of inventory of space, furniture, and equipment is a very useful tool in

architectural programming, to determine needs that should be met in a new facility. To document ongoing management philosophy, as well as the use of space, observers have recorded when and where the doors in mental wards are locked, as in research by Maxine Wolfe and Leanne Rivlin on children's psychiatric hospitals. In Harold Kayden's study of privately owned public spaces in New York, the conditions (e.g., amount of seating, quality of maintenance, presence of trees or other greenery) and accessibility of each such space was noted and documented.

All of these features are things done to the environment by people. What about the environment, as built? What features of it are important in relation to people's activities and experiences? These questions have received relatively less attention than have the activities, experiences, and attitudes of occupants. There are notable exceptions. Kevin Lynch, based on his own observations of cities and respondents' cognitive maps, found that certain urban design characteristics helped determine the imageability, or legibility, of cities. Oscar Newman drew on his own observations, as well as on crime records and resident surveys, to demonstrate that certain architectural features of buildings and public spaces in public housing affected the levels of crime, the fear of crime, and community cohesion. Each of the two latter studies contained theoretical tenets and empirical results. In other cases, researchers may adopt a more directly empirical perspective to discover which environmental features answer particular needs, or the needs of particular kinds of occupants, as in what kinds of layout, signage, and interior design enable wayfinding in hospitals, or the best features of a residential environment for people with Alzheimer disease. Or researchers determine how the view of a natural setting decreases length of hospital stay and how the presence of a green space in a residential environment affects very specific experiences and behaviors.

Built environments are also critiqued from the point of view of the behavioral needs of particular groups of people, needs that have typically been neglected. Recommendations for change and alternative environments are often presented. The needs of women in built environments, from the scale of houses to cities, have received attention, as have the needs of nontraditional households. How to meet the needs of the disabled has become an important topic with the passage of laws requiring accessibility for all.

A broad ranging, theoretically based, and systematized method of measuring built environments is spatial syntax analysis, first developed by Bill Hillier and Julienne Hanson in the 1980s. Typically, building floor plans are scrutinized to determine the structure of circulation from the entry point to all rooms. The plan is translated into a structural network of pathways represented graphically, with nodes as spaces and lines as connections; the representation illustrates the degree of accessibility to any given

space as well as the overall network of connections. One of several numerical outcomes is the depth of any node (the number of lines necessary to reach all other nodes) and the average mean depth of the system as a whole. What is being analyzed is the spatial logic embodied in the plan of a building or a neighborhood. Spatial syntax analysis is used to correlate numerical outcomes of the graphs with observed patterns of use of streets and sidewalks, as Bill Hillier and his colleagues have done, as well as to demonstrate how the social and cultural ideologies behind building types is embodied in built form, as Thomas Markus and Kim Dovey have done.

Records and Archives

Records, archives, reports, the popular press, and publications of all kinds are also used. To study crime and other community conditions, researchers use police reports and management reports of turnover, vacancy, and vandalism. Hospital records on length of hospital stay or on recovery rates, which also provide information on the patient, are another useful type of record. Roger Ulrich and others have used such records to relate length of stay to environmental features of the hospital room, such as having a view of a natural setting. Similarly, student records of test scores have been related to classroom conditions such as day lighting and noise level; records of attendance and days sick were studied before and after moving to new and improved housing.

Expert reports, design guidelines, other building or zoning related documents, projects proposed but never built, or architectural plans for projects that were subsequently revised or torn down, as well as old photographs and real estate brochures, can all be used for investigation, along with popular press and newspaper articles. This kind of archival research was very useful to Galen Cranz's history of the ideas and values behind park design and to Lawrence Vale's research on the history of the building and the subsequent redesign of housing projects in Boston. In each case, the ideology, and the changes therein, that lay behind the building and the modification of environments were explored. Marketing brochures, model homes, and other sorts of advertisements for buildings provide useful documentation, along with the oral and visual presentations by architects and other building professionals. Researchers may also keep their own records of environments, as Camilo Vergara does through his documentary photographs and written comments on the changes, often the deterioration, in buildings in urban neighborhoods over time.

In studying the design process as it proceeds, researchers may collect and scrutinize sketches and initial designs, using them both as a means to query designers on what their decision-making was and as illustrations of how

decisions evolved. These visual records are also used in conjunction with written records such as meeting minutes, change orders, and newspaper articles to analyze the evolution of a project. All kinds of maps of cities, neighborhoods, and individual blocks and building lots can be studied to understand changes in the built environment over time and to relate those changes to others indicators, such as census tract information. In her study of architectural change at the neighborhood level in San Francisco, Anne Vernez Moudon turned to past and current Sanborn maps that record building form, construction characteristics, internal uses, and details of land subdivision. Using the Global Information System (GIS) technology, the possibilities for using this method (layering a wide array of different kinds of digitized information, from different sources, over the same geographical area) have increased dramatically. The data can be manipulated, analyzed, and represented in a great variety of ways.

Architects and Building Professionals

For understanding the processes and factors behind the creation of particular environments, researchers often interview a variety of building professionals and their clients. This includes architects, landscape architects, interior designers, facility managers, planners, developers, municipal authorities, and members of community groups and other decision-making bodies. For understanding the design process more generally, researchers have interviewed architects and architecture students and have observed their design-related activities. For her study of professional architectural practice, Dana Cuff observed and recorded activities in architecture firms, including meetings between architects and their clients. To explore how personal memories play a role in the design process, Frances Downing interviewed students as well as established architects, incorporating sorting tasks and drawing tasks into the interview. Toby Israel used a variety of exercises and guided visualizations to explore how the personal environmental histories of several prominent architects have influenced their designs.

Current Status

The built environment in relationship to human behavior and experience continues to be studied in a variety of ways, for a variety of purposes. Although the degree of interest among individual practicing architects and architecture schools is considerably less now, at the beginning of the 21st century, than it was in the 1960s and 1970s,

the use of social science methods for understanding and evaluating environments appears to be more widespread. Professional firms continue to provide the services of post-occupancy evaluation, architectural programming, and facilitation of participatory design. Public agencies, including the United States Postal Service and the General Services Administration, as well as large institutions, hire consultants or employ their own staff to develop architectural programs based on behavioral research. Post-occupancy evaluations are now routinely conducted by many public agencies, both in the United States and other countries. After each of the many new U.S. federal courthouses is completed, it receives a thorough post-occupancy evaluation, the results of which are used to revise the design guide for future courthouses.

In society at large, there seems to be greater concern for the connections between the needs and activities of individuals and the built environment. Attention is being paid to how environments can be, and often must be, designed to meet special needs, including the needs of people with disabilities. How environments can be designed to be sustainable and to support less resource-consuming lifestyles is of increasing interest. The recent design and planning movements of new urbanism and transit-oriented development make particular patterns of activity (walking, community interaction, using public transit) centerpieces of their ideology. The possibility that dependence on the car and the absence of urban design features that encourage, or even allow, walking contribute to obesity and other health problems is a recent topic of research, as well as public discussion. In general, the relationships of the built environment to health and well-being is a growing area of research. Most professional organizations, journals, and degree-granting programs established earlier continue to exist, with new research endeavors and new books in continuous production. The topic of the built environment, from the perspective of social science, social concerns, and design, is alive and well.

Business Research, Theoretical Paradigms That Inform

Gayle R. Jennings

Central Queensland University, Rockhampton, Queensland, Australia

Glossary

axiology The study of ethics and values.

chaos theory Describes and explains a world of unstable systems (nonlinear and nonintegral) using descriptive algorithms. In the social sciences, the theory may be used metaphorically to describe a setting or organization as chaotic.

complexity theory A view of the world as being constituted of complex and open systems composed of agents, each of which interacts with the others to move from a state of disorder to order by self-organization.

critical realism A paradigm related to postpositivism in which truths, laws, and facts are fallible and theory bound to specific contexts (for example, social and historical). An objective epistemological stance recognizes that researcher biases and values may influence research projects. The methodology is primarily quantitative, although mixed methods may be incorporated. Axiology is value free and extrinsically based. Critical realism is utilized by value-based professions.

critical theory The ontology of this paradigm recognizes that there are complex, hidden power structures in the world that result in oppression and subjugation of minority groups. The researcher's role is to make visible these structures and to become the "champion" of the minority via a value-laden axiology that aims to change the world circumstances of those being studied, using a subjective epistemology and qualitative as well as some quantitative methodologies.

epistemology The science of knowledge; also the relationship between the researcher and that which is to be known. The relationship assumes either an objective or a subjective stance.

feminist perspectives A generic term used to describe a number of feminist perspectives, such as radical feminism, marxist/socialist feminism, liberal feminism, and postmodern

feminism. Each perspective has its own specific ontological viewpoint regarding the subjugated position of women. Feminist researchers use a subjective epistemology and engage in primarily a qualitative methodology. Axiologically, for feminist researchers, the research process is transactional and intrinsically value laden.

interpretive social science paradigm A model associated with the terms (social) constructionism, (social) constructivism, social phenomenology, hermeneutics, and relativist approaches; also referred to as the interpretive paradigm.

ontology The world view or representation of reality particular to a specific theory or paradigm.

paradigm A set of beliefs regarding how the world operates/functions. Paradigms have specific stances in regard to ontology, epistemology, methodology, and axiology.

participatory paradigm The world view (ontology) is generated collectively and recognizes multiple realities. The research process emphasizes participant involvement, a subjective epistemology, and the use of qualitative and quantitative methodologies based on the principles of action research and an action research cycle (design, implementation, evaluation). The axiology is predicated to practical knowing as well as cooperation. The research is undertaken for its intrinsic value.

phenomenology A philosophy, a paradigmatic view of the world (social phenomenology), as well as a tradition of undertaking research in the social sciences.

positivism A theoretical paradigm with an ontological stance (world view) that assumes that universal truths and laws are able to explain and predict behaviors and events. The epistemological stance is objective, and a quantitative methodology guides research processes. Axiologically, positivism is value free and research projects are extrinsically focused.

postmodernism The ontological position of postmodernism exhibits skepticism toward knowledge. This paradigmatic view recognizes that the world is constantly changing and,

subsequently, that no one position or perspective of the world should be privileged over any other. The epistemological stance involves researchers subjectively making “history”/reality via the deconstruction of texts. A qualitative methodology is used with a strong focus on the role of intersubjectivity and reflexivity. The paradigm is value laden and intrinsic in nature.

postpositivism A paradigm related to positivism. Ontologically, postpositivism assumes that the world, or “reality,” may only be probabilistically and imperfectly known. Researchers maintain an objective epistemological stance. The paradigm associates with predominantly a quantitative methodology and researchers essay to be value free and adopt an extrinsically focused axiology.

qualitative methodology Provides a framework for empirical material (data) collection and analysis that enables researchers to gather empirical information in its textual entirety. The empirical materials are not substantively reduced or represented numerically.

quantitative methodology Provides a framework for data collection and analysis that enables researchers to reduce, analyze, and report the collected data numerically and statistically.

social constructivism This paradigm maintains that the world is constructed of multiple realities. These realities become subjectively known through the use of a qualitative methodology and a value-laden axiology that acknowledges the intrinsic values of undertaking research projects. The term is sometimes used interchangeably with (social) constructionism, (social) phenomenology, interpretive social science paradigm, hermeneutics, and relativism. At a general level, such interchange reflects the view that the construction of reality (the social world) is a social act. However, when considered in greater detail, each approach differs in regard to ontology, epistemology, methodology and axiology.

Business utilizes a variety of theoretical paradigms drawn from the social sciences to support its research activities. The predominant paradigms are the positivistic and postpositivistic paradigms. These paradigms have traditionally provided business with its social sciences methods. However, during the second half of the 20th century, paradigms associated with the traditions of social constructionism, social constructivism, social phenomenology, and the interpretive social science paradigm were being used (and continue to be used) by business to provide alternative methods for the conduct of business research. Related to those paradigms are critical theory, feminist perspectives, and postmodern and participatory paradigms. Essentially, the positivistically derived paradigms (positivism, postpositivism, and critical realism) are associated with a quantitative methodology. Social constructionism, constructivism, phenomenology, or interpretivism and related paradigms are associated with a qualitative methodology.

Introduction

Business incorporates a number of fields/disciplines of study, including accounting, auditing and finance, commerce, economics, entrepreneurship, human resource management, management studies, marketing, organizational studies, political sciences, public administration, strategic management and planning, and tourism, among other fields and branches of study. Each field/discipline/branch has its own specific history and predilections toward social science methods. Because the study of each field is beyond the scope of this article, the discussion here focuses on applying “business” as a generic descriptor deemed to be representative of each of the related fields. A consequence of this application is that focus is restricted to the emblematic social science methods used across the contributing fields.

Paradigms That Inform Business Research

Business disciplines have historically been predicated on the adoption of the natural or physical sciences (also known as hard sciences) model of research. Literature indicates that the adoption of this model of conducting research was assumed to increase the credibility of business disciplines/fields, as each discipline has a relatively short history compared to disciplines in the hard sciences (such as mathematics, physics, botany, and biology). The natural sciences model of research as applied to the study of people, and specifically for business, is based on positivism. Positivism (or positive philosophy) was founded by the French philosopher, Auguste Comte (1798–1857), who also coined the term “positivism.” Positivism (also referred to as empiricism) has a particular ontological, epistemological, methodological, and axiological position. Specifically, positivism ascribes to universal truths and laws (ontology), an objective epistemology, a quantitative methodology, and a value-free and extrinsically based axiology. In the past (and also contemporaneously), the ontological viewpoint of positivism has been critiqued with regard to the universality or existence of such “truths” and “laws.” Other critiques were concerned with the mirroring of the social world with the physical world. Karl Popper (1902–1994), for example, critiqued positivism as espoused by Comte, and later by John Stuart Mills (1806–1973), for its view that people were akin to biological entities on whom the use of scientific methods could enable predictions of the future to be made. The paradigm of postpositivism emerged in response to such and other critiques of positivism.

Postpositivism differs from positivism in that its worldview (ontology) acknowledges that truth is mutable as well as historically and socially based, rather than being universal and apprehendable. Postpositivism also incorporates mixed methods into the research design, whereas positivism does not. Specifically, postpositivism has a worldview that acknowledges that “truth” is fallibilistically determined, because humans are involved. It assumes an objective epistemology, primarily uses a quantitative methodology (incorporates mixed methods—that is, both quantitative and qualitative methods in its research design), and essays to be value free and maintains an extrinsically focused axiology. A particular branch of postpositivism that is widely used in business disciplines is critical realism. Critical realism and postpositivism have a similar ontology, epistemology, and methodology. Axiologically, however, though the critical realist paradigm essays to be value free, some proponents purport that critical realist research should also result in emancipatory outcomes.

While postpositivism developed from critiques of positivism, two other theories have emerged, chaos and complexity theories, and these also provide critiques of both positivism and postpositivism. These theories developed within the hard sciences and reflect a mathematical orientation toward theory building. Both theories challenge the linear world views of positivism and postpositivism. For chaos and complexity theorists, the world is dynamic and ever changing and requires the use of non-linear explanations to account for such changing circumstances. Chaos and complexity theories, along with critical realism, some would argue, provide a midpoint position between positivism and the social constructionist, social constructivist, social phenomenological, and interpretive social science paradigms.

In the latter half of the 20th century, the social constructionist, social constructivist, social phenomenological, and interpretive social science paradigms began to be incorporated into research repertoires of business and business-related researchers. Some researchers positioned their research fully within social constructionist, social constructivist, social phenomenological, or interpretive social science paradigms, and others added the paradigms to their suite of research practices. Still others opposed the use of such paradigms due to the perception that the paradigms were not scientifically rigorous. Such positions continue to reflect attitudes toward paradigms that inform the conduct of business research at the commencement of the 21st century.

The paradigms of social constructionism, social constructivism, social phenomenology, and interpretive social science are concerned with the study of phenomena from an insider’s perspective of the social context being studied. Constructionism is particularly associated with the work of William Thomas (1863–1947). The beginnings of social

phenomenology stem from the philosophical phenomenology of Edmund Husserl (1859–1938). In particular, Alfred Schutz (1899–1959) drew on Husserl’s work to fashion what has become known as social phenomenology. Several of Schutz’s students, Peter Berger (1925–) and Thomas Luckmann (1927–), are recognized for their contribution to the development of social constructivism. The interpretive social science paradigm is linked to the work of Max Weber (1864–1920) and Wilhem Dilthey (1833–1911), especially their respective work in regard to *verstehen* (empathetic understanding). Hermeneutics is another related term appearing in the literature and is often described as aligned with the interpretive paradigm.

Within business literature (and other literature), there exist examples of the implicit or explicit use of these terms interchangeably and/or synonymously. At a general level, this practice recognizes that each of these approaches is associated with the social nature of the construction of social reality, as well as understanding the world from the perspective of an insider—specifically, how that insider constructs meaning in regard to the social context being studied (in this case, the business world). That being said, it must also be stressed that each term ascribes somewhat differing emphases in regard to ontological, epistemological, methodological, and/or axiological stances. To iterate, although the terms are sometimes used interchangeably, they do not in fact mean the same thing. Therefore, in the following discussions (where space permits), the four terms will be used together to remind readers that each is somewhat different from the other. Broadly speaking, then, these paradigms perceive the world as constituted of multiple realities (ontology), and assume to understand/interpret those realities through the tenets of a subjective epistemology, qualitative methodology, and value-laden and intrinsically based axiology. Associated with the paradigms of social constructionism, social constructivism, social phenomenology, and the interpretive social science are the related critical theory, feminist perspectives, postmodern, and participatory paradigms. These four paradigms are also utilized to design studies and research projects in business settings. Together with social constructionism, social constructivism, social phenomenology, and the interpretive social science paradigms; critical theory, feminist perspectives, postmodern, and participatory paradigms are associated with a “soft” science approach. The terms “hard” and “soft” sciences are used to distinguish between the scientific, objective inquiry of the natural or physical sciences and the naturalistic (as occurring in real world), subjective inquiry of the social or humanistic sciences. Critique exists in the literature regarding the use of the terms, because they are considered to be pejorative and do not effectively portray the different approaches each

type of science uses for the study of business and business related phenomena.

Table I provides an overview of the differences between each of the paradigms presented in this section. This table incorporates a summary of the various paradigms in regard to their origins, associated synonyms and related terms, and overall focus of the research intent, as well as stances in regard to ontology, epistemology, methodology, and axiology. (Due to space limitations, of the social constructionism, social constructivism, social phenomenology, and interpretive social science paradigms, only social constructivism is represented in Table I.)

Current State of Practice

Business disciplines remain predicated to positivistic and postpositivistic (critical realist) paradigms in regard to the majority of research conducted. However, critical debate occurs in each of the fields of study (as per articles in academic journals and texts) as to the ability of positivistic and postpositivistic (including critical realist) paradigms to explain fully business phenomena. Subsequently, other paradigms are being included and used to study business and business-related phenomena. These paradigms include chaos and complexity theory, the previously mentioned social constructionism, social constructivism, social phenomenology, and the interpretive social science paradigm, as well as critical theory orientation, the participatory paradigm, feminist perspectives, and postmodern perspectives. These paradigms are slowly and increasingly being used to explain business phenomena. It is important to comment that debate exists regarding whether feminist perspectives and postmodern perspectives are perspectives under the rubric of social constructivism, or are paradigms in their own rights.

For business, then, a continuum of research paradigms is available. Given this continuum, commentary in the literature would indicate that the issue is not which paradigm is better, but rather which best serves the research purposes and the current world context. Having identified a suitable paradigm, the epistemological position of that paradigm will determine the choice of methodology for that business research—quantitative or qualitative or mixed. Some business researchers advocate that paradigms may be mixed. However, controversy exists in regard to the incommensurability of ontological viewpoints between positivistic paradigms, at one end of the continuum, and the social constructionist, constructivist, phenomenological, and interpretive-oriented paradigms, at the other end, albeit that business researchers recognize commensurability between like paradigms (that is, between those paradigms that are positivistic in nature, or between those that are social constructionist, constructivist, phenomenological and interpretive oriented). Furthermore, the literature suggests that methods may be

mixed more readily than methodologies may be, because methodologies are informed by the ontological stance of each paradigm, and (as demonstrated in Table I) these differ across the paradigmatic continuum.

Quantitative and Qualitative Methodologies That Inform Business Research

A methodology is a set of principles that provides a guiding framework for the design of research. Each of the theoretical paradigms that can inform (business) research has a specific methodological orientation: quantitative or qualitative. The ontological, epistemological, and axiological stance of each of the paradigms will determine the methodology that will be used to design the overall research project. Positivistic and postpositivistic as well as chaos and complexity theory paradigms will align with a quantitative methodology. The social constructionist, social constructivist, social phenomenological, and interpretive social science-related paradigms will generally draw on a qualitative methodology. Research using mixed methods will utilize both quantitative and qualitative methodologies (and quantitative and qualitative methods) to varying degrees in and stages of the research project.

Due to the dominance (hegemony) of positivism and postpositivism, business research is predicated to the conduct of research using primarily a quantitative methodology. However, the use of a qualitative methodology is evident in business research reports, sector and academic publication outputs, and in the generation of qualitatively focused or inclined business journals (for example, some of the journals emanating out of Europe). Further, as a result of the critique of positivism and postpositivism in regard to their ability to explain business phenomenon adequately in its real-world contexts, and the subsequent development of midrange paradigms, a mixing of methods has resulted in order to achieve what some business researchers believe is the best of both methodologies. Essentially, a quantitative methodology, if well designed, will enable researchers to explain business phenomena deductively, systematically, and objectively, using probabilistically determined causal relationships that are generalizable and representative of wider study populations. Alternately, a qualitative methodology will enable business researchers to explain business phenomena inductively and subjectively, grounded in real-world contexts that demonstrate the multiple realities of the business phenomena ideographically in study-specific contexts that may be generalized to similar settings and contexts.

The mixing of methodologies may occur in different ways. Business researchers who mix methodologies often

<i>Descriptors</i>	<i>Positivism</i>	<i>Postpositivism</i>	<i>Critical realism</i>	<i>Critical theory</i>	<i>Social constructivism</i>	<i>Feminist perspectives</i>	<i>Postmodern</i>	<i>Participatory</i>
Origins	Founded in the hard/natural sciences (<i>Naturwissenschaften</i>)	Founded on principles of hard/natural sciences (<i>Naturwissenschaften</i>)	Founded on the principles of hard/natural sciences (<i>Naturwissenschaften</i>)	Founded in human (social) sciences (<i>Geisteswissenschaften</i>)	Founded in human (social) sciences (<i>Geisteswissenschaften</i>)	Founded in human (social) sciences (<i>Geisteswissenschaften</i>)	Founded in human (social) sciences (<i>Geisteswissenschaften</i>)	Founded in human (social) sciences (<i>Geisteswissenschaften</i>)
Synonyms and/or related terms/comments	Empiricism, realism, naive realism, objectivism, foundationalism, representationalism	New realism (note: developed as a response to critique of positivism)	Described as a midpoint between realism and relativism	A number of types: Marxist/socialist, postpositivist, postmodern critical theorists	Phenomenology, interpretivism, constructivism, constructionism	A number of types: Marxist/socialist, liberal, postmodern, poststructural, critical feminist empiricism, standpoint theorists	Ludic postmodernism, oppositional postmodernism, critical postmodernism	Cooperative inquiry, participatory action research, action inquiry, appreciative inquiry
Focus	Explanation (<i>Erklären</i>), realism, objectivism	Explanation (<i>Erklären</i>), realism, objectivism	Explanation (<i>Erklären</i>), realism, objectivism	Understanding (<i>Verstehen</i>), historical realism, perspectivism, interpretivism, intentionalism	Understanding (<i>Verstehen</i>), relativism, perspectivism, interpretivism, intentionalism	Understanding (<i>Verstehen</i>), relativism, perspectivism, interpretivism, intentionalism	Understanding (<i>Verstehen</i>), relativism, perspectivism	Understanding (<i>Verstehen</i>), relativism, perspectivism, interpretivism, intentionalism
Ontology	Truth and laws are universal	Truths are fallible and a product of historical and social contexts	Truths are fallible and a product of historical and social contexts	Sociohistorical multiple realities; realities reflective of power relations	Multiple perspectives/realities	Multiple realities mediated by gendered constructs	Multiple realities; no privileging of position; skepticism towards “truth” and “-isms”	Multiple realities collectively constructed via interactions
Epistemology	Objective	Objective: acknowledges potential for researcher bias	Objective: acknowledges potential for researcher bias	Subjective unless postpositivist critical theory (objective)	Subjective	Subjective: participants and researcher/s as coresearchers	Intersubjectivity	Subjective–objective
Methodology	Quantitative	Quantitative, (use of mixed methods)	Quantitative, inclusion of mixed methods	Qualitative, some quantitative	Qualitative	Qualitative (predominantly)	Qualitative	Qualitative, quantitative mixed method
Axiology	Value free: extrinsic purpose of research project	Essays to be value free; extrinsic purpose of research project	Essays to be value free; extrinsic purpose of research project; consideration of emancipatory role of research	Value laden; intrinsic focus of research project; political agendas, emancipatory, transformative	Value laden; intrinsic focus of the research project	Value laden; intrinsic focus of research project; political, emancipatory, transformative, educational	Skeptical of emancipation and transformation; continuous deconstruction process	Value laden; transformation

^a Developed from texts presented in Denzin and Lincoln’s 1994 and 2000 editions of the *Handbook of Qualitative Research*, particularly the work of Denzin and Lincoln (2000), Lincoln and Guba (2000), Schwandt (2000), and Guba and Lincoln (1994), as well as Guba’s 1990 text, *The Paradigm dialog*, and Jennings’ *Tourism Research*. The German terms used in this table are drawn from the writings of Dilthey (1833–1911).

use qualitative methodology as an exploratory phase in the overall research design, as well as a postphase to study unusual outlier cases. Alternately, each methodology may be used in its own right as a substantive part of an overall research design that is founded on an interdisciplinary and multiparadigmatic focus. The terms “methodology” and “methods” are sometimes used interchangeably; however, they are not the same. A methodology is a guiding set of principles used to frame a research design. Methods are the tools used to gather and analyze data. Methods are also linked to the overlying methodology and subsequently to the overarching theoretical paradigm, due to the latter’s role in informing research designs.

Quantitative Methodology

A quantitative methodology is generally associated with the use of hypotheses to represent causal relationships as per the ontological perspective of the paradigms informing this methodology. Subsequently, a quantitative methodology is associated with hypothetico-deductive paradigms (empiricism, positivism, postpositivism), which are deductive in nature because they deduce “reality” and then establish the nature of that reality by testing hypotheses. As a consequence, researchers generally design their research projects utilizing hypotheses and *a priori* theories. The research is conducted by the researcher from an objective stance; that is, the researcher takes an outsider position (an etic position) to ensure that bias and values do not influence any research outcomes. The empirical data gathered will be used to test the hypotheses to determine whether the empirical data support or do not support those hypotheses. The overall research design will be organized and reported so that it may be repeated. Sampling methods will tend to be random or probabilistically determined. The data that are collected will be reduced numerically and analyzed using mathematical and statistical methods. The reporting of quantitatively based research follows the structure of the hard sciences, i.e., introduction, literature review, methodology, findings, discussion, and conclusion. The voice used in the genre of reports is third person, passive. Findings from research projects using quantitative methodologies are usually representative and generalizable to the wider study population.

Qualitative Methodology

A qualitative methodology is associated with holistic-inductive paradigms (social constructionist, social constructivism, phenomenological, and interpretive social sciences approaches). Holistic-inductive paradigms enable researchers to study (business) phenomena in their totality and complexity, instead of focusing on sets of variables and subsequent causal relationships

representing parts of the overall whole of the business or business-related phenomenon being studied. Theory development is generated inductively from empirical materials (data) rather than through the use of *a priori* theories. Researchers employing this methodology essay to understand the business phenomenon as an insider. The term “emic” is applied to describe “insider” research. Sampling methods will be nonrandom or nonprobabilistically determined. Research designs emerge and consolidate in the process of empirical materials (data) collection and concurrent analysis. Designs are context specific. Research is normally undertaken with the full understanding of the persons involved in the phenomenon, and using their knowledge bases to interpret the empirical materials (data). Research is reported using a narrative-style genre. The voice of the texts is first person and active voice. A qualitative methodology generates multiple “truths” from real-world settings, such as business environments and contexts. Findings are related to the local setting and may be generalized to other similar settings and contexts.

Mixed Methods

The term “mixed methods” is sometimes used by business researchers to describe mixed methodologies. As previously noted, some business researchers would dispute the potential for this to occur, due to the incommensurability of the ontological perspectives of some paradigms. Mixed methodologies generally occur in different phases of research design. Some research designs may include concurrent methodologies, a quantitative and a qualitative methodology to gather the data or empirical materials to illuminate business phenomena from different paradigmatic perspectives. Generally, mixed methods infer methods (data collection and sometimes analysis) within a research design that may be identified as either primarily positivistic or social constructionist, social constructivist, phenomenological, or interpretive in nature. The following examples are of mixed methods as mixed methodologies:

1. Qualitative exploratory study (phase one of design) informs quantitative data collection tool construction (phase two) in a larger quantitative research design.
2. Quantitative exploratory study (phase one of design) informs qualitative research design (phase two of design).
3. Quantitative and qualitative studies conducted simultaneously or at separate times within a larger interdisciplinary research project.

Table II provides an overview of a comparison between quantitative and qualitative methodologies. Note that mixed methods have not been included, because essentially the mixing of methods will depend on which is the dominant paradigm informing the research process and

Table II Comparison of Methodologies

<i>Descriptors</i>	<i>Quantitative</i>	<i>Qualitative</i>
Paradigm	Hypothetico-deductive	Holistic-inductive
Ontological perspective	Based on causal relationships	Illuminating multiple realities
Nature of reality determined by	Hypotheses, <i>a priori</i> theories	Grounding in real-world business and business-related contexts
Epistemological stance	Objective	Subjective
Purpose ^a	Explanation	Understanding and interpretation
Research position	Outsider, etic	Insider, emic
Nature of research design	Structured, replicable	Emergent/developmental, content specific
Sampling	Probabilistically determined	Nonprobabilistically determined
Analysis	Mathematical and statistically determined	Emblematic themes
Report style	Scientific report	Narrative text
Outcomes	Generalizable to the population of interest	Case specific; may be generalized to other similar cases

^aThe “Purpose” descriptors are based on the work of Dilthey (1833–1911), particularly the terms *Erklären* (explanation) or *Erklärung* (abstract explanation) and *Verstehen* (understanding or empathetic understanding) (see Table I). *Verstehen* was also used by Max Weber (1864–1920). Mixed methods will assume varying positions regarding each of the descriptors, depending on the degree of proclivity toward either the hypothetico-deductive or holistic-inductive paradigm. The potential permutations are manifold.

whether the research is multiphase, in which case the dominant or specific paradigm for that phase should be read.

Conclusion

Business research is informed by positivistic and social constructionist, constructivism, phenomenological, or interpretive paradigms. Associated with the latter cluster of paradigms are critical theory, feminist perspectives, and postmodern and participatory paradigms. Within the positivistic paradigms, a quantitative methodology informs the overall research design. Social constructionist, constructivist, phenomenological, and interpretive paradigms will inform business research primarily through a qualitative methodology.

The positivistic paradigms and their associated methods of data collection and analysis hold greater sway, compared to other paradigms. A number of business researchers critique the hegemony of the positivistic paradigms, and as a result, the use of social constructionist, constructivist, phenomenological, and interpretive paradigms informing research gradually increased in the latter half of the 20th century, a trend that continues in the 21st century. Moreover, mixed methods reflect the recognition of the advantages of both types of data collection and an attempt to better represent knowledge and truths of the world by using both approaches. Consequently, within current world circumstances at the beginning of the 21st century, business researchers continue to discuss and/or query the dominant hegemony. Some scholars assume a position that recognizes that it is not an

“either/or” choice, but rather a choice of which is the best paradigm to use to achieve the information required. Still others engage in dialogue with each other to achieve greater understanding between paradigmatic positions, and some remain unmoved in regard to the dominance of positivistic paradigms for explaining business and business-related phenomena.

Business, Social Science Methods Used in

Gayle R. Jennings

Central Queensland University, Rockhampton, Queensland, Australia

Glossary

axiology The study of ethics and values.

data Units or records of information gathered in the course of a research study/project. The term is usually associated with quantitative methodology. Data units may be derived, for example, from answers to questions in surveys, observations, or records of experiments. Data units are usually aggregated, represented in numeric form, and subsequently analyzed mathematically or statistically.

empirical materials Information gathered through the processes associated with a qualitative methodology; may include, for example, records of observations, interview transcripts, and visual images. Empirical materials are usually recorded in textual or visual form rather than being reduced to numeric representations.

epistemology The science of knowledge; also the relationship between the researcher and that which is to be known. The relationship assumes either an objective or a subjective stance.

interpretive social science paradigm Also referred to as the interpretive paradigm, this term is associated with (social) constructionism, (social) constructivism, social phenomenology, hermeneutics, and relativist approaches.

method Strategy and/or tool used by researchers to collect and analyze data or empirical materials.

methodology A set of principles that provides a guiding framework for the design of research projects/studies.

ontology The worldview or representation of reality particular to a specific theory or paradigm.

paradigm A set of beliefs regarding how the world operates/functions. Paradigms have specific stances in regard to ontology, epistemology, methodology, and axiology.

participatory paradigm The worldview (ontology) is generated collectively and recognizes multiple realities. The research process emphasizes participant involvement, a subjective epistemology, and the use of qualitative and quantitative methodologies based on the principles of

action research and an action research cycle (design, implementation, evaluation). The axiology is predicated to practical knowing as well as cooperation. The research is undertaken for its intrinsic value.

phenomenology A philosophy or a paradigmatic view of the world (social phenomenology), as well as a tradition of undertaking research in the social sciences.

positivism A theoretical paradigm with an ontological stance (worldview) that assumes that universal truths and laws are able to explain and predict behaviors and events. The epistemological stance is objective, and a quantitative methodology guides research processes. Axiologically, positivism is value free and research projects are extrinsically focused.

postpositivism A paradigm related to positivism. Ontologically, postpositivism assumes that the world, or reality, may be known only probabilistically and imperfectly. Researchers maintain an objective epistemological stance. The paradigm associates with predominantly a quantitative methodology and researchers essay to be value free and adopt an extrinsically focused axiology. A form of postpositivism frequently applied in business research is critical realism. Some critical realists may assume an emancipatory axiological position.

qualitative methodology Provides a framework for empirical material (data) collection and analysis that enables researchers to gather empirical information in its textual entirety. The empirical materials are not substantively reduced or represented numerically.

quantitative methodology Provides a framework for data collection and analysis that enables researchers to reduce, analyze, and report the collected data numerically and statistically.

social constructivism Maintains that the world is constructed of multiple realities. These realities become subjectively known through the use of a qualitative methodology and a value-laden axiology that acknowledges the intrinsic values of undertaking research projects. The term is sometimes used interchangeably with the terms (social)

constructionism, (social) phenomenology, interpretive social science paradigm, hermeneutics, and relativism.

Methods of data collection and analysis in business research are guided by the overall paradigm that informs the research process. Each paradigm associates with primarily a quantitative or qualitative methodology. Some mixing of methodologies may also occur. Examples of quantitative methodological forms of data collection include surveys, experimental and quasi-experimental methods, observation, forecasting, nominal group technique, focus groups, the delphic method, the documentary method, case studies, and longitudinal studies. Qualitatively informed methods of empirical materials (data) collection include semistructured interviews, in-depth interviews, observation, action research, focus groups, the delphic method, the documentary method, case studies, and longitudinal studies. A quantitative methodology incorporates various methods of data analysis, including descriptive and inferential statistics, consideration of levels of significance, and Type I and Type II errors. A qualitative methodology draws on, for example, content analysis, successive approximation, constant comparison, domain analysis, ideal types, and grounded theory analysis for empirical materials (data) analysis.

Introduction

Business research is predominantly informed by the paradigms of positivism and postpositivism, particularly critical realism. However, other paradigms—social constructionism, social constructivism, social phenomenology, and the interpretive social science paradigms—are now being included in the repertoire of business researchers. Related to this group of paradigms are critical theory, feminist perspectives, and postmodern and participatory paradigms, although there is debate as to whether feminist perspectives and “postmodernism” are independent paradigms or differing perspectives among social constructionism, social constructivism, social phenomenology, and the interpretive social science paradigms. All of these paradigms espouse specific ontological, epistemological, methodological, and axiological tenets. In particular, the tenets of each paradigm influence the methodology used to design business research projects. To be specific, positivistic and postpositivistic as well as chaos and complexity theory paradigms draw on a quantitative methodology. Social constructionist, social constructivist, social phenomenological, and interpretive social science-related paradigms generally use a qualitative methodology. Research using mixed methods incorporates both quantitative and qualitative methodologies (and quantitative and qualitative methods) in differing amounts and phases of research projects.

Methods of Data Collection Used in Business

Research on business (used here as a generic term encompassing all related disciplines, fields, and branches) draws on a wide number of social science methods, each being informed by a quantitative and/or a qualitative methodology or some mixing of methodologies within the overall research design phases.

Quantitative Methods of Data Collection

Quantitative methods of data collection reflect the methodological framework from which they are derived—that is, a quantitative methodology. A quantitative methodology is usually associated with positivistic paradigms, such as positivism, postpositivism, and critical realism. Quantitative methods (tools) are designed to enable researchers to gather data that in turn will be analyzed to test causal relationships described using variables. Specifically, data collection will enable researchers to reduce the data to numerical representations. Quantitative methods, by nature of their design, also assist in ensuring that the researcher is objective throughout the data collection phase (and analysis phase). The most frequently used quantitative methods in business are surveys (structured interviews and questionnaires), experimental and quasi-experimental methods, and observation. Other quantitative methods used include forecasting, nominal group technique, focus groups, the delphic method, the documentary method, case studies, and longitudinal studies.

Surveys

The survey is a data collection tool; a survey can be administered orally (as interviewer-conducted structured questions) and as written self-completion questionnaires. A number of modes are used for implementing business surveys: mail, telephone, face to face, intercept, and electronic. The choice of mode will determine whether the survey is subsequently classified as either an interview or a questionnaire. Another variable in survey administration is location (intercept, household, or *in situ*, such as organizational surveys). Each type of survey method has advantages and disadvantages. [Table I](#) provides an overview of the main types of surveys and a relative comparison between each in regard to administration costs, time required for data collection, and response rates.

Mail Surveys (Questionnaires) Mail surveys are postal service-delivered questionnaires that are distributed to specific population samples. Targeted respondents are requested to complete the questionnaires and return them by mail (an addressed prepaid reply envelope is usually included). To increase response rates, mail

Table I Types of Surveys^a

<i>Type of survey</i>	<i>Implementation process</i>	<i>Cost relative to other survey types</i>	<i>Implementation time relative to other survey types</i>	<i>Response rates relative to other survey types</i>
By method of administration				
Mail surveys	Questionnaires distributed using postal services	Low	Long	Low
Telephone surveys	Interviewer-conducted structured interviews, conducted via telephone	Moderate	Short–medium	Moderate
Face-to-face interviews	Interviewer-completed questionnaire, conducted within businesses and business-related settings	High	Medium–long	High
e-Questionnaires	Questionnaires distributed electronically to recipients via e-mail and websites	Low	Short–long	Moderate
Self-completion surveys	Distributed to businesses and business-related contexts for completion by recipient	Moderate	Short–medium	Low (unless administrator present)
By location of administration				
<i>In situ</i> surveys (including organizational surveys)	Questionnaire or interview conducted within businesses and business-related settings	High	Short–long	Moderate–high
Intercept surveys	Questionnaire or interviewer-conducted structured interview or self-completion questionnaire, potential participants are contacted en route to, during, and en route from some business or business-related activity	Moderate	Short–medium	Low–moderate
Household surveys	Questionnaire or interview conducted at households (in this case, in relation to businesses and business-related issues)	High	Medium	Moderate–high
Omnibus surveys	Questionnaire or interview conducted at households (in this case, in relation to businesses and business-related issues); a number of businesses cluster together to distribute implementation costs; survey will be structured by groups of unrelated business themes	High	Medium–long	Moderate–high

^a Although relative comparisons have been made, both implementation and response rates may vary due to the number and nature of “reminders” used.

surveys often use reminder cards and/or reminder letters. An advantage of mail surveys for business is the relative cost-effectiveness (based on postal rates) of survey distribution and receipt. Low administration costs and the ability to reach broad geographic distributions are additional advantages. Disadvantages of mail survey methods are associated with their reliance on respondents being speakers of the language used in the questionnaire and having a suitable literacy level to participate in the study. There is also reliance on respondents to return questionnaires; more importantly, there is no way of

knowing whether the person targeted is the person who completes the questionnaire.

Telephone Surveys Telephone surveys are structured interviews conducted by an interviewer who records the answers to mostly closed-ended questions. Improvements in electronic technology, particularly computer-assisted telephone interview (CATI) systems, have enabled interviewers to enter responses immediately into databases that commence aggregation and analysis of the entered data. In addition to this advantage, telephone interviews

are relatively inexpensive to administer (unless calling long distance) and of short duration, compared to the time taken by respondents to complete written questionnaires. Disadvantages of telephone interviews include the limited range of times available to collect data, the potential expense of long-distances, and the limited ability to use open-ended questions.

Face-to-Face Interviews Face-to-face interviews are structured interviews conducted by trained interviewers who use a standardized interview protocol and a standardized set of responses for recording participants' responses. Face-to-face interviews may be conducted *in situ* (within businesses and business-related settings), at intercept sites associated with businesses and business-related activities, and in households. Advantages of face-to-face interviews are the ability to control interactions, to ensure that the targeted participant is the respondent, to ask complex questions, and to use probe mechanisms. Disadvantages are associated with the cost of training interviewers and placing them in the field, as well as the time required to conduct interviews. In addition, despite assurance by the interviewer, and because the interview is conducted in face-to-face mode, participants may have concerns regarding confidentiality.

e-Questionnaires e-Questionnaires are electronically administered questionnaires using e-mail and websites as settings for survey administration. The advantages of e-questionnaires are related to the low cost of implementation and the relatively quick access to widely distributed geographical regions. Disadvantages are associated with low response rates and participants' concerns regarding confidentiality.

Self-Completion (Intercept, *In Situ*, and Household) Surveys Self-completion surveys are questionnaires that rely on the respondent to complete the questionnaire. This is, in fact, the case in mail surveys, but self-completion surveys also belong to a category of survey that is not mailed. Other, self-completion surveys used by businesses are intercept, *in situ*, and household (including omnibus) surveys. Intercept surveys are face-to-face interviews (sometimes self-completion questionnaires) conducted en route to or from, as well as during, a business-related activity. Intercept and face-to-face interviews have similar advantages and disadvantages. Intercept interviews tend to be shorter in length than some face-to-face interviews because participants are being interrupted at work or in the course of a business activity, and thus the researcher will design the questionnaire in order to minimize inconvenience.

Household surveys may be conducted using the telephone, by mail, or face to face, and so, depending on the mode, will have advantages and disadvantages similar to

those of like survey methods. Within the household survey category, the omnibus survey is a subtype. Omnibus surveys contain questions in sections that are unrelated to other sections. The advantage of an omnibus survey is that a range of businesses may pool together to cover the cost of the administration and implementation of the survey; albeit that the survey will contain sections with questions germane to specific businesses. A major disadvantage arises when the number of businesses participating in the omnibus survey is large, thus restricting the number of questions; in this case, research design is critical to ensure that question sets are effective. All participating businesses receive information relating to their data sets as well as to the standard sociodemographic data sets collected in the survey.

Experimental and Quasi-experimental Methods

Experiments enable researchers to determine causal relationships between variables in controlled settings (laboratories). Researchers generally manipulate the independent variable in order to determine the impact on a dependent variable. Such manipulations are also called treatments. In experiments, researchers essay to control confounding variables and extraneous variables. Confounding variables may mask the impact of another variable. Extraneous variables may influence the dependent variable in addition to the independent variable. Advantages of experiments include the ability to control variables in an artificial environment. Disadvantages include the mismatch between reality and laboratory settings and the focus on a narrow range of variables at any one time. Laboratory experiments enable researchers to control experiments to a greater degree than those experiments conducted in simulated or real businesses or business-related environments. Experiments in the field (business and business-related environments) may prove to be challenging due to issues related to gaining access and ethical approval. However, field experiments (natural experiments) allow the measurement of the influence of the independent variable on the dependent variable within a real-world context, although not all extraneous variables are controllable. The classical experimental method involves independent and dependent variables, random sampling, control groups, and pre- and posttests. Quasi-experiments omit aspects from the classical experiment method (such as omission of a control group or absence of a pretest).

Observation

Within the positivistic paradigms, observations may be conducted in a laboratory setting, simulated setting, or in the field (business or business-related setting). As with experiments, laboratory or simulated settings are more controllable than are field settings. Using this paradigm

within businesses or business-related settings, observations tend to focus on specific behaviors. During observation periods, the researcher may be a participant or nonparticipant and may assume an overt or hidden role.

Recording of data during observations may be undertaken using checklists of static data, which are data that will not change in the course of the observation (for example, the number of people attending a business meeting and their administrative levels, or seating patterns during a meeting), and action data, which are data that may change in the course of the recording of observations (such as the number of times a person orally participates during a meeting, or the duration of oral participation and to whom the oral participation is directed). Field notes of observations or video and other electronic recording means may also be used and later analyzed and reduced.

Observations within this paradigm take an etic approach, in order that the observations are achieved in an objective and value-free manner. As noted before, observations may also be conducted without the knowledge of the participants (subsequent to receiving ethical approval) to minimize the effect of socially desirable response sets (acting in a manner that is perceived by the participant as socially desirable, although it may not be the usual response of the participant). Observation should not be used in relation to determining levels of emotions, value-based behaviors, or opinions, because these are not able to be determined etically from observation.

Observations may also be used to record counts of a behavior occurring, the number of interactions between people, and with whom interactions occur (this is similar to the example of oral interaction in business meetings), as well as types of activity and their repetition (and who is involved) and the locations of activities. Advantages of the observation method include the possible nonintrusive nature of the observations, if undertaken in a field setting, and the acquisition of data that are not influenced by the participants having knowledge of the purpose of the observations, and subsequently changing their patterns and activities. Disadvantages are associated with not knowing why the patterns or activities are occurring (unless observations are complemented by interviews), the potential for observing people without their knowledge (ethical issues), and the lack of flexibility (because checklists predetermine observations).

Forecasting

Forecasting within a business environment is associated with drawing on past data sets and knowledge to generate predictions relating to future business patterns and trends. Three time periods are associated with forecasting, short, medium, and long term. Short term is considered to range up to 2 years, medium term ranges from 2 to 5 years, and long term is from 5 to 15 years. Making predictions beyond 15 years is considered to be futurism.

Forecasting involves the use of formulae and statistical methods. In particular, time-series analysis assists business researchers in making forecasts. The two main methods are the simple additive model and the classic and more realistic multiplication model. An advantage of forecasting is that decisions are made based on historical patterns and trends. A disadvantage is associated with the inability of past trends to explain current complex, dynamic ever-changing business environments.

Nominal Group Technique

The nominal group in a positivistic framework is a method that enables businesses to determine issues and develop strategies and evaluation techniques using iterative processes. The method focuses on each of those three aspects in turn. The iterative process moves the data collection from individual standpoints to a whole-group consensus. Briefly, the process involves the researcher/facilitator organizing a group of participants. Each is asked to list factual statements/observations associated with the issue being addressed. The researcher then lists all individual responses to an issue and systematically clusters similar observations; subsequent group voting decides on a predetermined number of key statements for address by the whole group. Each statement is then processed in the same manner. Individuals brainstorm strategies to rectify the issue statements. These are listed and a smaller number for focus are identified by voting. In each phase, information is reduced and causal relationships between issues and solutions are determined by consensus and agreement, so achieving a collective and agreed worldview of the issues/problems, solutions and methods of evaluation. Advantages of the method are its systematic processing and its collective-based outcomes. Disadvantages of the method are related to its consensus-based outcomes, in which outlying statements and strategies are not considered, and to the omission of dialogue between participants regarding statements, strategies, and evaluation methods. The nominal group technique has some similarity with the delphic method (see later), a difference being that the former involves face-to-face engagements and the latter involves management of the process by questionnaire, without face-to-face engagement between participants.

Focus Groups

The use of focus groups within positivistic paradigms is predicated to a structured agenda and systematic approach to managing, recording, and analyzing the interactions associated with each of the agenda items. Focus group data and interactions are recorded in a reductionist manner using checklist categories, which are then tallied and mathematically analyzed in regard to *a priori* theory and determined variables, constructs, and categories. Within positivistic paradigms,

focus groups are utilized as part of the exploratory phase of research in order to determine variables that may be utilized to construct questionnaires and structured interviews. They may also be used to check the currency of established or *a priori* theories, constructs, and categories. Depending on the management of interactions, as well as on the recording and analysis of data from the focus group (whether full text or reduced text), the method will move from either positivistic or interpretive paradigms or to mixed methods. In a positivistic framework, the facilitator will systematically focus the discussion with a strict agenda and will refocus (when necessary) participants on that agenda.

The Delphic Method

The Delphic method is an iterative process that draws on expert opinion, *a priori* theories, and the literature to predict future events. It is a forecasting method used when other trend data are not available, such as historical business and business-related data sets. The researcher uses established theories (and expert opinion) to generate a questionnaire regarding the probability of a set of events occurring in the future; these are sent (by mail or e-mail) to experts. Experts complete the questionnaire and return it, and the questionnaire data are summarized and returned to panel members by the researcher.

In the next phase, events derived from the previous questionnaire are listed and panelists are required to assign dates, probabilities, and further events. The researcher analyzes these responses and presents the individual distribution of panelist responses (anonymously). Panelists are asked to reconsider their previous position. The researcher subsequently develops interquartile response summaries from the returned data. Following another iteration, the interquartile distributions are redistributed. Exceptions in each round outside the quartile ranges are also included and reasons are provided for their positioning. Iterations continue until all panelists reach consensus.

The delphic method in the positivistic framework is based on expert responses to questionnaires and the repeated questioning and analysis of responses until consensus is achieved. Interactions between panelists are mediated by a facilitator, who analyzes the responses and disseminates the findings of each repetition to the panel members. Advantages of the Delphic method include the use of expert opinion, the anonymity and confidentiality of expert participation, and objective data gathering, because participants are not swayed by the knowledge of which expert stated which set of data. Disadvantages include the number of iterations that may occur until consensus is reached along with the possibility that face-to-face interaction of experts may reduce the time taken to reach consensus. However, this introduces

subjectivity and thus does not match the paradigm that informs this approach.

The Documentary Method

The documentary method draws on secondary data sources. The diversity of sources includes company financial reports, annual reports, minutes of meetings, memorandum, e-mail correspondence, letters, position statements, policies, and addresses/speeches, among other business-related materials. Using a quantitative methodology, the researcher objectively classifies documents and/or their texts using preestablished categories or textual units. These classifications as well as the nature and number of occurrences will be reduced and recorded as numerical representations. Specifically, the researcher will determine the frequency (the number of times a text unit occurs), direction (positive or negative polarity of the text unit), intensity (level of strength in regard to negative or positive polarity), and space (measurement of the amount of physical space allocated to each text unit) of the textual units being analyzed. Advantages of the documentary method are associated with the ability to manage large textual documents into smaller manageable units and the analysis of textual units in a numeric, statistical, and objective manner. Disadvantages of the method are associated with the time it takes to amass and analyze the data and the difficulty in gaining access to all possible sources of data, because some gatekeepers may suppress some types of documentation.

Case Studies

Case studies are associated with the development of detailed information relating to a specific business phenomenon, with phenomena across similar organizations or settings, or with one specific case (person, organization, or setting). Case study method may draw on a number of methods to gather data, such as observation, experiments, structured interviews, questionnaires, and/or documentary analysis. Case study within a positivistic paradigm is subsequently guided by the tenets of a quantitative methodology. Advantages of case studies associated with case-specific detail is the obtainment of objective and use of multiple methods to gain detailed data on the case. Disadvantages are associated with resource allocation and (with field case studies) the inability to control all variables systematically.

Longitudinal Studies

Longitudinal studies (also known as panel studies) are used by researchers to measure changes over time in regard to a variable or variables being measured or a group of people being studied. A longitudinal study, for example, may assess the impact of e-mail, as the official form of organizational communication, on time allocated to all work tasks of middle management before, during,

and after implementation. Experimental research involving a pre- and posttest can be classified as a longitudinal study because it contains temporal measuring points (pre- and post-). Advantages of longitudinal studies relate to how they assist in determining cause-and-effect relationships, as well as in facilitating assessment and evaluation of changes in work practices. Disadvantages of longitudinal studies are associated with the length of time it takes to conduct the research, the cost of sustaining the study over time, and the potential for participants to “drop out” in the course of the study (research mortality).

Qualitative Methods

The principles of a qualitative methodology guide qualitative methods of empirical material collection and analysis. A qualitative methodology tends to be associated with social constructionism, social constructivism, social phenomenology, and interpretive social science paradigm, as well as the related critical theory, feminist perspectives, postmodern, and participatory paradigms. A qualitative methodology focuses on gathering empirical materials holistically in real-world business settings and contexts. As a result, “theories” are inductively determined through analysis that generates ideographic (thick and depthful) insights that are specific to the study site and possibly applicable to other similar business settings and contexts. Researchers who engage in qualitatively informed research usually assume a subjective epistemological stance in relation to empirical material collection and analysis.

Some examples of qualitative social science methods of empirical materials (data) collection used in business include semistructured interviews, in-depth interviews, observation, action research, focus groups, the delphic method, observation, the documentary method, case studies, and longitudinal studies.

Semistructured Interviews

Semistructured interviews, which are less formal than structured interviews, have generic foci and/or a set of themes. The order of discussion of each of the themes may vary between interviews, depending on the response to a “grand tour” question that is used to focus the discussion. Rapport needs to be established to ensure that in-depth information will be generated in the course of the interview. Issues of reciprocity (mutual exchange of information) need to be clearly outlined. Advantages of semistructured interviews are similar to those of unstructured (in-depth) interviews; they are interactive between the participant and the researcher and reflect conversational exchange similar to that in a real-world setting. Disadvantages are the time it takes to conduct them and the volume of material generated for analysis.

In-Depth Interviews

In-depth interviews are unstructured interviews that have similarities with a conversation—albeit a conversation with a purpose, i.e., the research topic. In-depth interviews range in duration from 1 hour to upward to 5 hours and beyond. Interviews in excess of 2 hours may be conducted over a series of sessions. The keys to successful interviews are the establishment of rapport, mutual respect, and reciprocity. Advantages of in-depth interviews are that the researcher will be able to gain from the interview process information with richness and depth. Disadvantages are related to the time taken to gather and analyze information.

Participant Observation

A number of typographies describe participant observation. Generally, participant observation may be described as a continuum of roles, ranging from a complete participant to a complete observer. Participant observation, as does all research, requires the adoption of ethical practices and approval. In some instances, participants may not be aware they are being observed. The reason for not disclosing a researcher’s observation role to participants is to enable the researcher to observe phenomena as authentically as possible in the everyday business or business-related setting. As a complete observer, the researcher does not participate as one of the group being studied, but observes as an outsider. At the other end of the continuum is the complete participant role. In this role, the researcher acts as an insider. Again, the identity of the researcher role may be hidden from the insiders in order not to change behaviors. Between the two end points of the continuum, researchers will adopt differing degrees of observation and participation as best suits the business research purpose.

Advantages of participant observation are that information is gathered in real-world business contexts and settings, first-hand primary information is gathered, and diverse methods may be incorporated (such as interviews, observations, and documentary analysis conducted within the context of the business study setting). Disadvantages of the method are associated with behaviors and patterns that may be influenced by the presence of the observer/participant, the difficulty in observing all interactions and events if only one observer is present in the business setting or study site, and with the fact that not all facets may be available to the observer because some contexts or interactions may be considered off-limits by the participants.

Action Research

Action research is specifically associated with the participatory paradigm, which views reality as collectively constructed from multiple realities/viewpoints. Action

research is used as a method to address problems within organizations or businesses by also involving organizational or business-related personnel. In this method, groups of people from the organization or business meet to discuss problems/issues as well as ways to resolve them. Strategies are generated, implemented, and evaluated over a specific time period. Primarily, action research literature tends to use problem solving, whereas another method, appreciative inquiry, uses a less pejorative focus and envisages positive potentials for an organization by drawing on past experiences, skills, and knowledge of participants related to the achievement of those potentials. Advantages of action research are associated with how this research is conducted in real-world settings, that is, *in situ* in business and business-related settings. It uses people who are insiders as researchers to change collectively the social context of their business environment. Participants have vested interests and ownership of the process and the outcomes; so success should be high if participation is voluntary. Against this advantage are disadvantages related to setting specific outcomes and the time associated with working through the process.

Focus Groups

Focus groups involve semistructured group interviews in which interactions between participants, as well as outcomes, are important parts of the focus group process. Focus groups are used in business to elicit attitudes, opinions, values, expectations, and perspectives; they are also a tool for forecasting. Focus groups work best with group sizes that do not exceed 10–12, otherwise interactions between members become more difficult to facilitate, and it is hard to ensure that all participate and there is enough time for all to contribute. The duration of focus groups is usually 1–2 hours. Focus groups have the advantage of including the interactions of participants as part of the empirical material collection; further, researchers are able to explore unexpected issues among the group, members are able to seek clarification from each other, and members subsequently are able to adjust opinions and stances as a result of interaction. Disadvantages relate to the potential for strong personalities to dominate the discussion and to the selection of participants resulting in a biased view. The overall success of focus groups depends on the quality of the focus group design and the quality and skill of the facilitator.

The Delphic Method

The delphic method has its roots in the ancient Greek custom of using oracles or soothsayers. After World War II, this method was used as a process for forecasting. The delphic method, as a qualitative method, involves the repeated interviewing of experts by a researcher to achieve a consensus. The participants are interviewed and information is collected and analyzed. The analytical

findings are then discussed with each of the experts individually. Opinions may be modified and the researcher repeats the process until a consensus is achieved regarding a number of multiple outcomes. Advantages relate to the in-depth information that is gathered and to the fact that the information is empirically sourced rather than determined by *a priori* theories. Disadvantages relate to the time taken in repeated interviewing rounds and maintaining panel participation throughout the process.

The Documentary Method

The use of the documentary method within the social constructionist, social constructivist, social phenomenological, or interpretive social science paradigms differs from use within the positivistic paradigms in that there is no *a priori* theory to guide the analysis specifically, although a process must be followed. The text documents are read and thematic units are identified, analyzed, and grouped into categories and subcategories so that a taxonomy of the materials is built up. The documents are analyzed in regard to their purpose, tone, tenor style, and explicit, implicit, and tacit texts. Advantages of this method are its unobtrusive impact and its access to temporal insights in regard to past and present businesses and business-related practices. Disadvantages relate to the need for repeated readings of texts, which results in different interpretations, and to the fact that the documents may be read without knowledge of the context of their origin.

Case Studies

Under the social constructionist, constructivist, phenomenological, or interpretive paradigms, case studies enable the extensive study of one case or similar cases across time or space using a set of methods such as interviews, focus groups, the documentary method, and participant observation. By using several methods, detailed information relating to the case or cases may be achieved. The depth of materials obtained in a case study and access to multiple sources of empirical materials (data) are distinct advantages, although the amount of time and resources required to gather details may be a disadvantage.

Longitudinal Studies

Longitudinal studies involve multiple methods of empirical material (data) collection in relation to one organization or business over time, one set of people over time, or similar organizations or sets of people over time. The purpose of longitudinal studies is to gather empirical materials in regard to changes in cultural, social, political, economic, and environmental trends concerning the research topic being studied. That temporally extended information can be gathered using a variety of methods is advantageous. The time taken to collect, analyze, and maintain the

empirical materials, as well as maintenance of databases for future phases of the study, are disadvantages.

Mixed Methods

Mixed methods may be used to study businesses and conduct business-related research. For example, a phenomenological research design may include some form of quantitative data collection (a questionnaire to determine sociodemographic details of participants), or

Table II Comparison between Methods which are Classified as Quantitative and Qualitative Methods

<i>Examples of methods</i>	<i>Quantitative</i>	<i>Qualitative</i>
Focus group Observation	Hypothetico-deductive approach	Holistic-inductive approach
Documentary method	Objective stance of researcher	Subjective stance of researcher
Case studies	Structured format	Semistructured or unstructured format
Longitudinal studies	Data reduced and mathematically and statistically analyzed	Empirical materials (data) maintained in their textual wholeness and analyzed in totality; textual units preserved
	Study units predominantly randomly assigned or identified	Study units identified non randomly

a positivistic research design may include qualitative data collection.

Quantitative and Qualitative Methods of Data Collection

As shown in Table II, some of the same terms may be used to describe both quantitative and qualitative methods of data/empirical materials collection. The alignment and influence of either a quantitative or qualitative methodology distinguish a method as either quantitative or qualitative. Table III lists quantitative and qualitative methods of data/empirical materials collection as well as those methods that may be utilized within overall research designs, which adopt mixed methods to varying degrees.

Methods of Data Analysis Used in Business

The methods of data analysis used by business researchers are varied; as with methods of data collection, the choice of method depends on the overall paradigm and methodological framework informing the research project, as well as on the purpose of the research.

Quantitative Methods of Data Analysis

A quantitative methodology as per the tenets of the positivistic paradigms ensures that causal relationships are tested. “Truth” is deductively determined using objective research methods (data collection and analysis) and the researcher remains value free throughout the entire

^a Qualitative researchers may use the terms “empirical materials” and “information” instead of “data.”

research process. The stance of the researcher is an etic (outsider) one, and the research design is systematic and replicable. Data collected are represented in numerical form and are mathematically and statistically analyzed; within the postpositivistic paradigm, there is an emphasis on theory falsification over theory verification. Findings of the research are represented in tables, graphs, and models, with report texts presented in third person, passive voice. Sampling, having been random (that is, probability based), will result in findings that can be generalized to the wider population from which the sample was selected. Table IV provides an overview of a number of quantitative methods of data analysis. In addition to the methods noted in Table IV for inferential statistics, researchers also consider levels of significance (the determination of the chance that an association between variables is a product of sampling error) and Type I (rejection of the null hypothesis when it is true) and Type II (acceptance of the null hypothesis when it is false) errors.

Qualitative Methods of Data Analysis

A qualitative methodology reifies the ontological, epistemological, and axiological position of social constructionist, constructivist, phenomenological, or interpretive paradigms. This means that the methodology ensures that

multiple perspectives are equally valued, that no one position is privileged over another, that the interpretation of the empirical materials (data) is subjectively informed by the researchers' emic knowledge of the research setting and the participants, as well as the participants being involved in validating the interpretations. The methodology continues to use qualitative methods that complement the empirical materials (data) collection methods used. Analysis also commences as soon as the researcher enters the field. The position of the researcher is reflexively and reflectively reviewed in the overall analysis. Subsequently, a qualitative methodology utilizes inductive practices, to illuminate "multiple realities," which are grounded in the real-world businesses and business-related settings being studied. The research design emerges in the course of the research process as concurrent analysis directs other empirical material (data) collection needs and directions. Emblematic themes arise in the course of the research. Empirical materials (data) collected is maintained as textual units that reflect the themes and motifs arising out of analysis. Reporting of the research findings should be in narrative form using first person, active voice. Because sampling practices are nonrandom, the research represents a "slice of life" from the setting and people being studied. Table V provides an overview of qualitative methods of empirical materials (data) analysis.

Table IV Examples of Methods of Quantitative Data Analysis

<i>Type of analysis</i>	<i>Examples</i>
Descriptive statistics	
Univariate analysis	Measures of central tendency (mode, median, mean); measures of variation (range, percentile, standard deviation)
Bivariate analysis	Cross-tabulation, scattergrams, measures of association—lambda (λ), gamma (γ), tau (τ), rho (ρ), chi-square (χ^2)
Multivariate analysis	Multiple regression analysis, path analysis, time-series analysis, factor analysis
Inferential statistics	
Statistical significance	
Nonparametric tests—nominal level	One sample: chi-squared test (goodness of fit) Two independent samples: chi-squared (test of independence), Fisher's exact test, z -test for proportions Two dependent samples: McNemar test More than two independent samples: chi-square test More than two dependent samples: Cochran Q test
Parametric tests—ordinal level	One sample: Kolmogorov–Smirnov test Two independent samples: Mann–Whitney U-test, Wald–Wolfowitz runs test Two dependent samples: Sign test, Wilcoxon test More than two independent samples: Kruskal–Wallis test, H -test More than two dependent samples: Friedman test
Interval/ratio level tests	One sample, two independent samples, and two dependent samples: t -test More than two independent samples, more than two dependent samples: analysis of variance

Table V Examples of Qualitative Methods of Empirical Material (Data) Analysis

<i>Type of analysis</i>	<i>Discussion</i>
Content analysis	Textual materials are read, annotated, and coded. Categories are generated from reading, annotating, and coding. Categories are evaluated in regard to relevance of emerging taxonomy in relation to the empirical setting from which they emerged. This involves reflection and questioning of assignment of codes and categories and the real world context
Constant comparative analysis	Constant comparative analysis involves two generic stages, coding and the comparison of codes to generate categories to build an ideographic representation of the study phenomenon. Theoretical sampling will also be applied to establish the repetitive presence of concepts. The method has similarities with grounded theory analysis
Successive approximation	The researcher will iteratively and reflectively compare codes and categories to develop concepts, relationships, and “theory.” Questions in regard to “goodness of fit” with the empirical world are posed constantly throughout the process. The method has similarities with constant comparison and grounded theory analysis
Domain analysis	Categorizes study units using a “cover term,” “included terms,” and a “semantic relationship.” Categorization is an ongoing process during data collection. Domain analysis is founded on Spradley’s <i>Participant Observation</i> as well as the study of culture
Ideal types	Ideal types (models of social interactions and processes) establish a standard to which reality may be compared. Ideal types emanate from the work of Max Weber (1864–1920)
Event-structure analysis	The chronological ordering of events highlighting the causal relationships for their occurrence
Matrices	Matrices demonstrate interactions between two or more elements of phenomena
Grounded theory analysis	Grounded theory is attributed to the work of Barney Glaser (1930–) and Anselm Strauss (1916–1996). It is an inductive process, as are all of the qualitative methods of empirical material analysis. In its original form, theory is produced by identifying conditions that result in a phenomenon occurring, which establishes a specific context, concomitant actions, and related consequences
Other examples of analysis	Networks, models, typologies, taxonomies, conceptual trees, mind maps, semantic webs, and sociograms

Mixed Methods

Mixing methods for data analysis results in the relevant method of analysis being selected from either a quantitative and qualitative methodology, to match the appropriate data or empirical material collection tool. Two examples of mixed methods being associated with analysis are (1) qualitative methods of data collection and quantitative data analysis and (2) open-ended questions in a questionnaire being analyzed using qualitative methods.

Conclusion

Once the paradigm that informs the overall business research project/study has been determined, business researchers utilize quantitative, qualitative, or mixed methodologies to guide the design of research projects. Within a quantitative methodology, researchers adopt quantitative methods of data collection. Primarily surveys (interviews and questionnaires), experiments and quasi-experiments, and observation are the key business methods. Other methods used variously within businesses

and business-related fields and disciplines are documentary analysis, longitudinal studies, forecasting, focus groups, the nominal group technique, and the delphic method. Some business fields and disciplines may use specific methods not utilized across disciplines or extensively due to their specific field or disciplinary nature. Examples of methods of data analysis include descriptive statistics, inferential statistics, tests of statistical significance, levels of significance, and consideration of Type I and Type II errors.

Within a qualitative methodology, empirical material (data) collection methods include semistructured and unstructured interviews, participant observation, action research, focus groups, the delphic method, the documentary method, case studies, and longitudinal studies. Analysis methods may include content analysis, constant comparative analysis, successive approximation, domain analysis, ideal types, event structure analysis, matrices, and grounded theory.

Examples of social sciences methods used in business represent a wide range of both qualitative and quantitative methods of data/empirical material collection and analysis, selected based on the relevant methodology and overarching paradigm that inform the overall research process.

Campaign Finance Data

Donald A. Gross

University of Kentucky, Lexington, Kentucky, USA

Glossary

Buckley v. Valeo U.S. Supreme Court 1976 decision that established many of the legal parameters for federal campaign finance law.

hard money Money given to political candidates and political parties that is subject to federal contribution limits and prohibitions.

independent expenditures Expenditures for campaign activities that are not coordinated with a candidate and do not expressly call for the election or defeat of a candidate.

issue advocacy Noncandidate campaign activity that does not expressly advocate the election or defeat of a candidate.

party soft money Money given to political parties for the purported purpose of party building that is not subject to federal contribution limits and prohibitions.

political action committees (PACs) Committees that collect contributions into a separate fund to support the political interest of the sponsoring organization.

soft money Money associated with federal elections that is not subject to federal contribution limits and prohibitions.

Campaign finance data encompass a wide variety of types of information that are usually defined in terms of the regulatory environment surrounding elections. As such, an understanding of systematic differences in regulatory environments is a necessary first step for any analyst. For example, in the context of the U.S. federal regulatory environment, campaign finance data are usually classified as either hard money data or soft money data. It is clear, at all governmental levels in the United States, that both the quantity and quality of campaign finance data has increased tremendously over the last 25 years. But, as regulatory environments continue to change and strategic actors continue to change their behavior, new types of campaign finance data will continue to emerge.

Introduction

Data Availability

Our understanding of the role of money in democratic elections and governance has increased dramatically in recent years. This increase in knowledge is very much tied to the ever increasing quantity and quality of campaign finance data that became available after campaign finance reform began to take hold in the mid-1970s. Prior to that, campaign finance data were difficult to obtain, generally not available for most elections, and of overall poor quality. Campaign disclosure laws for U.S. federal elections were a key component of laws passed in 1976. As the federal government continued to expand disclosure requirements, and as the states rapidly expanded their own disclosure requirements, the wealth of campaign finance data available to scholars continued to increase.

The General Use of Campaign Finance Data

To date, campaign finance data have been used to study a wide variety of social phenomena. Two general areas of research interests have formed the foci of most studies. The first focuses on issues associated with democratic elections—the impact of spending on electoral outcomes, electoral competition, voter information, participation, voter turnout, citizen engagement in the electoral process, partisan advantage, the incumbency advantage, and interest-group influence. The second group of analyses has focused on questions surrounding issues of governance: Do contributions affect how legislators vote, executives behave, or judges adjudicate? Do interest groups gain an institutional advantage as a result of contributions? Is the passage and implementation of policy affected by campaign contributions? All the numerous

questions being asked by scholars interested in campaign finance and the numerous methodologies used in attempts to address these issues require different types of campaign finance data.

The Problem

Solid research requires reliable and valid data. And, even though the quantity and quality of campaign finance data have increased dramatically in recent years, a fundamental problem remains—the nature and character of almost all campaign finance data depend on the regulatory environments surrounding the phenomena of interest. This problem is compounded by the fact that regulatory environments, both state and federal, continue to evolve over time. Thus, data availability changes over time and across government units, with the likelihood of new forms of data coming to the forefront remaining a strong possibility. As such, any discussion of campaign finance data must be viewed in the context of the evolving regulatory environments governing elections.

Article Overview

An exhaustive discussion of the regulatory environments found world wide is simply beyond the scope of this essay. The focus here is on campaign finance data in the United States, especially that available for federal elections. In addition, the article examines only the most widely used types of campaign finance data, recognizing that there are other types of data that are typically classified under particular regulatory characteristics of specific states. The focus is on the data that have become available since the mid-1970s. First, the general regulatory parameters that define the characteristics of particular types of campaign finance data are examined. Next, campaign finance data that typically classified under the rubrics of hard money and soft money are discussed.

The Regulatory Environment

Because the nature of campaign finance data is heavily dependent on regulatory environments, the quantity and quality of campaign finance data differ across time and across legal jurisdictions. Five characteristics of regulatory environments are of special interest: (1) reporting and disclosure requirements, (2) limits on contributions, (3) spending or expenditure limits, (4) public financing, and (5) enforcement provisions.

Reporting and Disclosure Requirements

Perhaps no characteristic of the regulatory environment is as important to the collection of campaign finance data as reporting and disclosure requirements. Very simply,

generally available records are essential to the collection of campaign finance data. Requirements are often specified in terms of the type of organizational unit involved in the expenditure of funds.

The highest quality campaign finance data typically are those for candidate committees. These are committees created for the specific purpose of electing an individual to office. At the federal level, all contributions and expenditures in excess of \$200.00 must be fully disclosed. Other information that must be reported include cash on hand, loans, money transfers, dividends, and interest. Although the threshold for reporting may differ, most states now have similar laws.

When we turn our attention to leadership political action committees (PACs) and political parties, data availability lessens compared to that available for candidate committees. At the federal level, at least since 1992, all contributions to these organizations over \$200.00 are fully disclosed. Their contributions given to a candidate are fully disclosed, as are all expenditures made in coordination with a candidate. However, in the case of party soft money, expenditures are not necessarily reported on a line-item basis. The transfer of monies to state parties is fully disclosed, but, because states often have weaker reporting requirements, the original source of the money and the particular use of the money are often lost.

If we consider individuals and other organizations, including PACs, the rules for reporting and disclosure change once again. Their direct contributions to candidates, political parties, and other PACs are fully disclosed. Federal law requires full disclosure of both contributions and expenditures when individuals and organizations undertake independent expenditures that directly call for the election or defeat of particular candidates, called direct advocacy ads. But when individual and organizations use issue advocacy advertisement, they generally fall outside federal regulation. They may, therefore, spend unlimited amounts of money without necessarily disclosing income or expenditures.

A similar pattern exists whenever we consider state-level reporting and disclosure requirements. Reporting requirements tend to be most extensive when evaluating candidate committees, less extensive when examining political parties, and least stringent when focusing on individuals and organizations such as PACs. However, there remains a great deal of diversity among the states in the regulatory stringency of their reporting and disclosure requirements. As such, the data that are available at the federal level and in some states, is simply nonexistent in other states.

Limits on Contributions

Other than reporting and disclosure requirements, limits on campaign contributions are the most prevalent

characteristic of campaign finance regulatory environments. Limits on contributions tend to differ in terms of three basic characteristics: (1) in terms of who or what organizations that make contributions, (2) in terms of who or what organizations that receive contributions, and (3) in terms of the dollar amounts of specific types of contributions (these differ across regulatory environments as well as across different electoral offices within a given regulatory environment).

The most typical organizations and individuals that are limited in the amount that they can contribute are individuals, political parties, the candidate and his or her family, unions, corporations, foreign nationals, PACs, and regulated industries. Organizations that receive contributions that have limits placed on the size of contributions given to them typically include candidate committees, party committees, and PACs. Dollar amounts differ from a total prohibition on contributions to no limit on the size of a contribution. In addition, in some jurisdictions, dollar amounts are adjusted over time to take into account the effects of inflation.

Limits that are in place for federal elections are illustrative of the possible combinations that we may encounter in a given regulatory environment. Corporations, unions, and foreign nationals are prohibited from making contributions to candidates and political committees, whereas there are specific limits on the size of a contribution from individuals, political parties, and PACs. Until the passage of the Bipartisan Campaign Reform Act in 2002, there were no major limits on the size of contributions to party soft money accounts. And, pending the outcome of current court action, the strict limits imposed by this legislation may become nullified. When we examine the regulatory environments in the states, we see a great deal of diversity in the parameters governing contributions. States such as Texas and Illinois have almost no effective regulations limiting the size of contributions, whereas states such as Kentucky and Vermont have stringent regulations governing contributions.

Spending or Expenditure Limits

The U.S. Supreme Court's *Buckley v. Valeo* decision in 1976 found that mandatory spending limits violated First Amendment protections of freedom of expression. A consequence of this ruling is that spending limits had to be voluntary, although legal jurisdictions could use public subsidies to encourage candidates to accept spending limits. Likewise, the decision meant that expenditures by individuals or groups that spend independently of a candidate cannot be limited. The analytical consequence of the *Buckley* decision is that, with the exception of a very few legal jurisdictions for a limited number of years, we cannot analyze the effects of spending limits in

jurisdictions that do not also have some form of public financing of elections.

In jurisdictions that have voluntary spending limits, the limits tend to differ in terms of the elective offices covered by spending limits, the formula used to specify the amount of the spending limit, and the mechanisms used to encourage candidates to abide by the limits. At the federal level, voluntary spending limits only exist for presidential elections. Although a limited number of states do have spending limits for state legislative races, it is the gubernatorial election that most often has spending limits associated with it.

For most elective offices, a spending limit is specified in terms of a flat sum of money that changes from year to year after being indexed for inflation. So, the spending limits for the presidential election in 1976 were set at \$10,900,000 for the primary season and \$21,800,000 for the general election and in 1996 rose to \$30,900,000 and \$61,800,000. A second way to specify the size of a spending limit is to multiply some given amount of money times a particularly relevant characteristic of the electoral district. So, for example, the limit for Hawaiian gubernatorial elections is \$2.50 times the number of qualified voters.

The coercive measures used to encourage candidates to abide by spending limits differ a great deal across jurisdictions. At the presidential level, public opinion and public financing are the two prime incentives. Some states add additional incentives. In Kentucky, for example, a gubernatorial candidate who agrees to abide by the spending limits receives matching public funds at a rate of 2 to 1. And if any candidate who is not receiving public funds does exceed the spending limit, then the candidates who did originally agree to abide by the spending limits have their limit raised to be equal to the noncompliant candidate's while still receiving the 2 to 1 public funds.

Public Financing

There are two basic types of public financing schemes: those that provide funds to political parties and those that provide funds directly to candidates. At the federal level, the major political parties are given some monies to help pay for their national conventions, but public funding is only given to candidates for the presidency. At the state level, depending on the specific years we are analyzing, approximately 20 states have some type of public financing system. Some give money exclusively to political parties, some give exclusively to candidates, and some give money to both political parties and candidates.

There are two primary mechanisms for funding the state-level programs that fund political parties. Approximately one-half the states rely on a taxpayer check-off system, whereby a taxpayer can designate part of his or her tax liability (normally \$1 to \$5) for the public funding system. In other states, a taxpayer adds money to the fund

by voluntarily adding a given amount of money to his or her tax liability. States also differ in the mechanisms for the allocation of funds to political parties. Some use a specific formula for the allocation of funds, but the majority of the states allow the taxpayer to use his or her tax form to specify which political party is to receive their contribution.

Programs designed to give money to political candidates tend to differ in terms of six basic characteristics. First, there is the issue of what type of candidate can receive funds. At the federal level, only presidential candidates receive funds. Among the 12 to 14 states that have public funding, most give it gubernatorial candidates and a few give it to legislative candidates. Second, there is the issue of whether public funding is available for the primary election or the general election or whether the state distinguishes between the two electoral periods. Third, the federal government and the states differ on the criteria for obtaining public funds, both for the major-party candidates and, especially, for third-party candidates. Fourth, differences exist in the mechanisms for allocating public funds. In some cases, candidates are given single or multiple grants of money up to a specified limit. In other cases, candidates are given matching funds, normally on a 1-to-1 or 2-to-1 basis, up to a specified limit. Fifth, there are vast differences in the amount of money given to candidates. Finally, there are differences in the requirements candidates are forced to accept in order to receive public funding, most typically, spending limits.

Enforcement Provisions

As might be expected, among the states and the federal government, there is a good deal of diversity in enforcement provisions and the implementation of campaign finance law. Malbin and Gais, in their excellent 1998 discussion of enforcement problems in the states, suggest that there are data collection errors and note that there appears to be little effort to systematically cross-check the validity of the information provided by candidates and organizations. Perhaps most important, as individuals and organizations become ever more creative in their attempts to avoid campaign finance laws, there can be ambiguities in the coding categories of data.

Even though we know that there are data collection problems, there is, at this time, no evidence to suggest that it is a serious problem for most analyses. But differences in the dissemination of information can create problems for some analysts. Often campaign finance information is only available on paper, which can become prohibitively expensive in terms of time and money. And although a number of states, like the federal government, are increasingly placing campaign finance data on the Internet, they are not always readily downloadable. Finally, states differ a good deal in the time frame for which campaign

finance data are available or will remain available in paper or electronic format. In some cases, records are only kept by the state for 5 years.

This discussion of the major parameters of regulatory environments is essential because it is the regulatory environments that help define most campaign finance data. We now turn to a discussion of hard money data.

Hard Money

Hard money is a term that has specific meaning in the context of the federal regulatory environment. It is money given to candidates and political parties that is subject to federal contribution limits and prohibitions. Although there is no limit on how such money is spent, it must be fully disclosed. The definition of hard money may differ in any given state. For simplicity, campaign finance data are presented here in the context of the federal regulatory environment, recognizing the fact that similar data obtained at the state level may not necessarily fit the strict definition of hard money.

Expenditure Data

Probably the most widely used campaign finance data are aggregate candidate expenditure data. Each datum is the total amount of money spent by a single candidate for a single election or electoral cycle. The Federal Election Commission makes these data available for all federal elections since 1978. Similar types of data are generally available for many state elective offices, although there are often serious data-availability issues when we attempt to obtain data over time or across state elective offices. Aggregate candidate expenditures for gubernatorial elections are readily available for almost all states from 1978 to the present. State legislative elections are more problematic, with complete data readily available only since the mid-1990s. For earlier years, availability is much more episodic.

There are a number of readily identified potential pitfalls when using aggregate candidate data. First, there are two interrelated problems that are of special significance when analyzing the effect of candidate spending on electoral outcomes or party competition; this is called the simultaneity issue. The first way to think about the simultaneity issue involves the interactive nature of campaign spending. Jacobson established in 1980 that in many cases candidates spend money in response to spending by other candidates. Thus, spending by one candidate becomes a function of spending by the others. A second way to think about the simultaneity issue is that candidate spending can be seen as a function of anticipated outcomes. Either view of simultaneity suggests that simple ordinary least-squares regression of candidate spending on electoral outcomes will necessarily result in biased

estimates for the effects of electoral spending. To resolve the problem, both two-stage least-squares regression and three-stage least-squares regression have been used.

A second pitfall in the use of aggregate expenditure data has to do with a series of problems associated with the need to ensure the comparability of the units of analysis. Any cross-temporal analysis necessitates taking into account inflationary effects. This is normally accomplished by selecting a base year and adjusting the dollar amounts for other years into constant dollar amounts. States also differ a great deal in the sizes of their population, and it is known that population size is a critical factor in determining the level of candidate spending. Spending per capita is often used to overcome this problem. In terms of political considerations, it is important to recognize that only one-third of all U.S. Senate elections occur every 2 years and the elections in any one cycle are not representative of all states. Finally, some senatorial elections occur in presidential election years and other do not; the presence of a presidential election is known to affect candidate spending.

Gubernatorial elections present a similar problem in that they are unevenly spread over a four-year cycle, differ in their population size, and may occur during a presidential election year, during off-year congressional elections, or when there are no federal elections. In addition, in some states, aggregate gubernatorial expenditures are broken down into the primary electoral season and the general election. Other states, like in U.S. Senate and House elections, make no distinction between primary and general elections when reporting expenditure data.

The very nature of aggregate candidate expenditure data prohibits the consideration of specific types of spending that can be of crucial theoretical importance. For federal candidates, however, disbursements can be broken down by functional categories such as media, travel, and administrative overhead. Similar types of data are not readily available for most state elections.

At the national level, party expenditure data are readily available for all major party committees. This is the case whether we are interested in aggregate expenditure data, transfers of funds to particular candidates and/or state parties, or expenditures for actual party activities such as media purchases and get-out-the-vote efforts. Although more difficult to obtain and often much less detailed, party expenditure data are also generally available at the state level.

Contribution Data

Perhaps the simplest type of contribution data is that which deals with the existence of the contribution limits themselves. The simplest approach is to treat each potential type of contribution limit as a dummy

variable, typically coded 0 or 1 for the absence or presence of a particular type of contribution limit. But, when we use this approach, we lose all variance in the size of the contribution limits among those states that have a limit.

An alternative is to use the state's actual contribution limit for those states that have a particular limit and to assign an arbitrarily high monetary value to those states that do not have a contribution limit. Because most state contribution limits are in the range of \$200 to \$5000 per electoral season, experience suggests that substantive conclusions are generally not fundamentally affected whether or not we assign a value of \$100,000 or \$500,000 to those states that actually do not have a particular contribution limit. We must also be careful in specifying limits because some states specify the limit in terms of a given amount per election, some specify the amount per year, and others specify the amount per election cycle.

The monetary value of contributions are another type of data that is often used in analyses. The total dollar amount for all contributions and the total number of contributors are two types of data that can be especially useful. It must be recognized, however, that it is rarely possible to get a completely accurate number for the total number of contributors because most jurisdictions do not keep a count of contributors who contribute below a given dollar value, \$200 for example; only the total amount of money given by all contributors below the threshold is generally available.

In many cases, we are interested in obtaining information on particular types of contributors. At the federal level, at least since the mid-1990s, it is possible to specify various categories of contribution data. We can specify the number (remembering the previous caveat) and amounts of contributions by the candidate themselves, individuals, PACs, and political parties. Standard industrial classification can be used to specify contributions by economic sectors such as union PACs, law, agriculture, construction, education, and health. At the state level, similar types of data are generally available for legislative and gubernatorial elections, at least since the mid-1990s.

Two final types of candidate contribution data that can be of interest are the timing of the contribution and whether the contribution comes from within the electoral district. Because most contribution lists provide the mailing zip code of the contributor, this generally can be used to determine whether the contribution comes from within the electoral district. The actual dates of contributions are also part of most contribution data sets and can be used to track the timing of contributions.

Soft Money

Like hard money, soft money is especially relevant in the context of the federal regulatory environment. Unlike

hard money, however, the term soft money has often had a somewhat ambiguous meaning. In its broadest sense, soft money is all money associated with federal elections that is not subject to federal contribution limits. This is a broad category of monies that includes numerous types of financial transactions. Within this context, there are really three types of activities that have received significant attention in the literature: party soft money, independent expenditures, and issue advocacy money.

Party Soft Money

For many analysts, party soft money is what is really meant by soft money. Party soft money is unlimited amounts of money given to political parties for the purported purpose of party building. The only limit on contributors is a prohibition against foreign nationals. The importance of soft money began to rise in the late 1980s as a result of efforts to try and balance the federal and nonfederal roles of political parties. This includes a national party role in gubernatorial elections, state legislative elections, and party-building activities such as get-out-the-vote efforts, party-registrations efforts, and voter identification. National party money can also be used to free up the availability of state party hard money to be used in federal elections and to transfer hard money back to the national parties.

Reliable data on party soft money are effectively unavailable for most research purposes before 1991. With new federal legislation, beginning in 1992, all soft money contributions to political parties over \$200 are fully disclosed. This includes funds given to the national parties and their affiliated groupings. Because there are no significant limits on who can contribute, data are available on corporate, union, PAC, and individual contributions.

Although party soft money contribution data after 1991 are quite good, expenditure data are more problematic because they are not necessarily reported on a line-item basis. Much of the difficulty results from the fact that for a number of activities parties need to meet a ratio of hard to soft money expenditures and the ratio tends to be more favorable (more soft money, less hard) when state parties do the spending. Thus, the national parties transfer much of their money to state parties. The transfer of monies to state parties is fully disclosed and so data on transfers are available. Finally, data on national party soft money expenditures for media issue ads and other types of advocacy activities, such as grassroots mail campaigns, voter contact, phone banks, and get-out-the-vote efforts, are available.

Independent Expenditures

Independent expenditures are monies spent on campaign activities that are not coordinated with a

candidate and expressly call for the election or defeat of a candidate. They can be undertaken by individuals, groups, or political parties. Spending is fully disclosed and there are no limits on how much can be spent on such activities. Depending on who is expending the funds, there may or may not be relevant contribution limits. Political parties must use hard money, and contributions to nonaffiliated committees, such as PACs, are also limited.

Because full disclosure is required, data are available on who makes independent expenditures in federal elections and the costs of the expenditures. Although data on contributions to political parties and nonaffiliated committees are available, it is not possible to link specific contributions to independent expenditures.

Issue Advocacy

Issue advocacy is noncandidate campaign activity that does not expressly advocate the election or defeat of a candidate. Generally speaking, any communication activity that does not use the words specified in the *Buckley* decision (vote for, support, cast your ballot for, elect, defeat, reject, or vote against) may be considered issue advocacy. National political parties have generally been restricted to a prescribed ratio of hard and soft money when undertaking issue advocacy. However, in all other cases, costs are not considered to be either a contribution or expenditure under the federal regulatory environment. Thus, in the case of issue advocacy, there are no contribution limits or prohibitions, no expenditure limits, and no itemized reporting requirements.

The lack of reporting requirements for most issue advocacy creates serious problems for the data analyst. As previously stated, there are data on national party activities. Some organizations voluntarily publish their expenditures and records can be obtained from television and radio stations to re-create the amount of money spent on these broadcast activities by organizations. This does not guarantee, however, that we can accurately specify the nature of the organization from the name listed as the purchasing agent for the media spot. We clearly cannot specify the ultimate source of the money. Expenditure data on PACs can be used to estimate their issue advocacy monies.

Other groupings, including 501s and 527s, whose names derive from their income tax designation, have traditionally not been required to publicly disclose either their contributors or their itemized expenditures. Recent federal legislation and pending court cases may change our ability to collect more comprehensive data on these organizations. For example, new disclosure requirements on 527s began in June 2002. Nevertheless, there simply are no data sets currently available that can be considered systematic, reliable, and comprehensive when it comes to

the full range of activities that fall under the rubric of issue advocacy.

Conclusion

The quantity and quality of campaign finance data are expanding every day. Entirely new categories of data are now available that were unheard of only 5 years ago or only available for a limited number of legal jurisdictions. In addition to governmental agencies, there are a number of organizations, both commercial and otherwise, that can provide campaign finance data. But, especially when we move from the federal level to the state level, we remain confronted with the possibility that data may only be available for a limited number of states or a limited time frame. In some cases, the data have been lost forever. Data availability on activities such as bundling, the use of conduits, and the use of internal communication by corporations and unions remains episodic. The multiple jurisdictions that help define the nature of campaign finance data often make direct comparisons among data sets difficult. Differences among jurisdictions can make it nearly impossible to follow the flow of funds across jurisdictions. Some data sets have reliability and validity questions associated with them. And as strategic actors change their behavior, it is likely that new types of campaign finance data will become available while other types become irrelevant.

Glossary

attitude Feeling or opinion about something or someone, learned in the process of becoming a member of a group, and the way of behaving that follows from this.

external validity Concerns the generalizability of a particular experimental outcome to other persons, settings, and times.

internal validity Concerns the validity of the claim that in a specific experiment the factor A, and factor A only, caused a change in factor B.

multitrait–multimethod matrix A correlational matrix measuring a set of traits by using a set of methods.

quasi-experiment A study that lacks random assignment but otherwise resembles a randomized experiment.

randomized controlled experiment A study in which subjects are assigned to either treatment or control groups at random to equal out preexisting differences between the groups.

The psychologist Donald T. Campbell (1916–1996) was one of the leading figures in American social science after the Second World War. He developed several influential concepts, such as quasi-experimentation and the multitrait–multimethod matrix, that would become widely used in the social sciences. This article discusses Campbell's work, which primarily aimed at enlarging the scope of applied social research.

Introduction

The career of the renowned American psychologist and methodologist Donald T. Campbell (see Fig. 1) developed in parallel to the ever-increasing influence of the field of psychology in the post-World War II era. Campbell acquired his first job as an army psychologist

during the Second World War—a period that would become crucial in the development of psychology from an academic specialty to a profession with widespread applications. After the war, psychologists convinced others, mostly policymakers, of the practical value of their expertise. When President Johnson launched his “War on Poverty” and “Great Society” initiatives in the 1960s,

Figure 1 Donald T. Campbell (1916–1996).

psychologists and other social scientists played a pivotal role in shaping these social programs. Johnson's Great Society was an attempt to solve policy problems by appealing to the expertise of social scientists such as psychologists. By capitalizing on these societal changes, social science reflected and shaped the values and demands of the developing welfare state.

Campbell's work goes back to educational research, where randomized controlled experimentation was first developed. The unifying theme underlying of all of his work was formed by the question of how to achieve dependable knowledge of the psychological and social world. Campbell argued that "real" knowledge could be found only "in the field," outside the isolated laboratory. Even if going into the field meant that "true" (that is, randomized controlled) experimentation would not be possible, Campbell regarded the kind of knowledge that could be found in the real world so valuable that he was willing to compromise. His compromise was a range of sophisticated research designs and accompanying statistical techniques that he called quasi-experiments. Campbell's quasi-experimental methods set out to expand the scope of experimentation and became a world-famous methodological paradigm. Although these methods loosened the notion of experimentation, Campbell remained very strict in the use of quasi-experimental methods. He was committed to designing standardized methods that could rigorously test hypotheses. For Campbell, real knowledge could be achieved only by using the "right" research methods and he spent his entire life developing and continuously refining such methods.

Campbell's methods became extremely influential in evaluation research, where social scientists quantitatively tested the effectiveness and efficiency of policy measures. His work, such as the book *Experimental and Quasi-Experimental Designs for Research*, became as much as a research "bible" for evaluation researchers. Moreover, Campbell's influence was not restricted to evaluation research. His methods became the standard equipment of many Western social scientists engaged in quantitative field research. Campbell's methods were received as ways to answer questions decisively, as indisputably and objectively as possible.

The next sections show how Campbell shaped a research methodology that had to result in a trustworthy body of knowledge. The emphasis is placed on Campbell's years at Northwestern University, where he spent the largest part of his career and wrote many of his influential publications.

A Methodologist in the Making

Donald Thomas Campbell (1916–1996) was born the son of an agronomist in Grass Lake, Michigan. After finishing

high school in 1934, Campbell chose to study psychology. He graduated from the University of California at Berkeley in 1939 and subsequently continued his studies for his Ph.D. degree at the same university. During the course of a traveling grant at Harvard University, the Second World War interrupted his graduate studies. In December 1941—a few days before the bombing of Pearl Harbor—Campbell decided to join his Berkeley professor Robert Tryon, who was working in Washington, DC, at what soon would become the Office of Strategic Services (OSS). Tryon was establishing a section of Social Psychology at the Research and Analysis Branch at the OSS. Here, Campbell participated in studies of social attitudes and propaganda. A year later, in 1943, he joined the U.S. Navy, where he remained in service for 2½ years.

After the war, at the age of 29, Campbell returned to Berkeley to finish his graduate studies in social psychology. His dissertation, "The Generality of a Social Attitude," was completed in 1947. This unpublished study investigated the prejudices that five American ethnic groups ("Negro," Japanese, Jewish, Mexican, and English) held toward one another. For example, Campbell tested to what extent one minority blamed the others for problems in the country by asking whether one agreed with statements such as "Do the English in this country use their power to the disadvantage of other Americans?" or "Do the Jews in this country do very little harm to the rest of us?"

Next, Campbell accepted a job in social psychology at Ohio State University. There, one of his main projects was a study of leadership and morale among submarine crews. His central research focus, however, remained the quantitative measurement of social attitudes. Campbell kept pursuing this interest after he moved to the University of Chicago in 1950. For example, he participated in the Superior–Subordinate Orientation Project, which set out to measure the personality type and attitudes that would cause someone to favor superiors over subordinates or vice versa.

In 1953, Campbell accepted a position as associate professor at Northwestern University. In this new setting, he started developing his methodological interests. Methodology was important to Campbell before he came to Northwestern University, but now he began to develop key notions, such as the "multitrait–multimethod matrix" and "quasi-experimentation," that would make him famous.

Campbell's Prolific Years at Northwestern University

Quasi-Experimentation

One of Campbell's most cited publications—and more generally, one of the most frequently cited publications

in social science—is the 84-page book *Experimental and Quasi-Experimental Designs for Research*. It was published in 1966 after it had first appeared as a book chapter in 1963 and was co-authored by the statistician Julian Stanley. In the book, Campbell and Stanley presented numerous true experimental and quasi-experimental research designs. They recommended true experimental designs, in which the experimenter had to compare at least two groups: an experimental group that received a certain treatment and a control group that did not. In order to make a comparison between the two groups—which was necessary to see whether the experimental variable had made any difference—both groups had to be the same. The best way, according to Campbell and Stanley, to ensure that the experimental and control groups were equal was randomization. Selecting people at random would dissolve differences within and between groups.

However, experimentation with randomly composed groups often is not possible. If, for example, one wants to test which teaching method would be most effective, these methods would have to be tested on existing school classes. For moral and for practical reasons, it would be impossible to just randomly select children and test several teaching methods on them. Moreover, even if randomized selection would be possible, regrouping children would be experimentally undesirable because this would create an entirely different situation, affecting the outcome of the experiment. To overcome these problems, Campbell and Stanley designed a range of so-called quasi-experiments. As the term indicates, quasi-experiments were not real or true experiments, yet they enabled experimenters to work with real groups. Sophisticated research designs and statistics had to ensure that quasi-experimental research diverged as little as possible from the ideal of randomized controlled research.

Campbell and Stanley's prime concern was with valid research results—and according to them, such results could be gained only by experimentation or, if reality put some constraints on the possibilities of experimentation, by quasi-experimentation. Only good methods could produce trustworthy results. Therefore, they assessed the quality of their research designs by scoring them on factors that could threaten the validity of their outcomes. Campbell and Stanley distinguished two types of validity: internal and external validity. Internal validity concerned the validity of the experiment itself: did the experimental treatment actually cause the outcome of the experiment or was it something else? Campbell and Stanley listed several factors that could threaten the internal validity of an experiment, such as “history,” “testing,” or “instrumentation.” All these factors concerned events occurring during the experiment that changed the outcome of the experiment. When, for example, the effect of propaganda materials is tested and at the same time a war breaks out,

the experimenter cannot tell whether the measured difference in attitude can be attributed to the effect of propaganda or is due to the outbreak of war. This is what Campbell and Stanley called the factor history: events happening outside the experimental setting influencing the experiment. This and other validity-threatening factors made it difficult, if not impossible, to discern whether the experimental treatment made any difference at all.

External validity, in contrast, had to do with the generalizability of the experiment: to which other populations or settings could the results of this particular experiment be generalized? An example of a factor threatening the external validity of an experiment are “reactive effects of experimental arrangements,” which meant that certain effects could be found only under experimental conditions, when people are aware that they are in an experiment. These effects cannot be generalized to a nonexperimental setting.

In order to facilitate the use of their experimental and quasi-experimental research designs, Campbell and Stanley listed them in extensive tables where for each design pluses and minuses indicated which factor threatened its internal or external validity. With these tables in hand, researchers could work out which design would be most appropriate to test their hypotheses and generate the most valid knowledge.

The book *Experimental and Quasi-Experimental Designs for Research* became a canonical text to social scientists who wanted to do field research. More than 300,000 copies of the book have been sold, an impressive number for such a technical work. It was translated into numerous languages and is compulsory reading for psychology students as well as students in other social sciences. In 1979, Thomas D. Cook and Campbell published an update of *Experimental and Quasi-Experimental Designs for Research*, entitled *Quasi-Experimentation: Design and Analysis Issues for Field Settings*, which elaborated on many of Campbell and Stanley's concepts. Where, for example, Campbell and Stanley listed 12 factors threatening validity, Cook and Campbell extended this list to 33 factors. This book was also widely used by social scientists of various disciplines.

The Multitrait–Multimethod Matrix

Experimental and Quasi-Experimental Designs for Research was one of Campbell's most cited publications, rivaled only by an article written together with Donald Fiske, “Convergent and Discriminant Validation by the Multitrait–Multimethod Matrix.” Just like *Experimental and Quasi-Experimental Designs for Research*, this was a methodological paper that focused on social measurement. Whereas Campbell and Stanley presented several experimental and quasi-experimental research designs and assessed the validity of these designs by enlisting

numerous factors that could threaten their validity, Campbell and Fiske directed their attention to the validity of tests and measurements. According to them, tests should be validated in two ways, by “convergent validation” and by “discriminant validation.” The validity of a test had to be examined by checking how different tests converged, that is, measured the same thing when they were intended to do so, and at the same time how those tests discriminated, that is, measured different things when they were intended to differ. In order to validate tests, Campbell and Fiske developed a so-called multitrait–multimethod matrix. In this matrix, at least two traits and at least two methods should be used to validate a test.

Campbell and Fiske’s primary aim was the evaluation of tests. However, they took the view that psychologists should not evaluate tests as if they were fixed and definitive, but rather use these evaluations to develop better tests. Just like Campbell and Stanley, Campbell and Fiske submitted research methods to close scrutiny. Only after testing the tests could a researcher be sure that he had the right research instruments in hand and only with the appropriate methods could one arrive at reliable research results.

Evaluation Research

Even though the article on the multitrait–multimethod matrix was widely read and cited, its influence is rather marginal compared to Campbell and Stanley’s experimental and quasi-experimental research designs, which became paradigmatic. Campbell’s work was foundational for the new field of “program evaluation” or “social experimentation.” This field evaluated the effectiveness of policies such as social programs. Examples of social programs are the New Jersey Negative Income Tax Experiments, Head Start, or Sesame Street, large-scale projects in the vein of President Johnson’s Great Society initiatives.

The New Jersey Negative Income Tax Experiments were designed to find out whether guaranteeing an income to poor working families might be an alternative to welfare. The concept of a negative income tax was that if an income were to drop below a certain minimum level, a negative tax would be levied, which meant that the tax system would pay out cash. This negative tax would be reduced when someone again earned an income above the minimum level. The experiments were carried out from 1968 through 1972 and involved a sample of more than 1200 households. These households were randomly divided into several experimental groups, which differed in the level of guaranteed income and in the reduction rate of negative taxes when earning income above the minimum level. The experiments had to test whether or not this system of a negative income tax created an incentive to work was tested. These experiments were the first

large-scale attempt to test a policy by employing randomized controlled experimentation.

Head Start and Sesame Street were compensation programs aimed at the improvement of education for disadvantaged preschool children. Head Start—a project still running in the early 2000s—started in 1964 and in its first season was already serving over half a million children. The project intended to give disadvantaged children a head start through extra training in their early childhood—the age at which they would be most receptive. Sesame Street had the same rationale: in this project, the effects of the educational television program, which was designed to teach things in a playful way to young disadvantaged children, were tested. Campbell was involved in one of the evaluations of Head Start as a member of the advisory panel for the Head Start Evaluation Design Project. He also wrote a few articles that pointed out the mistakes in previous evaluations of the program. One article claimed that one of the major quasi-experimental evaluations of Head Start—“the social experiment evaluation most cited by presidents, most influential in governmental decision-making”—mistakenly showed that the program had no or even harmful effects. These mistakes could be made because the experimental and control groups were not equal—the experimental group consisted of the neediest children, whereas the control group included untreated, on average more able, children from the same community.

Researchers evaluating the effectiveness of social programs asked causal questions—what exactly causes the success or failure of this program?—that were considered to be most decisively answered by using experimental or quasi-experimental methods. Using Campbell’s methods, evaluation researchers convinced policymakers that they could provide reliable and valid answers to their questions about “what works, why it works, for whom it works, and under what conditions it works.” Their experimental and quasi-experimental evaluations generated the quantitative data that policymakers needed to decide whether or not to continue a social program. At the same time, the administrative preoccupation with measuring the effectiveness and efficiency of policies advanced the rise of evaluative experimentation.

The “Experimenting Society”

Campbell not only developed the methods for the evaluation of social programs, he also had an ideal society in mind in which these methods would be used properly. This ideal society was the “Experimenting Society.” Campbell drew the contours of this society in articles with compelling titles like “Reforms as Experiments,” “Methods for the Experimenting Society,” and “The Social Scientist as Methodological Servant of the Experimenting Society.” The first article opened with the bold

statement that “the United States and other modern nations should be ready for an experimental approach to social reform.” New policies should be tried and tested thoroughly—preferably using experimental methods—before implementation. Most importantly, this testing would have to be consequential. When a certain program or policy proved to be ineffective, it would have to be discarded to make space for another possible solution that *did* work.

The utopian Experimenting Society would, according to Campbell, be an honest society, nondogmatic, accountable, and above all scientific—not scientific in the sense that one scientific theory established as true would be used to make policy decisions, but rather that this society would value open criticism and experimentation and would be willing to change once-advocated theories or policies in the face of experimental evidence.

Campbell considered hard-headed policy evaluation to be crucial for the proper functioning of a democratic society. In his eyes, “to be truly scientific we must be able to experiment.” Evaluation by using truly scientific, experimental methods was so important to him that he argued that society should be organized in a scientific way to make this evaluation possible. Scarce resources, such as vaccinations, should be distributed among the public at random. This ensured that their effectiveness could be tested thoroughly, because randomly composed groups would be available for experimentation. And, equally important, Campbell argued that allocating scarce resources randomly was most democratic—everyone would have an equal chance of receiving the benefit.

Cross-Cultural Psychology

Campbell not only became extremely successful in the multidisciplinary field of program evaluation, his quasi-experimental research methodology also was successfully introduced in other social sciences, such as sociology and economics. He even tried to extend his standardized methodology to a discipline that predominantly used qualitative research methods: cultural anthropology. This effort retrospectively made him one of the “founding fathers” of cross-cultural psychology, a subdiscipline between psychology and cultural anthropology.

Campbell constantly emphasized the need for psychologists to test their theories in the field and he argued that his quasi-experimental research methodology enabled them to do so. Using anthropological data to test psychological theories was to him a kind of quasi-experimentation. If, for example, one wanted to investigate the effects of different modes of child-rearing on personality formation, it would be impossible to conduct a randomized experiment. In these cases, anthropological data could form a quasi-experimental alternative to true experimentation.

However, before psychologists could use these anthropological data, they had to make sure that these data were reliable—at least according to their standards. Whereas psychologists were used to testing large groups of “respondents,” anthropologists relied on qualitative data gathered from small groups of people. This made anthropological data less trustworthy in the eyes of psychologists. Campbell presented his methods as most useful for standardizing anthropologists’ research efforts and detecting the factors that distorted results. With the help of others, he created field manuals: ready-made research designs to gather uniform data.

An example of such a field manual is *Materials for a Cross-Cultural Study of Perception*, by the anthropologist Melville Herskovits, Campbell, and Marshall Segall, developed for their study of differences in visual perception across cultures. Fieldworkers—cooperating anthropologists actually gathering the data—received very precise research instructions through the manual, such as exactly how to phrase their questions and from what angle and distance to show the images in the manual. In total, some 1878 respondents were questioned using this standardized research design.

Campbell was so satisfied with his “field manual method” that he decided to use it for investigating another topic, together with the anthropologist Robert LeVine. This was the topic of ethnocentrism. Campbell and LeVine developed an “Ethnocentrism Field Manual” to coordinate and standardize the collection of data by anthropologists participating in their cross-cultural study. The manual prescribed strict research procedures. It gave detailed instructions on how to choose informants and how to select interpreters and presented a uniform interview schedule. An example of one of the interview questions in the manual was the “Bipolar Trait Inquiry” asking interviewees to characterize members of other ethnic groups in dichotomies, such as peaceful or quarrelsome, hardworking or lazy, filthy or clean, stupid or intelligent, handsome or ugly. After data were gathered from approximately 20 societies all over the world, Campbell and LeVine’s field manual was used to interview 1500 people in East Africa.

In these cross-cultural research projects, Campbell chose subjects interesting to psychologists, and most importantly, these projects were shaped by his quantitative, standardized methodology. The field manuals were developed to make sure that the experimental conditions were as uniform as possible to ensure reliable outcomes.

Conclusion

Campbell resigned from Northwestern University in 1979 at the age of 63. By then, he had become one of the leading figures in his field. In 1970, he was granted

the Distinguished Scientific Contribution Award of the American Psychological Association, the organization of which he became President in 1975; he was a member of the National Academy of Sciences and was awarded quite a few honorary doctorates. However, his resignation from Northwestern was not a retirement. He accepted a position as Albert Schweitzer Professor at Syracuse University and a few years later he became University Professor of Sociology—Anthropology, Psychology, and Education at Lehigh University. Among other things, Campbell pursued his interest in the philosophy of science there. Throughout his career, Campbell had been interested in the theory of knowledge and, in particular, his concept of an evolutionary epistemology became rather well known.

In his work, Donald Campbell addressed a variety of issues. However, the pivotal question in all of his work was how to achieve trustworthy knowledge of the world. Campbell's answer was his methodology, which enabled social scientists to experiment outside the laboratory, in the field. Moreover, in a time when policymakers increasingly appealed to scientists to justify their decisions, Campbell convinced these policymakers that what he had to offer was exactly what they needed: methods that could decisively show what policy worked. This approach vastly expanded the scope of the applied social sciences and gave Campbell's work its significance.

Case Study

Jack Glazier

Oberlin College, Oberlin, Ohio, USA

Glossary

ethnography Used synonymously with fieldwork, or the activity of the research anthropologist; also refers to the written result, usually in book form. Ethnography focuses on human behavior and belief within a well-defined community.

fieldwork The characteristic research endeavor of cultural anthropology, involving residence of the anthropologist within a community in order to collect data based on observation and informant testimony.

holism Understanding a community as a social unit in which beliefs, values, and institutional arrangements are integrated. A holistic perspective requires that the anthropologist see any segment of behavior or belief in its natural context—in relationship to other parts of the culture and to the whole.

informants Members of a community on whom anthropologists rely for answers to questions asked in formal interviews or, more commonly, through informal interactions during fieldwork. Informant testimony can complement, support, or contradict the behavioral data the anthropologist gathers through participant observation.

participant observation A major research activity of fieldworkers that includes their immersion in the daily routines of community life. As anthropologists become increasingly familiar to their hosts over the course of many months, the effect of their presence on the data collected should be minimized. Ideally, the participant observer attempts to learn about local custom under conditions that are as “natural” as possible.

There is a relationship between case study materials and ethnographic data, on the one hand, and culture theory, on the other. Data and theory exist in dynamic tension within the field of anthropology. Textured ethnographic detail gives the case study a distinctive quality, emphasizing

cultural difference and limiting generalization. Broad comparisons, by contrast, reach for a high level of abstraction that permits more sweeping theoretical statements about cross-cultural convergences and regularities.

Introduction

The distinctive features of the anthropological case study in many respects capture the theoretical and methodological qualities of anthropology as a discipline. Accordingly, any discussion of the nature of anthropological case studies can proceed only by considering the general characteristics, methods, and goals of cultural anthropology. The case study in anthropology often but not exclusively represents an extended examination of the culture, or ways of life, of a particular group of people through fieldwork. The published case study is often referred to as an “ethnography.” During the first half of the 20th century, that examination often covered a wide range of topics. The breadth of early ethnographic monographs partly reflected a desire to preserve a record of historic cultures in the process of momentous change under the colonial impact. At the same time, anthropologists were documenting the range and particularly the variation in human cultures. American anthropology for the first four decades of the 20th century utilized the rich data of ethnography to point up the unique character of individual cultures, thereby undermining universal explanatory schemes based on cultural evolutionism, biology, or alleged human psychological or temperamental constants. Where early universalist theories alleged singular lines of cultural and psychological development, 20th century anthropologists, up to the 1940s, were finding endless difference and variation.

Since the 1920s, writing comprehensive ethnographies has steadily given way to more focused, problem-oriented studies within a broad ethnographic framework that

continues to emphasize difference over uniformity. Classic examples of early problem-oriented case studies are Margaret Mead's *Coming of Age in Samoa* and Bronislaw Malinowski's monographic examination of Freud's oedipal theory, *Sex and Repression in Savage Society*. Both Mead and Malinowski presented case studies characteristic of their time. Their work effectively overturned widely accepted explanations of putative human universals believed to be derivative of a shared biological substrate of the human species. Instead, Mead argued that the phenomenon of adolescence was an American cultural invention alien to the experience of the people of Samoa. Likewise, Malinowski demonstrated that the supposed universality of the oedipal complex was only an expression of a particular kind of family structure—the patriarchal organization familiar in Europe—unknown in matrilineal societies, such as in the Trobriand Islands. These two cases are emblematic of anthropology's abiding interest in cultural difference and the utility of ethnographic case material in challenging universalist claims.

The term “case study” may also refer to specific case material embedded within a larger ethnographic monograph. Here, detailed examples of dispute settlement in local legal procedures, richly documented ritual performances, and the like can effectively illuminate the dynamics of social life. Especially germane is the work of Max Gluckman, his students from the University of Manchester, and their colleagues who centered their ethnographic investigations in Zambia and other areas of Central Africa. Turner's concept of the “social drama,” for example, emerged from his detailed case material about social situations of crisis among the Ndembu of Zambia, where breaches of widely accepted rules create crisis conditions threatening to sever ongoing social relationships. Through formalized ritual or legal procedure, efforts at redress either may successfully avert schism, by reconciling antagonists, or may lead to social separation. Turner's “social drama” strategy focused closely on the processes of community life as it concentrated on a limited cast of players within a village, their multiplex relationships, and their shifting structural positions over time. Other Central Africanists pioneered similar detailed processual research, also referred to as the “extended case method” and “situational analysis.” In all instances, the emphasis lay on close description of the behavioral dynamics of real people and their complex social relationships.

Fieldwork

Though cultural anthropologists utilize multiple theoretical orientations and study a wide range of cultural topics, disciplinary characteristics suffusing the case study tradition can nonetheless be identified. That

cultural anthropology varies internally according to the practitioners' theoretical perspectives, intellectual interests, and distinctive training could hardly be otherwise in light of the large number of cultural anthropologists, now constituting approximately one-third of the nearly 11,000 members of the American Anthropological Association (Richard Thomas, personal communication, March 27, 2002). Nonetheless, the professionalization of anthropology beginning a century ago created a common universe of discourse, unifying the discipline despite its very considerable internal diversity. Over the past 15 years, however, that unity has proved very tenuous as empirically committed anthropologists have struggled with determined postmodernists, who question the fundamental assumptions of empiricism and science. Until the emergence of that recent controversy, fieldwork and empirical methods lay at the center of common understandings about the nature of anthropology.

Through intense and sustained fieldwork, case studies provide fine-grained documentation of the ethnography of everyday life. However they have defined their investigations—problem-oriented research, descriptive ethnography, extended case studies, social dramas, situational analysis—cultural anthropologists have customarily conducted their research within functioning communities. The hallmark of the fieldwork tradition is sustained residence in a community for at least a year and sometimes longer. Fieldwork is so crucial that few anthropologists have achieved professional standing without it. The self-identity of cultural anthropology—indeed, the very esprit among cultural anthropologists—is predicated on the shared experience of this characteristic mode of investigation. Consequently, it is not unusual for anthropologists to liken their initial period in the field to a rite of passage.

The day-to-day activity of the anthropologist in the field entails participant observation and working with informants. Informants are members of the community under study who provide the anthropologist with data and insights about local cultural life. Because no one controls all the information pertinent to the culture, the anthropologist must rely on those who bring particular expertise to the questions he or she is asking. For example, reconstructing the system of age sets and generation classes that once were the centerpiece of the social structure of the Mbeere people of Kenya has depended on elderly male informants. Because the age and generational systems were decidedly male institutions that still enjoyed some vitality in the 1920s, when male elders in the early 1970s were young men, the male elders have provided the anthropologist with vital sources of information. Likewise, other individuals (ritual specialists) in Mbeere have helped the anthropologist understand many of the arcane beliefs surrounding funerary practice.

Anthropologists often distinguish between immersed informants and analytical informants. The immersed informant, like people everywhere, lives his or her life with very little cultural introspection or questioning of local assumptions. Without much secondary explanation, such people can provide the anthropologist with important information. The analytical informant, on the other hand, not only answers the anthropologist's ceaseless inquiries but also provides valuable commentary and critical assessment about local custom. The analytical informant shares with the anthropologist an interest in getting beneath the surface of events and beliefs to discern meanings that cannot be immediately grasped.

Besides learning about a culture through the testimony of informants, anthropologists also gather data through participant observation. This technique is an extension of daily, local routines in which the anthropologist is caught up. Whether he or she is participating in work parties, attending rituals and ceremonies, observing dispute settlement, recording narratives, playing games, or participating in other leisure activities, the anthropologist gathers information based on the agreeable fiction that he or she is a member of the community. Indeed, over the course of many months that can stretch into a year or two, the anthropologist aims to become a familiar part of the local scene, no longer viewed as a stranger. Seeking rapport within the community, the anthropologist hopes that the trust established through his or her engagement in community activities will bring with it an understanding of culture from the inside. Accordingly, speaking the local language as a result of prior study or, if that is not possible, learning it in the course of fieldwork is extremely important; it is through language that a culture is codified and its most subtle features are expressed and apprehended. To the extent that anthropologists enter into the flow of social life and develop personal relationships with informants, the entire experience feels and appears unique.

Given the centrality of the fieldwork tradition in anthropology and the concentration on communities very far removed from the anthropologist's native experience, ethnographic documentation of diverse ways of living—a focus on differences—is an integral feature of traditional anthropology, often serving as an end in itself. Difference and certainly uniqueness are at odds with generalizations explaining multiple cases. Anthropologists have generally subordinated abstraction and theory building to the task of data collection, documentation, and description. In the case study approach, therefore, ethnographic data should lead rather than follow theory development. In other words, coming to terms with distinct personalities and individuals whom anthropologists get to know intimately predisposes seasoned fieldworkers to preserve the detail, context, and integrity of their data. The case study further induces some skepticism about predictive models of human behavior, for human agency within the broad

limits of culture represents a compelling anthropological reality. Still, the explanations and interpretations that do appear in anthropological monographs depend on a minimal level of abstraction and analysis. Recognizing an inevitable tension between ethnography and generalization, Geertz observes that many anthropologists prefer to “stay rather closer to the ground than tends to be the case in the sciences.”

Ethnography and Theory

The fieldwork tradition that integrates the anthropologist into the life of a community is closely connected to the kinds of data the anthropologist collects. At the same time, the relationship between method and data distinguishes anthropology from other social sciences and points to the particular strengths and weakness of the case study.

Participant observation and working with informants are ways of getting detailed information, more qualitative than quantitative, about a localized community. These fundamental fieldwork techniques aim for a sharp, ethnographically focused picture—a case study in effect—of a social order seen in the round. The material an anthropologist gathers is bound up with the intensely personal nature of fieldwork bringing the researcher into close daily contact with people in the community. He or she typically sees the cultural world in terms of distinctive individuals, not anonymous social actors playing out normative cultural scripts.

Understandings achieved through informants and participant observation contrast sharply with modes of data acquisition in other social sciences, such as sociology, dependent as they are on quantitative analysis, surveys, and other impersonal research techniques. Sociologists aim, by and large, for predictive models that will explain recurrent behaviors and beliefs. To do so, however, inevitably creates a considerable distance between the theoretical model and the reality of human lives. This discrepancy is not likely to be troublesome if the data feeding the model have been gathered through impersonal techniques. Whereas sociology has outpaced anthropology in the development of social theory, it has shown much less inclination in presenting rounded human-centered portraits of actual communities. Aside from the ethnographically oriented work of a relatively few sociologists, the discipline of sociology has valued theory over cultural fact, conceptual formulation over ethnographic reporting, and scientific explanation over description—analytical endeavors far removed from the detail of the anthropological case study.

Anthropology reverses this scale of research values. The strength of the ethnographic case study in providing richly textured descriptions of human thought and action in context immediately exposes its primary theoretical constraint—more interest in cultural difference than in

cultural similarity. Illuminating the oddities of a case places considerable limits on the anthropologist's ability to construct generalizations extending his or her findings to multiple ethnographic instances. Preferring to maintain the integrity of case material, many anthropologists opt for "experience near" as opposed to "experience distant" concepts. That is, the anthropologist's article or monograph stays close to the experience of the people and therefore limits the range and scope of generalization. By contrast, the more abstract, analytical efforts of sociology facilitate theory development through comparison and the analysis of similarity and recurrence; but the results, unlike those of the anthropological case study, are far removed from any specific ethnographic reality and community of real individuals. Whereas the anthropologist's findings illuminate the particularities of the case, any reader of the anthropologist's article or monograph may legitimately ask what light the case study can shed on ways of living in other places or in other times. Is the case representative of other cases and thus to some degree generalizable, or is it idiosyncratic and unique?

Cultural Similarities or Cultural Differences

Studies that effectively contribute to culture theory and the associated construction of generalizations are necessarily comparative, because theory entails an explanation of multiple cases of cultural regularity. But in extending the reach of the single case study, theory and generalization almost exist at cross-purposes with the ethnography of the single case. On the one hand, the case study stays very faithful to detail, to native perspectives, to the subtleties of the vernacular language of the community, and to the context of events considered in holistic fashion. That fidelity to detail inevitably gives each case study a very distinct character, because the particular content and concatenation of events, activities, personalities, informant statements, and the like are singular. The detailed ethnography deriving from fieldwork may well restrict theory development and broad comparisons, if one is bent on maintaining the integrity and holism of the data. For example, anthropological accounts of peoples as diverse as Cantonese villagers, Mundurucu or Yanomamo horticulturists in Brazil and Venezuela, Mbeere farmer/herders on the Mt. Kenya periphery, and Tikopia Islanders in Polynesia characterize them as "patrilineal." This designation refers to their mode of reckoning descent through the male line, ascending to father, grandfather, and so on, to an apical ancestor. Men and women descended from that ancestor through male links belong to a patrilineal group—a lineage, a clan, or a moiety. In this respect, the five peoples cited as well as many others appear similar in regard to their

construction of critical descent groups. The particular native designations of these male-descended kin groups are vastly different and the connotations of the various terms as well as the particular role the kin groups play are different in each case.

Differences between the Cantonese and the Mbeere amid the common theme of patrilineal descent are illustrative. The Cantonese lineage, a corporate patrilineal group of considerable genealogical depth, is extremely important in the death rituals of its members. The lineage represents a kind of kin-based religious congregation charged with venerating male ancestors of the lineage. By contrast, the Mbeere patrilineage in no sense constitutes a religious congregation responsible for either collective ritual at the death of a member or, subsequently, collective commemorative rites. Compared to the Cantonese, it is weakly corporate and genealogically shallow. Yet both represent examples of patrilineal descent groups organized by common principles. The Cantonese and the Mbeere are two examples among hundreds of societies that anthropologists classify as "patrilineal." Some anthropologists are, accordingly, very interested in the comparative problem of explaining the social circumstances promoting the widespread development of patrilineal descent, as documented in large cross-cultural samples. What is at play here is the chronic tension between the ethnographic case study and comparative analysis aiming for a theoretical explanation of multiple occurrences. The decision to remain close to the ethnographic facts or to integrate them into a more generalized explanation simply depends on the anthropologist's intention. A cultural system is unique and at the same time similar to other cultural systems, however self-contradictory this may seem. It all depends on the level of abstraction at which the anthropologist chooses to work. For example, the Mbeere and the Cantonese are unique among the world's cultures, because no other communities reproduce the distinct configuration of customary practices and organizational features defining each case. Indeed, even distinct Cantonese villages or Mbeere local communities assume their own individuality in the finest grained ethnographic descriptions of each people. The area inhabited by the Mbeere people is, for example, characterized by variation in local ecology based on elevation and rainfall. The arid plains constitute an ecological zone distinct from the much better watered upland areas, and these in turn lead to important internal differences in patrilineal organization.

Conclusion

The depiction of anthropology as a discipline traditionally more concerned with the uniqueness of case study material than with generalizations about culture of course

requires qualification. Though ethnographic study holds a venerable place within anthropology, comparative research is very important. Comparison serves several ends that can emphasize either cultural differences or similarities. For example, the Human Relations Area Files (HRAF) developed since the 1930s have provided a vast compendium of ethnographic data for comparative research based on large cross-cultural samples. The easy accessibility of data through the HRAF depends on a coding process for classifying diverse ethnographic information into analytical categories—lineages, exchange transactions, cosmology, residence, and the like. In the process of comparing cultural features subsumed by such categories and testing hypotheses about recurrence and regularity within large samples, anthropologists necessarily lose something of the context and meaning defining the original material.

Comparison may also occur on a much smaller scale. The comparison of a limited number of societies—perhaps only three or four drawn from the same cultural area—characterized what Eggan called “the method of controlled comparison.” This style of research offered very restricted, low-level generalizations that did not completely jettison either the context or the particularity of the case study materials that were compared. The particular and the general are best thought of as opposite points along a continuum marking different degrees of abstraction.

In their introduction to four ethnographic case studies of American Indian peoples, George and Louise Spindler capture the value of the case study in the terms emphasized in this article: “A student reading these four studies will understand much about the great diversity of native North America. No outline of culture patterns alone can do this. The studies . . . are complete enough so that one is not left with that unsatisfied feeling that one has gotten only the formal surface features. Each study is written with attention to living detail.” Others might be more inclined to look for common cultural occurrences in the collected case studies. But whether the primary interest is in cultural differences or similarities, the ethnographic case study and theories of cultural recurrence

exist in creative opposition to each other and define in part the dynamic character of anthropology.

Glossary

artificial neural network A type of data mining technique, based on biological processes, for efficiently modeling large and complex problems.

chi-square automatic interaction detection A method tailored to finding structure in high-dimensional categorical spaces where the dependent variable is also categorical.

data mining A mathematical and statistical tool for pattern recognition.

decision trees Methods of representing a series of rules.

entropy A measure of diversity for nominal variables.

entropy-based relevance analysis A simple data mining method for categorical variables. It identifies variables and their categories that are highly relevant to the prediction, reduces the number of variables and their categories in prediction, and improves both efficiency and reliability of prediction.

proportional reduction in error A criterion that has been used for choosing among the various conventional measures of association between variables.

Modeling strategies for categorical data encompass a wide range of data mining techniques; these strategies use the power of modern high-speed computers to discover meaningful patterns and relationships in large data sets.

Introduction

Until the 1980s, most statistical techniques were based on elegant theory and analytical methods that worked well

on the modest amounts of data being analyzed. They relied on the modeler to specify the functional form and the nature of the variable interactions. The increased power of computers, coupled with the need to analyze very large data sets, has allowed the development of new techniques based on a “brute-force” exploration of possible solutions. These new extensions of statistical methods, called data mining techniques, can approximate almost any functional form or interaction. Basically, data mining is the analysis of data and use of software techniques for discovering meaningful patterns, relationships, and trends by sifting through large amounts of data. Data mining uses pattern recognition technologies as well as statistical and mathematical techniques. The result is a description of the data that can be confidently used for valid prediction. Whereas statistical modeling produces an outcome that explains the different types of behavior of all the data, data mining identifies patterns of behavior for some (but not for all) of the data. Data mining became very popular after 1990, with the rise of accessible detailed data sets and the need of better prediction of consumer behavior.

The discussion here is restricted to methods that can be used for prediction, usually the main goal of data analysis. These methods use existing values to forecast what other values will be. Most of the numerous models of data mining can be thought of as generalizations of the statistical workhorse of prediction, the linear regression model. Unfortunately, many real-world problems are not simply linear projections of previous values. Specifically, many dependent variables are difficult to predict because

they may depend on complex interactions of multiple predictor variables. This is especially true for situations with categorical variables. Though logistic regression is a powerful modeling tool that predicts the proportions of a categorical dependent variable, it assumes that the response variable is linear in the coefficients of the predictor variables. The modeler must choose the correct inputs and specify their functional relationship to the response variable. Additionally, the modeler must explicitly add terms for any interaction. It is up to the model builder to search for the right variables, find their correct expression, and account for possible interactions.

A great deal of effort in the statistics, computer science, artificial intelligence, and engineering communities has been devoted to overcoming the limitations of the basic regression model. An alternative approach with modern technologies is to use data-driven pattern-finding methods rather than user-driven approaches. In data mining, relationships are found inductively by the software, based on the existing data. The two most well-known data mining techniques are decision tree methods and artificial neural networks. Both techniques are examined here. One decision tree method, the chi-square automatic interaction detection (CHAID), is assessed because such methods are tailored to finding structure in high-dimensional categorical spaces where the dependent variable is also categorical. Furthermore, decision tree methodology appears to offer the most advantages—a competitive predictive accuracy and minimal assumptions about data. Neural network methods can handle both categorical and continuous independent variables without banding; however, the dependent variable is usually continuous, and it may be difficult to transform it to a discrete categorical outcome.

The discussion begins with a relatively little known data mining method for categorical variables; this very simple technique, entropy-based relevance analysis, needs no special software.

Entropy-Based Relevance Analysis

Creating a predictive model from a large data set is not straightforward. Most of the variables are redundant or irrelevant, so a preliminary task is to determine which variables are likely to be predictive. A common practice is to exclude independent variables with little correlation to the dependent variable. A good start perhaps, but such methods take little notice of redundancy among the variables or of any relationship with the dependent variable involving more than one independent variable. Moreover, categorical variables are often handled awkwardly. Entropy-based relevance analysis (ERA) is a simple method that identifies variables and their categories

that are highly relevant to the prediction, reduces the number of variables and attributes in prediction, and improves both efficiency and reliability of prediction.

The ERA measure is based on the entropy (H) statistic as a measure of the variation of a nominal discrete variable, X :

$$H(X) = - \sum_i p_i \ln p_i, \tag{1}$$

where p_i is the probability of an observation belonging to category i of X , and $p_i \ln p_i = 0$ for $p_i = 0$. Definition (1) can be generalized to multivariate distributions by letting the index i run over all cells of the relevant multivariate cross-tabulation. For a two-dimensional table,

$$H(XY) = - \sum_{i,j} p_{ij} \ln p_{ij}, \tag{2}$$

where p_{ij} is the probability of an observation belonging to category i of X and category j of Y . It can be shown that definition (2) can be written as

$$H(XY) = H(X) + H(Y) - I(XY), \tag{3}$$

with

$$I(XY) = \sum_{i,j} p_{ij} \ln \left(\frac{p_{ij}}{p_{i\cdot} \times p_{\cdot j}} \right) \quad \text{and} \\ p_{i\cdot} = \sum_j p_{ij}. \tag{4}$$

$I(XY)$ is called the transmitted information between X and Y . If Y is dependent on X and if the variation of Y is measured by $H(Y)$, it can further be shown that $I(XY)$ can be considered as the variation in Y that is explained by X . The ERA of Y is defined as the ratio of $I(XY)$ to $H(Y)$:

$$\text{ERA}_{XY} = \frac{I(XY)}{H(Y)}. \tag{5}$$

One of the most appealing properties of ERA is that it takes values between 0 and 1. ERA is equal to 0 if and only if the variable to be explained is independent of the explanatory variables, and ERA is 1 if and only if the dependent variable can be predicted with certainty, given the values of the observations on the independent variables. This can occur only when the dependent variable has the same or fewer categories than each of the independent variables, and then occurs when each combination of categories of the independent variables scores on just one category of the dependent variable.

There is a strong analogy between the ERA and the coefficient of determination (the square of Pearson's correlation coefficient, R^2) for continuous variables. For example, the partial ERA of Y explained by X , given Z , is

$$\text{ERA}_{Y:Z|X} = \text{ERA}_{Y|XZ} - \text{ERA}_{Y|Z}. \tag{6}$$

Like R^2 , the ERA is a so-called proportional reduction in error (PRE) measure. The PRE criterion has been used for choosing among the various conventional measures of association between variables, because it always has a clear interpretation, irrespective of the distribution and the level of measurement of the data. It can also be shown that ERA is related to the likelihood ratio statistic G^2 :

$$I(XY) = \frac{G^2}{2n}, \quad (7)$$

where n is the number of observations. Equation (7) is used extensively in the modeling strategy as a test of the efficacy of the process. In addition to the ERA of a particular set of variables, the associated G^2 is examined in a real-world example in Section VI to judge if there are significant differences between one set of variables and categories, and a previous set of variables and categories.

The selection of variables and the reduction of the number of categories occur stepwise. The independent variable with the highest ERA is selected and the loss in the ERA for each (permitted) combination of pairs of categories is then examined. The combination with the lowest decrease in the ERA in the table is selected. The combining process is continued until the resulting ERA drops off sharply (indicated mostly by a significant loss in G^2 at the 1% significance level). This reduced category variable is the first explanatory variable. Additional variables are selected and combined in the same manner, and finally added to the model (normally only if there is a significant increase in G^2 at the 1% significance level). This method of variable selection and category combination is one procedure for obtaining reasonable subsets of cross-tabulations. [The ERA analysis can be accomplished with the Crosstabs procedure in Statistical Package for the Social Sciences (SPSS) software. The uncertainty coefficient in the Crosstabs procedure is equivalent to the ERA.] The ERA method does not attempt to find the best selection of categories and variables. It is therefore a heuristic method, because it does not guarantee optimality. An example of the use of ERA is presented in Section VI.

Decision Trees

Decision tree methods are both data mining techniques and statistical models and are used successfully for prediction purposes. Decision trees were developed by Morgan and Sonquist in 1963 in their search for the determinants of social conditions. In one example, they tried to untangle the influence of age, education, ethnicity, and profession on a person's income. Their "best" regression contained 30 terms (including interactions) and accounted for only 36% of the variance. As an

alternative to regression, they organized the observations into 21 groups. The income of an observation in a group was estimated by the group mean. The groups were defined by values on only two or three inputs. Nonwhite high school graduates had a mean income of \$5005. White farmers who did not finish high school had a mean income of \$3950 and so on. This method of prediction accounted for 67% of the variance. The study showed the inadequacy of regression to discern the underlying relationships in the data, how common the problem is in social research, and how easily decision trees get around it.

Decision trees are a way of representing a series of rules that lead to a class or value. For example, the goal may be to classify a group of householders who have moved to a new house, based on their choice of type of the new dwelling. A simple decision tree can solve this problem and illustrate all the basic components of a decision tree (the decision nodes, branches, and leaves). A number of different algorithms may be used for building decision trees. Some methods generate a binary tree with only two branches at each node. Other methods allow more than two branches, creating a multiway tree. Each branch will lead to another decision node or to the bottom of the tree, called a leaf node. By navigating the decision tree, it is possible to assign a value or class to a case by deciding which branch to take, starting at the root node and moving to each subsequent node until a leaf node is reached. Each node uses the data from the case to choose the appropriate branch. Decision trees are appealing because of their clear depiction of how a few inputs determine target groups.

Decision trees are "grown" through iterative splitting of data into discrete groups, where the goal is to maximize the "distance" between groups at each split. One of the distinctions between decision tree methods is how they measure the "distance." Each split can be thought of as separating the data into new groups, which are as different from each other as possible. Decision trees that are used to predict categorical variables are called classification trees because they place cases in categories or classes. Decision trees used to predict continuous variables are called regression trees. Tree size can be controlled via stopping rules that limit growth. One common stopping rule is to establish a lower limit on the number of cases in a node, allowing no splits below this limit.

The original tree program in the statistical community, automatic interaction detection (AID), created by Morgan and Sonquist in 1963, finds binary splits on ordinal and nominal independent variables that most reduce the sum of squares of an interval dependent variable from its mean. The best split is always found. AID attempts splits on nodes with the larger sum of squares first, so that the program may stop after splitting some number of nodes specified by the user. The program stops when the

reduction in the sum of squares is less than some constant times the overall sum of squares.

Chi-Square Automatic Interaction Detection

The chi-square automatic interaction detection is currently the most popular classification tree method. CHAID is much broader in scope than AID and can also be applied when the dependent variable is categorical. The algorithm that is used in the CHAID model splits records into groups with the same probability of the outcome, based on values of independent variables. Branching may be binary, ternary, or more. The splits are determined using the chi-squared test. This test is undertaken on a cross-tabulation between the dependent variable and each of the independent variables. The result of the test is a “ p -value,” which is the probability that the relationship is spurious. The p -values for each cross-tabulation of all the independent variables are then ranked, and if the best (the smallest value) is below a specific threshold, then that independent variable is chosen to split the root tree node. This testing and splitting is continued for each tree node, building a tree. As the branches get longer, there are fewer independent variables available because the rest have already been used further up the branch. The splitting stops when the best p -value is not below the specific threshold. The leaf tree nodes of the tree are tree nodes that did not have any splits, with p -values below the specific threshold, or all independent variables are used. Like entropy-based relevance analysis, CHAID also deals with a simplification of the categories of independent variables. For a given $r \times c_j$ cross-table ($r \geq 2$ categories of the dependent variable, $c_j \geq 2$ categories of a predictor), the method looks for the most significant $r \times d_j$ table ($1 \leq d_j \leq c_j$). When there are many predictors, it is not realistic to explore all possible ways of reduction. Therefore, CHAID uses a method that gives satisfactory results but does not guarantee an optimal solution. This method is derived from that used in stepwise regression analysis for judging if a variable should be included or excluded. The process begins by finding the two categories of the predictor for which the $r \times 2$ subtable has the lowest significance. If this significance is below a certain user-defined threshold value, the two categories are merged. This process is repeated until no further merging can be achieved. In a following step, each resulting category composed of three or more of the original categories is checked; if the most significant split of the compound category rises above a certain chosen threshold value, the split is carried into effect and the previous step is entered again (this extra step ensures a better approximation of

the optimal solution). Both steps are repeated until no further improvement is obtained. This procedure is executed for each predictor. For each predictor optimally merged in this way, the significance is calculated and the most significant one is selected. If this significance is higher than a criterion value, the data are divided according to the (merged) categories of the chosen predictor. The method is applied to each subgroup, until eventually the number of objects left over within the subgroup becomes too small.

The great strength of a CHAID analysis is that the form of a CHAID tree is intuitive. Users can confirm the rationale of the model. The most important predictors can easily be identified and understood. Also, a CHAID model can be used in conjunction with more complex models. As with many data mining techniques, CHAID needs rather large volumes of data to ensure that the number of observations in the leaf tree nodes is large enough to be significant. Furthermore, continuous independent variables, such as income, must be banded into categorical-like classes prior to being used in CHAID. CHAID can be used alone or can be used to identify independent variables or subpopulations for further modeling using different techniques, such as regression, artificial neural networks, or genetic algorithms. A real-world example of the use of CHAID is presented in Section VI.

Artificial Neural Networks

An artificial neural network (ANN) is another popular type of data mining technique. ANNs originate from attempts to model biological processes using computers. Neural networks offer a means of efficiently modeling large and complex problems in which there may be hundreds of predictor variables that have many interactions. Neural nets may be used for regressions (where the dependent variable is continuous), but also in classification problems (where the dependent variable is a categorical variable).

A neural network (Fig. 1) starts with an input layer, where each node corresponds to an independent variable. Each of the input nodes is connected to every node in a hidden layer. The nodes in the hidden layer may be connected to nodes in another hidden layer, or to an output layer. The output layer consists of one or more dependent variables. The input nodes (and output nodes) must have values between 0 and 1; therefore, transformations are used to convert independent categorical and continuous variables into this range.

After the input layer, each node takes in a set of inputs, multiplies them by a connection weight W_{XY} (e.g., the weight from node 1 to 3 is W_{13} ; see Fig. 2), adds them together, applies a so-called activation or squashing function to them, and passes the output to the node(s) in the

Figure 1 A neural network with one hidden layer.

Figure 2 A neural network with weights; W_{XY} is the weight from node X to node Y .

next layer. For example, the value passed from node 4 to node 6 is as follows:

Activation function applied to $[(W_{14} \cdot \text{value of node 1}) + (W_{24} \cdot \text{value of node 2})]$.

Each node may be viewed as an independent variable (nodes 1 and 2 in this example) or as a combination of independent variables (nodes 3 through 6). Node 6 is a nonlinear combination of the values of nodes 1 and 2 because of the activation function on the summed values at the hidden nodes. In fact, if there is a linear activation function but no hidden layer, neural nets are equivalent to linear regression; with certain nonlinear activation functions, neural nets are equivalent to logistic regression. The connection weights (W values) are the unknown parameters, which are estimated by using existing data with one of the available estimation methods.

In designing a neural network, either the user or the software must choose the number of hidden nodes and hidden layers, the activation function, and limits on the weights. For simplicity of discussion here, assume a single hidden layer. One of the most common methods proceeds as follows:

1. The value of the output node is calculated based on the input node values and a set of initial weights. The

values from the input nodes are combined in the hidden layer, and the values of those nodes are combined to calculate the output value.

2. The error in the output is computed by finding the difference between the calculated output and the actual values found in the data set. The error is distributed proportionally to their weights over the hidden layer nodes. The errors of the output node and the hidden nodes are used to adjust the weight coming into each of these nodes to reduce the error.

3. The process is repeated for each case in the data set. The data set will be passed through again and again, until the error no longer decreases.

Neural networks differ from many statistical methods in several ways. First, a neural network usually has more parameters than does a typical statistical model. For example, there are 13 parameters (9 weights and 4 constant terms) in the neural network shown in Fig. 2. In fact, a given result can be associated with several different sets of weights. Consequently, the network weights in general do not aid in understanding the underlying process generating the prediction. However, this is acceptable in many applications.

There are several critical issues or problems for those who use neural networks. First, neural networks are not easily interpreted. There is no explicit rationale given for the decisions or predictions a neural network makes. Second, they tend to overfit the data set unless very stringent measures are used judiciously. This is due to the very large number of parameters of the neural network, which, if allowed to be of sufficient size, will fit any arbitrary data set well. Finally, neural networks tend to work best when the data set is sufficiently large and the data are reasonably highly structured. Because they are so flexible, they will find many false patterns in a low-structured data set. Thus, on the one hand, ANNs can handle both categorical and continuous independent variables without banding, and can produce a model even in very complex situations because an ANN uses its hidden layers to estimate the forms of the nonlinear terms and interaction. On the other hand, the input requires that several parameters be set up prior to initiating processing (for instance, the number of hidden layers and the number of nodes per hidden layer). These parameters affect the model built. Furthermore, it is extremely difficult to explain the resulting set of weights, because they have no intuitive meaning.

An Application in the Social Sciences

Consider the question of understanding the variation in housing choice: the choice is between renting a single-family home, renting an apartment in a multiunit structure, and owning, for householders who have moved out

of a rented house. What variables go into understanding the choices of these households? There are three choices: own, rent an apartment, or rent a house. The three choices can be influenced by variables that measure household characteristics, including income (four categories), age (four categories), and size of household (four categories). In addition, the characteristics of the previous tenure type will likely influence the new choice: previous tenure type (two categories, considering only renters in public or private rental housing), size of the previous dwelling (four categories), type of previous dwelling (two categories), and the rent of the previous dwelling (five categories). Finally, the location of the unit is important; the data from The Netherlands, summarized in Table I, cover four regions.

The abbreviated data in Table I show the steps, the ERA value, and the final derived classification. The intermediate steps in selecting the final categorization are omitted because of space limitations. The procedure is a combination of forward and backward steps. Income is selected as the first variable and various combinations of the original income categories are examined (all permitted possibilities are only shown for the first step of this first categorization). At succeeding steps, additional variables are chosen and their categories are simplified. (The simplification of additional variables is not included

in this abbreviated table.) The decision-making with respect to variable choice and variable simplification rests on the change in the ERA value, and the likelihood ratio statistic G^2 can be used to assess whether further simplification should be pursued. For example, in the income case, if any simplification would involve collapsing categories 1 and 2, this would generate the lowest decrease. However, the reduction in the ERA is quite large and there is a substantial decrease in G^2 . The test suggests that income should maintain all four categories. No variables are added after step 3, but further possibilities of combining income categories are explored in the “backward” step 4. The values of ERA show possible alternative combinations of categories, which marginally decrease the ERA and of course reduce the number of categories in the analysis. In this example, the original cross-tabulation of income, housing market, and size of household had 192 cells and an ERA value of 0.219. The final result after step 4 is a table with no more than 54 cells, whereas the ERA value has been only slightly reduced, from 0.219 to 0.192.

CHAID also proceeds in a step-down fashion. The variables are selected in a forward fashion as in the ERA (Fig. 3). In the CHAID procedure, categories of an independent variable are merged if they have a comparable pattern of choices and it is permitted to combine them. As said previously, the technique provides

Table I Reducing a Large Cross-Tabulation on Housing with Entropy-Based Relevance Analysis (ERA)^a

<i>Independent variables</i>	<i>ERA</i>	<i>G²</i>
Step 1A: Selection of the first variable		
<i>Income (4 categories)</i>	0.111	710.4
<i>Age of the head of household (4 categories)</i>	0.064	409.5
<i>Size of household (4 categories)</i>	0.052	330.8
<i>Rent of previous dwelling (5 categories)</i>	0.039	248.8

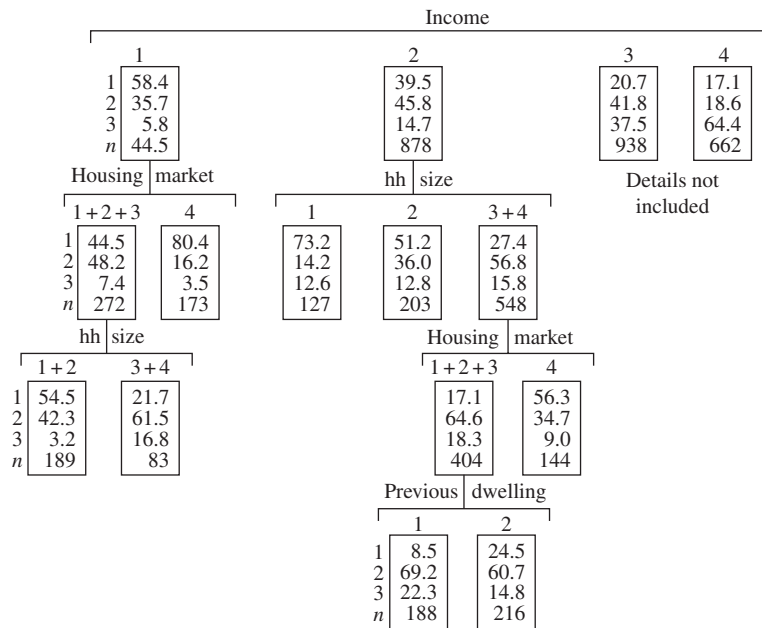

Figure 3 Chi-square automatic interaction detection dendrogram for influences on housing choice for previous renters (hh, household). Figure values are the percentages moving to each destination category: 1, multifamily rent; 2, single-family rent; or 3, owner occupied; n is the sample size. Adapted and modified from Clark *et al.* (1988), by permission of the Ohio State University Press.

optimal splits by maximizing the significance of the chi-square statistics at each step. For each of the categories of an independent variable selected in a previous step, the CHAID technique considers the most important predictor in the next step. Thus, the process “nests” the results and the end product can be presented as a tree (Fig. 3). As in ERA, in this example, the CHAID procedure selects income as the most important predictor and does not simplify the variable (only further splitting is shown for the first two categories of income in this presentation). Both housing market type and the size of the household are important predictors at the second and third stages for these low-income groups. Interesting additional information is contained in the way in which the two variables alternate in their contributions at different levels. Because the results from the CHAID analysis emphasize nesting of the independent variables within categories, the results suggest alternate lines of inquiry for a model of the data structure.

Observations for Data Mining

Categorical techniques have become more popular as the amount of survey data has increased, because much of those data involves measures of events that are discrete choices—moving or staying, owning or renting, a birth or

marriage occurring—and so on. Such discrete nonmetric conditions require models that can relate the discrete choice to a variety of independent variables, which may also be discrete or metric. An additional important reason to examine categorical methods is that they provide a sophisticated way of parsimoniously describing large tables. Previously, such tables were often only rudimentarily analyzed, or simply described. Now, with some of the exploratory table analyses outlined here, it is possible to provide a better interpretation of large-scale data tables and to reduce the amount of information for further analysis.

The predictive relationships found via data mining should not be confused with the causes of behavior. To ensure meaningful results, it is vital that the results of a data mining exercise be imbedded in theory and that the data at hand are understood. Entropy-based relevance analysis is a simple but useful method to greatly reduce the size of a large categorical data set. It efficiently removes variables and categories that would otherwise possibly confuse the modeling process; the end result is a more interpretable model and a better understanding of the underlying processes.

Both CHAID and ANNs can be used to create predictive models. When all or most of the independent variables are continuous, ANNs should perform better than CHAID. When all or most of the independent

variables are categorical, with high numbers of categories and implicitly containing relationships, CHAID should perform better than ANNs.

Software for Data Mining

In addition to the techniques discussed here, many other methods can be performed with a variety of data mining software. Such software is available from the well-known statistical software vendors, including SAS Institute Inc. and SPSS Inc.

AnswerTree is an SPSS product used to create decision trees. Four basic decision tree algorithms are used. Included are two CHAID algorithms, both of which SPSS has extended to handle nominal categorical, ordinal categorical, and continuous dependent variables.

Clementine, another SPSS product, has functions for association rules, classification, clustering, factor analysis, forecasting, prediction, and sequence discovery. Available techniques are Apriori, BIRCH, CARMA, Decision trees (C5.0; C&RT, a variation of CART), K-means clustering, neural networks (Kohonen, MLP, RBFN), regression (linear, logistic), and rule induction (C5.0, GRI). Perhaps the most unique feature of Clementine is its graphical user interface approach to data mining.

Enterprise Miner, available from SAS Institute Inc., has functions for association rules, classification, clustering, prediction, and time series. Available techniques are decision trees (CART, CHAID), K nearest neighbors, regression (linear, logistic), memory-based reasoning, and neural networks (Kohonen, MLP, RBF, SOM). An icon-based, point-and-click graphical user interface (not unlike SPSS's Clementine) creates a process flow to be performed by the data mining task.

Causal Inference

Alberto Abadie

Harvard University, Cambridge, Massachusetts, USA

Glossary

assignment mechanism The process that determines which units are exposed to a particular treatment.

covariate A variable not affected by the treatment.

experimental study A study that uses experimental data.

observational study A study that uses nonexperimental data.

outcome The variable possibly affected by the treatment.

treatment A variable, the effects of which are the objects of study.

Causal inference comprises a set of tools that aid researchers in identifying and measuring causal relationships from data using background knowledge or assumptions about the process that generates the data to disentangle causation from association.

Introduction

Establishing causal relationships is an important goal of empirical research in social sciences. Unfortunately, specific causal links from one variable, D , to another, Y , cannot usually be assessed from the observed association between the two variables. The reason is that at least part of the observed association between two variables may arise by reverse causation (the effect of Y on D) or by the confounding effect of a third variable, X , on D and Y .

Consider, for example, a central question in education research: “Does class size affect test scores of primary school students? If so, by how much?” A researcher may be tempted to address this question by comparing test scores between primary school students in large and small classes. Small classes, however, may prevail in

wealthy districts, which may have, on average, higher endowments of other educational inputs (highly qualified teachers, more computers per student, etc.) If other educational inputs have a positive effect on test scores, the researcher may observe a positive association between small classes and higher test scores, even if small classes do not have any direct effect on students’ scores. As a result, observed association between class size and average test scores should not be interpreted as evidence of effectiveness of small classes improving students’ scores.

This gives the rationale for the often-invoked mantra “association does not imply causation.” Unfortunately, the mantra does not say a word about *what* implies causation. Moreover, the exact meaning of causation needs to be established explicitly before trying to learn about it.

Causal Models

A Model of Potential Outcomes

In our example, we want to evaluate the *causal effect* of a treatment (small classes) on some *outcome* of interest (students’ scores). But how can we define causality? This section presents a causal model of potential outcomes. Let us introduce some notation first. D_i is an indicator of treatment intake for unit (individual) i . That is,

$$D_i = \begin{cases} 1 & \text{if unit } i \text{ received the treatment} \\ 0 & \text{otherwise} \end{cases}$$

For ease of exposition we consider only binary treatments (small vs. large classes). Let Y_i be the outcome variable of interest for unit i . As already argued, causality cannot be determined solely from association between D and Y . To define causality, we use the notion of *potential outcomes*:

Y_{0i} : Potential outcome without treatment for unit i . The level of outcome that unit i would

attain if not exposed to the treatment (test score for student i if in a large class).

Y_{1i} : Potential outcome with treatment for unit i .
The level of outcome that unit i would attain if exposed to the treatment (test score for student i if in a small class).

Potential outcomes refer to possibly counterfactual events. For a student in a large class, Y_{1i} represents test score if had been assigned to a small class. Similarly, for a student in a small class, Y_{0i} represents test score if had been assigned to a large class. For any particular unit, we cannot observe both potential outcomes (Y_{1i}, Y_{0i}); we only observe the realized outcome Y_i :

$$Y_i = \begin{cases} Y_{1i} & \text{if } D_i = 1 \\ Y_{0i} & \text{if } D_i = 0 \end{cases}$$

or

$$Y_i = D_i \cdot Y_{1i} + (1 - D_i) \cdot Y_{0i}$$

Once we have defined potential outcomes in this way, it is natural to define the causal effect of the treatment on the outcome for unit i as the difference between the two potential outcomes, $Y_{1i} - Y_{0i}$. Now, the fundamental identification problem of causal inference becomes apparent; because we cannot observe both Y_{0i} and Y_{1i} for the same unit, it is not possible to compute causal effects at the unit level, $Y_{1i} - Y_{0i}$. Even so, we still would like to estimate some average, such as the average treatment effect (ATE):

$$\alpha_{ATE} = E[Y_1 - Y_0]$$

or the average effect on the treated (also called the selected average treatment effect, SATE):

$$\alpha_{SATE} = E[Y_1 - Y_0 | D = 1]$$

where $E[\cdot]$ denotes averages over the population.

Unfortunately, comparisons of average outcomes between treated and untreated units do not usually estimate ATE or SATE:

$$\begin{aligned} E[Y | D = 1] - E[Y | D = 0] &= E[Y_1 | D = 1] - E[Y_0 | D = 0] \\ &= \underbrace{E[Y_1 - Y_0 | D = 1]}_{\text{SATE}} + \underbrace{\{E[Y_0 | D = 1] - E[Y_0 | D = 0]\}}_{\text{BIAS}} \end{aligned} \tag{1}$$

The bias term in Eq. (1) is not thought to be zero for most applications in social sciences. This is due to selection problems. Selection for treatment is usually associated with the potential outcomes that individuals would attain with and without being exposed to the treatment. I present some ways to overcome the selection problem later so that treatment effects can be estimated.

Other Causal Models

Causality has been studied using a variety of models. A structural equations model is a set of equations that describe causal relationships (i.e., potential outcomes). An alternative way to represent causation is through the use of causal diagrams. Models of potential outcomes, structural models, and causal diagrams are alternative ways of representing causal relationships. In the context of time series data, the term causality has been used to refer to predictive power; this is often referred to as Granger or temporal causality.

Identification and Estimation

Cross-Sectional Data

Randomized Experiments

Let us go back to Eq. (1). Suppose that treatment intake is independent of potential outcomes:

$$(Y_1, Y_0) \perp\!\!\!\perp D \tag{2}$$

By independence, we have that $E[Y_0 | D = 1] = E[Y_0 | D = 0]$ and therefore $\alpha_{SATE} = E[Y_1 - Y_0 | D = 1] = E[Y | D = 1] - E[Y | D = 0]$. Moreover, because it is also true that $E[Y_1 | D = 1] = E[Y_1 | D = 0]$, we obtain:

$$\begin{aligned} \alpha_{ATE} &= E[Y_1 - Y_0] = E[Y_1 - Y_0 | D = 1] \\ &= E[Y | D = 1] - E[Y | D = 0] \end{aligned} \tag{3}$$

So, $\alpha_{ATE} = \alpha_{SATE}$. In a randomized study, a randomized mechanism is used to assign experimental units to one of two groups: the treatment group and the control group. The individuals assigned to the treatment group are exposed to the treatment, whereas the individuals assigned to the control group are excluded from the treatment. That is, in a randomized study the assignment mechanism is randomized. The role of randomization is to force Eq. (2) to hold. Because the assignment mechanism is randomized, the treatment variable must be independent of potential outcomes.

Note that, although we focus the discussion on average treatment effects, randomization identifies the whole marginal distributions of Y_0 and Y_1 :

$$\begin{aligned} F_{Y_0}(y) &= P(Y_0 \leq y) = P(Y_0 \leq y | D = 0) \\ &= P(Y \leq y | D = 0) \end{aligned}$$

similarly $F_{Y_1}(y) = P(Y \leq y | D = 1)$. So we can assess the effect of the treatment not only at the mean but also at any quantile: $Q_\theta(Y_1) - Q_\theta(Y_0)$ (here, θ is a quantile index between 0 and 1 and $F_{Y_d}(Q_\theta(Y_d)) = \theta$, for $d = 0, 1$). Note, however, that randomization does not identify the quantiles of the treatment effect: $Q_\theta(Y_1 - Y_0)$. In contrast to what happens with means, the difference of quantiles is not the quantile of the difference.

Suppose that we conduct a randomized trial with n individuals. For each individual i , the toss of a coin determines whether i is assigned to the treatment group ($D_i = 1$) or to the control group ($D_i = 0$). After the treatment group is exposed to the treatment, information is collected about some relevant outcome variable for each individual, Y_i . The estimation is carried out by using sample analogs of the population results. Letting $\alpha_0 = E[Y_1 - Y_0](= \alpha_{ATE} = \alpha_{SATE})$, Eq. (3) suggests to estimate α_0 using a simple difference of sample averages between the treated and the untreated, $\hat{\alpha} = \bar{Y}_1 - \bar{Y}_0$, where:

$$\bar{Y}_1 = \frac{\sum Y_i \cdot D_i}{\sum D_i} = \frac{1}{n_1} \sum_{D_i=1} Y_i,$$

$$\bar{Y}_0 = \frac{\sum Y_i \cdot (1 - D_i)}{\sum (1 - D_i)} = \frac{1}{n_0} \sum_{D_i=0} Y_i$$

$n_1 = \sum_i D_i$ and $n_0 = n - n_1$. $\hat{\alpha}$ is an unbiased estimator of α_0 . Usual two-sample testing methods can be applied to perform statistical inference about α_0 .

Selection on Observables

In the absence of experimental data, the independence condition in Eq. (2) is rarely plausible. The reason is that treated and nontreated may differ in characteristics—other than treatment exposure—that also have an effect on the outcome variable, so Eq. (2) holds only for fixed values of those characteristics. In statistical jargon, those characteristics are called confounders. Let X be the vector of confounders, then:

$$(Y_1, Y_0) \perp\!\!\!\perp D \mid X \tag{4}$$

We say that there is selection on observables when all confounders are observed.

Following the same reasoning as shown earlier, if Eq. (4) holds, we have that $E[Y_1 - Y_0 \mid X] = E[Y_1 - Y_0 \mid X, D = 1] = E[Y \mid X, D = 1] - E[Y \mid X, D = 0]$. Therefore α_{ATE} and α_{SATE} are identified by:

$$\alpha_{ATE} = E[Y_1 - Y_0] = \int E[Y_1 - Y_0 \mid X] dP(X)$$

$$= \int (E[Y \mid X, D = 1] - E[Y \mid X, D = 0]) dP(X) \tag{5}$$

and

$$\alpha_{SATE} = E[Y_1 - Y_0 \mid D = 1]$$

$$= \int (E[Y \mid X, D = 1] - E[Y \mid X, D = 0]) dP(X \mid D = 1) \tag{6}$$

Matching Estimators When X is discrete and takes on a small number of values, it is easy to construct estimators of α_{ATE} and α_{SATE} based on Eqs. (5) and (6). Suppose that

X takes on J different cells $\{X^1, \dots, X^j, \dots, X^J\}$. Let n^j be the number of observations in cell j . Let n_1^j be the number of treated observations in cell j and n_0^j be the number of untreated observations in cell j . Finally, let \bar{Y}_1^j be the average outcome for the treated in cell j and \bar{Y}_0^j the average outcome for the untreated. The sample counterparts of Eqs. (5) and (6) are:

$$\hat{\alpha}_{ATE} = \sum_{j=1}^J (\bar{Y}_1^j - \bar{Y}_0^j) \cdot \left(\frac{n^j}{n}\right)$$

$$\hat{\alpha}_{SATE} = \sum_{j=1}^J (\bar{Y}_1^j - \bar{Y}_0^j) \cdot \left(\frac{n_1^j}{n_1}\right)$$

When X is continuous, an obvious strategy is to divide the support of X into a finite number of cells and apply what we know for discrete X . This method is called subclassification. Subclassification works if the distribution of X can be well-approximated by a discrete distribution over a small number of cells.

Let $j(i)$ be the cell to which X_i belongs (that is, if $X_i = X^k$, then $j(i) = k$). Then, it is easy to show that:

$$\hat{\alpha}_{SATE} = \frac{1}{n_1} \sum_{D_i=1} (Y_i - \bar{Y}_0^{j(i)})$$

That is, $\hat{\alpha}_{SATE}$ matches each treated observation with an average of the untreated observations in the same cell. This suggests that when X is continuous, α_{SATE} can be estimated using

$$\hat{\alpha}_{SATE} = \frac{1}{n_1} \sum_{D_i=1} (Y_i - Y_{m(i)})$$

where $Y_{m(i)}$ is the outcome of an untreated observation such that $X_i \simeq X_{m(i)}$. This method is called matching. Matching works if for each treated observation, it is possible to find an untreated observation with close covariate values.

Matching and subclassification are both easy to carry out when X contains only one variable. However, these methods break down if the dimension of X is large. In that case, subclassification is likely to create cells of X with either no treated or no untreated observations. Similarly, when the dimension of X is large, it may be hard to find, for each treated observation, an untreated observation with similar covariate values. The next section presents propensity score methods that are useful when the dimension of X is large.

Propensity Score Methods Under selection on observables, we define the propensity score as the selection probability conditional on the confounding variables: $P(D = 1 \mid X)$. To stress the fact that the propensity score is a function of the covariates, let $\pi(X) = P(D = 1 \mid X)$. Rosenbaum and Rubin proved in their 1983 study that if Eq. (4) holds, then conditioning on the propensity

score is sufficient to ensure independence between the treatment indicator and the potential outcomes. That is, if $(Y_1, Y_0) \perp\!\!\!\perp D \mid X$, then $(Y_1, Y_0) \perp\!\!\!\perp D \mid \pi(X)$.

This result suggests a two-step procedure to estimate causal effects under selection on observables: (1) estimate the propensity score $\pi(X)$ and (2) do matching or subclassification on the propensity score. The advantage of this strategy is that the dimension of the propensity score is always one, for any number of covariates in X .

Alternatively, under selection on observables, average treatment effects can be identified by weighting on the propensity score. It can be easily seen that:

$$E\left[Y \frac{D - \pi(X)}{\pi(X)(1 - \pi(X))} \mid X\right] = E[Y \mid X, D = 1] - E[Y \mid X, D = 0]$$

As a result, if $(Y_1, Y_0) \perp\!\!\!\perp D \mid X$, then by Eq. (5):

$$\alpha_{ATE} = E\left[Y \frac{D - \pi(X)}{\pi(X)(1 - \pi(X))}\right]$$

A similar result holds for α_{SATE} . The last equation suggests a two-step procedure to estimate causal effects under selection on observables: (1) estimate the propensity score $\pi(X)$ and (2) plug the estimated values of the propensity score into the sample analog of the last equation.

$$\hat{\alpha}_{ATE} = \frac{1}{n} \sum_{i=1}^n Y_i \frac{D_i - \hat{\pi}(X_i)}{\hat{\pi}(X_i)(1 - \hat{\pi}(X_i))}$$

This estimator weights treated observations with $1/\hat{\pi}(X_i)$ and untreated observations with $1/[1 - \hat{\pi}(X_i)]$. Estimators of treatment effects that weight on functions of the propensity score originated in 1952 with Horvitz and Thompson.

Regression Regression is customarily used to control for the effect of covariates when measuring the association between two variables of interest. How can we interpret (linear or nonlinear) regression in the context of selection on observables? Consider the conditional expectation $E[Y \mid D, X]$. Under $Y_1, Y_0 \perp\!\!\!\perp D \mid X$, the conditional expectation $E[Y \mid D, X]$ can be interpreted as a conditional causal response function: $E[Y \mid D = 1, X] = E[Y_1 \mid X]$ and $E[Y \mid D = 0, X] = E[Y_0 \mid X]$. Therefore, $E[Y \mid D, X]$ provides the average potential responses with and without the treatment. Of course, $E[Y \mid D = 1, X] - E[Y \mid D = 0, X] = E[Y_1 - Y_0 \mid D = 1, X] = E[Y_1 - Y_0 \mid X]$. The functional form of $E[Y \mid D, X]$ is typically unknown. Even so, it is possible to estimate a parsimonious parametric approximation to $E[Y \mid D, X]$ using least squares. To do that, specify a class of approximating functions $\mathcal{G} = \{g(D, X; \theta) : \theta \in \Theta \subset R^k\}$. Then, a least-squares approximation from \mathcal{G} to $E[Y \mid D, X]$ is given by $g(D, X; \theta_0)$, where:

$$\theta_0 = \arg \min_{\theta \in \Theta} E[Y \mid D, X] - g(D, X; \theta)^2$$

A well-known result is that θ_0 also defines the best predictor of Y within \mathcal{G} under quadratic loss: $\theta_0 = \arg \min_{\theta \in \Theta} E[(Y - g(D, X; \theta))^2]$. An analog estimator of θ_0 is:

$$\hat{\theta} = \arg \min_{\theta \in \Theta} \frac{1}{n} \sum_{i=1}^n [Y_i - g(D_i, X_i; \theta)]^2$$

For example, when \mathcal{G} is the set of linear functions in (D, X) , then $\hat{\theta} = (\hat{\alpha}, \hat{\beta})$, where

$$(\hat{\alpha}, \hat{\beta}) = \arg \min_{(\alpha, \beta) \in \Theta} \frac{1}{n} \sum_{i=1}^n (Y_i - \alpha D_i - X_i' \beta)^2$$

which is the familiar linear least-squares estimator. In summary, if condition (4) holds, then least-squares regression provides a well-defined approximation to an average causal response function. Of course, this estimator will provide poor information if $E[Y \mid D, X]$ cannot be well-approximated by the functions in \mathcal{G} . In such a case, nonparametric regression is a useful alternative.

The functions $h_1(X) = E[Y \mid D = 1, X]$ and $h_0(X) = E[Y \mid D = 0, X]$ can be estimated nonparametrically (for example using kernel regression, splines, or local linear regression). Integrating $h_1(X) - h_0(X)$ over $P(X)$ we obtain α_{ATE} . Integration over $P(X \mid D = 1)$ produces α_{SATE} . The propensity score result can be used to produce an estimator that conditions only on $\pi(X)$. First, the expectations $g_1(\pi) = E[Y \mid D = 1, \pi]$ and $g_0(\pi) = E[Y \mid D = 0, \pi]$ are estimated (where $\pi = P(D = 1 \mid X)$). Then, $g_1(\pi) - g_0(\pi)$ is integrated over the distribution of π for the treated to estimate α_{SATE} .

Instrumental Variables In many relevant settings, analysts think that observed variables cannot explain all the dependence between treatment selection and potential outcomes. When there is a variable, Z , which induces selection for treatment but does not have any direct effect on the potential outcomes, instrumental variable methods can be used to estimate causal parameters (then Z is said to be an instrumental variable or instrument).

This situation is common in experiments in social sciences in which experimental units do not always comply with the treatment protocol. Let Z be a variable that takes value equal to 1 for individuals assigned to the treatment group and 0 otherwise. In this scenario, assignment for treatment, Z , is randomized, but treatment exposure, D , is not because experimental subjects may decide not to comply with the assignment. If treatment assignment only affects the outcome of interest through its effect on treatment exposure, instrumental variable techniques can be used to recover an average treatment effect (although this average treatment effect is not, in general, ATE or SATE).

For ease of exposition, we assume that Z is scalar and binary. Generalizations to multiple and nonbinary instruments have been made by Heckman and Vytlacil.

To recognize the dependence between the treatment and the instrument we use potential treatment indicators. The binary variable D_z represents potential treatment status given $Z = z$. The instrument Z is assumed to affect the outcome variable Y only through its effect on selection for treatment, D . Therefore, the potential outcomes (Y_1, Y_0) do not depend on Z .

The treatment variable can then be expressed as $D = Z \cdot D_1 + (1 - Z) \cdot D_0$. In practice, we observe Z and D (and therefore D_z for individuals with $Z = z$), but we do not observe both potential treatment indicators (D_0, D_1) .

It is assumed that potential outcomes and potential treatments are independent of the instrument $(Y_0, Y_1, D_0, D_1) \perp\!\!\!\perp Z$, and that the instrument affects selection for treatment only in one direction: $D_1 \geq D_0$ with some units such that $D_1 > D_0$. In the context of experiments with imperfect compliance, the last condition means that some experimental subjects are induced to be treated by random assignment, but no experimental unit who will get the treatment if assigned to the control group will refuse to take the treatment if assigned to the treatment group. Units with $D_1 > D_0$, or equivalently $D_1 = 1$ and $D_0 = 0$, are called compliers because they are the subjects who always comply with the experimental protocol. Note that we cannot say who are compliers in a particular sample because we do not observe both D_0 and D_1 for the same individuals. Under these assumptions:

$$\begin{aligned}
 E[Y_1 - Y_0 \mid D_1 > D_0] &= \frac{E[Y \mid Z = 1] - E[Y \mid Z = 0]}{E[D \mid Z = 1] - E[D \mid Z = 0]} \\
 &= \frac{\text{Cov}(Y, Z)}{\text{Cov}(D, Z)} \tag{7}
 \end{aligned}$$

This result says that the average effect of the treatment for compliers is identified. This parameter is called the local average treatment effect (LATE) by Angrist, Imbens and Rubin.

Compliers are the units whose decision to take the treatment is determined by variation in the instrument. Whether compliers are an interesting group of the population depends on the particularities of each example. However, an important special case arises when $D_0 = 0$. This happens, for example, in randomized experiments when there is perfect exclusion of the control group from the treatment (not ruling out noncompliance in the treatment group). In such cases, $E[Y_1 \mid D_1 > D_0] = E[Y_1 \mid D_1 = 1] = E[Y_1 \mid Z = 1, D_1 = 1] = E[Y_1 \mid D = 1]$, and similarly $E[Y_0 \mid D_1 > D_0] = E[Y_0 \mid D = 1]$, so LATE is the average effect of the treatment for the treated (SATE). Note also that when $D_0 = 0$ or $D_1 = 1$ for every individual, then the condition $D_1 \geq D_0$ holds trivially.

The sample analog of Eq. (7) is often called the Wald estimator:

$$\left(\frac{\sum_{i=1}^n Y_i Z_i}{\sum_{i=1}^n Z_i} - \frac{\sum_{i=1}^n Y_i (1 - Z_i)}{\sum_{i=1}^n (1 - Z_i)} \right) / \left(\frac{\sum_{i=1}^n D_i Z_i}{\sum_{i=1}^n Z_i} - \frac{\sum_{i=1}^n D_i (1 - Z_i)}{\sum_{i=1}^n (1 - Z_i)} \right)$$

Abadie has extended the LATE result to the estimation of conditional average treatment responses for compliers: $E[Y_1 \mid X, D_1 > D_0]$ and $E[Y_0 \mid X, D_1 > D_0]$.

The Regression Discontinuity Design Sometimes assignment for treatment is determined based on whether a certain individual characteristic exceeds some threshold. That is:

$$D_i = \begin{cases} 1 & \text{if unit } X_i > \bar{X} \\ 0 & \text{otherwise} \end{cases} \quad \text{or} \quad D_i = \begin{cases} 1 & \text{if unit } X_i < \bar{X} \\ 0 & \text{otherwise} \end{cases}$$

For example, second-grade students who scored below a certain cut-off value were assigned to a compensatory reading program. Usually, the variable that determines treatment assignment is thought to be related to the outcomes of interest. Therefore, simple comparisons of outcomes between treated and nontreated do not provide valid causal estimates.

If the relationship between the covariate and the outcome is smooth, we can attribute any discontinuity in the conditional average of the outcome variable at the cut-off value, \bar{X} , to the effect of the treatment.

Here, we consider the case in which $E[Y_0 \mid X]$ and $E[Y_1 \mid X]$ are linear functions of X . The average potential outcomes conditional on X are given by:

$$E[Y_0 \mid X] = \mu_0 + \beta_0 X, \quad E[Y_1 \mid X] = \mu_1 + \beta_1 X$$

Therefore, the average treatment effect conditional on X is equal to $\alpha(X) = E[Y_1 - Y_0 \mid X] = (\mu_1 - \mu_0) + (\beta_1 - \beta_0)X$. Suppose that $D = 1$ if $X > \bar{X}$, and $D = 0$ otherwise. Figure 1 gives a graphical interpretation. Because D is determined given X , we have:

$$\begin{aligned}
 E[Y \mid X, D] &= D \cdot E[Y_1 \mid X] + (1 - D) \cdot E[Y_0 \mid X] \\
 &= \mu_1 D + \beta_1 (X \cdot D) + \mu_0 (1 - D) + \beta_0 (X \cdot (1 - D))
 \end{aligned}$$

So we can run this regression and estimate the effect of the treatment at \bar{X} as the analog of $\alpha(\bar{X}) = (\mu_1 - \mu_0) + (\beta_1 - \beta_0)\bar{X}$. In practice, there is an easier way to do this. It can be shown that

$$\begin{aligned}
 E[Y \mid X, D] &= [\mu_0 + \beta_0 \bar{X}] + \beta_0 (X - \bar{X}) + [(\mu_1 - \mu_0) \\
 &\quad + (\beta_1 - \beta_0)\bar{X}]D + (\beta_1 - \beta_0)((X - \bar{X}) \cdot D)
 \end{aligned}$$

Therefore, if we run a regression of Y on $(X - \bar{X})$, D , and the interaction $(X - \bar{X}) \cdot D$, the coefficient of D reflects the average effect of the treatment at $X = \bar{X}$. Even when the parametric specifications adopted for $E[Y_1 \mid X]$ and $E[Y_0 \mid X]$ allow us to estimate the effect of the treatment away from $X = \bar{X}$, the data per se are only informative about the effect of the treatment at $X = \bar{X}$.

Figure 1 Regression discontinuity design, linear case.

Identification of $\alpha(X)$ for $X \neq \bar{X}$ is done by pure extrapolation of lines.

Bounds When the outcome variable is bounded (when it has lower and upper bounds), the effect of the treatment can be bounded even if no other identification condition holds.

Here we focus on a simple case, in which the dependent variable is binary, so the lower bound is 0 and the upper bound is 1. For each individual, we observe Y and D , so we can estimate $E[Y_1 | D = 1](= E[Y | D = 1])$, $E[Y_0 | D = 0](= E[Y | D = 0])$ and $P(D = 1)$. We cannot estimate $E[Y_1 | D = 0]$ or $E[Y_0 | D = 1]$, but we know that they are in between 0 and 1. We can use this fact to bound SATE and ATE:

$$E[Y | D = 1] - 1 \leq \text{SATE} \leq E[Y | D = 1]$$

and

$$\begin{aligned} & (E[Y | D = 1] - 1) \cdot P(D = 1) - E[Y | D = 0] \cdot P(D = 0) \\ & \leq \text{ATE} \leq E[Y | D = 1] \cdot P(D = 1) \\ & - (E[Y | D = 0] - 1) \cdot P(D = 0) \end{aligned}$$

As always, we can estimate the bounds using sample analogs. It can be easily seen that, for a binary outcome variable, the width of the bounds is 1. Manski discusses restrictions that can help narrow the bounds further.

Longitudinal Data

This section presents estimation techniques that are especially suitable for longitudinal data.

Difference-in-Differences and Fixed Effects We have studied how to control for observed differences between treated and controls. However, often there are reasons to believe that treated and nontreated differ in unobservable characteristics that are associated with potential outcomes even after controlling for differences in observed characteristics.

When there are pretreatment and posttreatment outcome data available, we can think about comparing the outcomes for the treated after the treatment to the outcomes of the treated before the treatment. Effectively, we would like to use the treated before the treatment as controls for the treated after the treatment. However, comparisons of pretreatment and posttreatment outcomes for the treated are likely to incorporate biases due to temporal trends in the outcome variable or to the effect of changes in extraneous factors between both periods.

When only part of the population is treated, an untreated comparison group can be used to identify temporal variation in the outcome that is not due to the treatment. The difference-in-differences (DID) estimator is based on this simple idea.

As in previous sections, we define the causal effect of the treatment on the outcome as the difference between two potential outcomes. In contrast with previous sections, now we are dealing with longitudinal data, so potential outcomes are also indexed by a time indicator. $Y_{0i}(t)$ represents the outcome that individual i attains at time t ($t = 0, 1$) in the absence of the treatment. In the same fashion, $Y_{1i}(t)$ represents the outcome that individual i attains at time t if exposed to the treatment before t . The causal effect of the treatment on the outcome for individual i at time t is then naturally defined as $Y_{1i}(t) - Y_{0i}(t)$.

As before, for any particular individual i and time period t , we do not observe both potential outcomes $Y_{0i}(t)$ and $Y_{1i}(t)$; so we cannot compute the individual treatment effect $Y_{1i}(t) - Y_{0i}(t)$. We only observe the realized outcome, $Y_i(t)$ that can be expressed as $Y_i(t) = Y_{0i}(t) \cdot (1 - D_i(t)) + Y_{1i}(t) \cdot D_i(t)$ [$D_i(t)$ is a binary variable equal to 1 if individual i received the treatment before period t and 0 otherwise]. Because, in the simple two-period scenario considered here, the treatment is only administered after period $t = 0$, we can denote $D_i = D_i(1)$, from which it follows that $Y_i(0) = Y_{0i}(0)$ and $Y_i(1) = Y_{0i}(1) \cdot (1 - D_i) + Y_{1i}(1) \cdot D_i$. Given the impossibility of computing individual causal treatment effects, researchers typically focus on estimating the average effect of the treatment on the treated: $E[Y_1(1) - Y_0(1) | D = 1]$.

The next assumption is the crucial identifying restriction for DID. It states that average outcomes for treated and untreated will follow parallel paths over time in the absence of the treatment:

$$E[Y_0(1) - Y_0(0) | D = 1] = E[Y_0(1) - Y_0(0) | D = 0] \tag{8}$$

If Eq. (8) holds, then

$$\begin{aligned} & E[Y_1(1) - Y_0(1) | D = 1] \\ & = \{E[Y(1) | D = 1] - E[Y(1) | D = 0]\} \\ & \quad - \{E[Y(0) | D = 1] - E[Y(0) | D = 0]\} \end{aligned} \tag{9}$$

Figure 2 shows a graphical interpretation of this result. An estimator of the effect of the treatment on the treated can be constructed as:

$$\begin{aligned} & \left\{ \frac{1}{n_1} \sum_{D_i=1} Y_i(1) - \frac{1}{n_0} \sum_{D_i=0} Y_i(1) \right\} \\ & - \left\{ \frac{1}{n_1} \sum_{D_i=1} Y_i(0) - \frac{1}{n_0} \sum_{D_i=0} Y_i(0) \right\} \\ & = \left\{ \frac{1}{n_1} \sum_{D_i=1} \{Y_i(1) - Y_i(0)\} - \frac{1}{n_0} \sum_{D_i=0} \{Y_i(1) - Y_i(0)\} \right\} \end{aligned}$$

where n_1 is the number of treated individuals and n_0 is the number of untreated individuals. This estimator can be easily obtained as the least squares estimator of the coefficient on D in a regression of $\Delta Y = Y(1) - Y(0)$ on D and a constant. The regression formulation of the DID estimator is often used to introduce covariates by considering least squares estimators of:

$$\Delta Y = \delta + \alpha \cdot D + X'\beta + u \tag{10}$$

The rationale for introducing covariates is to allow for different dynamics for treated and untreated units (as long as these different dynamics can be explained linearly by observed covariates).

Alternatively, Eq. (10) can be expressed as a fixed effect regression:

$$Y_i(t) = \eta_i + \delta(t) + \alpha \cdot D_i(t) + X'_i\beta(t) + \varepsilon_i(t) \tag{11}$$

where η_i is a time-invariant individual fixed effect possibly correlated with $D_i(t)$. Therefore, selection for treatment is allowed to depend on time-invariant unobserved characteristics. As long as selection for treatment does not depend on the time-varying unobserved components, $\varepsilon_i(t)$, Eq. (11) can be estimated by least squares (using individual binary indicators as

Figure 2 Graphical interpretation of difference-in-differences.

regressors to account for η_i). When the data set contains information on two periods only, a least-squares estimation of Eqs. (10) and (11) produces identical estimators of α . However, the fixed-effects formulation in Eq. (11) is particularly useful when the data contain information about more than two periods because Eq. (11) can accommodate multiperiod data structures.

G-Formula The idea of identifying treatment effects through conditional independence has been extended to time-varying treatments. To keep the exposition simple, we only consider two periods $t = 0, 1$. As before, $D(t)$ is a binary variable that represents treatment during period t . The outcome of interest, Y , is measured after the second period. Potential outcomes are now indexed by the treatment in both periods. That is, $Y_i = Y_{d_0d_1}$ if $D_i(0) = d_0$ and $D_i(1) = d_1$. In addition, let $X(t)$ represent a time-varying covariate. In this context, selection on observables can be defined in the following fashion:

$$\begin{aligned} (Y_{00}, Y_{01}, Y_{10}, Y_{11}) & \perp\!\!\!\perp D(0) | X(0) \\ (Y_{00}, Y_{01}, Y_{10}, Y_{11}) & \perp\!\!\!\perp D(1) | X(0), X(1), D(0) \end{aligned}$$

That is, conditional on the present and past values of X and the past values of D , the treatment is independent of the potential outcomes. In other words, at every time t , the treatment assignment is “as good as random” conditional on the observed variables. Under this assumption it can be shown that:

$$\begin{aligned} E[Y_{d_0d_1}] & = \iint E[Y | X(0), X(1), D(0) = d_0, D(1) = d_1] \\ & \times dP(X(1) | X(0), D(0) = d_0) dP(X(0)) \end{aligned}$$

for d_0 and d_1 in $\{0, 1\}$. This formula is sometimes referred to as the G-formula or G-computation formula. In principle, average potential outcomes may be estimated nonparametrically based on the G-computation formula. Comparisons of average potential outcomes inform us about different treatment effects (e.g., the average effect of one additional period of treatment given treatment in the first period is $E[Y_{11} - Y_{10}]$). Based on these ideas, Robins has developed statistical models for characteristics of the marginal distributions of the potential outcomes (marginal structural models) and models for the effects of additional periods of treatment (structural nested models).

Glossary

accuracy A measure of the closeness of an estimate to the true value.

contingency table A cross-classified table of counts according to two or more categorical variables.

dual systems estimation A method for combining information from two sources to estimate a population total, including an estimate for the number of individuals missed by both sources.

gross error The total error in an estimate of a population total from a census, consisting of the sum of the errors of omission and the errors of commission; also known as erroneous enumerations.

imputation A statistical method for “filling in” values for missing data. In the context of census-taking values, missing questionnaire values are imputed as is the information for entire households if the Census Bureau believed them to be occupied.

mail-out/mail-back The primary method of collecting census information in the United States. Questionnaires are mailed out to all households listed in a master address file compiled by the Census Bureau; recipients fill them out and then return them by mail.

measurement error A variety of sources of error in the census enumeration process that cause the reported enumeration values to differ from the true values.

postenumeration survey A sample survey conducted after the census to provide a second source of information on households that can be used in dual systems estimation.

The United States conducts a census of population every decade to provide information for the reapportionment of Congress and for a variety of other legal requirements.

The U.S. census enumeration process both misses households and individuals within them and erroneously includes many individuals through duplication and other types of errors. Since 1940, the Census Bureau has worked to develop methods for correcting census error, primarily in the form of omissions. The size of census errors differs across population subgroups, leading to what has been known as the census differential net undercount. Statistically adjusting census enumeration counts for net undercount has been the topic of much controversy. The sources of census error and the methods that have been used to estimate the true population totals by geographic area and demographic groups are reviewed in this article.

Introduction

Taking an accurate and efficient population census of a large, rapidly growing, diverse, and mobile population such as that of the United States is fraught with difficulty. The results of the count are used to allocate political representation in Congress, tax funds to local areas, and votes in the Electoral College, and to design legislative districts at federal, state, and local levels of government. Thus, the adequacy of the census is no mere academic question. A local area overcounted or undercounted relative to others gets too much or too little political representation and tax revenue.

From the late 1960s to the early 2000s, the census faced challenges that it did not count well enough to serve its political functions, and in particular that it was biased

against poor areas and minority neighborhoods. Critics charged that the census missed millions of residents and that it missed a higher proportion of minorities and the poor as compared with white middle-class residents. The differential undercount of minority communities, poor urban neighborhoods, and remote rural areas became the most difficult political and technical problem the census faced. Dissatisfied local government officials sued the Census Bureau to force improvements in counting procedures and to mandate adjustment of population estimates to correct for the known undercount. Bureau officials faced scrutiny in tense congressional committee hearings, and statisticians challenged the agency to improve its counting techniques to eliminate the undercount.

The Census Bureau began to document and measure census error systematically in the 1940s. From the late 1960s, bureau officials focused on developing techniques to measure and correct the differential net undercount of geographic areas and racial and ethnic populations. The reported net undercount rate declined from 5.4% of the population in 1940 to 1.8% in 1990. But from 1940 to 1990, the differential undercount of minorities, for example, of Blacks relative to non-Blacks, was much more recalcitrant, and remained at the 3.4 to 4.4% level. In March 2003, the Census Bureau reported a net overcount of the Census 2000 total household population of 0.49%. They also reported that there was a net overcount of 1.13% for the non-Hispanic White household population, but a net undercount of 1.84% for the non-Hispanic Black household population. As is explained in the following discussion, the 2000 results have revealed new questions about the accuracy of the census. The differential undercount debate of the 1960s to the 1990s seems to be giving way to a new census accuracy debate, the implications of which are not yet clear.

Counting vs. Estimating

The American census is an old institution, mandated by the founding fathers in the 1787 Constitution, and thus the nation has a long history of population counting and experience in dealing with problems of accuracy. That experience has led the U.S. Census Bureau to follow one fundamental counting principle: devise a procedure to locate everyone in the country at their “usual place of abode” and then count them. The decennial census process produces what is commonly referred to as a “complete count,” although the completeness of the process is in fact in substantial dispute. Census officials break down the process of counting into manageable portions by devising hierarchical administrative systems that run from the national census office to the individual household. In 2000, for example, the Bureau of the Census national office in Suitland, Maryland created 12 regional census centers and 520 local census offices to collect and process the

forms. The district offices were responsible for counting about 200,000 housing units each. For the households slated to get a form either by mail or a bureau enumerator, the Bureau mailed one census form to each address in the country based on its master address file. All addresses were coded by state, county, other local geography, district office, census tract, “address register area,” census block, and “walking sequence” in case an enumerator had to reach a housing unit.

The final link in this chain of counting occurs at the household, in which one person reports, on the mail census form or to the enumerator, the number of people in the household. Forms are collected, edited, and tallied back to higher and higher levels of geography. The success of the system depends on the capacity of the procedures to deliver a census form or an enumerator to each household, and then to retrieve the information on one completed form from the household. Things can go wrong, from lost forms, to bad or missing addresses, to confused or suspicious respondents, to duplicate forms for a single household. The Bureau deals with such counting problems by building follow-up and checking procedures into the census process to catch errors and make sure that all households are counted once and only once. Nevertheless, the controversies surrounding the undercount have made the flaws in the counting systems painfully clear and thus have led critics to propose fundamentally new ways to count, derived from different traditions of counting.

These new methods all involve some form of systematic repeated counting, not just checking to make sure that the count obtained is accurate. The most promising method also involves using sampling methods to count households. The new methods rely on different guarantees for their efficacy. The traditional methods rely for their validity on careful bureaucratic procedures, the administrative chain of command, legal sanctions for non-response, and public cooperation of respondents. The new methods rely as well on the principles of statistical theory and probability for validity.

Errors and Uncertainty

Statisticians have a specialized vocabulary, and many of the terms they use have everyday meanings that differ from technical ones. For example, words such as “significant,” “power,” “random,” “unbiased,” and “independent” all have precise technical meanings that differ from the interpretations that are put on such words in everyday conversation. The word “error” presents a similar problem. No matter how carefully any scientific investigation is carried out, no measurement process is perfect and the statistician usually uses the term “error” to denote the difference between what is observed and what

was intended to measure. In common parlance, error is used to denote an intentional mistake and to impute blame or even censure. Nothing could be further from the intended use of the term in the context of the work of the Census Bureau on the decennial census.

Errors in measurement contribute to the uncertainty about the quantities that researchers attempt to measure. In the case of the census, much is known about possible sources of error, and the Census Bureau workers and others have studied many, if not all, of the sources to some degree. Also, some measurement errors that occur in the implementation of a particular stage of the census process are corrected in subsequent stages, whereas others are propagated on through to the data retained as official census records. For example, the error that occurs when a house is left off of the master list of addresses can be corrected at many subsequent stages, during which the location can be added back into the address file. On the other hand, the error of omission that results when a household respondent intentionally does not include one of the occupants on the census form may never be detected and corrected.

When the measurement process is complex and measurements are aggregated, as they are in the decennial census, some of these recorded errors fortuitously cancel one another out; others are compounded to induce systematic differences or biases in the estimates of the quantities of ultimate interest. Thus, the Census Bureau might fail to enumerate every one of the 29 occupants of an apartment building in Pittsburgh, Pennsylvania, and thus distort substantially the count for the census block in which the building is situated, but that error or undercount alone will have little impact on the population totals for Pennsylvania. The omission of these 29 apartment dwellers in Pittsburgh might balance against duplicate census records for 29 individuals in 29 different blocks in nearby Wilkesburg, Pennsylvania, yielding a net census error of 0 for the Pittsburgh metropolitan area—that is, there is no net undercount. But even if this canceling out of omissions and duplicates happens, there is an increase in the overall level of uncertainty about the total for the state of Pennsylvania and even to the total for the nation as a whole. Such uncertainty is best measured as gross error, which is the sum of all errors regardless of whether they are omissions, duplicates, or fabrications. In the example given here, 29 omissions and 29 duplicates result in a gross error of 58.

What has often been overlooked in discussions of census undercount is the array of errors in the census and how they contribute not only to the undercount estimates but also to uncertainty regarding the overall quality of the decennial census at disaggregated levels. The following list provides some examples of sources of error in the census enumeration process and indications of their

possible implications for the accuracy of the census enumeration counts:

1. Missed households: Despite the enormous efforts to construct a master address file that includes all housing units in the United States, the Bureau “misses” housing units. In 1990, 30.5% of the average error came from housing units that were not enumerated at all.

2. Refusals: Some housing units and their occupants refuse to participate in the census. Some of their occupants are “included” statistically, however, by coverage-improvement programs (see later).

3. The appropriateness of census concepts and definitions: The census concepts of “housing units” and “families” are often difficult to apply in practice, especially by respondents and enumerators in minority communities where non-traditional physical and family structures may be the norm. Individuals and households are often missed as a consequence. Also, individuals who are connected with multiple households may well be counted multiple times.

4. Census day vs. census operations: Few people were enumerated at their household locations on exactly April 1. Yet many components of the census assume that people are correctly reported in the exact location where they resided on April 1.

5. Use of household respondents: One person completes the census form for each household. This person serves as a filter for information on others in the household and for household characteristics. Errors that enter into census data as a result of the “filter” applied by the household respondent are extremely difficult for anyone to correct.

6. Problems of understanding connected with the instructions and questionnaire wording: Many individuals in the population may have difficulty in interpreting the instructions on the census form. For example, the census form is quite explicit that college students should be counted where they lived while attending school. Nonetheless, many respondents believe that the students should be counted at home and thus college students are often double-counted as a result.

7. Recording error: Individuals completing the census questionnaire may check the wrong answer inadvertently.

8. Enumerator error: When a household fails to return the mailed-out census questionnaire, a census enumerator may complete the questionnaire as a result of a visit to the household location. Enumerators may record information that differs from that supplied by the household respondent.

9. Duplication error: Some households mistakenly receive two census forms. Some households provide multiple returns, either from the same household respondent or different ones. Sometimes these duplicates are easy to catch and sometimes not. This may be the result of geographic coding or other types of errors (see later).

10. Coding and processing errors: After a census questionnaire is completed and returned to the Bureau, the information must be transferred to a computer file and subsequently processed and checked for consistency. Errors creep into the official files despite the new technologically based methods for data capture.

11. Geographic coding errors: These errors occur at various stages in the process, from the compilation of initial mailing lists as part of the Topologically Integrated Geographic Encoding Reference (TIGER) system all the way through coding. In 1990, local communities complained that the census master address file missed housing units. These errors could result from geographic coding problems, thus placing an address in the wrong place. Some of these errors, presumably, lead to geographic coding errors in census records. Despite all of the “corrections” that occurred throughout the various forms of data review, residual geocoding errors place people in the wrong census blocks.

12. Fabrication: In every census, there are anecdotal reports of enumerators “curbstoning,” i.e., fabricating questionnaires for real and often imaginary households, and of respondents providing fabricated information. The Bureau has a variety of methods to catch such fabrication, but inevitably, a substantial number of fabricated questionnaires are included in the official census results.

13. “Last resort” information: Some questionnaires are actually filled out as a last resort by enumerators without their directly seeing or interviewing any household occupants. The household may not submit a form, and the enumerator fails after repeated tries to contact the household. In such cases, enumerators use information from mail carriers, neighbors, or building managers, that is, proxy respondents, that may be inaccurate, incomplete, or even intentionally false.

14. Imputation: The Census Bureau uses various forms of statistical estimation (based either explicitly or implicitly on statistical models) to “fill in” values for missing data. This process of filling in is usually referred to as imputation. If the Bureau had no information about the occupancy status of a housing unit (e.g., from last-resort methods), it imputed a status to it, i.e., either occupied or vacant. If a unit was imputed as occupied, or if the Bureau otherwise believed it to be occupied, then it imputed a number of people to the household, as well as their characteristics. The current method of choice for imputation, known as the “sequential hot-deck” procedure, selects a housing unit proximate in processing as the donor of the characteristics. The assumption in the statistical “model” underlying the imputation method is that neighboring housing units are likely to have similar characteristics. In 1980, the Bureau added 3.3 million people to the census through imputation. Of these, 762,000 were added into housing units for which the Bureau had no knowledge concerning whether the units were occupied. The 1990 census had a much lower

imputation rate, but it rose again to 5.7 million people in 2000. This has been the cause of serious investigation by those evaluating the census outside the Census Bureau.

The impact of each of these sources of error needs to be understood when assessing the accuracy of data from the census counts. The census process moves from addresses (i.e., labels for physical structures) to housing units, to housing units that are enumerated, either through mail-out/mail-back or some other process, to actual individuals. At each stage, there is a cumulative impact of errors leading to units or people not counted or miscounted in terms of information recorded about that unit or individual in the census files. Errors in the classification of housing units inevitably propagate into errors in enumerating housing units, and errors in enumerating housing units propagate into errors in the enumeration of individuals. As noted previously, at some levels of aggregation, the “miscounts” do not show up as errors, e.g., in determining the population total, but when discussing who makes up the population total and where they reside at the state or local level, the miscount category may be very important.

Gross error provides a measure of the total impact of these census errors. It is not as well understood or publicized as net error, and as yet has not been the subject of analysis of its impact on the distributional functions of the census. Unofficial estimates of gross error for the censuses from 1980 to 2000 are given in Table I. Erroneous enumerations include people who are counted more than once, are counted at the wrong location, or are fabricated. The estimates of erroneous enumerations given here are not especially well documented by the Census Bureau and have varied over time. In fact, reports on the errors for 2000 went through a number of revisions, shifting from a net undercount to a net overcount. Thus, important things about the values reported are (1) their order of magnitude and (2) that the level of gross error can be very high when erroneous enumerations and omissions appear to “net” out across the nation.

Two quantitative techniques have been used in the United States to estimate the undercount at a national level: demographic analysis and the dual systems (capture–recapture) technique.

Demographic analysis combines aggregate birth, death, immigration, and emigration records with other administrative records such as enrollment in Medicare,

Table I Measuring the Net Undercount (in millions)

<i>Census year</i>	<i>Erroneous enumerations</i>	<i>Omissions</i>	<i>Gross error</i>
1980	6.0	9.2	15.2
1990	10.2	15.5	25.7
2000	12.5	15.8	28.3

to carry forward the population from one census to the next, deriving an estimate of the overall population size to be compared with the census count. The population of 2000, for example, is estimated as follows:

$$\begin{aligned} \text{Population 2000} &= \text{population 1990} + \text{births since 1990} \\ &\quad - \text{deaths since 1990} \\ &\quad + \text{immigration since 1990} \\ &\quad - \text{emigration since 1990.} \end{aligned}$$

The methodology can provide population and undercount figures by age, race (typically restricted to Black and non-Black, at least through 1980), and sex, but only at a national level. The approach was introduced by the demographer Ansley Coale as a check on the results of the 1950 census, and bureau demographers advanced the technique in successive censuses.

The accuracy of the demographic analysis depends on the accuracy of the inputs. Several of the statistical inputs are incomplete. For example, all births are not registered in vital statistics sources, and emigration data are generally poor. Further, the growth of illegal immigration since the 1970s poses special problems, which has led demographers to develop special estimates for this component of the population. The major strengths of the demographic analysis estimates are their use of independent data sources and their basic consistency from one census to the next. The weaknesses are that racial data are available in a reasonable form mainly for Black versus non-Black comparisons, and only at the national level. Geocoding errors of the typed described previously cannot be measured. Nor can demographic analysis identify omissions and duplications and fabrications if these “net” out in the national figures. Further, the errors and uncertainties associated with undocumented immigrants and shifting racial identification, combined with increasing intermarriage, make the numbers increasingly problematic, except as a broad coverage evaluation tool. This is, of course, what demographic analysis was created to do. In 2000, the Census Bureau released multiple versions of their demographic analysis estimates, attempting to correct the numbers of illegal immigrants and the extent of birth registration, but there was not widespread acceptance of the assumptions that lay behind the reported figures.

The second technique for estimating census error and the net national undercount, dual systems estimation (DSE), was the method of choice adopted by the methodologists at the Census Bureau in 1990 (after some 40 years of testing). It has been the subject of the ongoing controversy about methodology for a statistical adjustment. The basic premise of DSE is the use of two sources of information to arrive at a better estimate of the population than could be obtained from one source alone. In 1990, the second survey was called the Post-Enumeration Survey (PES); in 2000, the name was

changed to the Accuracy and Coverage Evaluation (ACE). DSE is an old procedure, widely accepted among statisticians, and has been used for a host of different practical population estimation problems. It is most familiar in the context of estimating the size of wild life populations, where it is known as the “capture–recapture” technique.

The DSE technique can be illustrated with a hypothetical example: Suppose the task is to estimate the number of people living on a block in the Bedford–Stuyvesant neighborhood of Brooklyn. First, the population in the census is counted, yielding a list of the names and addresses of people counted. Assume that 300 people were counted by the census on this particular block. For the second count of the population, imagine a specially commissioned, independent count carried out with even greater care than the census, and yielding 400 people. In the hypothetical Bedford–Stuyvesant block, the second count will surely include many of the same 300 people counted by the census. The number of people counted both times is determined by comparing the list of names and addresses in the first count with the list of names and addresses in the second count, and matching those that are the same. Suppose that, through matching these two lists, it is found that 250 people out of 400 counted in the second count on this block were also included in the census. The three observed categories of the population, and their sizes, are thus the 250 counted both times, the 50 counted the first time but not the second, and the 150 counted the second time but not the first. Thus, 450 people have been observed. If the second count is a random sample of the population of the block as a whole, then 250 out of 400, or 5/8 of the whole population of the block, were counted in the census. The fraction of members of the second count included in the census is an estimate of the fraction of the total population of the block counted in the census. Finally, an estimate of the total population is the number of people counted in the census, or 300, divided by 5/8. This yields an estimate of the total population of 480 people. Thus, the estimated census undercount in this hypothetical block is 180 people out of 480, or 3/8 of the population.

The data can be displayed in the form of a 2×2 contingency table with rows corresponding to presence and absence in the first count and columns corresponding to presence and absence in the second count (Table II). The task at hand is to proceed from this information to an estimate of the total number in the population, including an estimate of a fourth class of people, those not counted either time. This can be done as long as the two counts are independent random samples. A random sample by its nature permits estimation of the incidence of any observable characteristic in the larger population from which the sample is drawn. In this case, the characteristic of interest is that of having been captured in the first count. The examination of the random sample—the second

Table II Dual-Systems Estimation Setup for a Hypothetical Block: 2 × 2 Contingency Table

Day 1 count	Day 2 count		Total
	In	Out	
In	250	50	300
Out	150	?	?
Total	400	?	??

count—showed that 250 out of 400 people, or 5/8 of the sample, had been captured in the first count. Generalizing from the sample, the conclusion is that 5/8 of the total population was captured in the first count.

Having learned that 5/8 of the total population was covered by the first count, it is now possible to estimate the true population size, N , on the basis of the available information. The total number of people counted the first time, 300, is 5/8 of the total population, i.e., $300 = 5/8N$, where N is the estimate of true population size. To arrive at the estimate, a little high school algebra suffices: $N = 8/5 \times 300 = 480$. Of this estimated 480 total population, 450 have been observed in one or the other or both of the two counts. Thus, it is inferred that there are 30 persons who were not counted either time.

It is desirable to continue the analysis by calculating different rates of capture for different population groups in the block in Bedford–Stuyvesant, e.g., Blacks and others. This requires separate estimates for the numbers of Blacks and non-Blacks in this block. The breakdown this time might be quite different, as shown in Table III. This time, the vast majority of people in the block are Black; the estimates for the total numbers of Blacks and non-Blacks in the block are $N_{\text{Black}} = 360/214 \times 262 = 440.74$ and $N_{\text{non-Black}} = 40/36 \times 38 = 42.2$. Again, counting only the whole numbers of people, the total is $440 + 42 = 482$. The result is slightly higher than the earlier estimate of 480 from the two groups combined, and this is because the catchabilities are so different and the numbers so disproportionate. There is a very serious differential undercount in this hypothetical block, however, with $100(1 - 262/440) = 40.5\%$ of the Blacks being missed, compared with only $100(1 - 38/42) = 9.5\%$ of the non-Blacks being missed.

Because the undercount rate varies among different kinds of blocks, it is necessary to estimate separate undercount rates for each of a sample of blocks. It would not, for example, be expected that the dual-systems estimate of the undercount rate of a block in Bedford–Stuyvesant says very much about the undercount in an expensive suburb. Accordingly, in selecting the sample, it is important to start with a list of all the blocks or equivalent-size rural units in the United States, and group the blocks into categories, or “strata,” according to their demographic

Table III Dual-Systems Setup for Hypothetical Block by Race

Census (Black)	Recount (Black)			Census (non-Black)	Recount (non-Black)		
	In	Out	Total		In	Out	Total
In	214	48	262	In	36	2	38
Out	146	?	?	Out	4	?	?
Total	360	?	?	Total	40	?	??

and geographic characteristics. Such characteristics might include region, racial composition, proportion of homeowners to renters, and average household size. Rates of undercount for particular demographic groups are determined for a sample of blocks within each stratum by dual-systems estimation. Note that the original stratification applied to census blocks, but the estimates for undercount apply to individuals.

These estimates of undercount can be disaggregated further by demographic groups, forming what the Census Bureau calls poststrata. Estimates of undercount are generated for each poststratum (for example, non-Black females aged 30–49 living in a rental unit, in large metropolitan areas in the northeast). The actual correction of the census counts consists of multiplying the adjustment rate for the poststratum by the raw census count for each poststratum to compensate for the estimated undercount. Thus, the poststratification applies to individuals.

This is the basic idea and methodology underlying the dual-systems approach employed by the Census Bureau in 1990 and 2000. More formal descriptions and critiques can be found in the literature. ACE and dual-systems estimation are designed to correct for census error. Dual-systems estimation in the census context is considerably more complex in practice, and, like the census, is also subject to measurement error. In the absence of serious measurement error, ACE methodology should, in principle, improve the raw count. But there are several sources for measurement error in ACE and each contributes to both the bias and the variability of ACE-adjusted counts; these have been the focus of the evaluation of the adjustment process:

1. Erroneous enumerations: Unlike demographic analysis, dual-systems estimation in a census context measures erroneous enumerations. That is, before matching the records from the census and the survey to measure omissions, the bureau evaluates if a person is correctly counted at the current location in the census. If the person is enumerated erroneously (for example, is a duplicate enumeration), the case is removed from the file before starting the matching process. Without this procedure, the erroneous enumerations would elevate the nonmatch

rate and skew the dual-systems estimation estimates. The role of erroneous enumerations in the census is poorly understood, and became a subject of technical evaluation as a by-product of the use of dual-systems estimation in 1990 and 2000. In 2000, the dramatic differences in undercount estimates generated by demographic analysis and the ACE prompted the Bureau to conduct new evaluations of erroneous enumerations, by searching the entire census file for duplicate enumerations in the E sample of the ACE. The Bureau currently believes there were 5.8 million duplicate enumerations in Census 2000, and that the original ACE results reported in March 2001 “dramatically underestimated these duplicates.”

2. Matching error: Dual-systems estimation assumes that those in the sample can be matched without error to those in the census without error. In fact, the computerized matching approaches used in 1990 led to the imputation of match status for a substantial fraction of the cases, and concern was expressed regarding the implications of this problem. Evidence from ACE evaluations suggests that the matching error rate for 2000 was substantially lower than in 1990.

3. Correlation bias: This term is used variously to describe both dependencies between the census and the sample and heterogeneity in response rates. In fact, in the dual-systems setting, the two components are not really distinguishable. Dual-systems estimation assumes that the responses to the census and the ACE are independent. The ACE survey operations were structurally separate from those of the census, but this still does not mean that the behavioral responses are independent of each other. Capture probabilities clearly vary among individuals within adjustment areas or groups, and the net effect of this variation (under relatively weak assumptions) is that it induces a positive dependence between the responses to the census and the sample in the aggregate.

4. Balancing error: Differences in search strategies for erroneous enumerations and matches lead to balancing error.

5. Synthetic error: The synthetic assumption implies that net census coverage rates do not vary within adjustment areas or groups.

6. Limitation of the ACE universe: In 2000, ACE was limited to a sample of the household population, and did not cover the roughly 8 million people living in group quarters. Insofar as there are differences in coverage for the household and group-quarters populations, the ACE cannot provide estimates of undercoverage in the group quarters, and hence the total population.

As Bureau officials modified classic dual-systems estimation methodology for the census context, they began to understand the impact of overcounts on census accuracy. They also began to develop the data that were used to construct the gross estimates in [Table I](#).

Nevertheless, until recently, officials believed that omissions loomed as a bigger numerical problem. Because the Census Bureau saw overcounts as less important as a source of coverage error, less research has been devoted to understanding and correcting for overcounts. Thus, the description of the dual-systems estimation methodology provided here is a simplified version of the Census Bureau plan for 2000. By the time it had completed its evaluation of the Census 2000 results in March 2003, the overcount errors were clearly visible, and the Bureau revised its evaluation methodology to attempt to develop estimates of duplications not detected in the ACE processes and “correcting” for some other forms of measurement error.

In both 1990 and 2000, the results of the dual-systems estimates were not used to adjust the official census results. In 1991, the Census Bureau staff and director recommended adjustment but were overruled by the Commerce Secretary. In March 2001, the Census Bureau staff recommended against adjustment, primarily because the ACE estimates and demographic analysis estimates of the population diverged sharply. The Bureau could not explain the discrepancy in time to meet the deadlines for releasing the redistricting data. Subsequent criticism of and revision to the demographic analysis estimates did not solve the problem. In October 2001, the Bureau decided not to adjust the postcensal estimates because it deemed the ACE to be too flawed for this purpose. It reaffirmed that decision in March 2003. At this writing, the Census Bureau’s internal evaluation and the external critiques of Census 2000 agree that the number of erroneous enumerations in the 2000 census count may be considerably larger than previously believed, and that the 2000 ACE procedures did not capture and eliminate their impact.

Looking to the Future: Census-Taking in 2010 and Beyond

Central to the Census Bureau’s plans for the future of the decennial census is the elimination of the census long form, which has gone to roughly 1 in 6 households nationwide, replacing it with a rolling national survey that has been called the American Community Survey. This action would have a variety of benefits for planning census activities and in particular would lead to what all observers hope will be a dramatic improvement in the master address file, which plays such a crucial role in a household-based census. There appears to be an expectation that this change, coupled with improvements in technology such as the field use of global positioning satellite systems, will improve census-taking sufficiently that there may not be

a need for the adjustment-based approaches from the past. Nevertheless, the Bureau will likely have to plan an evaluation program to determine if the omissions and erroneous enumerations that have plagued recent decennial censuses will affect the 2010 census. The Bureau will again need careful evaluation tools and postcensal surveys to assess the accuracy of future censuses. The plans for those evaluations will of necessity draw on the experiences of the past two censuses, though at this writing, the nature of the 2010 evaluation program has yet to be determined.

Where to Learn More

The list of publications at the end of this article is an excellent source for literature on census analysis. Margo Anderson provides a comprehensive historical source on the U.S. Census. Margo Anderson and Stephen E. Fienberg describe the technical basis for census adjustment and the debates leading up to Census 2000. Harvey Choldin treats the undercount debates from the 1980 and 1990 censuses; and Barbara Everitt Bryant and William Dunn provide the perspective of 1990 Census Director, Barbara Everitt Bryant. For technical explanation of census methods and history, there is also the recently published *Encyclopedia of the U.S. Census* by Anderson. For the critics of adjustment, see Freedman and Wachter, Kenneth Darga, Peter Skerry, and Lawrence D. Brown and co-workers. For responses, see Anderson, Daponte, Fienberg, Kadane, Spencer, and Steffey and Anderson and Fienberg.

Over the past decade, various panels of the Committee on National Statistics at the National Academy of Sciences have issued major reports dealing with the Census Bureau adjustment methodology and the 2000 decennial census. These subjects have been addressed by Steffey and Bradburn, Edmonston and Schultze, Cohen *et al.*, and Citro *et al.*

Census, Retail Trade

Louis G. Pol

University of Nebraska, Omaha, Nebraska, USA

Glossary

economic census A statistical program designed to obtain, categorize, and publish information every 5 years (in years that end in 2 and 7) for nearly all U.S. businesses.

enterprise An organization (company) that comprises all of the establishments that operate under the ownership or control of a single organization.

establishment A single physical location where business is conducted or where services or industrial operations are performed.

industry A detailed category in a larger classification system used to describe and group business activities.

merchandise line A numerical system used to group major categories of merchandise sold.

North American Industry Classification System (NAICS) A numerical classification scheme jointly developed by Mexico, Canada, and the United States to facilitate the collection, tabulation, presentation, and analysis of data on establishments.

retail trade The trade sector is made up of businesses engaged in selling merchandise, usually without transformation, and providing services incidental to the sale of the merchandise.

sector classification A numerical system used to group and describe similar businesses.

Standard Industrial Classification (SIC) A numerical scheme or code utilized to classify industries and products; superseded in 1997 by a new method, the North American Industry Classification System.

The retail trade sector (sectors 44 and 45 in the North American Industry Classification System) is made up of establishments engaged in retailing merchandise. Services that are incidental to the sale of the merchandise are also included in these sectors (e.g., warranty services on new automobiles). Retailers, in general, are the final

step in the process of distributing merchandise to customers, usually following manufacturers and wholesalers. They sell products in relatively small quantities to consumers. Retailers vary greatly in employee size, from the one- or two-person “mom and pop” storefront to the hundreds of persons that make up the staff of each Super Target store. Chains of retailers often dominate local and regional markets as well as the channels of merchandise distribution (e.g., Wal-Mart). Retailers also vary with respect to the method by which customers are reached. That is, there are both store and nonstore retailers, with the latter selling merchandise using direct-response advertising, telemarketing, broadcast infomercials, catalogues, door-to-door sales, and the Internet, among other methods of reaching customers.

History of the Economic Census—Retail Trade

The history of economic censuses that focus on retail trade can be traced back to 1930, the first time retail trade data were gathered in the United States. Other economic data had been gathered in U.S. censuses as early as 1810, but the range of information was limited. The economic component of the 1930 decennial census was much broader than in previous decennial and special censuses, and was subsumed under queries related to distribution (wholesale and retail) enterprises. The 1930 census of distribution was composed of data gathered only by a field canvas, and the retail trade component covered establishments engaged in some manner of retail trade, although a limited number of service businesses were also included. Six questionnaires were utilized to gather data from 1.5 million stores. Data items such as number of stores, sales, personnel, payroll, and operating expenses were included.

Most of these items can be found 70 years later in the 1997 and 2002 economic censuses. The 1935 Census of Business covered retail trade much in the same way as it had been covered in 1930, with the exception that in this instance the Census of Business was not part of the decennial census. In 1940, retail trade data were gathered as part of decennial census activities, and with a few exceptions, the types of information gathered were identical to those collected in 1930 and 1935.

In 1948, the U.S. Congress passed Public Law 80-671, which authorized the Census Bureau to conduct an economic census in 1948 and every fifth year thereafter. The 1948 business census had a retail trade component and gathered data from a wide range of firms. To gather more detailed information, the sampling consisted of 1 in 10 of small independent firms, large retailers (sales in excess of \$100,000), and multiestablishment firms. A more limited amount of data were gathered from small, single-establishment firms. Enumerators left one of two questionnaires at most single-establishment firms, and these were to be returned to the Census Bureau by mail. Enumerators completed the questionnaire on-site for most of the multiestablishment firms in the sample. Non-respondents to the mail-back universe of establishments were mailed a reminder form, and follow-up visits to the firms were made. This census was also marked by the establishment of temporary field offices to facilitate data collection, and the collection of data via reenumeration to estimate undercoverage by the census. In 1948, it was estimated that the enumeration efforts missed 3.6% of retail establishments.

The U.S. Congress did not provide funding for the 1953 economic censuses, but after a great deal of debate and the appointment of a special commission to study such censuses, funds were appropriated to support a 1954 economic census, including a retail and wholesale trades component. This census was also noteworthy because it marked the first attempt by the Census Bureau to utilize administrative records as a method for deriving a small number of data items for retail nonemployers (retailers without paid employees). Retail employers were enumerated using a mail-out/mail-back procedure. Field offices were again established, and letters and telephone calls were utilized in follow-up activities. The 1958 and 1963 economic censuses closely resembled 1954 efforts, and once again the retail and wholesale trades were considered to be one category.

In 1967, the U.S. Congress altered the years in which economic census data were collected, changing to years ending in 2 or 7, the standard seen today. Wholesale and retail trades were still considered to be one category, and data for retail nonemployers were gathered using Internal Revenue Service income tax records. Procedural improvements were made, including reliance on computers for data processing. The 1972 economic censuses were much

like those in 1967, and again administrative records were used as a source of data for a large number of businesses.

More than one-half of the enterprises enumerated in 1977 had their data extracted from administrative records. Unlike the previous censuses, retail trade and wholesale trade were treated as separate enterprise categories. Although there were a number of methodological improvements over the next decade, the census of retail trade for 1987 was very much like the 1977 version; between 1982 and 1987, however, there was a 20% increase in the number of merchandise line questions.

The 1992 economic census was characterized by the most significant expansion in over 50 years, particularly in regard to an increase in the number of businesses covered. In all, about 98% of all economic activity was covered, up from 75% for 1987. There were also surveys of minority-owned business enterprises, women-owned businesses, and characteristics of business owners. For the most part, data from the census were made available for the nation, states, metropolitan areas, counties, and places of 2500 or more population, although some retail trade data were made available only at the zip code level. A subject series report on merchandise line sales was produced along with one on major retail centers. In general, content on the questionnaire remained the same as that for 1987. Response rates were improved by emphasizing the mandatory nature of the census, standardizing the size of questionnaires, improving the quality of cover letters, utilizing more effective direct-mail techniques, and prenotifying large companies that the census questionnaire would be sent. In addition to making the transition from Standard Industrial Classification (SIC) codes to the North American Industry Classification System (NAICS), the 1997 economic census was marked by methodological changes. Although computer self-administered questionnaires were used in the 1992 census, their use in 1997 was much more extensive. The Internet was used to promote awareness of the census as well as to disseminate census products. The 1997 census data were available faster and in more forms (e.g., via the Internet and on compact disks) than in previous censuses. The content of the questionnaires, particularly in regard to retailing, stayed much the same.

Virtually all of the changes for the 2002 economic censuses concerned improved data availability/access and advancements in data collection methodologies. The content for retail trade businesses remained the same. Faster release of industry series (e.g., retailing) data was accomplished by producing industry-specific reports. The surveys of business owners, including minorities and women, were expanded as well as the survey of owner characteristics. In an effort to improve coverage and, therefore, data quality, establishments were divided into mail and nonmail universes. Large

employers and a sample of small employers, i.e., single-establishment firms with a payroll below a fixed point, received mail surveys and the appropriate follow-up. Data for the nonmail universe were derived or estimated from administrative records of other federal agencies. Published reports in electronic format include those on merchandise line sales, establishment and firm size, and miscellaneous subjects.

Method of Data Collection

Currently, data for the Economic Census—Retail Trade are collected utilizing mail-out, mail-back surveys, with telephone follow-up, and through the examination of administrative records. More than 5 million large and medium-size firms, including firms known to operate more than one establishment, were sent questionnaires or a classification form in December 2002 for the Economic Census—Retail Trade, 2002. The forms were due back on February 12, 2003. Respondents also had the option of downloading spreadsheet-like forms and submitting data electronically. The questionnaires were tailored to the type of business in the retail sector, and in 2002 over 600 different questionnaires were utilized. For example, form NC-99510, which was sent to automobile dealers, contained questions about the location of the enterprise, sales, number of employees, and first-quarter payroll (January–March 2002) for each location if there was more than one physical location for the business. Form RT-44101, also sent to automobile dealers, contained questions on months in operation (for 2002), e-commerce sales, class of customer (i.e., individuals; other retailers and wholesalers), method sales, type of vehicle sold, and receipts from services (e.g., auto repair) rendered, among others. Some of the forms could be completed in a few minutes, but several took much longer. In the event that an establishment did not mail back a questionnaire, a re mailing of the questionnaires occurred, several times in some cases. Telephone follow-ups were also utilized to maximize the response.

Data for small firms, usually with 10 or fewer employees, were gathered from administrative records (e.g., the Internal Revenue Service). These firms represent about 10% of all sales of establishments covered in the economic census. Information for the standard queries (sales, payroll, and employment) was directly extracted or estimated based on data from these records.

Several cautionary notes are appropriate at this juncture. The user of the data should be aware that rules for data disclosure affect data availability, particularly for small population areas. In addition, conversion from SIC to NAIC categories must be done carefully when making comparisons across time. A bridge table is available on the Census Bureau web site. Metropolitan

statistical area (MSA) and zip code boundaries change over time due to the addition or subtraction of counties. Any time series comparisons for MSAs and zip codes must be preceded with a check on boundary changes.

Uses of the Data

Economic census data are widely used, especially in light of their ready availability via compact disk read-only memory (CD-ROM) format and on the Internet. Data are available for a wide variety of geographic units, although it is important to consider that some retail markets, e.g., health aids and books, are linked less to geography now than in the past because of purchasing via the Internet and direct advertising. Retail trade data from monthly and annual U.S. Census Bureau surveys are often combined with census data for analysis purposes. There are several broad categories of usage for economic data.

Market Conditions and Changes

Analysis of retail trade data can provide national, regional, and local information on current conditions and the aggregate effect of shifts in the structure of retail markets. The emergence of warehouse clubs, supercenters, and superstores, for example, has shifted customers toward these larger entities, which, in turn, now play a major role in local, regional, and national markets. It is possible to determine how a particular kind of business dominates a merchandise line by assembling data from two or more economic censuses. For example, in 1997, about 84% of all hardware, tools, and plumbing and electrical supplies were sold by 41,981 building materials and supply dealers in the United States. However, fewer than 10% of the stores, home centers, accounted for 23% of all sales. Comparing 1997 with 1992 and 2002 data would provide documentation of the growing concentration of sales by home centers of products in this merchandise line. Comparisons across merchandise lines would allow for a comparison of the market of home centers for a range of products sold.

Market Share

Market share refers to the percentage of sales of a product in units, dollars, or some other meaningful measure made by a business relative to all sales of that product, usually for a specific geographic unit and always for a specific time period, e.g., December 2003. It is useful to know absolute sales and trends in sales for a business, but the value of these data can be extended greatly if market share is calculated. So, if a local clothing store has experienced a recent increase in sales, e.g., a 50% rise over the past 4 years, but market share has declined, then it may be the case that even though a favorable demographic profile

for the market exists, competitors, both old and new, made significant advances in the market. Additional calculations may show that if that business had held its market share for those 4 years, clothing sales would have grown 150%, not the 50% realized.

Data from the Economic Census—Retail Trade can provide the denominator for calculating market share for one or more periods of time. Data for the numerator come from a specific store or chain of stores. Market share for one areal unit, e.g., a county, can be followed for several time periods in order to better understand trends in market dominance. Market share information for one market may also be used as a benchmark or to establish expectations for a new market. For example, if Regents Sporting Goods claims 12% of the Lincoln County market, then 12% may become the expected market share in Payne County, assuming that the demographic composition, industry structure, and nature of the competition are similar. A market share of less than 12% in Payne County may be interpreted as an indicator of operational problems for Regents Sporting Goods in that location.

Assess Competition

Although the Economic Census—Retail Trade data do not make available the names and associated data for individual competing businesses, the available data can be very useful, when combined with other information, in understanding and measuring the effects of competitor strength. Telephone business listings, Chamber of Commerce memberships, and other readily available data can provide basic information on new and old competitors, including their location, within a particular market. The same sources can provide data on business expansions, e.g., new locations, as well as on closings. Figures for individual businesses (numerator) and U.S. Census Bureau retail trade data (denominator) can be used to calculate market share, but in the context of additions or exits to and from the market. If a “mom and pop” grocery store loses 30% of its market share in Jefferson County between 1997 and 2002, and in 1999 a new Wal-Mart store opens in Jefferson County, the likely reason for the decline in market share would be the presence of the new Wal-Mart store, provided that other business conditions in the market remained basically the same.

Site Location

Retail trade data can be combined with other demographic indicators as well as information on existing businesses to make decisions about where physically to locate a new business. Areas with lower than expected per capita or per household retail sales, accounting for income variations and the location of competitors, present

opportunities for retail expansion. Retail grocers, for example, study the growth in population in expanding areas with respect to present and projected sales of grocery items for those places. Opportunities exist for new grocery stores in areas that are underserved, that is, have less than expected retail grocery sales. Once a market is seen as having measurable potential, then a specific site for a retail store must be found. Site location decisions are based on availability and cost of land and labor, traffic flows, the location of current competitors, and forecasts of other new competitors in that market. Sites are chosen in part to minimize the travel distance/time of potential customers. Financial analysis for competing locations is performed to determine if targeted levels of return on investment (ROI)/return on equity (ROE) are likely to be achieved.

Information to Attract Investors

Investors, i.e., venture capitalists and banks, are impressed by unique and important business ideas, but they are more impressed by business plans that include detailed financial analysis. Utilizing data from the Economic Census—Retail Trade, projected sales and market share for a given location can be produced and then used as input to present information on the profitability of the new location. In the case of small businesses, these calculations are particularly important, given the high failure rate for such establishments. Retail trade data can be used to document the size of the market (sales) for a specific retail category, e.g., furniture. Sales data can be projected, given certain growth assumptions. A specific business plan can forecast a market share, and that market share multiplied by market size will yield projected sales. It is those projected sales figures, provided that they can be justified, that drive the remaining financial indicators such as ROI. Good indicator figures can be used to attract investors.

Locate Business-to-Business Markets

Most often, retail business data are analyzed with respect to the buyers of the finished products being sold. However, retail establishments are customers for a host of products and services that are required in order to conduct business. Business-to-business marketing is an important category of economic activity. The same data on establishments, sales, and employees that can be used to calculate market share and assess market potential for retail sales can be used by other businesses to estimate the market for store fixtures, microcomputers, and cash registers, items needed by retailers to carry out business operations. Geographic areas with many establishments represent large markets for these kinds of products, and combining data for several geographic contiguous areas

within a state (or contiguous states) can facilitate the creation of sales territories. Although territories vary in terms of population, population differentials are not a good predictor of variations in the number of retail establishments because those establishments can vary greatly in size. Therefore, the market for retail store products must be further differentiated based on the distribution of retail store type and size. Once the market is understood, a trained sales force can be used to fulfill market needs.

Evaluate and Compare Sales Effectiveness

Good businesses evaluate the effectiveness of sales efforts in order to allocate sales resources and determine at what level to set incentives for the sales force. Utilizing retail trade data from local, regional, or national markets, targets or sales expectations can be established for retail stores and sales quotas can subsequently be set for individual sales persons. Additional demographic and competitor data can be used to adjust expectations levels up or down. For example, sales figures for retail stores that specialize in computer equipment and software should be higher in market areas that are characterized by higher-than-average income and fewer competitors than sales figures in markets that have lower incomes and where the level of competition is greater.

Expectations for sales, and thus an assessment of sales effectiveness, are different for two stores that are part of the same retail chain but in different types of markets. In this type of situation, human and other resources can be reallocated from the established market to the burgeoning one in order to capture sales potential.

Data from the Economic Census—Retail Trade can be used to estimate sales expectations, both for markets and for individual stores. Underperforming stores may require reconsideration in the recruiting and training of salespersons and/or the rewards structure designed to encourage sales productivity.

Measures of Retail Trade Activity

Change in Absolute Numbers and Percentages

Although the utilization of more complex measures of retail activity is helpful in understanding markets, it makes best sense to first examine raw data and simple percentages that describe current conditions and/or changes over two or more time intervals. To assess the current (1997) level as well as change in retail trade for the state of Nebraska between 1992 and 1997, two sets of data are needed (Table I). Simple change measures show that although the number of retail establishments in Nebraska declined by 107 (−0.9%) between 1992 and 1997, there were substantial gains in sales revenue (42.0%), annual payroll (37.6%), and number of paid employees (13.1%) over the same time interval. Comparison data for the United States show a small increase in the number of establishments (2.3%), lower increases in sales (34.4%) and payroll (30.4%), and a higher increase in paid employees (15.0%) when compared to Nebraska. These data can be used by state officials in tax revenue forecast models.

Similar analyses using specific categories of retailing (NAICS) can be used to document trends in specific types of retail activity. Table II shows establishment and sales

Table I Retail Trade Activity in Nebraska: 1997 and 1992^a

<i>Year</i>	<i>Establishments</i>	<i>Sales (\$1000)</i>	<i>Annual payroll (\$1000)</i>	<i>Paid employees</i>
1997	11,268	16,350,932	1,799,417	149,478
1992	11,375	11,521,818	1,307,961	132,157
Nebraska change (%)	−0.9	41.9	37.6	13.1
U.S. change (%)	2.3	34.4	30.4	15.0

^a Data from the U.S. census web site at www.census.gov

Table II Retail Trade by Establishments and Sales for Nebraska: 1982–1997

<i>Business type</i>	<i>Establishments</i>				<i>Sales (\$1000s)</i>			
	<i>1982</i>	<i>1987</i>	<i>1992</i>	<i>1997</i>	<i>1982</i>	<i>1987</i>	<i>1992</i>	<i>1997</i>
General merchandise stores	328	276	300	299	784,103	1,084,413	1,567,227	2,199,033
Food stores	1229	1222	1095	1040	1,419,864	1,672,434	2,156,006	2,284,888
Automotive dealers	822	841	817	858	1,295,442	1,792,514	2,376,629	3,718,928
Apparel and accessory stores	1022	977	907	786	344,553	365,021	492,112	490,348

data for Nebraska for the period 1982 to 1997. Several patterns can be seen in these data. Although there was an increase in the number of automobile dealers over the 15-year period, the number of establishments for the remaining three categories declined. In particular, there was a more than 20% decrease in the number of apparel and accessories stores. In addition, the growth in sales for general merchandise stores and automobile dealers nearly tripled over the period. Growth in the remaining categories was much more modest. These data can be used by state and local government officials to understand the economic restructuring of the state. Persons in the private sector can use the same data to help identify market opportunities or threats.

Market Share

To calculate 1997 market share for a furniture and home furnishings store in the Omaha, Nebraska MSA, two sets of data are needed (Table III). The data in Table III show that in 1997, the Omaha Furniture Company (fictitious company) held nearly 12% of the Omaha MSA furniture and home furnishings market. An expanded analysis would help document trends in market share (i.e., comparison data for 1992 and 2002), determine what percentage of the Omaha MSA annual payroll and paid employees it took to support the 11.7% market share, and identify what percentage of the Omaha Furniture Company's sales came from outside the MSA (data from company records).

Pull Factors

One way to estimate the extent to which a community or place draws its customers from outside its boundaries is to calculate a pull ratio. Pull ratios are normally produced with a specific area of retail trade in mind. For the following example, the focus is on the extent to which Douglas County, Nebraska draws its customers for new automobiles from outside the county. Two sets of data are required to calculate the pull ratio for the scenario

Table III Furniture and Home Furnishing Sales Market Share for a Furniture Company, 1997^a

Coverage	Furniture/home furnishings sales (\$1000)
Omaha MSA ^b	566,775
Omaha Furniture Co. ^c	66,500
Market share	11.7%

^a Source: U.S. Bureau of the Census (1999). 1997 Economic Census, Retail Trade, Nebraska, Table 2. U.S. Government Statistical Office, Washington, D.C.

^b MSA, Metropolitan statistical area.

^c Fictitious company.

described (Table IV). A set of straightforward manipulations is required to arrive at the pull ratio:

$$\begin{aligned} \text{Pull factor} &= (\text{Douglas County per capita new} \\ &\quad \text{auto sales/state per capita new} \\ &\quad \text{auto sales}) - (\text{state per capita income}/ \\ &\quad \text{county per capita income}) \\ &= (2.284/1.904) - (19,613/22,879) \\ &= (1.199) - (0.857) \\ &= 1.027. \end{aligned}$$

The first component of the pull factor, the new auto sales ratio (county per capita sales/state per capita sales), produces an index of per capita sales using the state per capita figure as the standard or average figure. Any ratio larger than 1.0 means that Douglas County new automobile sales exceed the statewide average; in the example here, a ratio of 1.199 means that per capita sales in Douglas County are nearly 20% greater than the state average. However, the first ratio must be "adjusted" for income differences, and in this instance, state per capita income is less than that of Douglas County. That is, purchasing power for the state is lower than that for Douglas County. The new ratio, 1.027, means that Douglas County pulls 2.7% more new automobile sales than would be expected based on population and income data alone.

The analysis can be expanded to include multiple points in time to determine if pull is increasing, decreasing, or staying the same. The pull factor can be calculated for different retail NAIC systems (e.g., gasoline stations and used cars) to determine where retail pull is the greatest and least in Douglas County. Moreover, calculating pull factors for numerous NAIC systems and several counties can provide valuable information on dominant markets for different retail sectors.

Per Capita Sales, Sales per Household

Many times, analysts wish to compare retail sales figures for two or more markets when those markets differ in size.

Table IV Automobile Sales, Population, and Per Capita Income: Douglas County, Nebraska and the State of Nebraska^a

Region	Automobile sales (\$1000)	Population	Per capita income
Douglas County	1,007,465	441,006	\$22,879
State of Nebraska	3,155,814	1,657,000	\$19,613

^a Sources: U.S. Bureau of the Census (1999), 1997 Economic Census, Retail Trade, Nebraska (Table 3) and U.S. Bureau of the Census (2002), Census 2002, Nebraska (Table DP-3), U.S. Government Printing Office, Washington, D.C.

Transforming absolute sales figures into per capita measures offers a way to make reasonable comparisons. Three sets of data are used in Table V for illustration purposes. Per capita furniture and home furnishings are \$1251, \$61, and \$443 for Douglas County, Sarpy County, and Nebraska, respectively. Sales per household totals are \$3030, \$167, and \$1103 for Douglas County, Sarpy County, and Nebraska, respectively. The large discrepancy in per capita figures clearly shows how dominant Douglas County is with regard to furniture and home furnishings sales. In fact, the Douglas County pull factor for furniture and home furnishings is quite high, 2.420! As it turns out, Douglas County furniture and home furnishing retailers draw customers from a five-state market area. The market is dominated by one retailer, Nebraska Furniture Mart.

Actual Versus Potential Sales

Pull factors, per capita data, and household per capita data are easily used to compare actual sales across geographic units to determine if there is market potential in one or more of those units. That is, although low values on any of these indicators suggest that a dominant retailer may exist in an adjacent county, they also show that a significant local market may be found. Caution must be emphasized in the use of these data, however. The large per capita and

per household furniture and home furnishings sales figures for Douglas County, and comparison low per capita and household numbers for Sarpy County, suggest at first examination significant market potential in Sarpy County. Although some potential probably exists, the dominance of Douglas County retailers for furniture and home furnishings sales has a long history, and Douglas County competition for a new Sarpy County furniture retailer is substantial.

Focusing on a different retail category, gasoline stations, other comparisons are possible. All three of the counties have per capita sales at gasoline station figures that are substantially smaller than those found for the entire state (Table VI). All other factors being equal, if Sarpy County residents spent as much per capita as did residents statewide, there would be \$106,065,000 in sales ($86,232 \times 1.23$). The difference in the two figures, nearly \$20 million, represents potential new sales. Other confounding factors, e.g., commuting patterns, drive-to-work distance, and the range of products/services offered at gas stations, that affect the demand for products sold as well as where people stop to purchase gasoline and related products and services must be accounted for before business decisions are made. It is easier to establish clear sales potential in markets that are not adjacent to others, especially if the products are not sold via the Internet or by direct sales.

An alternative way of exploring retail opportunities is to examine retail supply in one or more market areas. Table VII shows data for seven Nebraska counties with respect to food and beverage stores (NAIC 445). Although the range in the number of establishments is relatively small (11), there is substantial variation in the average number of persons employed in those stores. On average, the stores are small in Antelope and Boyd counties and they are larger in Adams and Platte counties. Extended analyses in each county would identify individual stores to determine if one or two dominate the market. By combining contiguous counties or places (cities) that were in close proximity, the market potential for a new competitor could be determined.

In conclusion, data from the Economic Census—Retail Trade are used for a wide range of business and government purposes. When combined with other U.S.

Table V Furniture and Home Furnishing Sales, Population, and Households for Douglas and Sarpy Counties and the State of Nebraska^a

<i>Region</i>	<i>Furniture and home furnishing sales (\$1000)</i>	<i>Population</i>	<i>Households</i>
Douglas County	552,054	441,006	182,194

Glossary

long-form items Additional items asked of a sample of households and individuals on the census long-form questionnaire (the long form also includes the short-form items).

population coverage Census count divided by the census count plus the estimated net undercount (people missed in the census minus duplicates and other erroneous enumerations).

public use microdata sample (PUMS) files Contain records for households and people sampled from census long-form records, processed to protect confidentiality.

short-form items Basic demographic items asked of everyone; short-form items are included on the short-form and long-form questionnaires.

summary (SF) files Contain census tabulations for geographic areas, down to the block level (short-form tabulations) and the block group level (long-form tabulations).

The U.S. decennial census (hereafter census) is conducted every 10 years as required by Article 1 of the Constitution. The first census in 1790 obtained minimal information for each household. The 2000 census ascertained six basic items, plus name, for everyone (short-form items) and more than 60 population and housing items for approximately one in six households on long-form questionnaires. (The number of long-form items exceeded the number of questions, some of which had multiple parts.) The data are available in tabular and microdata formats. The basic data serve constitutional purposes of reapportioning the House of Representatives, drawing new legislative district boundaries, and enforcing provisions of the Voting Rights Act. The short-form and long-form data are widely used by federal, state, and local governments, the private sector, academia, the media, and the

general public. For appropriate use of census data, users should consider such dimensions of data quality as timeliness, population coverage, nonresponse error, measurement error, and sampling variability (long-form data). For analyses over time, users should consider changes in definitions, data processing procedures, and categories used in tabulations, all of which affect comparability.

Census Content and Products

Evolution

For the first census in 1790, U.S. marshals obtained for each household counts of free white males aged 16 and older and under age 16, free white females, all other free persons, and slaves. The 1820 census was the first to ask additional questions, including the number of household members engaged in agriculture, manufacturing, and commerce. Censuses in the late 19th and early 20th centuries had large numbers of questions. The 1940 census first used statistical sampling to add questions without burdening the entire population: it asked several new questions of a 5% sample of the population; it also included the first housing census. The 1960 census—the first to use the U.S. Postal Service for questionnaire delivery—introduced the concept of separate “short” and “long” forms.

Data from the earliest censuses were provided to the public in printed volumes, beginning with a single 56-page report in 1790 and growing to multiple voluminous reports. Tabulations were provided for political jurisdictions, including states, counties, places, and villages. Beginning in 1910, census data were provided for a growing number of small statistical areas defined to be useful for local analysis and planning. The first such

areas were census tracts (neighborhoods), defined in eight cities in 1910. By 2000, all counties in the nation were divided into census tracts of approximately 2500 to 8000 residents each. Beginning in 1940, census data were provided for yet smaller units—namely, individual city blocks—in 191 cities. The block program expanded and, in 1990, blocks were identified nationwide—approximately 10 million in all.

Following the 1960 census—the first to use computers for data processing—the Census Bureau released machine-readable data products in addition to printed reports. These products included summary (SF) files of tabulations for geographic areas as small as census tracts, block groups, and blocks (short-form items only). SF files support small-area analyses that are not possible with other available data sources (household survey sample sizes are too small and administrative records are limited in content). Computerized products also included public use microdata sample (PUMS) files, containing anonymized records for households and persons sampled from the census long-form records. Through the initiative of the research community, PUMS files are or will be available for censuses from 1850 through 2000, except for 1890 (most of the records for that census were destroyed in a fire). PUMS files permit rich analyses over time and across population groups. Although their subject content is more limited than most household surveys, their sample size (at least 1% of the population) supports analyses for such small groups as the oldest old, which would not be possible with smaller samples.

Originally, SF and PUMS files were available on magnetic tape. Today, they are available on CD-ROM/DVD and on the Census Bureau's Web site (available at <http://www.census.gov>).

2000 Census Content and Products

The 2000 census used mail-out/mail-back and personal enumeration techniques to obtain information for 115.9 million housing units, of which 105.5 million were occupied, and 281.4 million people, including 273.6 million household residents and 7.8 million residents of group quarters (e.g., prisons, college dormitories, nursing homes). Six items plus name—age, race, sex, ethnicity (Hispanic origin), household relationship, and housing tenure (owner, renter)—were asked of everyone; an additional 36 population items and 26 housing items were asked of a sample of the population on the long form. (Table I compares 2000 census population content with earlier censuses.) The overall long-form sample size was about 1 in 6 (17% of the population). Four sampling rates were used—1 in 2, 1 in 4, 1 in 6, and 1 in 8—with larger rates used for people in small governmental jurisdictions and the smallest rate used for people in larger census tracts.

The 2000 census information is provided to users in several forms (see Table II). SF1 and SF2 files contain short-form tabulations for geographic areas as small as blocks; SF3 and SF4 files contain long-form tabulations for areas as small as census tracts and block groups. Two PUMS files became available in 2003: 1% and 5% samples of the population. Geographic identification varies on the files; no area is identified with fewer than 100,000 people. Compared with previous censuses, some of the 2000 PUMS file content was reduced to minimize disclosure risk, which has increased with the availability of sophisticated matching software and data on the Internet that can potentially be linked to census data.

Population Estimates

Another important census data product comprises regularly updated small-area population estimates that the Census Bureau develops based on each census. The Bureau produces estimates of total population by single years of age, sex, race, and Hispanic origin on a monthly basis for the United States and annually for states and counties as of July 1 of each year. The Bureau also produces total population estimates every 2 years for incorporated places and minor civil divisions of counties (in states that have such divisions). The Bureau has begun producing biennial estimates of total population and children aged 5 through 17 for school districts. Population estimates are produced by updating the census year figures with data from such sources as birth and death records and immigration statistics.

American Community Survey

With few exceptions, there are no sources during the decade of estimates on long-form topics for small areas, such as census tracts. The American Community Survey (ACS) is designed to fill that gap: it is planned to be a large-scale, continuing monthly sample survey of housing units in the United States, conducted primarily by mail, with content similar to that on the census long form. If the ACS is successfully implemented, there will likely be no long form in the 2010 and subsequent censuses.

From 1999 through 2003, the ACS was conducted in 31 sites, chosen to facilitate comparison with the 2000 census. In addition, from 2000 through 2003, the Census Supplementary Survey, using the ACS questionnaire, sampled approximately 700,000 households yearly nationwide. Beginning in summer 2004, contingent on funding, the full ACS will sample 250,000 housing units each month, for an annual sample size of approximately 3 million housing units spread across the nation. Over a 5-year period, the ACS sample addresses will cumulate to approximately 15 million housing units, somewhat smaller than the 2000 long-form sample size of approximately

Table I Census of Population Content

2000 Short-form population items	
Age, race, sex	Asked in every census from 1790 to 2000
Hispanic origin	Asked in 1930 (in the race question), 1970 (long form), 1980–2000
Relationship to household head	Asked in 1880–2000
2000 Long-form population items	
Ancestry	Asked in 1980–2000
Citizenship, year of immigration	Citizenship asked in 1820, 1830, 1870, 1890–2000; year of immigration asked in 1990–1930, 1970–2000; year of naturalization asked in 1920; eligibility to vote asked in 1870
Disability (several questions)	Items related to physical or mental disabilities asked in 1830–1890, 1900–1930, 1970–2000
Education (school attendance, whether public or private, educational attainment)	School attendance asked in 1850–2000; public or private school asked in 1960–2000; educational attainment asked in 1940–2000; literacy asked in 1840–1930; vocational training asked in 1970
Employment status last week	Asked in 1930–2000; duration of unemployment asked in 1880–1910, 1930–1950, 1980
Hours usually worked per week	Asked in 1980–2000; hours worked last week asked in 1940–1990
Income (total and by source)	Asked in 1940–2000; categories expanded over time
Language (whether language other than English is spoken at home, how well English is spoken)	Language spoken at home asked in 1890–1940, 1960–2000; how well English is spoken asked in 1980–2000; language of parents asked in 1910, 1920
Marital status	Asked in 1880–2000 (short form prior to 2000); other marriage-related questions asked in 1850–1910, 1930–1980; number of children living asked in 1890–1910; number of children ever born asked in 1890–1910, 1940–1990
Occupation and industry of current employment, class of worker (e.g., private, government)	Occupation asked in 1850–2000; industry asked in 1820, 1840, 1910–2000; class of worker asked in 1910–2000; occupation, industry, and class of worker 5 years ago asked in 1970; activity 5 years ago asked in 1970, 1980
Place of birth	Asked in 1850–2000; place of birth of parents asked in 1870–1970
Place of work, transportation to work (several questions)	Asked in 1960–2000
Responsibility for grandchildren in the home	New question in 2000
Prior residence (5 years ago), farm residence (housing item)	Prior residence asked in 1940–2000; farm residence asked in 1890–2000; year moved to present residence asked in 1960, 1970, 1980–2000 (housing item); whether ever farm resident asked in 1940, 1950
Veteran status (including period of service), years of military service	Veteran status asked in 1840, 1890, 1910, 1930–2000; period of service asked in 1930, 1950–2000; years of military service asked in 1990, 2000; questions on dependents of veterans asked in 1890, 1940
Weeks worked last year	Asked in 1940–2000
Year last worked	Asked in 1960–2000

Source: U.S. Census Bureau (1973); author's inspection of 1980, 1990, and 2000 questionnaires.

18 million housing units. The Bureau plans to issue annual products containing yearly averages of monthly data for areas with 65,000 or more people and multiyear averages for areas with fewer people (5-year averages for the smallest areas).

Constitutional Purposes

Reapportionment

The decennial census plays a fundamental role in the U.S. political system by providing population counts for each

state once a decade for reallocation of seats in the U.S. House of Representatives. This primary role for census-taking is mandated in Article 1 of the U.S. Constitution and elaborated in Title 13 of the U.S. Code, which stipulates that the Census Bureau must provide state population counts to the president by 9 months after Census Day (December 31 of the census year) for determining the number of representatives for each state from the prescribed apportionment formula. Congress enacted this procedure in 1929 so that reapportionment would occur automatically each decade, precluding what happened after the 1920 census, when Congress could

Table II 2000 Census Data Products

Summary (SF) Files	
Census 2000 Redistricting Data Summary File (P.L. 94-171 File)	
Counts of the population, total and aged 18 and over, by 63 race categories, by Hispanic, not Hispanic, by state, county, place, minor civil division, voting precinct (if specified by the state), census tract, block group, block	
Summary File 1 (SF1, tabulations of short-form items; file for each state unless noted)	
1. Population counts for 63 race categories and Hispanic, not Hispanic—down to the block level	
2. Population counts for many detailed race and Hispanic categories and American Indian and Alaska Native tribes—down to the census tract level	
3. Selected population and housing characteristics—down to the block level	
4. National-level file—tabulations for states, counties, and places; urban—rural tabulations	
Summary File 2 (SF2, detailed tabulations of short-form items)	
1. Population and housing characteristics iterated for many detailed race and Hispanic categories and American Indian and Alaska Native tribes—down to the census tract level (file for each state)	
2. National-level file—tabulations for states, counties, and places; urban—rural tabulations	
Summary File 3 (SF3, tabulations of long-form sample items; file for each state unless noted)	
1. Population counts for ancestry groups—down to the census tract level	
2. Selected long-form population and housing characteristics—down to the block group level	
3. National-level file—tabulations for states, counties, places	
Summary File 4 (SF4, detailed tabulations of long-form sample items)	
1. Long-form population and housing characteristics iterated for many detailed race and Hispanic categories, American Indian and Alaska Native tribes, and ancestry groups—down to the census tract level (file for each state)	
2. National-level file—detailed tabulations for states, counties, places	
Census Transportation Planning Package Files (CTPP)	
Tabulations of place of work by place of residence for traffic analysis zones	
Public Use Microdata Sample (PUMS) Files	
(All items for households and persons sampled from long-form records)	
1-Percent Sample Files, containing ~1 million household and 3 million person records	
Geographic identification: states, areas of 400,000 or more population	
5-Percent Sample Files, containing ~5 million household and 15 million person records	
Geographic identification: states, areas of 100,000 or more population	
Printed Reports	
Demographic Profiles; Congressional District Demographic Profiles	
Selected population and housing short-form characteristics; demographic, social, economic, and housing long-form characteristics (3 separate tables), by state, county, place, minor civil division, census tract; congressional district (106th, 108th Congresses)	
Summary Population and Housing Characteristics (PHC-1)	
Short-form tabulations down to the place level	
Population and Housing Unit Counts (PHC-3)	
Short-form tabulations down to the place level, includes selected historical counts	
Summary Social, Economic and Housing Characteristics (PHC-2)	
Long-form tabulations down to the place level

Note: SF and PUMS files and demographic profiles are available on the Internet and CD-ROM/DVD; PHC reports are available on the Internet; all files have been processed to protect confidentiality.

not agree on a reapportionment bill. The current apportionment formula, which uses the method of “equal proportions,” was written into law at the time of the 1940 census.

Historically, controversies about which people to include in the reapportionment counts have involved three groups: (1) noncitizens, (2) Americans overseas, and (3) people not counted in the census who are estimated to be

part of the U.S. population through a coverage estimation program, such as the 2000 Accuracy and Coverage Evaluation Program.

Noncitizens

Since 1790, the census has had a goal to count all U.S. residents, including people who are not citizens of the United States (except for tourists and other

temporary visitors from abroad and foreign government representatives). With the increased numbers of illegal immigrants in the 1970s and 1980s, lawsuits were filed prior to the 1980 and 1990 censuses to exclude such immigrants from the apportionment counts. The plaintiffs argued that including illegal immigrants unfairly benefited states with larger numbers of them at the expense of states with fewer of them. The defendants countered that the Constitution did not limit the apportionment counts to citizens or potential voters but included the entire population. Defendants also argued that it was impractical to identify and exclude illegal immigrants in the census. The U.S. Supreme Court decided the cases on the narrow grounds that the plaintiffs did not have “standing” to bring the suits. In commentary the Court stated that the Constitution intended to provide representation to everyone and not just to potential voters. The 2000 census followed historical practice by striving to include all U.S. residents in the apportionment counts.

Americans Overseas

Rules for counting Americans who live overseas have varied from census to census. In 1970, 1990, and 2000, federal military and civilian employees (and their dependents) living abroad were assigned a “home” state from administrative records and included in the state reapportionment counts, but not in other data releases. This overseas population totaled 576,000 people in 2000 (0.2% of the U.S. population). Tests will be conducted in 2004 of counting private U.S. citizens who live overseas.

Population Coverage

Research on census coverage, which began with analyses of undercounts of draft-age men and young children in the 1940 census, estimated a net undercount of the population in every census from 1950 to 1990. Research also estimated higher net undercount rates for some population groups than others, such as higher rates for blacks than for nonblacks and children than for adults. Beginning in 1970, the Census Bureau made special efforts to cover hard-to-count population groups, although research showed that such efforts were only partly effective. Beginning in 1980, the Bureau worked on a dual-systems estimation (DSE) method, based on data from a post-enumeration survey and a sample of census records, that could be used to statistically adjust census counts for measured net undercount. The Bureau originally planned to use DSE methods to adjust 2000 state population totals for congressional reapportionment, but a January 1999 decision by the U.S. Supreme Court precluded such adjustment. The Bureau also planned to adjust 2000 counts for other purposes, but that was not done.

Legislative Redistricting for Equal Population Size

A second primary function of the U.S. census, deriving from its constitutional mandate for reapportionment, is to supply small-area population counts for redrawing congressional and state legislative district boundaries to meet court-mandated standards for equal population size. In the 19th century, Congress usually passed a statute at each census requiring all states to redistrict and to establish single-member districts that were contiguous, compact, and as nearly equal in population as practicable. After the 1920 census, Congress declined to reapportion the House because of the concerns of rural interests about cities’ tremendous population growth, particularly from immigration. The 1929 act that provided for automatic reapportionment each decade set no standards for redistricting. The U.S. Supreme Court held that the omission was intentional and that it was up to the states to develop their own standards until and unless the courts decided to intervene.

From 1929 through the 1950s, the courts generally declined to intervene in redistricting. Many states did not redistrict after a census, unless they gained or lost seats, and those that did often paid little attention to achieving equal-size districts. Congressional and state legislative districts became increasingly unequal in population size: after the 1960 round of redistricting, the largest congressional district in the United States had over five times the population of the smallest district; disparities among state legislative districts were even greater.

The “one-person, one-vote” Supreme Court decisions, beginning in the early 1960s, changed the requirements for redistricting drastically. In *Baker v. Carr* (1962), the court held that reapportionment and redistricting matters were subject to judicial review under the equal protection clause of the 14th Amendment. In *Wesberry v. Sanders* (1964), the court held, under Article 1 of the Constitution, that congressional districts must be as nearly equal in population as practicable. In *Reynolds v. Sims* (1964), the court held, under the 14th Amendment, that both houses of a state legislature must be apportioned on a population basis and that states should strive for population equality. In *Karcher v. Daggett* (1983), the court rejected a New Jersey congressional redistricting plan in which the smallest district was only 0.7% smaller in population than the largest district. However, the courts allowed more deviation among state legislative seats than among congressional districts—deviations in state district sizes as high as 10%, and sometimes as high as 16%, were accepted.

In 1975, Congress required the Census Bureau to provide census tabulations to state officials for redistricting within 1 year after the census date [Public Law (P.L.) 94-171; section 141(c) of Title 13]. States could suggest

block boundaries and specify geographic areas for which they required tabulations; if no special areas were identified, the Census Bureau provided tabulations for blocks. The P.L. 94-171 file in 2000 provided population counts for people under and over age 18 by 63 race categories, by Hispanic, not Hispanic, for states, counties, places, minor civil divisions, voting precincts (when specified), census tracts, block groups, and blocks. (The need to show 63 race categories resulted from the new option in 2000 to mark more than one race.)

Voting Rights Act and Redistricting

The 1950s and 1960s civil rights movement led to legislation, court decisions, and administrative practices that required the use of census race and ethnicity data for redistricting. The Voting Rights Act, passed in 1965 (P.L. 89-110) and amended in 1970, 1975, 1982, and 1992, is the key legislation. Its original intention was to help blacks in the South participate in elections. The 1972 and 1975 amendments extended the act's protection to all areas of the country that had voting barriers, not only for blacks, but also for language minorities—Hispanics, American Indians, Asian Americans, and Alaska Natives.

In *Allan v. Board of Education* (1969), the Supreme Court held that changes such as moving from single-member to multimember districts were “practices or procedures” subject to review under the act because they might “dilute” the black vote. The Justice Department instructed legal officers in covered jurisdictions to clear every change in voting procedure, including redistricting plans that lessened the effectiveness of minority votes—for example, by placing minority voters in as few districts as possible. Census race and ethnicity data continue to be the basis for devising districting plans that can withstand legal scrutiny.

Voting Rights Act and Bilingual Voting Assistance

Section 203 of the Voting Rights Act, adopted in the 1975 amendments and modified in 1982 and 1992, requires counties, cities, and townships to provide election materials and oral assistance in another language as well as in English for language minorities who are not literate in English. The Census Bureau makes the determination of covered areas after each census. The definition of a covered area is generally one in which 5% of the citizens of voting age speak a single minority language, do not speak English very well, and have a higher illiteracy rate in English (defined as failure to complete 5th grade) than the nation as a whole. Approximately 300 jurisdictions are required to provide bilingual voting assistance based on the 2000 census results.

Federal Program Agency Uses

Federal program agencies use data from the census for a wide range of purposes to fulfill the requirements of legislation, court rulings, and other directives. Indeed, nearly every item in the 2000 census was required in order to serve a specific federal purpose. Such purposes include implementation of sections of the Voting Rights Act, allocation of federal funds to states and localities, assessment of employment discrimination, and planning, monitoring, and evaluation of federal programs.

Fund Allocation

Over \$200 billion of federal funds are allocated each year to states and localities by formulas, many of which use census data and population estimates. Examples include the following:

(1) Medicaid (\$145 billion obligated in fiscal year 2002): Reimburses a percentage of each state's expenditures for medical care services for low-income elderly and disabled people and families with dependent children by a formula that uses per capita income estimates. The U.S. Bureau of Economic Analysis develops these estimates with data from administrative records, the decennial census long-form sample and other censuses and surveys, and census-based population estimates (as denominators). Other programs use the Medicaid formula.

(2) Title I of the Elementary and Secondary Education Act (\$9.5 billion obligated in fiscal year 2002): Allocates funds to school districts to help educationally disadvantaged children by a formula that includes estimates of school-age children in families with incomes below the official poverty threshold. The estimates previously derived from the most recent census long-form sample; currently, they derive from Census Bureau statistical models, which include census poverty data as one input.

(3) Community Development Block Grants and Entitlement Grants (\$3 billion authorized in fiscal year 2002): Allocates the larger amount from two formulas to states, metropolitan cities, and urban counties; the formulas use census data on total population, people living in poverty, overcrowded housing (first formula), and housing built before 1940 (second formula).

Equal Employment Opportunity

The U.S. Equal Employment Opportunity Commission and the U.S. Department of Labor's Office of Federal Contract Compliance regularly use census labor force data on occupation and industry for zip codes and other geographic areas to monitor compliance and investigate charges of employment discrimination by age, sex, race, and ethnicity. Also, federal agencies, as employers, use

such data to evaluate their own recruitment and promotion systems. Recent censuses have provided special data products for equal employment opportunity analysis.

Program Planning, Monitoring, and Evaluation

Two examples of the numerous federal uses of census data for program planning and evaluation are as follows:

(1) The U.S. Department of Transportation (USDOT) uses long-form disability data for traffic analysis zones (TZAs, or groups of census blocks) to monitor compliance with the Federal Transit Act and the Americans with Disabilities Act. Since 1960, USDOT has helped develop a Census Transportation Planning Package (CTPP) for use by local governments. The CTPP provides tabulations of place of residence by place of work for TZAs. Its primary use is to describe the characteristics of commuter flows; it is also the only census product to provide data on workers at the workplace (all other tabulations are by place of residence).

(2) The U.S. Department of Housing and Urban Development uses long-form data to construct fair market rents (FMRs) for nonmetropolitan counties and most metropolitan areas. FMRs are used to determine rent subsidies to eligible families from the Section 8 Housing Assistance Payments Program; they are set at a percentile of the distribution of gross rents for recently occupied two-bedroom apartments with electricity and complete kitchen and bathroom.

Federal Statistical Agency Uses

Census long-form data and census-based population estimates serve important functions for federal statistical agencies. Four examples are as follows:

(1) Since 1950, the U.S. Office of Management and Budget has used long-form data on commuting patterns to help define metropolitan statistical areas. In turn, these areas have many uses, such as determining eligibility for fund allocations.

(2) Statistical agencies that conduct surveys of special populations often use census data to select a sample. For example, since the 1960s, the Science Resources Statistics Division of the National Science Foundation has commissioned a sample survey of college graduates drawn from the census long-form records, oversampling scientists and engineers.

(3) Census-derived population estimates are used as denominators for important national and subnational statistics, such as birth and death rates for the United States, states, and local areas, by age, sex, and race, from the National Center for Health Statistics.

(4) Federal household surveys, such as the Current Population Survey (source of official employment and poverty statistics), use census-based population estimates as survey controls—that is, the survey estimates are adjusted to agree with national population estimates by age, sex, race, and Hispanic origin. Such reweighting is needed because household surveys typically cover the population less well than the census.

State and Local Government Uses

State and local governments use small-area census data for such purposes as fund allocation, program planning and evaluation, facility planning, disaster planning, and economic development and marketing.

Formula Allocation

Examples include using census estimates of children in families with income below the poverty line in a formula to allocate state child welfare block grants to counties and using census estimates of female-headed households living in poverty with dependent children in a formula to allocate state crisis counseling funds to counties.

Program Planning and Evaluation

Examples include using long-form data on English-language proficiency, language spoken at home, and years of school completed to identify neighborhoods whose residents may need assistance in using local government services and developing socioeconomic profiles of census tracts for federal grant applications.

Facility Planning

Examples include using long-form data on commuting patterns to help redesign bus routes and plan new roads and using census socioeconomic data and administrative records data on public health needs to locate health clinics.

Disaster Planning

Examples include using long-form data on vehicle ownership and disability to estimate the numbers of people who would need to be evacuated in a disaster and how many might need transportation and using long-form place of work and place of residence data to estimate daytime populations to develop disaster plans for employment centers.

Economic Development and Marketing

Examples include using long-form data on educational attainment, occupation, and labor force participation to

attract businesses by the availability of an appropriately skilled labor force and using long-form data on ancestry and language to inform businesses of opportunities to serve particular markets.

Private Sector Uses

Retail outlets, banks, media and advertising firms, insurance companies, utilities, health care providers, and other businesses and nonprofit organizations use census data. A new industry developed after 1970 to repackage census data, use them to construct lifestyle cluster systems (neighborhood types that correlate with consumer behavior), and relate them to other data through address coding and computer mapping services. Private sector uses of census data include site location, targeting of advertising and services, and compliance with government requirements. Five examples are as follows:

(1) A retail or service business uses population estimates to determine when a growing suburb will reach a threshold for opening a new store.

(2) A church compares members' characteristics to census characteristics for the surrounding community to identify similarities and differences and develop an outreach program.

(3) An insurance company sets performance standards for branches by relating small-area socioeconomic profiles to continuing and lapsed customers' characteristics for each branch.

(4) Banks use median household income and income distributions by census tract to document compliance with federal mortgage lending guidelines regarding race.

(5) Employers use census small-area data on occupation by sex, age, race, and ethnicity to assess compliance with federal equal opportunity employment and anti-discrimination laws.

Research Uses

Researchers use census data for analyses on topics such as aging, educational attainment, migration flows, environmental exposures, and concentrated poverty. Many research studies based on census data have important public policy implications.

Aging

Census summary tabulations support analyses of migration flows and concentrations of the elderly by geographic area for subgroups defined by living arrangements, income, labor force attachment, and other characteristics. PUMS files support detailed

analyses of small groups of elderly, such as those with different disabilities.

Education

Researchers use census summary data on median years of school completed, average income, and unemployment to describe challenges facing communities; they use PUMS files to assess age and race group differences in educational level, income, and housing quality.

Environment

Census small-area socioeconomic information related to environmental hazards data permit analyses of the environmental effects on different population groups.

Migration

Census small-area data are an unparalleled resource for the study of migration among regions, states, counties, and places, and consequences for different parts of the country. The Census Bureau publishes data on county-to-county migration flows; the PUMS files permit detailed analysis of the characteristics of long-distance and short-distance movers and nonmovers.

Poverty

Analyses of 1970 and 1980 census summary data revealed large increases in densely populated (mainly black) urban neighborhoods with more than 40% poor families. These findings stimulated further census-based research on concentrated urban poverty.

Issues for Users

Users should learn what is known about the quality of census data, in comparison with other sources, and determine which source is best suited to their use. Quality concerns include the following:

Timeliness

Census data are collected once every 10 years and made available 1 to 3 years after collection, which may affect analyses for areas experiencing rapid change. Population estimates update the basic demographic information for small areas; the ACS is intended to provide updated long-form-type information if it is implemented.

Coverage

The census misses some people, duplicates others, and puts others in the wrong location. Although the census is

the best source of population counts (it has better coverage than household surveys), recognition of coverage problems is important when using the data.

Nonresponse Error

The census strives to obtain complete data for everyone but, even after follow-up, obtains no or limited information for some households. Imputation methods use data from nearby households to supply records for whole-household nonrespondents and to fill in individual missing items on person and housing unit records. Missing data rates are high for some long-form items, such as income and housing finances, and for residents of group quarters. Imputation introduces variability in estimates and may bias estimates if nonrespondents differ from respondents in ways that the imputation procedures do not reflect.

Measurement or Response Error

People may underreport or overreport items such as age, income, and utility costs, which can introduce bias in tabulations if under- and overreports do not cancel each other out. People may also have different interpretations of questions such as ancestry.

Sampling Variability (Applicable to Long-Form Data)

Long-form estimates are based on large samples, but they can have substantial uncertainty for small areas or small groups. Sampling variability for the ACS, if implemented, will be higher than for the long form.

Definitional and Other Changes

For analyses of more than one census, changes in definitions or processing features can affect comparability across time. For example, the 2000 and 1990 race questions differ importantly, as do the education questions before and after 1990.

Glossary

behaviorism In psychology, the study of human being in terms of observable behavior, characteristically stressing stimulus and response, without reference to values, beliefs, and attitudes.

behaviorism, pluralistic In sociology, the view that the individual and interaction among individuals constitute the basic units of analysis, and that social structures consist of externally similar acts.

cultural lag A situation where elements of a culture change at different rates causing disruption, typically when science and technology change more rapidly than social institutions.

eugenics The study of human heredity to improve humankind through selective breeding.

evolutionism, unilinear The theory that all cultures develop along similar lines from the simple to the complex, often coupled with a belief in progress.

latent function The unintended and unrecognized consequences of an activity for group adaptation, for example, the reinforcement of group identity in a Native American rain dance.

mores Binding, extra-legal social norms considered essential to a group's welfare.

objectivism A philosophical term to describe the view that objects of knowledge exist independent of human perception, often used pejoratively by humanistic sociologists who allege that positivistic sociologists treat human beings as material objects.

operationalism The view that the only valid scientific concepts are those that prescribe the means of measuring the concept.

positivism The belief that knowledge comes only from the senses and that the methods of the natural sciences thus provide the only accurate means of attaining knowledge.

positivism, instrumental The use of measurement, statistics and other quantitative techniques in formulating social policy.

scientism A term, usually pejorative, applied to positivistic social science, broadly to social evolutionism, more

narrowly to the extreme sociological positivism of the inter-war years.

sociometry The study of group structure with reference to the feelings of the members of a group for one another.

synchronous cycles Parallel changes in material culture and social institutions that create changes within a larger group or nation.

Sociologist, administrator, and academic entrepreneur, F. Stuart Chapin played a key role in the creation of a quantitative, statistical sociology in the United States in the years between World Wars I and II (1920s–1940s). Moving from an early interest in social evolutionism to statistics, Chapin devised “living room scales” to measure social class by items in the home; conducted studies of civic participation as a key to social adjustment; and proposed methods for comparative study using experiment and control groups. A theorist as well as quantifier, he outlined a cyclical view of social change, and later anticipated work on latent and manifest functions. Chapin also helped professionalize American sociology, being a prime mover in the formation of the Social Science Research Council and an active participant in the American Sociological Society (Association) and other professional organizations.

Background and Early Influences

Born in Brooklyn, New York, F. Stuart Chapin (1888–1974) was reared in comfortable surroundings on Manhattan's East Side. Although not wealthy, his family enjoyed a distinguished lineage dating to early New England. One of his maternal ancestors served with Washington in the Revolution, while other forebears included merchants, lawyers, judges, and clergymen.

His father, Charles B. Chapin, a Presbyterian minister, served pastorates in Manhattan, upstate New York, and Pennsylvania. His mother, Florence Johnson, loved poetry and painting.

Chapin's youth was centered on family, the institution that was the focus of much of his later work. In 1895, he entered the Chapin Collegiate School, where his grandfather was headmaster and his father and several generations of male relatives had studied. In 1904, this comfortable world unraveled when his father left Manhattan for a pastorate in Rochester, New York. Attending the local high school for the senior year, F. Stuart suddenly developed a love of mathematics and dabbled in inventions ranging from a primitive thermostat to a new photo developing process. In 1905, he entered the University of Rochester to study engineering, dashing his father's hopes that F. Stuart would follow him into the ministry.

Chapin's life was again upended in 1906 when his mother died of a stroke. In response, he veered suddenly in a new direction, studying oil painting at a local institute. Although he did not pursue art as a career, painting, with inventing and fishing, occupied his leisure hours throughout his life. Chapin, unlike many of his contemporaries, recognized no gap between science and art, work, and leisure. Whether experimenting with oil paints or measuring and recording his fishing catches, "science" afforded standards and stability that "tradition" could no longer provide. In 1908, Chapin transferred to Columbia, where he received a Bachelor of Science degree the following year. Social science, however, was already his first love. At Rochester, he was influenced by the historian William Carey Morris and the psychologist George Mather Forbes, both members of the American Social Science Association, an organization that nurtured sociology and the other modern social sciences.

Chapin's return to Manhattan brought him in contact with his uncle, Henry Dwight Chapin (1857–1942), whom he later called "the greatest influence" in his development. A specialist in children's diseases, the elder Chapin worked tirelessly for children's welfare, tenement house reform, and sanitary legislation. In this enthusiasm for scientific reform, he also toyed with eugenics and proposed sometime-draconian solutions to social problems (for example, permanent quarantine for "all tramps, cranks, and generally worthless human beings"). Seeing no conflict between his inherited Calvinism and Darwinian science, he condemned social policies that perpetuated the "unfit." This tutelage left his nephew with a just-the-facts attitude toward reform and a suspicion of programs based on feeling.

In the graduate program in sociology at Columbia (Ph.D., 1911), Chapin studied with sociologist Franklin Henry Giddings and anthropologist Franz Boas, among others. Giddings, a social evolutionist in the tradition of

Herbert Spencer and an advocate of statistics, was a major influence. In his *Principles of Sociology* (1896), Giddings described social evolution as a three-fold process of aggregation, imitation, and selection whereby useful practices are preserved and the "ignorant, foolish, and harmful" extremes are eliminated. As a quantifier, Giddings built on a Columbia tradition dating to the economist Richmond Mayo-Smith, author of *Statistics and Sociology* (1895) and a major figure in the faculty of political science until his premature death in 1901. Unlike Mayo-Smith, however, Giddings based his work on Karl Pearson's *Grammar of Science* (1892), a work that urged investigators to abandon the search for reality underlying appearances, to confine attention to observable externals, and to substitute "correlations" for "causes." From anthropologist Franz Boas, Chapin developed an interest in "primitive" societies, an appetite for facts, and a skepticism toward all "broad and beautiful" generalizations. The most important non-Columbia influence was *Folkways* (1906) by William Graham Sumner of Yale.

Social Evolutionism to Statistics

In *Education and the Mores* (1911), his doctoral thesis, Chapin combined the work of these mentors with statistical analysis. The issue was whether elementary education fostered "useful tradition" and social adaptation, as urged by Columbia's John Dewey and other progressive educators, or whether it conserved "obstructive tradition and mischievous prejudice." Following Sumner, Chapin conceptualized tradition as mores—customs accepted "without attention." Chapin ranked mores in terms of their universality and rationality: tradition (general and partly rational), customs (local), and superstition and prejudice (irrational and emotional). The enemies were provincialism and passion. Adopting Giddings' theory of imitation (derived from French sociologist Gabriel Tarde), Chapin stated that the mores were "the objective products of interstimulation and response," a step beyond Sumner and toward behaviorism that reviewer Charles Ellwood criticized in 1912 in the *American Journal of Sociology*.

Although education in primitive societies fostered superstition and prejudice, Chapin argued, modern schooling introduced the scientific view, especially in the "content studies" of geography, science and history, each a potential challenge to existing mores. As taught in American schools, however, these subjects failed at this task. Using previously published data, Chapin calculated the time allotted to the "3 Rs" and to the "content studies" in schools in selected American and European cities, the time given to these newer studies at different grade levels, and the percentage of students completing each grade level. This analysis showed that, despite the rise of

progressive education, the majority of students never encountered the newer subjects or else studied them at a level where they were saturated with popular prejudice (patriotic history, for example).

From 1911 to 1921, Chapin's quest for a scientific perspective took several forms. Teaching at Wellesley (1911–1912), he offered courses in economic history, conservation, and municipal socialism. In the *Independent* in 1915, he touted science and efficiency as the answers to the nation's social problems—through accident, health, and old-age insurance on the German and British models, through state-sponsored, centralized labor exchanges, and through less wasteful logging and coal mining. In *Popular Science*, he endorsed a variety of eugenic policies in language that echoed Henry D. Chapin's calls for elimination of the "unfit." In *An Historical Introduction to Social Economy* (1917), he traced the development of modern social insurance from earlier forms of charity and poor relief.

At Smith College (1912–1921), Chapin joined psychiatric social worker Mary C. Jarrett to organize the Smith College School of Social Work. In the *Scientific Monthly* in 1918, he argued that sociology and social work, if properly scientific, were complementary. Before an audience at the annual meeting of the National Council of Social Workers in 1919, he argued that work could be made more effective if investigators dispassionately and objectively applied the inductive method. As a Red Cross executive during the war, he gained further lessons in the practical applications of social theory. This path, however, led only indirectly to the statistical scales and social experiments that would soon be Chapin's trademark. In a study of voting following Woodrow Wilson's victory in 1912, he again used previously collected data to measure the variability in overall voting and in party pluralities in presidential elections since 1856. In the same journal 2 years later, he lectured readers on the uses of statistical averages (mean, mode, and median) to ascertain the representative nature of a sample. In *Scientific Monthly* in 1917, he argued that the statistical method provided the best means of overcoming problems inherent in social experimentation.

Chapin's new interest in part reflected the growing popularity of the British "new statistics" based on Karl Pearson's work with correlation coefficients, multiple correlation, and frequency curves, work Chapin first encountered in a course with statistician Henry L. Moore at Columbia. For his expositions, Chapin drew on several popularizations by English statisticians: Arthur L. Bowley's *An Elementary Manual of Statistics* (1910), George Udny Yule's *Introduction to the Theory of Statistics* (1912), and William P. and Ethel M. Elderton's *Primer of Statistics* (1909). But his interest in statistics also reflected his changing political views and a more pessimistic assessment of social evolution. Although Chapin

was never as socially activist as some of his sociological colleagues, his interest in progressive education, in conservation, and in municipal socialism aligned him with many prewar progressives. His 1912 analysis of presidential elections concluded that the rise of the independent voter promised more enlightened politics. In *An Introduction to Social Evolution* (1913), a summary of unilinear evolutionism, he predicted that increasing material abundance would bring better social relations. Like Giddings, he found a model for social policy in nature's balance between stability and change.

Following the outbreak of war, however, Chapin prefaced support for eugenics with a scathing attack on the human depravity that produced "brutally unscrupulous" businessmen and the "flimsy pretext" that had ignited the "holocaust of Europe." Although his enthusiasm for eugenics proved temporary, it rested on the conviction that "societal" (psychic) evolution, such as in most social reforms, failed to "stay put," and must be supplemented by "social" (physical) evolution to improve the race biologically. In *Scientific Monthly* in 1917, he coupled the argument that statistics provided the only way to make social experimentation feasible with evidence that the history of social reform was one of unintended consequences or outright failure.

Chapin's engagement with evolutionism led indirectly to statistics. His argument that mores evolved through natural selection in a process of trial and error was inherently statistical in that the overall outcome was probabilistic in the same way as a multiple rolling of dice. Sumner, being ignorant of selectionism, did not share this view of the mores and thus remained wedded to a crudely inductive view of sociological method. Chapin, like Giddings, gravitated naturally to the new statistics, in that both questioned the optimistic assumption that social selection guaranteed moderate social change. Social evolutionism was also an obstacle to the development of scientific sociology. A staple of "armchair" theorists, it impeded empirical work. The alliance with biology undercut claims of disciplinary autonomy. It also made sociology a target of growing antievolutionist forces, as Chapin learned a few years later when some Christian fundamentalists attacked social evolution texts as among the most "sacrilegious and scornful" books in print. Chapin continued to be both quantifier and theorist, as attested by his later study of "synchronous cycles" in *Cultural Change* (1928). But, absent progress and direction, "social evolution" became "social change" and statistics the method of choice.

Field Work and Social Research (1920), a summary of lessons Chapin learned in social work during the Smith College years, was one of the first books in the United States to provide a systematic inventory of sociological methods. The presentation was in three parts: a plea for a rigorously inductive method; an analysis of case work, sampling, and total enumeration; and a discussion

of the technical problems of gathering and evaluating material. Although reviewers judged the book a useful introduction, some also noted that it did little to advance the cause of statistics. The economist Frank A. Ross, writing in the *Journal of the American Statistical Association*, observed that Chapin gave readers no comprehension of the gap that separated the case study's "sympathetic and subjective" rendering of detail and the statistician's impartiality. Nor, he added, were the Pittsburgh and other prewar surveys instances of "sampling," as Chapin maintained, but rather were case studies with cities as the unit. An English reviewer in the *Journal of the Royal Statistical Society* criticized the "highly artificial" device of assigning numerical values to factors such as "care in avoiding dust" as a measure of ventilation. Informing these criticisms were inherent differences between the case study and social surveys of the social worker, on the one hand, and statistical analysis, on the other. This tension continued to shape Chapin's work as he moved from Smith College to the University of Minnesota in the fall of 1922.

Social Measurement

At the University of Minnesota, Chapin moved steadily toward behavioral analysis and scientific neutrality. The results were the "living room scales" and "social experiments" that won him a reputation as a pioneering technician of the new sociology. Although the first courses in sociology at the university dated to the early 1890s, Minnesota did not establish a formal department in the field until 1910, initially staffed by an ethnographic popularizer and two reformers in the Social Gospel tradition. In the half-dozen years before Chapin arrived, a separate department, Social and Civic Training, was established under Yale Ph.D. Arthur J. Todd; the department was subsequently merged with the Department of Sociology.

Appointed at age 33 to replace Todd, Chapin was the youngest chairman of a major sociology department in the nation. His passion for order was just what the situation demanded. The department he entered was the site of a three-way tug of war among an older generation of amateurs, social workers and social surveyors, and Luther L. Bernard, a Chicago Ph.D. who was the sole voice for what was now termed "sociological objectivism" and who made no secret of his disdain for the other factions. When Chapin appointed Russian émigré Pitirim Sorokin in 1923, Bernard feared that this distinguished theorist was being groomed as his replacement.

Chapin did not initially transform the department, partly because his own interests remained extremely broad and partly because the merger of sociology and social work gave a practical, socially oriented cast to

work in both areas. As late as 1929, seminars in sociology included Applied Sociology, Social Theory, Evolution, and Rural Sociology, a subject Chapin had introduced at Smith over conservative opposition. Early doctoral theses written under his supervision reflected the reform-oriented nature of Minnesota sociology, "unscientific" by later standards; examples include Paul Perigord's *International Labor Organization* (1924) and Harold A. Phelps's *Comparative Study of Unionism* (1925). Chapin's colleagues and former students later romanticized the open and "democratic" character of these early years before the austerity of the man and his sociology became legend.

By 1925, several developments helped create a new Chapin. One was the increasing importance of educational foundations, with their emphasis on quantitative rigor. Chapin initially became involved with the Laura Spelman Rockefeller Memorial when applying for support of a bibliographical service for sociologists, *Social Science Abstracts*, which he edited during its brief existence from 1930 to 1933. A second was a personal crisis when Chapin's wife, Nellie Estelle Peck, died of peritonitis in 1925 at age 36. During their 14-year marriage, which produced three children, their relations with the world were outgoing and informal. Things changed, his colleagues later reported, following his remarriage 2 years later to a socially ambitious woman who was highly protective of her husband's reputation. Burdened with the care of three young children, Chapin had begun to show autocratic tendencies even before his remarriage. But his aloofness increased with each passing year.

Departmental affairs also demanded a firm hand. In 1925, Luther Bernard left under a cloud of scandal that absorbed much of Chapin's time. Sorokin complained that his \$2000 salary was half that of most professors and disliked Chapin's increasingly autocratic ways. Chapin's strained relations with the "practical" sociologists were an open secret. One graduate student wrote Bernard that there was a set policy to get rid of anyone "who wishes to say something about Dept. and U. affairs." Although several appointments after 1926 strengthened the department, things fell apart during Chapin's 3-year absence in New York while editing *Social Science Abstracts*. Sorokin and the rural sociologist Carle Zimmerman left for Harvard and the criminologist Edwin Sutherland left for the University of Chicago. The collapse of the *Abstracts* project compounded Chapin's disappointment, completing his transformation into the formal, austere, and intensely private person that colleagues later remembered. Departures in Chapin's scholarship between 1924 and the early 1930s reflected these changes: (1) a more rigorous application of statistics, (2) an explicit rejection of unilinear evolutionism in *Cultural Change* (1928), coupled with a redefinition of social institutions in behavioral terms, and (3) the creation of "living room" and other scales to measure social status.

During 1924, Chapin returned to measuring standards of living. In *Field Work and Social Research*, he had proposed a “score card” method to standardize measures of “structural conditions,” “congestion,” and other variables by assigning points within an arbitrarily chosen range, much as breeder’s associations and produce exchanges grade animals and grains. Now he turned to statistics to evaluate 11 studies of room crowding among Italian workmen in Chicago. He demonstrated that overcrowding in sleeping rooms in one study of 212 cases could be better stated statistically in terms of means and standard deviations than verbally; and, further, that the mean among all the studies differed less than the distributions within any one, proof that they were well-chosen samples and that statistics have practical value in demonstrating “the essential fairness of the original field work.”

In *Cultural Change* (1928), Chapin described what he now called “synchronous cultural change.” A variation of William F. Ogburn’s theory of cultural lag (typically a lag between technology and social institutions), the theory combined Luther Bernard’s work on technology, recent anthropological studies, and a cyclical conception of change derived in part from Chapin’s colleague Sorokin. Cycles of change are of three orders: material, as in technology; nonmaterial, as in religion or the patriarchal family; and composite, as in nations or civilizations. When a significant number of cultural forms of the first and second order change together (“synchronously”), the larger group or nation reaches maturity and ultimately declines. Cultural change is thus “selectively accumulative in time, and cyclical or oscillatory in character.” Nor, as some maintained, are these characteristics in opposition. Selective accumulation describes the “upward rise of the culture cycle,” but not the stages of equilibrium, strain, and disintegration. Unilinear evolutionists erred in assuming that all societies follow a universal evolutionary path. History, in short, does not repeat itself.

Behind Chapin’s countless distinctions and numerous charts lay two assumptions that reflected his postwar disillusionment. Just as unilinear evolutionism implied progress, so the cyclical view seemed to deny its possibility. The triumphs of human intelligence, whether in material or social invention, were subject to an unending cycle of growth and decay. The proliferation of material goods and new needs (consumerism, although Chapin did not use the term) created perennial “maladjustments.” Danger lay in the creation of “new social machinery” and in the breakdown of common standards and shared values. A second assumption, reaffirming the lessons of Karl Pearson, was that sociology should measure differential rates of change rather than explain underlying principles. Chapin did not entirely abandon his liberal faith in progress. Statistical measurement would provide the means of controlling cultural cycles, much as a thermostat regulates heating, and allow escape from history’s endless

cycle of rise and decline. The book’s frontispiece pictured the newly built Chicago Tribune Tower, a skyscraper with a Gothic exterior to illustrate Chapin’s hopeful thesis that change is cumulative. But, as historian Dorothy Ross has observed, its jarring image of flying buttresses atop a reinforced steel structure better dramatizes his uneasy coupling of historicism and instrumental positivism.

In *Social Forces* the same year, Chapin redefined social institutions in behavioral terms, building on the work of the psychologist Floyd Allport, among others. So conceived, a social institution such as family or church consists of four relatively rigid and persistent “type parts” functioning as a unit: attitudes and behavior (affection and reverence) symbols (wedding ring and cross), utilitarian material items (home furnishings and altar), and oral and written specifications (wills and creeds). This formulation differed from his earlier view in several ways. The unit of analysis was no longer “organic society” but the products of individual behavior (wearing a ring); institutions consisted of the interrelations of individuals (being loyal to others) rather than being an inevitable expression of the collectivity, and culture was learned behavior, not an irresistible force.

This sociological behaviorism led directly to new and more ambitious social measurement. The first, begun in 1926 and published 3 years later, examined student extracurricular activities. In this study and related follow-ups, Chapin and his associates concluded that student leaders have superior ability to think symbolically and abstractly, that grades measure these abilities, and hence that there is a high correlation between leadership and grades.

Chapin’s “living room scale” developed in stages, from work in seminars in 1926 through 1927 to a final revision in 1933. The initial study focused on 39 families, measuring four “objective” elements: cultural possessions (books, magazines), effective income, participation in community organizations, and “household equipment.” Points were assigned within each category (one point for membership in a community organization, for example, two for attendance, and so on). Social status was then computed within each category, and the rankings compared with one another and with rankings using scales proposed by earlier investigators. When further analysis revealed that “household equipment” correlated highly with other categories, Chapin decided this scale could stand alone as measure of social status. Chapin was not the first or only social scientist to measure social status quantitatively. His “living room scale” joined related attempts to measure “social distance” (Emory Bogardus), “social adequacy” (Thomas C. McCormick), and “social attitudes” (Floyd Allport and Louis L. Thurstone). But Chapin ranked high in the diligence with which he multiplied distinctions among household items. A fireplace with three utensils or an electric light was worth 8 points, and hardwood floors, 10. A kerosene heater, sewing machine, or alarm clock in

the living room cost 2 points. Chapin was aware that these judgments were culturally conditioned: a different scale would be needed for homes in China or India or for a different time in the United States. He insisted nonetheless that using objective factors to measure status avoided problems of interviewer bias and provided a valuable tool for social workers in placing children in foster homes.

Social Theory and Social Practice

Elected president of the American Sociological Society (ASS) for 1935, Chapin stood at the top of his profession. Beginning in 1923, he served on the editorial boards or as advisor to 13 scholarly journals, including the *American Sociological Review*, which he co-edited from 1944 to 1946 with his Minnesota colleague, George B. Vold. He was on the board or an officer of numerous organizations, including the American Council of Learned Societies (1919–1920), the Social Science Research Council (SSRC) (1923–1928), and the American Association for the Advancement of Science (vice-president, 1942). From 1926 to 1963, he was chief editor of *Harper's Social Science Series*.

As president of the ASS, Chapin helped launch the *American Sociological Review*, which, in 1936, replaced the Chicago-based *American Journal of Sociology* as the organization's official publication. In 1936, Chapin also led a move to found the Sociological Research Association (SRA), an invitation-only seminar of sociologists who wished to make the discipline more "scientific." Although the SRA was neither as exclusively empirical nor as elitist as some critics contended, it drew fire from dissidents who for several years had been working to make the ASS more open, democratic, and overtly reformist.

Returning to Minnesota in 1930 after the collapse of the *Abstracts* project, Chapin made quantitative work a department priority. Doctoral theses increasingly emphasized measurement rather than social movements or organizations; examples include Raymond F. Sletto's "Construction of Personality Scales" (1936) and Louis Guttman's "The Prediction of Quantitative Variates" (1942). Another graduate who earned distinction for statistical work was population expert Conrad Taeuber (Ph.D., 1931) of the U.S. Census Bureau. From the mid-1930s until his retirement, Chapin refined his earlier methods. In *Contemporary American Institutions* (1935), he expanded the institutional analysis developed in earlier articles. Repeating his distinction between "nucleated" (family, church, and local government) and "symbolically diffused" (art, mythology, and language) institutions, he focused exclusively on the former, the "core elements" of which were subject to precise measurement. He also anticipated a distinction between "manifest" and "latent"

functions, although not in the meaning it would eventually assume. For Robert Merton, whom Chapin met while teaching summer school at Harvard in 1935, a "latent" function was the unintended and unrecognized consequences of an activity for group adaptation (a Hopi rain dance, for example, which reinforces group identity). As reviewer Everett Hughes commented in the *American Journal of Sociology*, Chapin sometimes defined "latent" as secretive, hidden activity (bootlegging), and at other times as something not yet formulated (children learning a language, unaware of its grammar)—neither of which was Merton's definition.

These developments in Chapin's professional life and his scholarship took place against the background of the Great Depression, a nationwide economic collapse that convulsed the still-fragile discipline of sociology. Hard times meant salary cuts and a shrinking job market. Membership in the association plunged, as did sociology enrollments at many universities. Money put an edge on discussions of the Association's annual program, because having an official role was essential in getting a member's expenses paid. For proponents of scientific sociology, the Depression posed a special challenge. Expensive collaborative projects collapsed for lack of funds, *Social Science Abstracts* being an example. Demands for radical action from within the Association threatened to return sociology to the prewar reform tradition. Although Chapin's interest in social work and rural sociology tempered his calls for a value-neutral sociology, the narrowing of the sociologist's sphere of action became a subtext of many of his writings during the 1930s. In a 1934 symposium, he drew a sharp distinction between the "political-economic" and the "social" realms, effectively limiting sociology to the family, schools, churches, and welfare organizations. In his presidential address to the American Sociological Society in 1935, he distinguished between a "goal-directed" action and its "unintended consequences," a Weberian phrase also soon to be popularized by Robert Merton. Goal-directed action—planning—was the business of leaders; unintended consequences were the subject of social science.

By the mid-1930s, Chapin was also sympathetic to the operationalism of his former student George Lundberg. By "operationally," Chapin told colleagues at the ASS, he meant that "social concepts" must be defined "in terms of the operations and processes used in attempts to measure them or test them by experiment." Concepts not so testable were meaningless (for example the terms "social class, wage slaves, proletariat, bourgeoisie, socialite, aristocrat, plutocrat")—not by coincidence the rhetorical arsenal of the Left.

Chapin was ambivalent toward the New Deal. In *Contemporary American Institutions*, he cautiously applauded the experimentation of the "First New Deal" (1933–1935; the "planning" phase), but then analyzed

without refuting a long list of criticisms. He later termed Social Security a “patchwork” that had been created by a fusion of the “unexpressed wish fantasies” of the aged with modern communications. “Unplanned results” were bound to occur. By tracing these results, “non-normative theory” could provide the necessary check.

From Statistics to Social Experiments

During and after World War II, Chapin saw new opportunities for planning: measuring national morale, gauging psychological crosscurrents that might affect peacemaking, organizing postwar conferences, and facilitating postwar demobilization. Previously confined to communities and nations, social measurement was now a global priority. Against this background, Chapin moved in two directions. From 1941 to 1951, he was a contributing editor to *Sociometry*, a journal founded by Jacob Levi Moreno to study group dynamics. Chapin evidenced an interest in sociometry in the earlier sense of “social measurement” in his studies of classroom behavior, leadership, and conference procedures. He rejected, however, narrower definitions of sociometry as the quantification of informal friendship constellations (Moreno’s program), or as a therapeutic tool. An exception was an attempt in the *American Journal of Sociology* in 1950 to prove that individuals ranked sociometrically as “stars” or leaders were socially isolated and aloof, a conclusion that drew almost immediate criticism in a subsequent issue of the same journal. Chapin, the authors observed, was “an otherwise skilled social scientist who is relatively inexperienced in the sociometric field.”

In *Experimental Designs in Sociological Research* (1947), Chapin revisited the problem of providing controls in social experiments, no longer convinced that statistics could give a truly “scientific” result. “Experimental designs” required “experiment” and “control” groups to be determined by frequency distributions of designated traits. Comparisons could be made at a single time (“cross-sectional design”), “before” and “after” (“projected”), or after the fact, as an effect is traced backward to previous causes (“ex post facto”). Applying his method, he divided 102 former Boy Scouts into two groups: the first group consisted of those who dropped out of scouting after an average of 1.3 years; the second included those whose tenure averaged 4 years. These “control” and “experimental” groups were then paired by equating frequency distributions on place of birth, father’s occupation, health rating, and mental ability. After 22 cases were eliminated to make the groups equal, two groups of 40 were compared for performance in later life as measured by a “Social Participation Scale.” Although the methodology

grew ever more complex, the issue remained social adjustment. Whether the subject was “social insight,” the effects of good housing, active versus dropout scouts, or work relief, the conclusions were similar: people who join more organizations have higher social intelligence; persons affiliated with political, professional, social, and civic groups rank highest in social insight; good housing and active scouting foster adjustment; and work relief is better than the dole. Sociometry, as Chapin defined it in a 1943 article, was “essential to human adjustments in an expanding social universe.”

Evaluation and Legacy

Chapin’s critics increased in number as he approached retirement. Mathematicians took his “designs” to task for their statistical inadequacies and others questioned the possibility and utility of quantifying human experience. Interviewed by Chapin’s biographer Ronald Althouse in 1963, Malcolm Willey confided that Chapin was inadequately grounded in statistics, “simply mechanical” in his attempts to quantify cognitive concepts, and unaware of what his subject meant in “human terms.” Also speaking confidentially to the same interviewer, a second Minnesota colleague faulted the “absurdity” of attempting to understand a group through use of random sampling. A third wondered whether anyone really knew more about public housing or student extracurricular participation as a result of Chapin’s studies. Although Willey also conceded that Chapin uniquely “symbolized” the movement to sociological positivism, this muted praise, like the negative assessments of the other Minnesota colleagues, underestimated Chapin’s considerable influence over many decades. From the 1930s onward, studies of social status, participation and leadership, and housing policy—numbering in the dozens—routinely cited and built on his work. Among the most important were Louis Guttman’s refinement of the living room scale in 1942, Stuart Queen’s measurement of the relation between community disorganization and individual participation in 1949, and Robert Nash Parker’s use of more sophisticated measurement techniques in 1983.

Like Chapin’s contemporaries, historians of sociology have had mixed opinions regarding his work and its legacy. Writing in 1960, Minnesota sociologist Don Martindale was the first of several writers to grant Chapin a prominent role in the development of pluralistic behaviorism. In a laudatory doctoral dissertation, Ronald Althouse presented Chapin as a case study of the shift from the Protestant ethic to the scientific ethos. By the 1970s, opinion shifted. Radical sociologists Herman and Julia Schwendinger in 1974 lumped Chapin with other “liberal syndicalist” defenders of corporate capitalism, citing especially his dismissive analysis of social protest and

utopian theory. In his satirical study *Class* (1983), literary critic Paul Fussell presented a humorous send-up of Chapin's living room scale ("Identifiable Naugahyde aping anything customarily made of leather—subtract 3"). Historian Dorothy Ross (1991) included Chapin among American social scientists who turned to scientism to escape the Gilded Age crisis of liberal historicism that seemed to threaten the faith in American exceptionalism.

The fact that historians on the whole have accorded Chapin a relatively minor role in the shaping of the discipline in part reflects the fact that those with quantitative tastes are less inclined to write history. Reputation in sociology, Jennifer Platt has observed, often depends less on the merit of the quantitative work than the field in which it is applied, social work being a liability in Chapin's case. Like many scholars, Chapin's short-run influence was greater than his long-term reputation. But his were shoulders on which much important later work rested. As advocate, organizer, and exemplar of the interwar movement toward sociological positivism, Chapin had few if any peers.

Classical Test Theory

Wim J. van der Linden

University of Twente, Enschede, The Netherlands

Glossary

classical test model Two-level model for observed scores on a test, one level for the score of a fixed person and another for a random person from a population, underlying all derivations in classical test theory.

measurement error Difference between an observed score and a true score.

observed score Random variable representing the test score of a person.

reliability Extent to which the true score agrees with the observed score in a population of persons, measured by the squared linear correlation coefficient between the two.

true score Expected value of an observed score over replications of the test for a fixed person.

validity The degree of success in using the observed scores on a test to predict the score on an independent criterion, measured by the linear correlation coefficient between the two.

Classical test theory is a theory of measurement error. It is customary to consider the work of Charles Spearman, published in 1904, as the origin of this theory. In his paper, Spearman adopted the model of an observed score as a sum of a true score and an error, and showed how to correct the linear correlation between observed scores for their errors. This correction is now known as Spearman's correction for attenuation. The name "classical test theory" is somewhat misleading in that it suggests a theory for test scores only. The theory applies to any type of measurement for which the notion of random variation across replications is meaningful. In fact, it shares its formal structure with most of the theory of error for physical measurements commonly used in the natural sciences, but misses its notion of systematic error as well as the platonic interpretation of the true score associated with it.

Classical Model

Charles Spearman's 1904 model of an observed score as a sum of a true score and an error seems simple, but it initially generated much controversy and confusion. Spearman viewed observed scores as random, whereas others rejected this interpretation. But even among those who accepted the idea of randomness, there was much confusion between the notions of randomness of an observed score over replications and randomness due to sampling of persons from a population. Another debate was on the nature of the true score. According to some, it represented a property existing independently of the observed score (so-called definition of platonic true score), whereas others had difficulty with such obscure properties and wanted a more formal definition.

In 1996, Melvin Novick published an axiomatization of classical test theory (CTT) based on a minimal set of assumptions, in which CTT was treated as a theory for measurement error in a hierarchical experiment with two different levels—one level at which a random person is sampled from a population and another at which his/her observed score is obtained. Both levels involve separate model assumptions. Novick's assumptions were used in collaboration with Frederic Lord in their 1968 treatment of CTT.

Model for a Fixed Person

Let X_{jt} be the observed score of person j on test t . This score is viewed as a random variable with a distribution over replications of the test for j (sometimes referred to as propensity distribution). For most physical variables, measurements can be replicated, but for more psychological properties, replications are usually hypothetical. Humans are able to remember and learn between measurements, even though in practice it is seldom possible

to maintain exactly the same conditions. For the majority of variables in the social sciences, the only realization of X_{jt} is the single observed score at hand.

An observed score X_{jt} can be used to define the following two new quantities:

$$\tau_{jt} = \mathcal{E}(X_{jt}), \tag{1}$$

$$E_{jt} = X_{jt} - \tau_{jt}, \tag{2}$$

where $\mathcal{E}(X_{jt})$ is the expected value of X_{jt} . The first definition is of the true score for examinee j on test t , the second is of the error. Observe that τ_{jt} is fixed but E_{jt} is random. The definitions of τ_{jt} and E_{jt} are based on a convention. Nothing in the distribution of X_{jt} forces us to have an interest in its mean instead of, for example, its median. The distribution of E_{jt} follows directly from the arbitrary choice of true score.

The definitions in Eqs. (1) and (2) imply the following model for the score of a fixed examinee:

$$X_{jt} = \tau_{jt} + E_{jt}. \tag{3}$$

This model is nothing else than a representation of the two definitions in Eqs. (1) and (2). No separate assumption of linearity is made; the linearity in Eq. (3) follows entirely from the definition of E_{jt} as a difference. X_{jt} is defined on the scores U_i , $i = 1, \dots, n$, for n items in the test, often as a (weighted) sum of the scores. This definition does not need to be made for Eqs. (1) and (2). The definitions of a true score and error in CTT hold for any definition of observed score.

Model for a Random Person

At this level, the test is still considered as fixed, but the person is obtained by random sampling from a population. An extension of CTT to the case of random sampling of a test from a pool of items also exists (see below). Let J denote a random person sampled from the population and T_{jt} be his/her true score. This true score is also random. The observed score and error of a random person, X_{jt} and E_{jt} , now are random due to two different sources: one source is the sampling of the person from the population, the other is the “sampling” of an observed score from his/her distribution.

Due to sampling of persons, the model in Eq. (3) therefore becomes:

$$X_{jt} = T_{jt} + E_{jt}. \tag{4}$$

Again, the only additional assumptions needed to extend the model in Eq. (3) to this model for a random person is on the random status of its variables.

Summary

Let $F_{X_{jt}}(\cdot)$ be the distribution function of observed-score X_{jt} for a fixed person and $F_{T_{jt}}(\cdot)$ be the distribution function of the true score for the population of persons. The two models in Eqs. (3) and (4) can be summarized as the following two-level model:

$$X_{jt} \sim F_{X_{jt}}(x; \tau_{jt}), \tag{5}$$

$$\tau_{jt} \sim F_{T_{jt}}(\tau). \tag{6}$$

It is important to note that both distribution functions are unknown. Also, the presence of the true score τ_{jt} in the argument of the function for X_{jt} in Eq. (5) should not be taken to suggest that the observed-score distribution is a member of a parametric family indexed by it. It is necessary to know the distribution to identify this parameter, not the other way around. Additional assumptions that lead to known parametric families of distributions for Eqs. (5) and (6) are discussed in the context of stronger true-score theory (see later).

The model in Eqs. (5) and (6) is equivalent to a one-way analysis-of-variance model with random person effects, albeit that the latter is usually accompanied by the extra assumption of a normal distribution for X_{jt} . Observed scores are usually discrete and have a bounded range. The definition of the true score as an expected observed score implies the same range as for the observed score, but with real values. The error is also real valued, but its range runs between the maximum possible value of X_{jt} and its negative. Now that the score definitions in CTT have been made precise, for notational convenience, their indices, wherever possible, will be omitted.

Classical Theory

In spite of its almost tautological nature, it is amazing how many results relevant to measurement in the social sciences can be derived from the classical model in Eqs. (5) and (6). The goal of these derivations is “to derive unobservables from unobservables,” that is, to express unobservable quantities defined in terms of true scores and measurement error as functions of observables. The following equations are examples of results derived directly from the model in Eqs. (5) and (6):

$$\mathcal{E}(E_{jt}) = 0, \tag{7}$$

$$\sigma_{E_{jt}}^2 = \sigma_{X_{jt}}^2, \tag{8}$$

$$\text{Cov}(X_{jt}, X'_{jt}) = 0, \tag{9}$$

$$\text{Cov}(T, E) = 0, \tag{10}$$

$$\sigma_X^2 = \sigma_T^2 + \sigma_E^2, \tag{11}$$

and

$$\Pr\{X'_{jt} \leq x_o\} \geq \Pr\{X'_{jt} \geq x_o\} \quad \text{for } x_o \text{ large.} \quad (12)$$

The first three results show that, for a fixed person j , the expected error is equal to zero, the variance of the error is equal to the variance of the observed score, and the covariance between the observed score and a replication X'_{jt} is equal to zero. In all three equations, the left-hand side contains an unobservable quantity and the right-hand side contains an observable quantity. The result in Eq. (10) shows that the covariance between true scores and observed scores in any population is always equal to zero. The derivation of this result is less obvious, but it follows directly from the fact that Eq. (7) implies a horizontal regression line of X on τ . The zero covariance in Eq. (10) leads directly to the equality of the observed-score variance with the sum of the true-score and error variances in Eq. (11).

The property in Eq. (12) shows that if there is a large test score x_o and the test is replicated, it is more likely that a smaller (rather than larger) second score will be observed. (By a large test score is meant a score larger than the median; a comparable statement is true for a score below the median.) This simple property, which is a trivial consequence of the assumption of a random observed score, explains the often misunderstood phenomena of regression to the mean and capitalization on chance due to measurement error.

More useful results are possible if the observed score, true score, or error is used to define new test and item parameters. Such parameters are often defined with a practical application in mind (for example, item and test analysis, choice of test length, or prediction of success in a validity study). Some results for these parameters can be derived with the model in Eqs. (5) and (6) as the only assumption; for others, an auxiliary assumption is needed. A commonly used auxiliary assumption is the one of parallel scores on two measurement instruments. Scores X_t on test t and X_r on a second test r are strictly parallel if

$$\tau_{jt} = \tau_{jr}, \quad (13)$$

$$\sigma_{X_{jt}}^2 = \sigma_{X_{jr}}^2, \quad (14)$$

for each person j in the population. This definition equates the first two moments of the score distributions of all persons. Weaker definitions exist but are not reviewed here.

Reliability

A key parameter in CTT is the reliability coefficient of observed score X_{jt} . This parameter is defined as the

squared (linear) correlation coefficient between the observed and true score on the test,

$$\rho_{TX}^2. \quad (15)$$

Though this parameter is often referred to as the reliability of a test, it actually represents a property of the observed score X defined on the test. If the definition of X is changed, the value of the coefficient changes. The use of the correlation coefficient between X and T in Eq. (15) can be motivated as follows: If $\rho_{XT} = 0$, it holds that $X = T$ for each person in the population and X does not contain any error. If $\rho_{XT} = 1$, it holds that $X = E$ for each person and X contains only error. A squared correlation coefficient is used because of the standard interpretation of this square as a proportion of explained variance. From Eq. (11) it follows that

$$\rho_{TX}^2 = \frac{\sigma_T^2}{\sigma_X^2}, \quad (16)$$

which allows interpretation of the reliability coefficient as the proportion of observed-score variance explained by the differences between the true scores in the population.

One of the major uses of the reliability coefficient is for calculating the standard error of measurement, which is the standard deviation of errors in the population, σ_E . From Eqs. (11) and (16), it follows that

$$\sigma_E = (1 - \rho_{XT}^2)^{1/2} \sigma_X. \quad (17)$$

Internal Consistency

The internal consistency of a test is the degree to which all of its item scores correlate. If the correlations are high, the test is taken to measure a common factor. Index $i = 1, \dots, n$ denotes the items in the test; a second index k is used to denote the same items. A parameter for the internal consistency of a test is coefficient α , which is defined as

$$\alpha = \frac{n}{n-1} \left[\frac{\sum_{i \neq k}^n \sigma_{ik}}{\sigma_X^2} \right]. \quad (18)$$

This parameter is thus equal to the sum of the item covariances, σ_{ik} , as a proportion of the total observed score variance for the test (corrected by a factor slightly larger than 1 for technical reasons).

As will become clear later, a convenient formulation of coefficient α is

$$\alpha = \frac{n}{n-1} \left[1 - \frac{\sum_{i=1}^n \sigma_i^2}{\sigma_X^2} \right]. \quad (19)$$

For the special case of dichotomous item scores, coefficient α is known as Kuder–Richardson formula 20 (KR20). If all items are equally difficult, this formula

reduces to a version known as Kuder–Richardson formula 21 (KR21).

Validity

If a test score is used to predict the score on another instrument, e.g., for the measurement of future success in a therapy or training program, it is important to have a parameter to represent its predictive power. Let Y denote this other score. We define the validity coefficient for the observed test scores, X , as the correlation coefficient.

$$\rho_{XY}. \tag{20}$$

The reliability coefficient remains an important parameter in predictive validity studies, but the correlation of observed score X with Y , instead of with its true score T in Eq. (15), becomes the ultimate criterion of success for it in prediction studies.

Item Parameters

Well-known item parameters in CTT are the item-difficulty or item π value, the item-discrimination coefficient, and the item validity coefficient. Suppose that the items are scored dichotomously, where $U_i = 1$ is the value for a correct response to item i and $U_i = 0$ is for an incorrect response. The classical parameter for the difficulty of item i is defined as the expected value or mean of U_i in the population of examinees,

$$\pi_i = \mathcal{E}(U_i). \tag{21}$$

The discrimination parameter of item i is defined as the correlation between the item score and the observed test score,

$$\rho_{iX} = \text{Cor}(U_i, X) = \sigma_{iX} / \sigma_i \sigma_X. \tag{22}$$

where σ_{iX} , σ_i , and σ_X are the covariance between U_i and X , and the standard deviation of U_i and X , respectively. Analogously, the correlation between its score and observed score Y defines the validity parameter for item i :

$$\rho_{iY} = \text{Cor}(U_i, Y) = \sigma_{iY} / \sigma_i \sigma_Y. \tag{23}$$

Obviously, a large value for π_i implies an easier item. Likewise, a large value for ρ_{iX} or ρ_{iY} implies an item score that discriminates well between persons with a high and a low observed score X and criterion score Y , respectively. Because X is a function defined on the item-score vector (U_1, \dots, U_n) , the scores on all other items than i have an impact on the correlation between U_i and X too. It is therefore misleading to view ρ_{iX} as an exclusive property of item i . This

interpretation problem does not exist for the item-validity coefficient, ρ_{iY} .

It is helpful to know that the following relation holds for the standard deviation of observed score X :

$$\sigma_X = \sum_{i=1}^n \sigma_i \rho_{iX}. \tag{24}$$

Replacing σ_X^2 in Eq. (16) by the square of this sum of products of item parameters leads to

$$\alpha = \frac{n}{n-1} \left[1 - \frac{\sum_{i=1}^n \sigma_i^2}{\left(\sum_{i=1}^n \sigma_i \rho_{iX}\right)^2} \right]. \tag{25}$$

Using comparable relations, the validity coefficient can be written as

$$\rho_{XY} = \frac{\sum_{i=1}^I \sigma_i \rho_{iY}}{\sum_{i=1}^I \sigma_i \rho_{iX}}. \tag{26}$$

Except for the (known) test length n , these expressions for α and ρ_{XY} are entirely based on the three item parameters σ_i , ρ_{iX} , and ρ_{iY} . They allow evaluation of the effect of the removal or addition of an item to the test on the value of the internal consistency and validity coefficients. The application of CTT to test construction relies heavily on these two relations.

Key Theorems on Reliability and Validity

As examples of more theoretical derivations possible from the classical model in Eqs. (5) and (6), the following three theorems are presented:

$$\rho_{XT}^2 = \rho_{XX'}, \tag{27}$$

$$\rho_{XT}^2 \geq \alpha, \tag{28}$$

and

$$\rho_{XT} \geq \rho_{XY}. \tag{29}$$

The first theorem shows that the reliability coefficient of a test is equal to the correlation between its observed score X and the observed score X' on a replication of the test. This theorem is important in that it demonstrates again how CTT allows expression of an unobservable quantity, such as the squared relation between an observed and a true score, as a quantity that, in principle, can be observed.

Though $\rho_{XX'}$ is observable, for most psychological or social variables it is seldom possible to replicate an administration of the measurement instrument. For such cases, the second theorem is convenient. It shows that the reliability of an observed score can never be smaller than the internal consistency of the item scores on which it is calculated. Because coefficient α can be estimated from

a single administration of a test, we often resort to this relation and estimate ρ_{TX}^2 by an estimate of this lower bound. The bias in this estimate is only negligible if the test is unidimensional in the sense that it measures a single factor.

The third theorem shows that the predictive validity coefficient of a test can never exceed the square root of the reliability coefficient. This inequality makes sense; it implies that an observed score always correlates at least as well with its own true score as with any other observed score. It also illustrates the previous claim that, if the test is used to predict another score, the reliability coefficient remains important; high reliability is a necessary condition for high validity.

Test Length

If the length of a test is increased, its reliability is expected to increase too. A well-known result in CTT is the Spearman–Brown prophecy formula, which shows that this expectation is correct. Also, if the lengthening of the test is based on the addition of new parts with parallel scores, the formula allows calculation of its reliability in advance.

Suppose the test is lengthened by a factor k . If the scores on the $k - 1$ new parts are strictly parallel to the score on the original test according to the definition in Eqs. (13) and (14), the Spearman–Brown formula for the new reliability is

$$\rho_{ZZ}^2 = \frac{k\rho_{XT_X}^2}{1 + (k - 1)\rho_{XT_X}^2}, \tag{30}$$

where Z is the observed score on the new test and T_Z its associated true score.

Attenuation Corrections

As already discussed, attenuation corrections were the first results for CTT by Spearman in 1904. He showed that if we are interested in the correlation between the true scores T_X and T_Y and want to calculate it from their unreliable observed scores X and Y , the following relation can be used:

$$\rho_{T_X T_Y} = \frac{\rho_{XY}}{\rho_{XT_X} \rho_{YT_Y}}, \tag{31}$$

where ρ_{XT_X} and ρ_{YT_Y} are the square roots of the reliability coefficient of X and Y (also known as their reliability indices). If we want to correct the validity coefficient in Eq. (19) only for the unreliability of one score, Y , say, the correction is given by

$$\rho_{XT_Y} = \frac{\rho_{XY}}{\rho_{YT_Y}}. \tag{32}$$

This correction makes sense in validity studies, where we want to predict the true criterion score T_Y but always have to predict from the unreliable observed score X .

Parameter Estimation

The statistical treatment of CTT is not well developed. One of the reasons for this is the fact that its model is not based on the assumption of parametric families for the distributions of X_{jt} and T_{jt} in Eqs. (5) and (6). Direct application of standard likelihood or Bayesian theory to the estimation of classical item and test parameters is therefore less straightforward. Fortunately, nearly all classical parameters are defined in terms of first-order and second-order (product) moments of score distributions. Such moments are well estimated by their sample equivalents (with the usual correction for the variance estimator if we are interested in unbiased estimation). CTT item and test parameters are therefore often estimated using “plug-in estimators,” that is, with sample moments substituted for population moments in the definition of the parameter.

A famous plug-in estimator for the true score of a person is the one based on Kelley’s regression line. Kelley showed that, under the classical model, the least-squares regression line for the true score on the observed score is equal to

$$E(T|X = x) = \rho_{XT}^2 x + (1 - \rho_{XT}^2)\mu_X. \tag{33}$$

An estimate of a true score is obtained if estimates of the reliability coefficient and the population mean are plugged into this expression. This estimator is interesting because it is based on a linear combination of the person’s observed score and the population mean with weights based on the reliability coefficient. If $\rho_{XT}^2 = 1$, the true-score estimate is equal to observed x ; if $\rho_{XT}^2 = 0$, it is equal to the population mean, μ_X . Precision-weighted estimators of this type are typical of Bayesian statistics. For this reason, Kelley’s result has been hailed as the first Bayesian estimator known in the statistical literature.

Strong True-Score Models

To allow stronger statistical inference, versions of the classical test model with the additional assumption of parametric families for Eqs. (5) and (6) can be used. These models remain entirely within the framework of CTT; their main parameter and the classical true score are one and the same quantity. For this reason, they are generally known as “strong true-score models.”

Binomial Model

If the item scores are dichotomous, and observed score X_{jt} is defined as the number-correct score, the observed-score distribution can sometimes be approximated by the binomial with probability function

$$f(x) = \binom{n}{x} \pi_{jt}^x (1 - \pi_{jt})^{n-x}, \tag{34}$$

where π_{jt} is the binomial success parameter. For the binomial distribution it holds that $\pi_{jt} = \mathcal{E}(X_{jt})$, which proves that this distribution remains within the classical model. The assumption of a binomial distribution is strong in that it only holds exactly for a fixed test if π_{jt} is the common probability of success for j on all items. The assumption thus requires items of equal difficulty for a fixed test or items randomly sampled from a pool. In either case, π_{jt} can be estimated in the usual way from the number of correct responses in the test.

The assumption of a beta distribution for the binomial true score, which has density function

$$f(\pi) = \frac{\pi^{a-1} (1 - \pi)^{b-n}}{B(a, n - b - 1)}, \tag{35}$$

with $B(a, n - b - 1)$ being the complete beta function with parameters a and $b - n + 1$, is natural. The beta distribution is both flexible and the conjugate of the binomial. In addition, convenient closed-form estimators for its parameters exist. Finally, the validity of the two distributional assumptions can be checked by fitting a predicted observed-score population distribution, which is known to be negative hypergeometric, to a sample estimate.

Examples of stronger statistical inferences for the beta binomial model are with respect to the standard error of measurement for a person, which is the binomial standard deviation $[\pi_{jt}(1 - \pi_{jt})]^{1/2}$, and true-score population parameters, such as the population median, variance, and interquartile range.

Normal–Normal Model

Another strong true-score model is based on the assumptions of normal distributions for the observed score of a fixed person and the true scores in the population:

$$X_{jt} \sim N[\mu_{jt}, \sigma_{jt}], \tag{36}$$

$$\mu_{jt} \sim N(\mu_T, \sigma_T). \tag{37}$$

Parameter μ_{jt} in this model is also the classical true score. Further, the model allows for inference with respect to the same quantities as the beta binomial model. The normal–normal model has mainly been used to study sampling distributions of classical item and test parameters. The results from these studies provide only

a rough approximation of the empirical distributions. Observed scores are discrete and often have a bounded range; the assumption of a normal distribution cannot hold exactly for such scores.

Applications

The major applications of CTT are item and test analyses, test assembly from larger sets of pretested items, and observed-score equating.

Item and Test Analyses

Item and test analyses are based on a pretest of a set of items or a test. Such pretests yield empirical estimates of relevant item and test parameters, which can be inspected to detect possibly dysfunctional items or an undesirable feature of the test. Typical parameters estimated in item and test analyses are item difficulty and discrimination, test reliability or internal consistency, standard error of measurement, and validity coefficients.

Test Construction

If a larger set of items exists and a test of length n has to be assembled from this set, the usual goal is maximization of the reliability or validity of the test. The optimization problem involved in this goal can be formulated as an instance of combinatorial programming. Instead of optimizing the reliability coefficient, it is more convenient to optimize coefficient α ; because of Eq. (28), ρ_{XT}^2 is also optimized. Using the facts that n is fixed and

$$\sigma_X = \sum_{i=1}^n \sigma_i \rho_{iX}, \tag{38}$$

maximizing Eq. (19) is equivalent to minimizing

$$\frac{\sum_{i=1}^I \sigma_i^2 x_i}{(\sum_{i=1}^I \sigma_i \rho_{iX} x_i)^2}. \tag{39}$$

Because the denominator and numerator are based on expressions linear in the items, optimization is possible by solving a linear problem consisting of the maximization of

$$\sum_{i=1}^I \sigma_i \rho_{iX} x_i,$$

subject to the constraint

$$\sum_{i=1}^I \sigma_i^2 x_i \leq c, \tag{40}$$

with c a well-chosen constant. A comparable approach is available for the problem of optimizing the validity coefficient of the test in Eq. (20).

Test Equating

If a new version of an existing standardized test is constructed, the scales of the two versions need to be equated. The equating transformation, which maps the scores on the new version to equivalent scores on the old version, is estimated in an empirical study, often with a randomly-equivalent-groups design in which the two versions of the test are administered to separate random samples of persons from the same population. Let X be the observed score on the old version and Y be the observed score on the new version. In classical equipercentile equating, a study with a randomly-equivalent-groups design is used to estimate the following transformation:

$$x = \varphi(y) = F_X^{-1}[F_Y(y)]. \quad (41)$$

This transformation gives the equated score $X = \varphi(Y)$ in the population of persons the same distribution as the observed score on the old version of the test, $F_X(x)$. Estimation of this transformation, which actually is a compromise between the set of conditional transformations needed to give each person an identical observed score distribution on the two versions of the test, is sometimes more efficient under a strong true-score model, such as the beta-binomial model in Eqs. (34) and (35), because of the implicit smoothing in these models. Using CTT, linear approximations to the transformation in Eq. (41), estimated from equating studies with different types of sampling designs, have been proposed.

Current Developments

The main theoretical results for the classical test model were already available when Lord and Novick published their standard text in 1968. In fact, one of the few problems for which newer results have been found is the one of finding an approximation to the conditional standard error of measurement $\sigma_{E|T=\tau}$. This standard error is the one that should be used instead of the marginal error σ_E when reporting the accuracy of an observed score. Other developments in test theory have been predominantly in item-response theory (IRT). Results from IRT are not in disagreement with the classical test model, but should be viewed as applying at a deeper level of parameterization for the classical true-score in Eq. (1).

For example, it holds that

$$\mathcal{E}(U_i) = 1p_i(\theta) + 0[1 - p_i(\theta)] = p_i(\theta), \quad (42)$$

which shows that the IRT probability of success for a dichotomous model, $p_i(\theta)$, is the classical true score at item level. Likewise, it holds for the true score at test level that

$$\tau = \mathcal{E}\left(\sum_{i=1}^n U_i\right) = \sum_{i=1}^n [\mathcal{E}(U_i)] = \sum_{i=1}^n p_i(\theta), \quad (43)$$

which is the test characteristic curve (TCC) in IRT.

The IRT probability of success for a dichotomous model, $p_i(\theta)$, has separate parameters for the person and the item properties. Due to this feature, IRT is more effective in solving incomplete-data problems, that is, problems in which not all persons respond to all items. Such problems are common in test-item banking, computerized adaptive testing, and more complicated observed-score equating designs, compared to the randomly-equivalent-groups design.

Glossary

clinical psychology The application of psychological knowledge to a range of psychological and physical problems across the life span.

life span approach The study of development and change from infancy to old age.

psychotherapy The use of verbal and behavioral methods by skilled practitioners to help individuals improve or cope more effectively with a variety of personal and interpersonal problems.

reflective practitioner model The therapist's understanding of the personal issues and needs that arise in the practice of therapy, and appropriate action taken to work on such issues.

scientist-practitioner model The application of psychological knowledge in the formulation of psychological problems following a strategy of hypothesis testing, monitoring, evaluation, and assessment of interventions and outcomes.

Clinical psychology is the application of psychological knowledge to a wide range of mental and physical problems across the life cycle, across a range of different client groups, and in a wide range of settings, with its primary focus being on the individual.

Introduction

Clinical psychology is a subject that focuses on the psychological (that is, the emotional, biological, cognitive, social, and behavioral) aspects of human functioning in

varying socioeconomic, clinical, and cultural groups as well as in different age groups. This life span approach necessitates a focus on developmental psychology as well as on the dynamics of change for behavior, emotion, and cognition. The aim of clinical psychology is to understand, predict, and treat or alleviate disorders, disabilities, or any kind of maladjustment. This aim involves a variety of clinical specialities and competencies, such as the assessment of problems or impairments, the formulation of problems (which is linked to clinical judgment), and the indicated treatments for these problems. A second aim is to act on a preventative level to promote human adaptation, adjustment, and personal development, thereby placing a focus also on the prevention of mental health conditions.

In relation to the type of professional work involved, "clinical psychology" is an umbrella term that defines a collection of possible but not necessary theories and activities, akin to Wittgenstein's definition of "game." Wittgenstein argued that, although we all understand the concept, there are no essential defining criteria for "game," because there is always an example of a game to which any individual criterion does not apply. We suggest that the theory and practice of clinical psychology also have such problems of definition. Despite the plethora of evidence that has arisen from basic psychology, clinical psychology is inherently an area of applied research, which transfers findings into practice. It refers to direct work with clients and indirect work through other professionals, carers, and policy-related constructs. The professional practice of clinical psychology has now been defined in most countries to include specified training routes, registration of practitioners, and continuing professional development.

Clinical psychologists are involved in research, teaching and supervision, program development and evaluation, consultation, public policy, professional practice, and other activities that promote psychological health in individuals, families, groups, and organizations. Clinical psychology practitioners work directly with individuals at all developmental levels (infants to older adults), as well as with groups (families, patients of similar psychopathology, and organizations), using a wide range of assessment and intervention methods to promote mental health and to alleviate discomfort and maladjustment. This work can range from prevention and early intervention of minor problems of adjustment, to dealing with the adjustment and maladjustment of individuals whose disturbance requires them to be institutionalized. In terms of work settings, these include individual practice, mental health service units, managed health care organizations, counseling centers, and different departments in hospitals, schools, universities, industry, legal systems, medical systems, and government agencies.

Background

Historically, psychology was considered academically as a component of philosophy until the late 19th century; a separation arose through the application of the scientific empirical method. The scientific empirical method replaced philosophical analysis as the primary method for approaching problems and added an additional source of information linked to the hermeneutic (interpretive) method in order to gain insight. Wilhelm Wundt established the first psychological laboratory in Leipzig in 1875; his influence was widespread initially in Germany, but this spread quickly to Britain and the United States, where psychological laboratories were established along the lines of Wundt's model in Leipzig. A student of Wundt's, Lightner Witmer, coined the term "clinical psychology," which he defined in 1895 as follows: "While the term 'clinical' has been borrowed from medicine, clinical psychology is not a medical psychology. I have borrowed the word 'clinical' from medicine, because it is the best term I can find to indicate the character of the method, which I deem necessary for this work. . . . The term 'clinical' implies a method, and not a locality. Clinical psychology likewise is a protest against a psychology that derives psychological and pedagogical principles from philosophical speculations and against a psychology that applies the results of laboratory experimentation directly to children in the school room."

Strongly under Wundt's influence, Witmer founded the first psychology clinic in Philadelphia in 1896 and applied the scientific method and knowledge of psychological principles to a range of psychological problems,

particularly developmental disorders. The hermeneutic approach has been revived in the emergence of psychoanalysis—less, however, in its philosophical tradition, but more in terms of its meaningfulness for inference in clinical practice. Since the beginning of the 20th century, clinical psychology has grown considerably in theoretical scope and application, and as a consequence different types of measurement have evolved.

Theory

Clinical psychology has been an area that has incorporated the approaches and perspectives of diverse, even contradictory, schools of psychology, including behaviorism, psychoanalysis, cognitive psychology, humanism, and systems approaches. Each of the schools incorporates a wide variety of theoretical models and empirical evidence from a particular domain, such as the biopsychosocial domain, the behavioral domain, the cognitive—emotional domain, and the psychodynamic domain. The models developed in these schools can best be understood as "paradigms" because they employ an exclusive language code and are based on common assumptions.

Traditionally, the most widespread paradigm in psychopathology and theory is the psychoanalytic, or psychodynamic, paradigm, originally developed by Freud. The essential assumption within psychodynamic theories is that psychopathology arises from unconscious conflict. On the other hand, the biological paradigm of abnormal behavior is a broad theoretical perspective; it assumes that mental disorders are caused by aberrant somatic or biological processes. This paradigm has often been referred to as the medical, or disease, model. The learning (behavioral) paradigm assumes that normal and abnormal behaviors are learned and acquired through experience, or shaped by environmental stimuli. Emotional and cognitive approaches have in some ways evolved as a response to these contradictory approaches, with a combination of focus both on the inner world and on the outer world. Apart from these "paradigms," a variety of internal and external processes (related to cognition and emotion) may also be used to explain the psychodynamic responses between external stimuli and inner conflicts.

In addition to the basic psychological models within each of the schools of clinical psychology, a variety of integrative approaches now span different schools, and are often pervasive in scope. For example, theories and models of emotion regulation, attachment, learned helplessness, and self-control have expanded from a distinct area of interest to the development of sets of common psychological principles. Some of these models are selectively outlined in the following discussions, in order to show how the theories of different schools can be combined into integrative models.

The first example is that of emotion regulation, which refers to the way different types of emotions are evoked in a person by different kinds of events or by actions of others, how these emotions are experienced, processed, expressed, and communicated to others, and how these emotions affect cognition. From a cross-cultural point of view, emotion theorists have long emphasized that emotion regulation is widespread among adults in different cultures. The universal aspects of emotional experience and expression are likely to be associated with biological factors and common social experience, because even very early in child development, children develop a sophisticated arsenal of emotion regulatory strategies. By adulthood, managing personal feelings would seem a natural candidate for the growing list of automatic responses that people draw on in everyday life, and would seem so overlearned that such strategies would have a strong impact on cognition and behavior. However complex the dynamics, the manner in which external responses regulate internal emotion processes also opens the way for clinical therapeutic interventions, given the fact that most emotions are elicited in the close relationships with which the therapies are concerned.

It is on the interpersonal dimension of emotions that attachment theory focuses. Attachment theory describes the propensity to form close relationships with others and the way emotions are regulated in these attachment relationships. This theory reduces the scope of emotion to those feelings that are experienced in attachment relationships. It has strong ethological underpinnings, but it has been rediscovered in psychoanalytic, interpersonal, and in cognitive behavior theories because the model can also explain key reactions in the psychotherapeutic relationship. Psychoanalysts have referred to these concepts in theories as “affect regulation,” whereas “emotion regulation” is more a term used in cognitive behavioral psychology.

A third example is that of a behavioral theory, which has had quite widespread influence in the “learned helplessness” paradigm. As a behaviorist, Martin Seligman formulated the learned helplessness theory in 1975; this had a major influence on the psychological research on depression in the 1970s. Seligman identified and defined the phenomenon of learned helplessness through the laboratory study of the effects of inescapable shock on active avoidance learning in dogs. Seligman found that prior exposure to inescapable shock interfered with the ability to learn in a situation in which avoidance or escape was possible. It is important to appreciate that cognition has been at the heart of Seligman’s and others’ subsequent development of the theory; thus, learned helplessness affects other psychological processes, such as motivation (resulting in reduced positive motivation with no incentive to try new coping responses), cognition (resulting in an inability to learn new responses to overcome prior

learning that trauma is uncontrollable), and emotion (the helpless state resembles depression). Seligman and subsequent researchers found a strong relationship between learned helplessness and human depression because there are similarities between helplessness and the symptoms of depression in humans. The theory has since been used as a paradigm for combining behavior, cognition, and emotion into integrative models.

Assessment

Assessment in clinical psychology involves determining the nature, causes, and potential effects of personal distress, types of dysfunctions, and psychological factors associated with physical and mental disorders. It involves the statistical, methodological, research, and ethical issues involved with test development and use, as well as their proper application in specific settings and with specific populations. The development, use, and interpretation of tests based on psychological theory, knowledge, and principles have seen considerable expansion and effort in the past 10 years. The ongoing advances in scientifically based assessment systems, computer technology, and statistical methodology, the increasingly sophisticated uses of psychological instruments in clinical settings, and the widespread use of psychological tests in making decisions that affect the lives of many people have created an exponentially growing body of knowledge and practice that requires the expertise of the assessment specialist. The complexity of the dimensions and tasks in clinical psychology has necessitated development of a wide range of methods of assessment, each appropriate to the different needs of basic psychology. There is no other field that utilizes such varied assessment approaches; these include unstructured and structured clinical assessment and rating approaches, observational methods (including audio/video), psychometric normative attitudinal assessment, neuropsychological standardized tests, and physiological methods. The potential strength of the diversity of methods is that rather than relying on one particular type of approach, the comparison of different sources of information allows a much more complex insight into a disorder or problem.

This variety of assessment forms has evolved from the problem that inner states are not directly observable. It is this problem that caused a dialectic between the nomothetic versus idiographic approach in clinical psychology. The nomothetic strand relies exclusively on the normative approach toward measurements—that is, by drawing references from any kind of a norm group in regard to the respective traits or state under consideration; moreover, all individuals have a score or value on a nomothetic test. The normative reference might include a variety of standardized approaches (population, subpopulation,

clinical subgroups, or age groups). An example is Costa and McCrae's NEO, the most widely known nomothetic test that measures the so-called "big five" personality traits, the factors of neuroticism, extroversion, openness ("NEO"), agreeableness, and conscientiousness. In contrast, the idiographic approach rejects the potentiality of drawing normative references along traits that are applicable to all, but, instead, argues that the only method to gain insight into inner states is through the unique personalized assessment of each individual and their relevant experience. An example of an idiographic assessment method is Kelly's repertory grid technique in which bipolar constructs are elicited; these may be unique to the individual (e.g., an individual sees the world on a dimension such as "good" vs. "fat") and not applicable to others. The two empirical approaches to personality assessment, nomothetic and idiographic, are contradictory. The dialectic between the two approaches is a typical phenomenon that occurs regularly in clinical and other branches of psychology. One suggestion is that it is the interlinking of these approaches within a dialectical approach that provides the most comprehensive coverage and inclusiveness in assessment, both theoretically and practically. As an example, the repertory grid technique can be modified to include nomothetic constructs that are measurable across all respondents (e.g., "stable-neurotic"), in addition to the unique constructs elicited from a particular individual.

Interrelated with these two ways of gaining an understanding of a person's inner states are methodological issues and problems involved in clinical psychology. From a methodological point of view, quantitative approaches have been distinguished from qualitative approaches. Quantitative approaches are based on empirical methods, measurement, and statistics whereas qualitative approaches follow a heuristic empirical approach. Clinical psychology needs criteria to judge the quality of the clinical assessment obtainable from either approach. Because inner processes are not directly observable, quantitative measures can only approximate some "true state of the individual," and so qualitative criteria for the psychometric methods employed are needed. Classic psychometric theory has developed a number of criteria that indicate how objective, reliable, and valid psychometric instruments are. The reliability of a method indicates how precisely a measure assesses a construct; it refers to two types—the internal consistency of a measure and the stability of a measure when repeated across time. The validity of a measure indicates to what extent the underlying construct is genuinely measured. Validity is a complex concept and has many subtypes. A diagnosis, for instance, may have concurrent and discriminant, as well as predictive, validity. A clinician's diagnosis has concurrent validity, for instance, if other symptoms that are not part of the

diagnosis substantiate the diagnosis (for example, when measured by a self-report scale or a structured interview, which act as a "criterion" for the diagnosis). Discriminant validity indicates that the measure is not related to measures of conceptually unrelated concepts. Predictive validity refers to the ability to predict similar future behavior as part of the disorder (for example, if a hopelessness scale predicts future parasuicidal behavior). The different psychometric criteria are not independent of each other, because reliable measurement is based on objective assessment and the superior criterion of validity can be achieved only with measures that are already reliable; thus, if a measure of diagnosis has poor interrater or test–retest reliability, then the measure would automatically fail to have validity.

Modern psychometric theory has provided probabilistic methods to ascertain whether sets of items that are theoretically assumed to pertain to underlying dimensions can meet the requirements of fundamental measurement (invariance across items and persons), with item and person estimates on the same continuum being the defining parameters. The theoretical field has evolved as item response theory (IRT), the most prominent model of which is the Rasch model. These models can be used with both self-report and observer report methods.

Neuropsychological testing forms another major area of development in clinical psychology. Initially, such tests tended to focus on a unitary concept of intelligence or intellectual functioning, based on the early education-based work of Alfred Binet in France. Binet introduced the concept of the intelligence quotient (IQ) at the beginning of the 20th century and it has been highly influential, albeit controversial, ever since. In relation to neuropsychological assessment, however, the concept of unitary IQ is of little value, because the same overall score can be achieved by a variety of means; thus, similar scores across a range of subtests would lead to the same overall score, as high scores on some subtests and as low scores on others, the latter pattern perhaps providing more diagnostic information from a neuropsychological assessment perspective. Modern neuropsychological assessment has therefore come to focus on increasingly specific tests of function, such as tests of attention, memory, learning, visuospatial performance, and so on. Such tests highlight the fact that some cognitive functions may be impaired while other related ones may not be, which suggests different brain organization (either structurally, functionally, or an integration of both) for such functions. When combined with recently developed neuroimaging methods such as magnetic resonance imaging (MRI), computer-assisted tomography (CAT), and positron emission tomography (PET), it is clear that significant advances will be made in the next decade in relation to understanding brain structure and function and using this information in clinical therapies.

Treatment and Intervention

The variety of theoretical approaches developed both within and in areas adjoining clinical psychology has led to a number of major treatment innovations (for example, behavior therapy, cognitive therapy, person-centered therapy, interpersonal psychotherapy, and psychodynamic approaches). One of the key generic contributions of clinical psychology across this range of interventions has been that of the application of theory-based psychological principles to individual cases, incorporating salient features of individual history and etiology. Theory-based developments in behaviorism, cognitive psychology, and psychoanalysis have led to developments in interventions based on these models.

Behavior therapy was derived primarily from the theoretical developments of Pavlov, with classical conditioning, and Skinner, with operant conditioning. The two-factor theory of Mowrer combined these two approaches in 1939 to demonstrate how fear can be acquired by classical conditioning (typically, the experience of a traumatic or aversive event) and maintained by operant conditioning (such as avoidance of trauma-related events or situations). Subsequent behavior therapy approaches, such as developed by Wolpe, sought to combine increasing trauma-related anxiety while preventing avoidance, in order to demonstrate that anxiety will decrease naturally without the need for avoidance. Although Wolpe initially focused on anxiety arousal in imagination, behavior therapists have instead come to use more direct methods of exposure to events and situations.

Limitations of behavior therapy became apparent not only from further studies of fear acquisition by Rachman and others, but also from attempts to apply behavior therapy to other disorders such as depression. For example, key aspects of depression, such as low self-esteem, suicidal ideation, guilt, and sadness, are not explicable within the behavioral approach. Cognitive and cognitive-behavioral approaches began to be developed in the 1960s and 1970s, with the major approach being the cognitive therapy approach of Beck in 1976. Cognitive therapy aims to identify and challenge depression-related thoughts and beliefs that contribute to the onset and maintenance of depression; such thoughts and beliefs typically center on the need to be loved and taken care of, and the need for achievement and success. The occurrence of critical life events that threaten these fundamental beliefs, such as the separation or loss of a love partner, or failure in an achievement-related domain, is considered to lead to depression; the aim of therapy is therefore to help the individual modify the overinvestment in these beliefs and to develop more appropriate coping strategies and deal more effectively with future adversity. The success of Beck's cognitive therapy for dealing with depression has resulted in its adaptation for the treatment of

a range of other conditions, such as anxiety disorders, personality disorders, and, more recently, schizophrenia and bipolar disorders.

As noted previously, clinical psychology perhaps has made the least contribution to the development of psychodynamic approaches, in part because of the strong emphasis of the experimental psychology approach in clinical psychology, combined with Freud's dismissal of the experimental approach as being irrelevant to psychoanalysis. Notwithstanding this potential conflict, many clinical psychology practitioners in North America have been heavily influenced by psychoanalysis and have helped contribute to North American developments in understandings of self and social factors in the theory and practice of psychodynamic approaches. For example, the development of short-term approaches to therapy, as in the increasingly influential interpersonal psychotherapy approach, has stemmed from these multiprofessional North American influences. In contrast, the development of clinical psychology in the United Kingdom and other Northern European countries has focused primarily on behavior therapy and cognitive behavior therapy, so it is only more recently that psychodynamic approaches have come to play a role in those countries. Nevertheless, the practice of cognitive behavior therapies has come to recognize the need to address the therapeutic relationship and problems in this relationship, especially because these approaches have been extended to cover more long-term chronic disorders, such as those seen in individuals with personality disorders.

The initial focus in clinical psychology on individual mental health has subsequently expanded so that therapeutic interventions are now offered for a range of disabilities, including learning difficulties and physical disabilities. The life span approach now also includes a range of interventions for children and adolescents and for older adults. Moreover, there is also a diversification beyond individual approaches to include group as well as family therapy and organizational level interventions. There is, therefore, a considerable overlap in activities between clinical psychology and psychotherapy, counseling, and aspects of psychiatry, nursing, psychosomatics, and health psychology. Many of the methods developed by theorists and practitioners in each of these groupings are widely used by others. Clinical psychologists also engage in program development, evaluate clinical psychology service delivery systems, and analyze, develop, and implement public policy in all areas relevant to the field of clinical psychology. National psychological associations set the standards for clinical psychology graduate programs and recognize programs meeting these standards through an accreditation process. In all states in North America, practitioners require a license to practice clinical psychology, and most European countries either have statutory registration requirements following

defined training pathways, or are in the process of implementing registration policies for clinical psychologists and psychotherapists.

Applied Research

In the spirit of Lightner Witmer's experimental influence, the so-called scientist-practitioner model was formulated at a meeting in Boulder, Colorado in 1947. The scientist-practitioner model is based on the proposition that clinical practice must be based on systematic experimental investigation into psychopathology, assessment, and intervention. It supports empirically based clinical practice as well as the training of clinical psychology students in the methods of scientific investigation and decision making, and their application to practice. Training in clinical psychology therefore has an emphasis on research skills, which now go well beyond the specifics of the behaviorally dominated Boulder model to include methods such as single-case quasi-experimental designs, longitudinal research, clinical outcome studies, randomized controlled trials, survey methods, and so on. This broad research training cuts across quantitative and qualitative methods and provides clinical psychology with an ever-increasing role in applied research, especially in North America.

Current and Future Developments

The current and future areas of development in clinical psychology are too numerous to itemize, but a few examples can be highlighted from different areas. Clinical psychology evolved primarily within the area of mental health and mental disorder, and there is a continuing advancement of methods for working with the more chronic and severe mental health problems as seen in schizophrenia, bipolar disorders, and personality disorders. However, considerable advances have also been made in the treatment and management of somatic conditions, dealt with in the fields of psychosomatics, medical psychology, and health psychology, each placing a focus on either particular diseases, the medical setting, the entire health care system, or the prevention of disorder. In general, these fields describe etiology and symptomatology, as well as diagnostic and intervention approaches in (1) psychosomatic disorders, (2) comorbid mental disorders, (3) specific psychological problems in the medical field (e.g., in dermatology and gynecology), (4) problems evolving as a consequence of the interaction with modern medical technology, (5) alleviating the coping processes with medical conditions, and (6) the area of prevention of medical conditions (e.g., through interventions on lifestyle and health behaviors). These fields are extremely

important given the increasing occurrence of epidemics such as diabetes, obesity, and coronary heart disease. It has been well demonstrated that most of these conditions are related to individual risk factors, mainly associated with health behavior. It has also been recognized that these risk factors are related to certain styles of emotion regulation, which offer extensive scope for the development of further interventions. The more recent focus on prevention shifts away from the previously exclusive focus on abnormal behavior to encompass the entire spectrum of variation in behavior and attitudes toward health and well being.

Summary and Conclusions

The aim here has been to convey something of the range and diversity of theory and practice in clinical psychology. From its origins just over a 100 years ago as an experimental clinical method, clinical psychology has expanded to cover a vast range of often contradictory and conflicting methods. Sometimes the applied nature of the subject has led to pragmatic integrations, such as the originally conflicted areas of behaviorism and cognitive psychology, which are now integrated in the cognitive-behavioral therapies. However, there is no area of clinical psychology theory or practice that is not opposed in one way or another by a different viewpoint; examples include the opposition between behavioral and psychodynamic approaches, between qualitative versus quantitative research methods, between the scientist-practitioner versus other models of training and practice, and between curative versus preventative services and in regard to the format of therapy, the location of delivery of services, and so on. Although at times each of the factions has been extreme and destructive (e.g., Hans Eysenck's vitriolic attacks on psychoanalysis), nevertheless, the creative tension and energy resulting from differences in perspective have led clinical psychology to offer an increasing number of areas of innovation in both theory and practice in health care taken in its broadest sense.

Glossary

agglomerative algorithms Hierarchical clustering algorithms that begin with each entity as its own (singleton) cluster and then iteratively merge entities and clusters into a single cluster, constituting the entire group of entities.

divisive algorithms The reverse of agglomerative algorithms; begins with the entire set of entities as one cluster, which is then iteratively divided (usually bifurcated) until each entity is its own (singleton) cluster.

hierarchical clustering The most commonly used form of clustering in the social sciences, probably because of widely available software and the resultant dendrograms (inverted tree structures). The only form of pairwise overlap of clusters allowed is that one must be a proper subset of another.

multidimensional scaling A wide variety of techniques, usually leading to representation of entities in a coordinate space of specified dimensionality.

overlapping clustering In contrast to hierarchical clustering, entities may simultaneously be constituent members of more than one cluster. Hierarchical clustering is subsumed as a special case.

partitioning clustering Each entity belongs to exactly one cluster, and the union of these clusters is the complete set of entities.

Clustering should be among the first multivariate data analysis techniques employed in attempting to identify

homogeneous groups, equivalence classes, or multimodal data. A cluster is usually a subset of the n entities under consideration, but what constitutes a cluster is generally defined, sometimes only implicitly, by the method of clustering used in the data analysis. John A. Hartigan's explanation, "Clustering is the grouping of similar objects . . . [and] is almost synonymous with classification," slightly oversimplifies the matter. Though there is no single problem or purpose that requires the development and use of cluster analysis, the empirical use of cluster analysis is overwhelmingly more exploratory than confirmatory, and as such is closely related to the approach presented in Phipps Arabie and Lawrence Hubert's *Clustering and Classification*.

Relevant Types of Data

Users of cluster analysis are often confused by compatibility between data types and types of cluster analysis. Because the literature of statistics sometimes increases the confusion, it is helpful to summarize a multidimensional scaling taxonomy developed by J. Douglas Carroll and Phipps Arabie. There are two types of matrices, (a) one with n rows and an equal number of columns, with entries depicting direct judgments of pairwise similarities for all distinct pairs of the n objects (e.g., people, products, stimuli, or other discipline-specific names), and

(b) the other matrix with n rows of objects and m columns of attributes of the objects. Although both matrices have two ways (i.e., rows and columns for the entities being clustered), the first type of matrix (a) is called “one mode,” because both of its ways correspond to the same set of entities (i.e., the n objects). But the matrix (b) of objects, by their attributes, has two disjoint sets (and thus two modes of entities corresponding to the ways). It is often necessary to compute an indirect measure of proximity (e.g., Euclidean distances) between all pairs of rows/columns in a two-mode, two-way matrix to convert it to a one-mode, two-way matrix, because the method of clustering intended for the analysis can only accept a one-mode matrix. Omission of explicit statements about this distinction has clouded much of the literature of cluster analysis and has even led designers to make serious errors; in widely circulated software, John Gower devised a measure explicitly designed for mixed data (over scale types, discrete versus continuous, etc.) commonly encountered in the behavioral sciences. Unfortunately, most statistical software packages do not include a provision for computing Gower’s coefficient, and consequently it has been greatly underemployed.

Hierarchical Clustering

Another important distinction is the degree of overlap allowed by the method of clustering. For “hierarchical clustering,” the traditional requirement is that in any two distinct clusters, one is either a proper subset of the other (“nesting”) or there is no overlap at all. Most hierarchical methods assume a one-mode, two-way input matrix; the highly popular method developed by Joe H. Ward is a major exception. In agglomerative algorithms for hierarchical clustering, the algorithm begins with each of the n objects as a singleton cluster and then begins amalgamating the objects into clusters, according to which pairs of objects or clusters are most similar if the data are similar (as in correlations) or least dissimilar (as in distances). The process continues stepwise until the result is only one cluster containing the entire set of the n objects. Divisive algorithms take the opposite route, beginning with one cluster and stepwise splitting it successively until only singleton clusters remain. Deciding on where in the resulting chain of partitions is the “right” place to claim as the final solution is generally an unsolved problem, with a solution usually dictated by the user’s fiat, typically toward a comparatively very small number compared to n . The results of this iterative formation of a hierarchically nested chain of clusters are frequently represented in output from statistical software as a “dendrogram,” or inverted tree, often printed in “landscape” (i.e., horizontal) format for mechanical reasons. This dendrogram can

be implemented in two ways. Using the full tree is the less common way and possesses two caveats: (1) for most methods of clustering, the terminal nodes (i.e., the singleton clusters) have no preferred ordering and can readily be pivoted around the internal nodes, and (2) if the dendrogram is very complex and cannot be printed legibly, some software simply omits some of the bifurcations that give rise to the internal nodes. The user consequently receives no indication of which bifurcations were omitted or why. The most common use of a dendrogram is to find a horizontal “slice” that necessarily yields a partition with an implicit choice of the “right” number of clusters.

For decades, there was much folklore surrounding the relative advantages and disadvantages of agglomerative versus divisive algorithms for hierarchical clustering, and confusion about the topic still reigns in many textbooks. The former algorithms are more useful for pedagogical reasons, and can even be carried out manually for small data sets. For large data sets (e.g., $n > 100$), divisive algorithms can be easier to use because their graph-theoretic analogues are available in large-scale software. The choice between algorithms has always been overblown. Nicholas Jardine and Robin Sibson have introduced a useful distinction between methods of clustering and the algorithms for implementing clusters: “It is easy to show that the single-link method, for example, can be implemented by a divisive algorithm, an agglomerative algorithm, or by an algorithm which belongs to neither category.” The three most commonly used hierarchical methods are complete link, average link, and single link (for which there are various synonyms across disciplines, especially in the behavioral sciences). Although the single-link method is often favored by biologists, it rarely produces substantively interpretable results in the behavioral sciences, where complete- and average-link methods have been found superior. Most of the various linkage types of hierarchical clustering can be subsumed by the classic algebraic formulation of G. N. Lance and William T. Williams that, although not computationally very efficient, nonetheless provides theoretical insights into how various types of hierarchical clustering are interrelated.

What Is the “Right” Number of Clusters?

Deciding on an appropriate number of clusters, as well as choosing the “appropriate” number of dimensions for a multidimensional scaling solution and other techniques for multivariate data analysis, are problems shared by both hierarchical and partitioning clustering. It seems apparent that the general problem for clustering will never be analytically solved (especially for large data

sets), but various heuristic approaches are used and/or proposed for answering the question of what is the correct number of clusters for any given data set, for various methods of clustering. The situation is worsened by the fact that many approaches to clustering are based not on any explicit model but rather on an available algorithm. There is thus no goodness-of-fit measure to be optimized.

Additive Trees and Network Models

Some methods of hierarchical clustering have been generalized to “additive trees” and other somewhat related graph-theoretic network models. These methods often assume a one-mode, two-way matrix and entail sophisticated algorithms. Fortunately, at least one generally available software package (SYSTAT) includes such an algorithm for users’ analyses when additive trees are sought.

Partitioning

For some researchers, “clustering” is (erroneously) synonymous with partitioning, which allows no overlap: each object is in exactly one cluster and no overlap is allowed among clusters. Most algorithms to implement partitioning assume a two-mode, two-way input matrix and are variations of MacQueen’s K-means approach. Many applications of partitioning involve hundreds of thousands of objects and there is the major problem of finding a globally optimal representation. Few methods of clustering can guarantee a global, as opposed to a merely local, optimal solution that is computationally feasible, and the resulting partition is highly dependent on the starting configuration, which may either be random, supplied by an earlier analysis using hierarchical clustering, or based on some other strategy. It therefore sometimes becomes necessary to repeat the analysis with different starting configurations and then to attempt to decide which solution is “best” in some sense. Moreover, few methods of clustering of any kind can obtain a global optimum unless the data set is very small and/or complete enumeration (possibly implicit, as in dynamic programming) is used.

Overlapping Clustering

There is a fourth approach, overlapping clustering, which in turn has two variations: discrete versus continuous. In discrete clustering, an object may simultaneously belong to more than one cluster and membership within a cluster

is all-or-none. Some of these approaches also estimate numerical weights for the clusters, the number being specified by the data analyst. Many methods of such overlapping clustering assume one or more two-way, one-mode matrices. In continuous clustering, one common approach is “mixture” models, which assume the data (generally two-way, two-mode) are inherently multimodal. Mixture methods attempt to identify these modes and then assign a probability of membership in each mode for each of the n objects. There are many different approaches (mostly parametric) to mixture models and consequently a burgeoning literature on that approach to clustering.

Consensus Clustering

For hierarchical and for partitioning clustering, it is common to obtain several different clusterings, using different methods, and then use logical algorithms to form a “consensus” clustering. Not surprisingly, the literature on such algorithms is often closely related to that of rules for voting or social choice.

Hybrid Approaches to Clustering and Multidimensional Scaling

Work on “hybrid” approaches simultaneously fitting both a clustering and a multidimensional scaling solution, whereby the two are interrelated in a single analysis. Extensive software is freely available for fitting hybrid and also many user-constrained structures to the kinds of data previously described, and further developments in this area of research, with both new models and extensive software for such analyses, are anticipated.

Selecting from a Large Set of Variables

As with many other techniques of multivariate data analysis, clustering is nowadays often applied to enormous data sets that would have been impossible to analyze before recent advances in computing algorithms and hardware. For two-mode, two-way data sets, the number of columns of variables depicting the characteristics of the row objects may be in the thousands, and in most applications, there can be little doubt that the great majority of the column variables are useless for the particular analysis at hand. The problem, of course, is deciding on which ones to discard. Just as in stepwise multiple discriminant analysis, researchers have sought to devise methods for weighting and possibly discarding selected variables

altogether. These attempts have focused on hierarchical and on partitioning clustering, but the results have been mixed.

Glossary

codebook A guide to the database that the researcher is creating—a guide sufficiently rich that it not only enables the researcher to code his or her data reliably but also allows others to replicate, reproduce, update, or build on the variables housed in the database, as well as any analyses generated from it.

observable implications (or expectations or hypotheses) What we expect to detect in the real world if our theory is right.

reliability The extent to which it is possible to replicate a measurement, reproducing the same value (regardless of whether it is the right one) on the same standard for the same subject at the same time.

theory A reasoned and precise speculation about the answer to a research question.

variable Observable attributes or properties of the world that take on different values (i.e., they vary).

variable, values of Categories of a variable (e.g., male and female are values of the variable gender).

Coding variables is the process of translating attributes or properties of the world (i.e., variables) into a form that researchers can systematically analyze. The process entails devising a precise schema to account for the values that each variable of interest can take and then methodically and physically assigning each unit under study a value for every given variable.

Introduction

Social scientists engaged in empirical research—that is, research seeking to make claims or inferences based on

observations of the real world—undertake an enormous range of activities. Some investigators collect information from primary sources; others rely primarily on secondary archival data. Many do little more than categorize the information they collect; but many more deploy complex technologies to analyze their data.

Seen in this way, it might appear that, beyond following some basic rules of inference and guidelines for the conduct of their research, scholars producing empirical work have little in common. Their data come from a multitude of sources; their tools for making use of the data are equally varied. But there exists at least one task in empirical scholarship that is universal, that virtually all scholars and their students perform every time they undertake a new project: coding variables, or the process of translating properties or attributes of the world (i.e., variables) into a form that researchers can systematically analyze after they have chosen the appropriate measures to tap the underlying variable of interest. Regardless of whether the data are qualitative or quantitative, regardless of the form the analyses take, virtually all researchers seeking to make claims or inferences based on observations of the real world engage in the process of coding data. That is, after measurement has taken place, they (1) develop a precise schema to account for the values on which each variable of interest can take and then (2) methodically and physically assign each unit under study a value for every given variable.

And yet, despite the universality of the task (not to mention the fundamental role it plays in research), it typically receives only the briefest mention in most volumes on designing research or analyzing data. Why this is the case is a question on which we can only

speculate, but an obvious response centers on the seemingly idiosyncratic nature of the undertaking. For some projects, researchers may be best off coding inductively, that is, collecting their data, drawing a representative sample, examining the data in the sample, and then developing their coding scheme; for others, investigators proceed in a deductive manner, that is, they develop their schemes first and then collect/code their data; and for still a third set, a combination of inductive and deductive coding may be most appropriate. (Some writers associate inductive coding with research that primarily relies on qualitative [nonnumerical] data/research and deductive coding with quantitative [numerical] research. Given the [typically] dynamic nature of the processes of collecting data and coding, however, these associations do not always or perhaps even usually hold. Indeed, it is probably the ease that most researchers, regardless of whether their data are qualitative or quantitative, invoke some combination of deductive and inductive coding.) The relative ease (or difficulty) of the coding task also can vary, depending on the types of data with which the researcher is working, the level of detail for which the coding scheme calls, and the amount of pretesting the analyst has conducted, to name just three.

Nonetheless, we believe it is possible to develop some generalizations about the process of coding variables, as well as guidelines for so doing. This much we attempt to accomplish here. Our discussion is divided into two sections, corresponding to the two key phases of the coding process: (1) developing a precise schema to account for the values of the variables and (2) methodically assigning each unit under study a value for every given variable. Readers should be aware, however, that although we made as much use as we could of existing literatures, discussions of coding variables are sufficiently few and far between (and where they do exist, rather scanty) that many of the generalizations we make and the guidelines we offer come largely from our own experience. Accordingly, sins of commission and omission probably loom large in our discussion (with the latter particularly likely in light of space limitations).

Developing Coding Schemes

Regardless of the type of data they collect, the variables they intend to code, or even whether they plan to code inductively or deductively, *at some point* empirical researchers require a coding schema, that is, a detailing of each variable of interest, along with the values of each variable—for example the variable RELIGION of a survey with, say, “Protestant,” “Catholic,” “Jewish,” “none,” and “other” as the values. With this sort of information in hand, investigators can prepare codebooks—or guides they employ to code their data and that others can

use to replicate, reproduce, update, or build on the variables the resulting database contains and any analyses generated from it.

In the section that follows, we have much more to say about codebooks. For now let us home in on this first phase—developing coding schemes—and begin by reinforcing a point suggested by our emphasis on the phrase “at some point”; namely that, in terms of research design, many steps typically proceed the step developing a coding schema, such as devising research questions, theorizing about possible answers, generating observable implications, and so on. Even when it comes to coding variables, researchers may not begin with developing a coding schema. But—and this is our chief point—they almost always perform this task during the course of a project’s life. This holds for those who create databases, as well as for those who work with databases developed by others, such as the General Social Survey and the American National Election Study; that is, users need to devise a plan of their own if they desire to transform variables contained in existing databases.

We also ought acknowledge at the onset that the nature of the coding task (especially its relative difficulty) varies depending on the types of variables under investigation. If we are conducting a survey of students, all of whom are between the ages of 18 and 21, then it is relatively trivial to develop a coding scheme for the variable AGE: it would take on the values “18,” “19,” “20,” and “21.” Devising the values for many other variables is not as straightforward a task. To see this, return to the deceptively simple example of the variable RELIGION, for which we listed five possible values: “Protestant,” “Catholic,” “Jewish,” “none,” and “other.” This may work well for some studies, but we can imagine others for which it would not. Consider, for example, an investigation into the attitudes of individuals who belong to a Jewish synagogue wherein the researcher desires to include the variable RELIGION. Assuming that nearly all the subjects are Jews, the five values we have listed would make little sense (nearly 100% would fall into the “Jewish” category). Accordingly, the investigator would need to alter the schema, perhaps by incorporating finer divisions of “Jewish”: “Jewish-Orthodox,” “Jewish-Conservative,” “Jewish-Reform”—or whatever schema most appropriately enables the researcher to capture the information necessary to the research task.

Other problems may exist with our original values of RELIGION; for example, what of respondents who are interdenominational in their religious preferences? They will be forced to choose among the values of RELIGION or perhaps respond with “other,” even if their preference is one that combines Catholic and Protestant tenets. And, for that matter, what should we make of the “other” category? Depending on the subjects under analysis, it may be appropriate (meaning that it would be

an option selected by relatively few respondents) or not. But our more general point should not be missed: Accounting for the values of the variables of interest, even for seemingly straightforward ones, may be a non-trivial task.

To facilitate the efforts of researchers to perform it, we offer the three recommendations that follow: (1) ensure that the values of the variables are exhaustive; (2) create more, rather than fewer, values; and (3) establish that the values of the variables are mutually exclusive. These guidelines reflect standard practice, along with our own experience. But there is one we presuppose: Researchers must have a strong sense of their project, particularly the piece of the world they are studying and how that piece generated the data they will be coding, as well as the observable implications of their theory that they will be assessing. Because this point is obvious, if only from the brief examples we have provided, we do not belabor it. We only wish to note that an adherence to all the suggestions that follow will be difficult, if not impossible, if researchers lack a deep understanding of the objects of their study and an underlying theory about whatever feature(s) of behavior they wish to account for.

Ensure that the Values of the Variables Are Exhaustive

Our first recommendation, simply put, is that the values for each variable must exhaust all the possibilities. To see why, consider a simple example, from a 2000 study by Frankfort-Nachmias and Nachmias, in which the values of the variable *MARITAL STATUS* are enumerated as “married,” “single,” “divorced,” and “widowed.” This is not an exhaustive list because it fails to include “living together but not married” and, as such, may ultimately be a source of confusion for respondents who are asked to describe their marital status or for coders who must make a decision about another’s status.

To skirt the problem, investigators typically include the value “other.” As a general matter, this is not only acceptable but typically necessary. It may be the case that researchers, however well they know their project and however well developed their theory, cannot anticipate every value of a particular variable. Moreover, even if they did, it may be impractical or inefficient to include each and every one. At the same time, however, because we can learn very little from a database replete with variables mostly coded as “other,” researchers should avoid the overuse of this value when it comes time to code their data. Only by having a thorough understanding of their project—or at least an understanding (perhaps developed through pretesting) sufficient enough to be able to write down an exhaustive list of the likely-to-occur values—will they steer clear of this pitfall. Pretesting

or conducting a pilot study when possible and is in general a useful way to detect potential problems of all sorts—including the overuse of “other.” When pretesting reveals that “the ‘other’ response accounts for 10 percent of more of the total responses,” Shi (1997) suggested in a 1997 study (as a rule of thumb) that researchers should add new values.

Create More, Rather than Fewer, Values

To some extent our second recommendation counsels “when in doubt, include a value rather than exclude it.” It reinforces from our first recommendation because this will help to avoid the problem of too many “other” codes. But it suggests something else; that analysts create values that are more, rather than less, detailed.

To see why, consider the example of researchers who want to explain why lower federal appellate courts (the U.S. Courts of Appeals) sometimes reverse the decisions reached by trial courts and sometimes affirm them. For such a project investigators need to enumerate the values of the variable *DISPOSITION*, which they could merely list as “affirm” and “reverse” because these are the dispositions that concern her. The problem here is that appellate courts do not always simply affirm or reverse; these courts have many options available to them, as [Table I](#) indicates.

Even though our analysts are interested solely in a court’s decision to affirm or reverse, the guideline of “creating more, rather than fewer, values” suggests that they start with all possible values of *DISPOSITION* (as listed in [Table I](#)). To be sure, the researchers should know which values of the *DISPOSITION* ought count as a “reverse” and which should count as an “affirm”; and we would require them to specify that (e.g., values 2, 3, 4,

Table I Possible Dispositions in Cases Decided by the U.S. Courts of Appeals

<i>Value</i>	<i>Value label</i>
0	Stay, petition, or motion granted
1	Affirmed; or affirmed and petition denied
2	Reversed (including reversed & vacated)
3	Reversed and remanded (or just remanded)
4	Vacated and remanded (also set aside & remanded; modified and remanded)
5	Affirmed in part and reversed in part (or modified or affirmed and modified)
6	Affirmed in part, reversed in part, and remanded; affirmed in part, vacated in part, and remanded
7	Vacated
8	Petition denied or appeal dismissed
9	Certification to another court

Source: U.S. Court of Appeals Data Base, available at: <http://www.polisci.msu.edu/pljp/databases.html>

6, 7 listed in [Table I](#) might be considered “reverse”). But beginning with the more detailed values has two clear advantages (both of which have even more bearing on the second phase of the coding process, discussed later). First, whoever eventually codes the data will make fewer errors. Think about it this way: If our investigators tell their coder in advance to report values 2, 3, 4, 6, and 7 as “reversals,” the coder must take two steps: (1) identify the disposition by examining the court’s decision and, then, (2) identify whether it is a reversal or affirmance. But if the researcher simply has the coder identify the disposition, then the coder has only one step to take. Because every step has the possibility of introducing error, researchers should seek to reduce them.

A second set of advantages accrue when the investigators turn to analyzing their data. Because they have now coded the variable `DISPOSITION` quite finely, they can always collapse values (e.g., they can create “reverse” from values 2, 3, 4, 6, 7 in [Table I](#)) to generate a new variable, say, `DISPOSITION2`, which would house the two categories of primary interest to her (“reverse” and “affirm”). At the same time, and again because they have coded `DISPOSITION` finely, they will be able to ascertain whether any particular coding decision affects their conclusions. Suppose, for example, that, in collapsing values of `DISPOSITION`, they count value 6 (in [Table I](#)) as a “reverse,” even though the court affirmed in part. Because this represents a judgment on their part (although one they should record, thereby enabling others to replicate their variable) and because the converse coding (counting 6 as an “affirm”) is plausible, they will be able to examine the effect of their judgment on the results. Of course, none of these advantages ensue if they initially list only two values of disposition (“reverse” and “affirm”); while researchers can always collapse values, they cannot disaggregate those coded more coarsely. This point cannot be understated; we can never go from fewer categories to many without returning to the original data source (which oftentimes, for example, in survey research, is impossible). Coding data as finely as possible allows the researcher to encode a greater amount of information.

Despite all the advantages of creating more (rather than fewer) values, limits do exist. Consider researchers who must devise values for the variable `INCOME` (representing survey respondents’ “total family income, from all sources, fall last year before taxes”). Following the recommendation of creating detailed values might lead the investigators to ask respondents simply to report their precise income. Such, in turn, would provide them with an exact dollar figure—or the finest possible level of detail on the variable `INCOME`. But very few (reputable) surveyors operate in this fashion. This is because they realize that individuals may not know that exact dollar amount or may not want others to know it. Hence, rather

than running the risk of reliability problems down the road, researchers typically create values that represent income categories (e.g., “under \$1000,” “\$1000–2999,” and “\$3000–3999”).

We can imagine other projects/variables for which our recommendation of developing detailed values would not be advisable. But, in the main and depending on the project/variable, it is a general principle worth considering.

Establish That the Values of the Variables are Mutually Exclusive

Under our third guideline, researchers must be sure that they have created values such that whatever unit is under analysis falls into one and only one value. It is easy to see how the failure to follow this recommendation could lead to confusion on the part of respondents and coders alike but, unfortunately, it is also easy to violate it. Consider the simple example from the 2000 study by Frankfort-Nachmias and Nachmias of a variable `LIVING ARRANGEMENTS OF STUDENTS` for which investigators have enumerated four values: “live in dormitory,” “live with parents,” “live off campus,” and “live with spouse.” To the extent that the values seem exhaustive and detailed, this schema meets the two other recommendations but not the third—a student could “live with parents” and “live off campus,” or, for that matter, live off campus with a spouse, live with parents and a spouse, or (at some universities) live in a dorm with a spouse. The values are not mutually exclusive. Guarding against the problem requires that researchers, once again, understand their project; pretesting also may be a useful step.

Assigning Each Unit Under Study a Value

After (or perhaps concurrently with) developing a coding schema, analysts must methodically and physically assign each unit under study a value for every variable. Doing so typically requires them to (1) create a codebook to house the schema and other relevant information and (2) determine how they will ultimately enter their data into a statistical software package so that they can analyze them.

Codebooks

In line with our earlier definition, codebooks provide a guide to the database that the researchers are creating—a guide sufficiently rich that it not only enables the researchers to code their data reliably but also allows others to replicate, reproduce, update, and build on the variables housed in the database as well as any analyses

generated from it. Indeed, the overriding goal of a codebook is to minimize human judgment—to leave as little as possible to interpretation.

Accordingly, while codebooks contain coding schemes (that is, the variables and the values that each can take), most contain much more—including the details about various features of the research process (e.g., information about the sample and sampling procedures, data sources, and the time period of the study). We do not provide a listing of each of these components here. (Researchers should investigate the Inter-university Consortium for Political and Social Research, ICPSR, and the Data Documentation Initiative, DDI, which is “an effort to establish an international criterion and methodology for the content, presentation, transport, and preservation of ‘metadata’ [codebooks or, in DDI’s words, “data about data”] about datasets in the social and behavioral sciences.”) We instead focus on those relevant to coding variables: variables, values, missing values, and coding notes.

Variable Names

When researchers enumerate the values of their variables, those variables have (or should have) precise meanings. To return to our previous examples, investigators may name their variable *INCOME* but understand that to mean “total family income, from all sources, before taxes.” Likewise to researchers coding the variable *DISPOSITION*, this variable may signify “the rulling of a U.S. Court of Appeals.”

Codebooks contain both a short variable name (e.g., *INCOME*) as well as the investigators’ precise definition (“total family income, from all sources, last year before taxes”). The reason for the former is that many statistical software packages (into which researchers ultimately enter their data) still limit the length of the variable name, to, say, eight characters. Hence, to ensure that the variable name in the codebook corresponds to the variable name in the database, codebooks typically contain the abbreviated name. (Worth noting is that limits on length are becoming less of a concern in current versions of software packages, although being able to refer to variables using some shorthand is typically valuable for other reasons.)

Conventions for naming variables abound. But because other sources provide detailed discussions of this matter we need not delve into them here. What is worthy of emphasis is this advice, from ICPSR: “It is important to remember that the variable name is the referent that analysts will use most often when working with the data. At a minimum, it should not convey incorrect information, and ideally it should be unambiguous in terms of content.”

In addition to the shortened variable name, researchers supply a longer, descriptive name for each variable

(for *INCOME*, “total family income, from all sources, last year before taxes”), along with the form each variable takes (for *INCOME*, dollars). (For variables created from survey questions, the descriptive name typically is the exact question asked of respondents.) The name should convey a strong sense of the contents of the variable, and it ought be listed in the codebook and in the database (most statistical packages allow the user to enter a longer variable identifier or variable label).

Values

When researchers develop their coding schema, they create values—usually in the form of labels—for each variable, such as the nine descriptive values in [Table I](#) for the variable *DISPOSITION*. After (or concurrently with) doing this, they typically assign a unique number to each value (as in [Table I](#)). The codebook contains both the value numbers and the value labels (e.g., in [Table I](#), 0 = stay, petition, or motion granted; 1 = affirmed, or affirmed and petition denied; and so on); the ultimate database houses both, but it is typically the number that the coder enters for each unit of analysis.

As is the case for variable names, conventions for assigning numbers to the values of variables abound. For example, values ought be convenient, intuitive, and consistent with the level of measurement. So, for example, even though the values of a discrete variable, say *GENDER*, could be 1010 = male and 5020 = female (because matters of size and order are irrelevant), this convention counsels that the researcher ought begin with 0 and increase by 1 (e.g., male = 0; female = 1). Starting with the lowest values with the fewest digits, however, need not mean that the researcher must sacrifice sophistication. Manheim and Rich in their 1995 article detailing how researchers interested in a finely coded *RELIGION* variable can devise a numbering system that is simultaneously simple, intuitive, and refined make this point nicely. Rather than merely assigning values 1–4 to various Protestant denominations (say, 1 = Baptist, 2 = Methodist, 3 = Presbyterian, and 4 = Lutheran), values 5–7 to various forms of Judiasim (e.g., 5 = Orthodox, 6 = Conservative, and 7 = Reform), and value 8 to Catholic, researchers can classify numbers in a logical, meaningful way (10 = Baptist, 11 = Methodist, 12 = Presbyterian, 13 = Lutheran; 20 = Jewish Orthodox, 21 = Jewish Conservative, 22 = Jewish Reform; 30 = Catholic). Under this system, each major category of religion (Protestant, Jewish, Catholic) receives the same first digit, with the second digit representing a subdivision. As Inter-university Consortium for Political and Social Research explains, “This type of coding scheme permits analysis of the data in terms of broad groupings as well as individual responses or categories.”

Ease of use, intuition, and logic also should guide the assignment of values to continuous variables. This

typically means that researchers should record the original value, reserving transformations for later. For example, even if the logarithm of AGE will ultimately serve as an independent variable in the analysis, the researcher ought code the raw values of AGE and do so sensibly (if a person is 27, then the value of the variable AGE for that person is 27).

Two other rules of thumb are worthy of note. One is that wherever and whenever possible, researchers should use standard values. If the ZIP CODE of respondents is a variable in the study, it makes little sense to list the codes and then assign numerical values to them (11791 = 1, 11792 = 2, 11893 = 3, and so on) when the government already has done that; in other words, in this case the researcher should use the actual zip codes as the values. The same holds for other less obvious variables, such as INDUSTRY, to which the researcher can assign the values (e.g., 11 = Agriculture, 22 = Utilities, and so on) used by the U.S. Census Bureau and other agencies.

The remaining rule is simple enough and follows from virtually all we have written thus far—avoid combining values. Researchers who create a variable GENDER/RELIGION and codes a male (value = 0) Baptist (value = 10) as value = 010 are asking only for trouble. In addition to working against virtually all the recommendations we have supplied, such values become extremely difficult to separate for purposes of analyses (but GENDER and RELIGION, coded separately are simple to combine in most software packages).

Missing Values

However carefully researchers plan their project, they will inevitably confront the problem of missing values. A respondent may have failed (or refused) to answer a question about his/her religion, a case may lack a clear disposition, information simply may be unavailable for a particular county, and so on. Investigators should be aware of this problem from the onset and prepare accordingly. This is so even if they plan to invoke one of the methods scholars have developed to deal with missing data because it might affect the analyses. That is because the various solutions to the problem assume that researchers treat missing data appropriately when they create the original database.

At the very least, investigators must incorporate into their codebook values to take into account the possibility of missing data—with these values distinguishing among the different circumstances under which missing information can arise. These can include “refused to answer/no answer,” “don’t know,” and “not applicable,” among others. Whatever the circumstances, researchers should assign values to them rather than simply leaving blank spaces. Simply leaving missing values blank can cause all types of logistical problems—for example, is the observation truly missing, or has the coder not yet completed

it? Using an explicit missing-value code eliminates this type of confusion and can also provide information about why a specific variable is missing.

One final point is worthy of mention: Although in this entry our primary concern is with coding variables to be included in an initial and original database—not with imputing missing data (or recoding or otherwise transforming variables)—we do want to note that if the researcher has imputed missing data, she should indicate this in the final version of the codebook. The Inter-university Consortium for Political and Social Research suggests one of two possible approaches: “The first is to include two versions of any imputed variables, one being the original, including missing data codes, and the second being an imputed version, containing complete data. A second approach is to create an ‘imputation flag,’ or indicator variable, for each variable subject to imputation, set to ‘1’ if the variable is imputed and ‘0’ otherwise.”

Coding Notes

As we have noted earlier, the overriding goal of a codebook—and indeed the entire coding process—is to minimize the need for interpretation. As far as possible, human judgment should be removed from coding, or, when a judgment is necessary, the rules underlying the judgments should be wholly transparent to the coders and other researchers. Only by proceeding in this way can researchers help to ensure the production of reliable measures.

To accomplish this in practice, analysts certainly ought be as clear as possible in delineating the values of the variables. But they also should write down a very precise set of rules for the coders (and other analysts) to follow and should include that information for each variable housed in their codebook. Such a list should be made even if investigators code the data themselves, because without it, others will not be able to replicate the research (and the measure). Along these lines, an important rule of thumb is to imagine that the researchers had to assign students the task of classifying each case by its disposition and that the only communication permitted between the researchers and the students was a written appendix to the article detailing the coding scheme. This is the way to conduct research and how it should be judged. (We do not deal with the topic of transforming original variables here, but, of course, if researchers create new variables from existing ones, they should note this.)

Coding and Data Entry

Once researchers have devised their codebook, they must turn to the tasks of (1) employing the codebook to assign a value for every variable for each unit under study and (2) entering these values into a statistical software program. They can perform these tasks concurrently or

separately. Analysts making use of computer-assisted telephone interviewing (CATI) or computer-assisted personal interviewing (CAPI) programs, for example, do not separate the two; they use direct data entry. At the other extreme, researchers who are coding their data from a host of sources may record the assigned values on coding sheets and then transfer the information to a software program. To see why, let us return to the example of the analysts coding court DISPOSITIONS and suppose that, in addition to the values of this variable, they also desire data on the PARTY AFFILIATION of the judges deciding the case. Because she cannot obtain information on DISPOSITION and PARTY AFFILIATION from the same source, she may find it prudent to create a coding (or a transfer) sheet, assign values to each case on the variable DISPOSITION, and then do likewise for PARTY AFFILIATION. Once she has collected and coded all the data, she can enter the information (now on coding sheets) into her software package.

The rules covering coding sheets have been outlined elsewhere. What is important here is understanding the trade-off (often a necessary one) that researchers make when they enter data from sheets rather than directly into their computer. On the one hand, researchers must realize that every extra step has the potential to create error—recording information onto coding sheets and then transferring that information into a computer introduces a step that is not necessary in direct data entry. On the other hand (and even if data are derived from one source only), they should understand that coding and data entry typically represent two separate tasks—asking a singular person to perform them concurrently may also lead to errors in one, the other, or both.

Whatever choices researchers make, they should evaluate them. Reliability checks on the coding of variables are now standard—researchers drawing a random sample of cases in their study and asking someone else to recode them is a simple way to conduct them. So too analysts ought assess the reliability of the data entry process, even if they made use of sophisticated software to input the information. Although such programs may make it difficult, if not impossible, for investigators to key in wild or out-of-range values (e.g., a 7 when the only values for GENDER are 0 = male, 1 = female), they typically do not perform consistency or other checks. And when using multiple coders, it is necessary to have several coders code a set of the same observations to allow the researcher to assess reliability among the coders.

Researchers can undertake the process of cleaning their data set in several ways (e.g., running frequency

distributions or generating data plots to spot outliers, or creating cross-tabulations to check for consistency across variables). But the key point is that they should do it, because as Babbie well states in a 2001 study, “‘dirty’ data will almost always produce misleading research findings.” The same, of course, is true of data that have been collected and coded via asystematic, unthinking means—that is, via means that these recommendations are designed to thwart.

Cognitive Maps

Reginald G. Golledge

University of California, Santa Barbara, California, USA

Glossary

- anchor point** A dominant environmental cue.
- bidimensional regression** Regression in the spatial coordinate domain.
- cognitive map** The product of perceiving and thinking about environments external to one's body. It represents a store of experienced sensations that have been perceived, noticed, identified, encoded, and stored in memory for later manipulation and used in problem-solving or decision-making situations.
- cognitive mapping** The process of perceiving, encoding, storing, internally manipulating, and representing spatial information.
- configurational matching** The assessment of the degree of congruence between actual and created spatial configurations.
- displacement error** The absolute distance between an objective and a subjective location.
- fuzziness** The variance associated with a set of spatial measures.
- landmark** A generally well-known feature, distinct because of its physical, social, or historical properties.
- multidimensional scaling** An iterative procedure for finding a minimal dimensional solution for configuring spatial knowledge.
- place cells** Elements of the brain in which specific spatial features are stored.
- pointing** Use of a device or body part to identify direction from current location to a distant location.
- reproduction task** An act of using body-turning or locomotion to represent an experienced angle or distance.
- sketch map** A hand-drawn representation of what one recalls about an environment.
- spatial cognition** The thinking and reasoning processes used to manipulate, interpret, and use encoded spatial information.
- spatial decoding errors** Errors of translating encoded spatial information for manipulation in working memory.
- spatial encoding errors** Errors of perceiving or sensing feature or object location.

- spatial product** The external representation of recalled spatial information.
- task environment** The defined setting in which experimental procedures are carried out.
- wayfinding** The process of searching out a path to reach a goal.

The term “cognitive map” is generally accepted to be a hypothetical construct that refers to one's internal representation of the external world. At various times, the concept has been interpreted as a metaphor or a cartographic-like representation. It is accepted that people may think and reason by constructing images—some of which may indeed be map-like—but that the “map” portion of the term is just a convenient fiction that may facilitate the understanding of how thought processes deal with spatial and social information. A popular interpretation is that cognitive maps are the outcome of information processing that organizes places and locations and makes clear the spatial relations that connect them.

Definition and Use

Cognitive Maps and Cognitive Mapping

Although Tolman originally defined the cognitive map as an internal representation of a specific spatial area (a maze in which he was conducting learning experiments with Norwegian rats), the term has broadened considerably and generally refers to one's internal representation of the surrounding world. A narrower view of the concept refers to a level of spatial information processing in which an environment is organized as a system of interconnected locations, places, and relationships. In both views, the concept also incorporates a series of transformation

Table I Methods for Obtaining Spatial Products

-
- Collecting unidimensional scaling measures of spatial characteristics, such as interpoint distances or directions
 - Reproducing spatial properties from memory, such as walking distances or turning angles
 - Recording paths of travel
 - Using sketch mapping to define what people know and recall about the structure and content of large urban environments
 - Construction of latent spatial relations using indirect distance or proximity judgments and nonmetric multidimensional scaling procedures
 - Using trilateration procedures to construct configurations from interpoint distance estimates
 - Constructing three-dimensional table models of routes and environments that have been experienced
 - Use of imagined locations at which to complete spatial tasks
 - Examination of verbal reports of spatial wayfinding and layout knowledge
 - Determining whether people without sight can reproduce distances, directions, and layouts
 - Use of projective convergence or classical triangulation methods to determine location of obscured features
 - Spatial updating after location translation
 - Exploring spatial relations in virtual environments
-

rules and is often interpreted as a combination of declarative and procedural knowledge.

An internal representation of the world outside the body is necessarily incomplete, simply because one's senses cannot absorb all possible information about that world. The clear implication is that there is a need to balance the tension between encoding and storing as much useful information as possible and needing to be able to manage and use this information. There is strong support for the argument that a cognitive map is a valid and reliable concept that is useful for comprehending the actions of humans and some other species, but there is much less certainty whether the term "cognitive map" is an appropriate one for many other animal species, since the term "cognitive" implies directed thinking and reasoning.

Internal manipulations of spatial information take place in working memory, and the results are related to specific settings, situations, or tasks. Twenty-five years ago, O'Keefe and Nadel hypothesized that the hippocampus was one's cognitive map. Neurobiological research is examining this and other hypotheses about the storage of information in the brain by examining what have been termed "place cells." Despite growing interest in these problems, the exact location of where spatial/environmental information is stored in the brain is not known, nor is it known exactly how the mind manipulates this information internally in working memory in response to task situations. By obtaining externalized representations of recalled information, it can be inferred that certain types of information must exist in memory or that what is stored can be manipulated by natural or learned processes to produce specified outcomes. These externalizations are termed "spatial products."

The term cognitive mapping has been used to summarize the total process of encoding, storing, manipulating, and using information in task-specific and problem-solving situations that require original thinking or

reproductive elaboration of experienced spatial relations among stored bits of information. Different methods for obtaining spatial products are summarized in [Table I](#).

In designing related experiments, researchers have focused on activities such as wayfinding, direction-giving, pointing, interpoint distance estimation, configurational or layout representation of settings, neural net modeling, computational process modeling, revealed place preference analysis, protocol analysis of verbal summaries, and many other devices that illustrate that people are capable of recalling stored information and then revealing or unpacking spatial relations among bits of data in ways that conform to locational patterns, connections, or interactions in objective reality. Such matching indicates that environmental knowing occurs and that the result of such knowing can be used to help explain human actions and reactions in the spatial domain.

The Use of Cognitive Maps

Since one's senses usually constrain the space over which one can experience environments at any given moment in time, one continually supplements this information with that stored in one's cognitive maps. The information stored in long-term memory is updated constantly as one changes viewpoints or perspectives, as environments themselves change, as one develops and ages, and as one's cultural, social, economic, belief, value, and other systems are brought to bear on one's experiences. Using cognitive maps is such an integral part of everyday life that the universality of the process must be recognized. It must also be recognized that spatial relations and spatial behavior are fundamental to all human groups, regardless of ableness or impairment. The completeness, fuzziness, distortion, or other characteristics of stored information are chiefly determined by factors such as the frequency with which exposure to information has been achieved,

the simplicity or complexity of the situation experienced, and the type of perceptual process that dominates encoding. It is reasonable, therefore, to assume that there are substantial individual differences in the nature, complexity, and accuracy of cognitive maps, but also that there must be a significant amount of commonality in what has been coded and stored for later use in order to communicate with other humans.

Measuring the Essence of Cognitive Maps

This section addresses the questions related to collecting evidence of and assessing the spatial nature of cognitive maps. Reviews of the different procedures for obtaining spatial products have been published elsewhere. This section focuses on measurement practices, illustrating how spatial products can be obtained and evaluated with respect to real-world settings and structures.

The Geometries

Much of cognitive map measurement has been focused on specific geometric components—depicted in terms of points, lines, simple or complex networks, sequences or strings, areas, hierarchies, and configurations or layouts of places. Information stored in long-term memory does not necessarily take the form of what is traditionally recognized to be a cartographic map. Discovering the spatial nature of stored information and the spatial relations that are embedded within it has resulted in a wide variety of experimental designs and innovative task situations including metric and nonmetric formats. Most efforts have concentrated on two-dimensional Euclidean space—although some researchers have shown that city block metric (i.e., Minkowskian space of $R = 1$) is most likely used by many people. Using a two-dimensional map metaphor to describe spatial products has the convenience of allowing access to a variety of graphic, cartographic, and geometric measurement procedures that allow comparisons to be made between the characteristics and structure of spatial products and their counterparts in objective reality.

Locating Places

In objective reality, locations are often known by several labels or identities (e.g., “the corner of High and Main”; “the bank corner”; “the center of town”). Before one can determine locational accuracy, one must find by which label a location is best known. In a designed experiment, locations can be arbitrarily identified by a single name or symbol, thus removing this ambiguity. Location is usually specified in one of two ways: absolute or relative. Absolute

location requires the use of a reference frame and some type of referencing system (e.g., coordinates). Relative location often uses a fuzzy spatial preposition (e.g., “near the school”; “between Fifth and Sixth Streets”). In the case of absolute location, accuracy can be measured by examining distortion—the absolute difference between real (u, v) and estimated (x, y) coordinates. Direction of error may be equally important. By establishing the reference frame (e.g., a real or arbitrarily defined north line), directional deviation may be exposed. The angular distortion can be signed or absolute, depending on the experimenter’s need, with signed directional error usually being preferred.

Identity, location, magnitude, time, and distance have at various times been suggested as the essential primitives of spatial knowledge. An occurrence is recognized as existing by giving it an identity, e.g., a label or name. Once known to exist in real or imagined space, an occurrence requires the attribute of location to be placed in that space. Since matter comes in various-sized units, a measure of magnitude needs to be attached to the locational attribute, providing a basis for differentiating between occurrences. In a dynamic universe, an occurrence may occupy a location perpetually, may exist for only a limited amount of time at a specific place before ceasing to exist, or may change locations over time. As more than one occurrence is identified, their degree of separation is determined by the concept of distance. Comprehension of environmental complexity can be enhanced by classifying occurrences into classes. In the spatial domain, spatial distributions form point patterns and acquire characteristics of density and dispersion. When occurrences are linked together, they form sequences or networks. The spaces that contain points, patterns, shapes, and networks, independently distributed or connected in some way, are said to be contained within bounded places called areas. Boundaries establish reference frames. Reference frames, in turn, allow local as well as global or universal locational and other spatial descriptors to be developed. These include distance, direction, connectivity, proximity, inclusion, sequence, association, and layout. Thus, awareness of the essential geometry of spaces and the things contained therein (usually called settings or environments) includes a host of spatial relational properties that have supported the continued use of the hypothetical construct of a cognitive map.

Defining what is known is one thing. Determining whether what is known bears a definable relationship to what exists in objective reality is another. Together, these two problems are the *prima facie* reasons for research into the measurement of cognitive maps. In the following sections, the format chosen is to proceed from simple, unidimensional measurement to more complex, multidimensional measurement procedures.

Measuring Cognitive Distances

The separation between two or more locations can be measured with varying degrees of accuracy. Interpoint distances measured in metric terms are usually the most precise, whereas nonmetric measures based on proximity, similarity, closeness, sequence, and order are less precise. Measurement of cognized interpoint distances was classified by Montello in 1991 into five categories (Table II).

Both magnitude and ratio estimation methods require estimation of cognized separation in relation to a given scale (e.g., a 1-in. line representing 10 units of measurement or a given distance between two well-known places). These measuring techniques require an understanding of the concept of a scale—i.e., that a given unit of measurement can be taken as a representative fraction of the real

distance between places. Although these methods have been in common use, there is doubt concerning the ability of participants to estimate distance and to understand the idea of scale as a representative fraction. This is of particular concern when dealing with young children. Some of the most reliable results of research on cognitive distance are summarized in Table III.

Measuring Configurations

Multidimensional Scaling

In contrast to simply matching estimated and actual data, a procedure that comes closer to the metaphorical idea of producing a map as the spatial product involves the development of a distance or similarities matrix. Assuming symmetry in judgments between pairs of places, only the top diagonal half of such a matrix is used. Typically, this is input to a metric or nonmetric multidimensional scaling algorithm; these can be found in most statistical software packages. Most of these are based on the original ideas developed by Kruskal and Wish in the 1960s. The essence of such an algorithm is to generate a set of distances that satisfy the same monotonic relationship that is expressed in the values in the data cells of the distance matrix. Starting with a random configuration, a method is used in a series of iterations to converge the two monotonic sequences. At each iteration, a badness-of-fit statistic gives an indication of whether the iterative procedure has reached a satisfactory or acceptable minimum dimensionality. When dealing with interpoint distances in the real world, the actual configuration of distances can be the starting configuration. Using this procedure, the real pattern is warped to most closely match the subjective pattern in the data matrix. Achieving best fit may involve translating or rotating the subjective configuration. When the actual configuration is used as the starting configuration, however, a fit statistic can be interpreted as an accuracy measure. In most cases, output is forced into a two-dimensional solution so that matching can occur.

Table III Outcomes of Cognitive Distance Analyses

Reliability and validity	Except for the work of Kitchin (1996), researchers have focused little attention on determining the <i>reliability and validity</i> of cognitive distance measures, and there is little evidence indicating whether any individual might give the same responses to estimating distances over various methods and at various times. Kitchin argues that, considering cognitive distance measures, both the validity and reliability of product measurements are uncertain.
Regression toward the mean	Estimates of cognitive distance usually show patterns of overestimation of short distances and underestimation of longer distances. Over a population’s response set, there is a tendency to regress toward the mean.
Comparison of cognized and objective distances	Traditionally, cognized and actual distances are compared using linear regression analysis. The typical pattern of overestimating shorter distances and underestimating longer distances favors the nonlinear type (e.g., $Y = aX^b$ rather than $Y = a + bX$) (where Y is the cognitive distance, a is the intercept, X is objective distance, and b is the slope coefficient).

Interpreting Configurations

Multidimensional scaling unpacks the latent two-dimensional (or higher) structure that is embedded in a series of unidimensional distance judgments. It does so without requiring the individual to expressly know a specific distance measure (e.g., meters, kilometers, yards, miles). Although multidimensional scaling is accepted as a powerful technique to recover latent structure, criticism is sometimes leveled at the procedure because of potential impurities in the interpoint distance matrix. For example, if people are required to estimate the distances between unfamiliar pairs of points, they may guess. A good guess may be consistent with other information and allow a reasonable configuration to be estimated. A bad guess might considerably warp otherwise useful and accurate patterns of estimation.

A second criticism is that the use of similarities rather than distances may invoke functional dimensions rather than spatial dimension. Thus, appropriate low-dimensional output may exist in three or more dimensions rather than the two dimensions usually required for congruence mapping with real-world locational patterns. Like factor analysis, researchers must identify the dimensions of an output configuration. Often it is assumed that the lower dimensional configurations are most likely matched to spatial coordinate systems (e.g., traditional north, south, east, west frames). This may not be so. A necessary step before accepting such an assumption would be to regress the coordinate values along a specific dimension with the coordinate values along a particular north, south, east, or west axis. If the correlations are not high, then functional or other dimensions may be the critical ones involved in making the distance or similarity judgments. Despite these shortcomings, the production of interpoint distance matrices and analysis by metric or nonmetric multidimensional scaling procedures has become a common and useful way of measuring cognized spatial configurations.

Matching Configurations

One simple way of illustrating divergence between cognized and actual spatial data is through a grid transformation. This is achieved by first locating a standard regular square grid over an objective configuration. The same-sized grid is then applied to the cognitive configuration. The latter grid structure is warped to illustrate distortions in the cognized layout. Good matches between cognitive and real-world configurations produce very little grid distortion, whereas poor fits between the two require considerable grid distortions (Fig. 1). Distorted grids can be compiled using standard contouring or interpolation procedures. Measures are also available in most geographic information system software packages.

Measuring Accuracy and Precision in Spatial Products

Accuracy and precision can be determined from multidimensional scaling methods.

Bidimensional Regression

Comparisons between cognitive and objective configurations can be made using bidimensional regression, but only after the output configuration has been rotated to make it maximally congruent with the real-world distribution.

Accuracy

Accuracy is indirectly related to the amount of systematic bias in a measurement. In particular, it focuses on the systematic or noncompensating error. Accuracy also implies comparison with some type of norm that has been measured by independent means or, in the case of real environments, represents a selected subset of objective reality. Precision is used in reference to unsystematic error and focuses on variability over the range of values found in a set of measurements. Measuring the dispersion of the estimates requires calculating the standard deviation about the mean center. This deviation needs to be calculated along both an X axis and a Y axis and this allows the production of a standard deviation ellipse. If the ellipse is not a circle, then a dominant axis hosts the maximum value of the standard deviation of the coordinates and the orthogonal axis contains the minimum standard deviation value. This standard deviation along any X or Y axis can be calculated as follows:

$$SD(x' \text{ axis}) = \sqrt{\frac{\cos^2 \Theta \sum x^2 + 2 \sin \Theta \cos \Theta \sum xy + \sin^2 \Theta \sum y^2}{N}}$$

$$SD(y' \text{ axis}) = \sqrt{\frac{\sin^2 \Theta \sum x^2 - 2 \sin \Theta \cos \Theta \sum xy + \cos^2 \Theta \sum y^2}{N}}$$

The major and minor axes of a standard ellipse can be found by equating the derivative of a standard deviation function with regard to Θ to zero. The maximum and minimum values are found by solving for $\Theta\mu$ and substituting them in the following pair of equations:

$$\begin{aligned} \frac{d(SD)}{d\Theta} &= \frac{(\sum y^2 - \sum x^2) \cos \Theta \mu \sin \Theta \mu + \sum xy (\cos^2 \Theta \mu - \sin^2 \Theta \mu)}{\sqrt{\cos^2 \Theta \mu \sum x^2 + 2 \sin \Theta \mu \cos \Theta \mu \sum xy + \sin^2 \Theta \mu \sum y^2}} \\ &= 0. \end{aligned}$$

Alternatively, a solution to this problem can be found using the eigenvalues and eigenvectors of the covariance matrix. Here, the first eigenvalue can be interpreted as the amount of stretch along the axis representing the maximum variance and the second eigenvalue similarly serves for the minimum value along a secondary axis. The

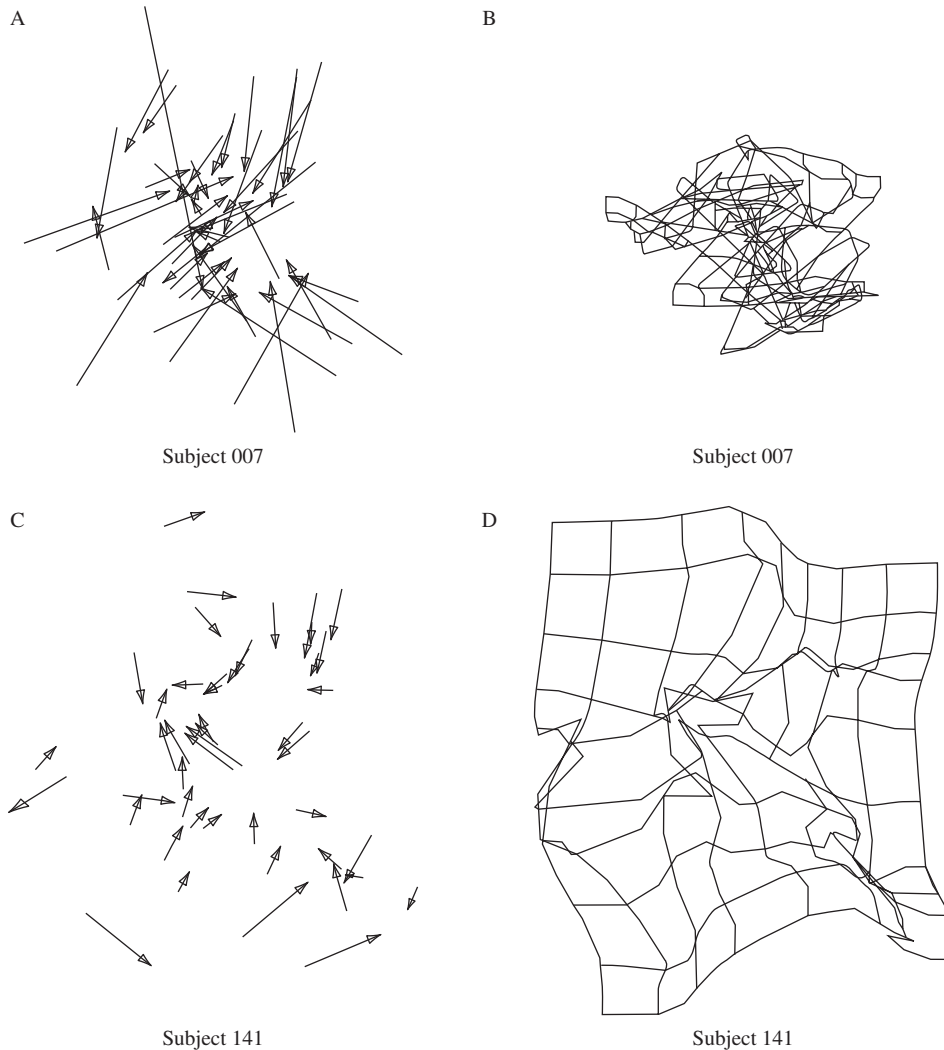

Figure 1 Examples of distorted grids. (A) Distortion vectors for a newcomer to a setting. (B) Distorted grid for a newcomer to a setting. (C) Distortion vectors for a long-time resident of a setting. (D) Distorted grid for a long-time resident of a setting.

eigenvectors will define the directions of the maximum and minimum variance. An example of the use of standard deviational ellipses is seen in Fig. 2.

Distortion and Error

Distortion and error can be measured for some spatial products, such as those produced by multidimensional scaling. Bidimensional regression has frequently been used to measure the congruence of real-world and cognitive configurations. Bidimensional regression is a combination of product moment correlation and ordinary least-squares regression procedures. It operates on two sets of coordinates and is sensitive to rotations, translations, and changes of scale. Obtaining the best correspondence between cognized and real coordinate systems may at times require reflection, which can be done prior to the calculation of the bidimensional regression

coefficient. Using software such as DARCY, TRILAT, or CMAP, a series of options is available for representing the similarity of cognitive and actual configurations.

In bidimensional regression, the parameters a and b of the standard regression equation $Y = a + bX$ become

$$a = \begin{pmatrix} a_1 \\ a_2 \end{pmatrix} \text{ and } b = \begin{pmatrix} b_{11} & b_{12} \\ b_{21} & b_{22} \end{pmatrix}.$$

The bidimensional regression equation then becomes:

$$\begin{pmatrix} u_j \\ v_j \end{pmatrix} = \begin{pmatrix} a_1 \\ a_2 \end{pmatrix} + \begin{pmatrix} b_{11} & b_{12} \\ b_{21} & b_{22} \end{pmatrix} \begin{pmatrix} x_j \\ y_j \end{pmatrix} + \begin{pmatrix} e_j \\ f_j \end{pmatrix},$$

where e_j and f_j are the residual errors, and a_1 and a_2 are analogous to the intercept terms of the standard linear regression model and are used to perform appropriate translations. Scaling and rotation are produced by the

Figure 2 Standard deviation ellipses. A composite cognitive configuration for a group of long-term residents is shown.

matrix of b_{ij} , which are analogous to the slope coefficients of standard regression. Constraining b_{12} to equal $-b_{21}$ maintains a rigid Euclidean rotation and constraining $b_{22} = b_{11}$ adjusts the scale on both axes by the same amount. An r^2 equivalent ranging between 0 and 1 represents the degree of variance in the cognitive coordinates that can be explained by the objective coordinates. This measure of association is represented as:

$$R = \sqrt{1 - \frac{\sum_{i=1}^n (x_j - u_i) \sum_{i=1}^n (y_i - v_i)}{\sum_{i=1}^n (x_j - u) \sum_{i=1}^n (y_i - v_i)}}$$

Here R equals the bidimensional regression coefficient or association measure. (x_i, y_i) are the real-world coordinates and (u_i, v_i) are the cognitive coordinates. This formulation was developed by Wakabayashi in 1994. R varies between zero and 1.0, with 1.0 representing a perfect fit.

To produce a best fit, scale changes of the configurations may be required. A scale value less than 1 indicates that the (u, v) space had to be contracted to fit the (x, y) space and a scale value greater than 1 would indicate that the (u, v) space had to be expanded to achieve this fit.

Measuring Cognized Directions

Direction is a spatial primitive essential for understanding configurational structures of places. In many circumstances, direction contains more relevant information than does distance. Cognitive maps incorporate directional knowledge and biases.

Self to Object and Object to Object Directions

Directional estimates usually are investigated in either of two forms: self to object or object to object. Self to object directions can be revealed by processes such as pointing with a wand, finger, nose, or other body part or by turning the entire body to face a particular place. Object to object directions often involve gridded coordinate structures or clock-face statements (e.g., “B is at 2 o’clock from A”).

Direction is frequently measured using a compass oriented along the wand, arm, body part, or total body such that an angle of deviation (or turn) from an original facing direction is recorded. Directional estimates also may be given in terms of clock-face measure with the facing direction representing 12 o’clock (e.g., “shop at 4 o’clock”; “bus stop at 10 o’clock”). Alternatively, direction may be given in terms of angles referred either to an anchoring facing direction or to a standardized directional line (e.g., a north line). In the first of these two cases, the angular range is often recorded in sectors up to 180° left or right of the facing direction (e.g., 17° right or 140° left). When a standardized north line is used, directions are usually requested in 360° form (e.g., 110°, 290°). Procedures used for collecting such information may include recording a standard compass reading or providing a participant with a sheet of paper on which is drawn a circle. If an assumption is made that the individual is standing at the middle of the circle and the circle can be aligned such that the north line on paper represents the current facing direction, then vectors can be radiated out from the center of the circle to indicate the directional position of specified objects. Alternatively, the north line on the paper can be oriented with respect to compass north and the same procedure requiring radiating vectors in the direction of selected objects can be followed, but measurements are given in terms of north/south/east/west axes. As an alternative to a paper-and-pencil task, the circle can be represented on a computer screen with instructions concerning the nature of an orientation line (i.e., representing either the facing direction or a compass direction). Vectors again can be drawn toward target objects using a stylus or cursor. When paper-and-pencil or computer-based renderings of direction are obtained, angular measures of the deviation of each vector are then calculated. In the paper-and-pencil task, a protractor can be used to measure angles. In the computer-based situation, mathematical software can

record direction and enter it in a data set without the need for instrumental measurement.

Research on the validity of directional estimates has indicated that whole-body pointing seems to obtain the best results. A simple way of investigating the accuracy of whole-body turning is to place a participant within a hoop that is graduated in degrees. A stopper is placed on the hoop at a particular angle. After grasping the hoop, the individual then turns the body and slides the hands until the angular block is reached. The task can be repeated several times and then the block is removed. The final task is for the individual is to turn the body and re-create the turn angle previously experienced. Estimates show that people are capable of doing this with an average of approximately 5° error.

Measuring the accuracy of directional estimates again involves comparing test results with objectively determined angular measures. As with the case of distances, association between the two can be measured using linear or nonlinear regression. There are measurement problems associated with this technique since direction estimates are constrained to a 360° range and because of this circularity, cognitive direction estimates can be no more than 180° from the objective direction value. By examining the average percentage differences between objective direction values and cognitive direction estimates, an absolute accuracy score can be obtained. Jacobson and co-workers have used the measure

$$\text{RAS} = \left\{ \frac{\sum_{i=1}^n [(OAS^i - CAS^i)/180] \times 100}{n} \right\},$$

where n is the number of angle segments, RAS is the relative accuracy score, OAS is the objective angle segment, and CAS is the cognitive angle segment.

However, whereas the above measurement problems emphasize unidimensional estimation procedures, inter-point directions can be examined using multidimensional spaces.

Projective Convergence

A two-dimensional map of the location of places based on directional estimates can be obtained using a traditional surveying triangulation procedure called projective convergence. In surveying, the location of a point or an object may be estimated by using an alidade to sight on the object from a plane table placed at a known location and then drawing a projection vector toward the target location after ensuring that the plane table on which a drawing is placed is oriented in a standard direction. A convergence of three directional lines is usually subject to a small amount of error resulting from the plane table orientation errors. However, the projected lines create a triangle of error and the simple process of bisecting each angle of the triangle to define a midpoint gives a best estimate of the target point's location. In projective convergence,

participants are required to point to a distant and perhaps unseen object or provide a bearing (clock-face or degrees) to that object from three different locations. The intersect of the vectors defines the triangle of error around the unseen location and determining its midpoint produces a reasonable estimate of actual location.

An abbreviated version of this technique involves drawing vectors of a standard length toward an object from three given locations, constructing a triangle from the end-points of these three vectors, and then finding the center of that triangle to give a best estimate of location. In general, projective convergence techniques are most useful when small distances are involved. Otherwise, the resulting triangles of error can be quite large and may require more complex mathematical solution procedures than the simple graphical ones suggested here.

Cognizing Layouts

This section deals explicitly with measuring cognized layouts rather than indirectly creating layouts from unidimensional judgments of spatial relations. Thus, the section starts with discussion of a two-dimensional plane instead of deriving it or assuming that one can be derived.

Anchors

As knowledge about environments is accumulated, increased understanding or familiarity allows the various structural properties of environmental layouts to be enhanced. Studies of the development of knowledge of large-scale complex environments has shown that, initially, except for a few key points labeled "anchor points," reliable information is sparse and structural information is distorted and fuzzy. Repeated excursions (e.g., journeys to work, shop, and educate) add information on a regular basis and, by so doing, assist in the process of knowing where things are and where they are in relation to other things. Given sufficient exposure, environmental knowing reaches a steady state in which a basic spatial structure becomes evident. Eventually, except for minor adjustments as better knowledge is obtained about less frequently visited places, or as new or important features are added in the environment that may grow to the stage of anchor points, the known spatial structure becomes relatively stable. For the most part, researchers have paid little attention to the development of spatial layout knowledge over time. Rather, they have assumed that cognitive maps would become stable. Indeed, Blades showed in 1991 that sketch map representation of environmental knowledge remains fairly constant over successive time periods once a stage of adequate learning has been achieved. Thus, when attempting to measure spatial layouts, it is generally assumed that people are familiar

Table IV Measuring Configurations

Freehand sketch mapping	Measurements made on sketch maps usually consist of counts of individual features, classification of such features into point, line, or areal categories, feature class counts, the imposition of traverses or profile lines to determine whether features are represented in appropriate linear sequence. Information can be obtained at both the individual (disaggregate) level and the population (aggregate) levels. The nonmetric information collected by such devices is often used as an adjunct to information collected by other procedures.
Controlled sketching	The information obtained from various controlled sketching procedures is essentially measured in terms of content classification (e.g., Lynch's elements of paths, edges, districts, nodes, and landmarks). The maps are analyzed to record how many of each type of feature occur. No <i>a priori</i> decisions of what to look for on the sketches are needed; instead, one can use panels of judges or focus groups to determine possible information classes. Sequence and ordering characteristics can be collected by referring features to relative positions with regard to the cued places.
Layout completion tasks	Measures include counts of infilled material by feature class, correct sequencing of features, correct identification of features in segments, and correct identification of nearest neighbor.
Recognition tasks	Measures include correct matching of features. Measures parallel the classic types of measurement models and represent a trend toward using forms of traditional psychometric spatial abilities tests to evaluate people's memory of specific configurations (point, line, and area). Generally called configuration tasks, they emphasize a respondent's ability to recognize which of several possible alternatives displays the same spatial relations as are displayed in a cued display. Typical tasks involve estimating which of a series of alternative building floor plans matches a recalled plan (after several learning trials).
Verbal or written spatial language	Measuring recognition of layouts may require respondents to match one of a series of statements with a verbal statement previously given or require participants to identify which of a series of layouts would be the most appropriately described by a set of logical connectives (such as "and," "or," "not or").
Placement knowledge	Classic nearest-neighbor analysis could be implemented by asking which function (e.g., named recreation area) was the closest nearest neighbor to a given function (e.g., named recreation area). Each of a set of features in turn can represent the anchor of a judgment procedure. Counts of the number of correct responses can be made. A simple rank correlation can be determined between the actual ordering of nearest neighbors and the cognized responses. If placement is determined via MDS, accuracy measures and fuzziness ellipses can be calculated.
Hierarchies	Measures include the number of matches between actual and cognized spatial neighbors.
Model building	Measures include scoring the model on completeness, the number of correct line segments, number of correct turn angles, sequencing of landmark cues, and orientation with respect to a given frame.

with the layout and that any representation they provide would be consistent with similar representations obtained at a later date.

Given an assumption of familiarity with an environment, cognized layouts can be measured in a number of straightforward ways (Table IV).

Graphic Representations

Freehand Sketching

The oldest and most widely used of these procedures is that of freehand sketching. Epitomized by the innovative work of Lynch in 1960, this procedure requires the production of a freehand sketch map of a given environment (such as a city). Although originally treated as if the resulting information was metric, it has become commonly accepted that these sketch maps relied so much on graphicacy skills and had no production controls (e.g., scales or north lines or other orienting features) that their use was very limited.

Controlled Sketching

Controlled sketching provides some information to the respondent before the sketching task takes place. This may be in the form of one or more key locations (such as current position and a significant distant landmark) or it may take the form of providing a scale bar, north line, and a keyed location. Criticisms of controlled sketch map approaches usually focus on mistakes of attributing metric properties to nonmetrically represented features, underestimating the distribution of individual differences in graphicacy skills, and confusing preferred drawing styles with content accuracy. This methodology is shown to have considerable drawbacks when dealing with children and with different disabled groups (e.g., the blind).

Completion Tasks

The extent of layout information is sometimes measured using a completion task. In this case, individuals may be given representations with selected information missing

and be required to insert that information (e.g., object locations, network links, or named neighborhoods) into the incomplete task environment. For example, testing national geographic knowledge, a respondent might be given an outline map of the United States on which are located the cities of New York, Chicago, Houston, Tampa, Phoenix, and San Francisco and be asked to add in the locations of Portland, Minneapolis, Atlanta, and Washington, DC.

Recognition Tasks

Recognition tasks may involve simple shape recognition (iconic tasks), identifying which rotated, scaled, or translated figure best matches a skewed figure (e.g., the classic psychometric rotation measurement task, which is an analogue measurement), or matching layouts that are represented by different symbols (symbolic matching).

Verbal or Written Spatial Language

An increasing interest in the use of natural and technical spatial language to reveal information stored in cognitive maps has resulted in a proliferation of procedures tied to text descriptions of spatial relationships. For example, an individual may view a video, a computer scene, a photograph, or some other representation for a period of time, be distracted for some intervening period, and then be required to correctly identify answers to questions such as “The bicycle is parked to the left of the garage door—true or false?” Language interpretation tasks are often given in sets and, consequently, scored in terms of the frequency of correct answers. The number of correct answers is usually compared with chance expectations. Recognition tasks are sometimes quite useful for populations who are not able to express answers in a traditional way (e.g., blind or vision-impaired people who cannot produce sketch maps or who cannot experience visualizations of problem scenarios).

Placement Knowledge

Layout knowledge can also be tested in various recall situations by requiring people to recall relative placement of features in an environment. Here, after viewing an environmental representation (e.g., map, photo, slide, image, model), respondents may be asked to extract the layout pattern of a particular class of features.

Hierarchies in Cognitive Maps

Cognitive spatial information is apparently stored in a number of different levels. For example, individual buildings may represent nodes in one’s cognitive map

of a campus. However, the campus itself may appear only as a single node in one’s cognitive map of the city in which the campus is located. At a higher level, the city may appear only as a node in the cognitive map of a state, and so on. In this type of structure, as the scale of the environment changes, so does the detail that is incorporated into the knowledge structure.

Model Building

Particularly useful when dealing with visually impaired or blind populations, model-building techniques can recover the configurational layout of learned or remembered environments. Replacing simple sketches with the building of three-dimensional models extends the investigation of cognitive mapping beyond the domain of the sighted. Using different symbols (e.g., blocks for objects, flexible links for paths or roads, flat solids for water bodies), it is possible to construct a three-dimensional model representation of a route or of an area experienced by following multiple routes through it. Casey successfully used this technique in 1978 to explore cognitive maps of the blind and vision-impaired. Since vision traditionally provides the greatest volume of and precision for spatial information, it is not surprising that those without vision produce models that have markedly fewer features than do those with full visual capabilities. Despite significantly smaller numbers of features that appear to be encoded in the cognitive maps of the blind or severely vision-impaired, there has been repeated evidence that such groups can develop complex and comprehensive cognitive maps of familiar environments. Such cognitive mapping capacities have also been confirmed by walking reproduction tasks for representing experienced distances and by body rotation and pointing tasks with respect to recalled directions.

Idiosyncratic and Common Components of Cognitive Maps

Cognitive maps contain some information that is somewhat unique to an individual and some that appears in the cognitive maps of many people. Usually termed “idiosyncratic” and “common,” respectively, they refer to personalized spatial information needed for episodic activities (e.g., one’s home location, a private place for reflection, a particular view or scene) or for more general social information (e.g., local landmarks, named ethnic districts, highways, town or city names). The former represent powerful anchors that are relevant mostly to a given individual and the latter represent equally powerful and essential cues or features that facilitate communication and interaction. Most people will not find their home boldly printed on a local city map, nor will they find

the particular park bench on which they like to sit. Each person has individual likes and dislikes, so what to one constitutes a “pleasing” scene or view or what they consider to be an important neighborhood landmark, such as “the house with the barking dog” or “an unusually constructed mailbox,” may not even register with another person. The idiosyncratic components of cognitive maps can rarely be aggregated. However, for social interaction, for communicating about or describing places, or for giving travel directions, commonly recognized or “familiar” features must be defined. These will appear in most people’s cognitive maps. Examples might be a highly visible landmark (e.g., the Eiffel Tower), a place of worship (e.g., a cathedral), a place of historical interest (e.g., a place where a political leader lived), or a political feature (e.g., an international boundary), all of which qualify as common features readily identified by many people. When attempting to aggregate spatial products to produce “common” maps of, say, a city, usually only the common features can be explicitly counted or combined, and simple frequency counts of the number of times a feature is identified are an indication of the most familiar environmental cue or feature. For aggregation and representation purposes, these are the common anchors that allow a researcher to find out how well an environment (particularly a large geographic area such as a city) is known to residents, visitors, or information seekers by matching the cognized locational pattern of key common features to their places in objective reality.

The cognitive map, therefore, is a repository for personal and group information, includes information about places, features, and relations, and is suffused with personal and social beliefs and values.

Glossary

amygdala A structure deep in the brain; coordinates autonomic and endocrine responses in conjunction with emotional states.

cerebellum A highly foliated part of the hindbrain; coordinates and modulates movement and is involved in learning motor skills.

cognitive map A representation of the spatial characteristics of an individual's environment; enables movement directly from one place to another regardless of starting point.

dendrite The structural part of a neuron; receives and conveys information to the cell body of a neuron.

galvanic skin response (GSR) A change in electric conductivity of the skin; thought to be due to an increase in activity of sweat glands when the sympathetic nervous system is active during emotional states.

hippocampus A structure deep in the temporal lobe of the brain; receives information from the association cortex, and is required for the storage of new memories.

in vitro Latin for "in glass"; refers to the technique of working with tissue that has been removed from the body and stabilized in a culture dish using physiological buffers.

neural network The structures and interconnections that comprise a functional unit within the brain.

nucleus A collection of neurons that are functionally related and located within a relatively confined area of the brain.

soma The cell body of a neuron; inputs reach the cell body via extensions known as dendrites, and the output leaves along the axonal projection.

Neuroscience is a comprehensive term that includes the study and modeling of the nervous system from the molecular–biochemical level to the behavioral level.

Cognition is a more abstract notion that involves awareness, consciousness, and, perhaps, "thinking." The compound term "cognitive neuroscience" refers, then, to the study of the neurobiological mechanisms of cognition. This necessarily involves a multidisciplinary approach and involves a vast amount of research using model systems for the analysis of cognition. The model system includes the animal model (i.e., the species), the paradigm (i.e., the task that will be used to invoke and measure cognition), and the methods of analysis. The study of cognitive neuroscience includes an analysis of more than just simple sensory-response properties; it also includes an analysis of the highest orders of neural processing and the problems that arise with changes to the system, whether due to aging, disease, genetic mutation, or drug abuse. Changes in behavior due to the latter factors have an enormous impact on society, and society can thus only benefit from a better understanding of the neurobiological mechanisms underlying cognition. The discussion here concentrates on cognitive neuroscientific studies of learning and memory, the area of special expertise of the authors.

Model Paradigms

The rigorous scientific study of cognition has benefited from objective measures using well-defined tasks and situations. Subjective responses from humans can be valuable, but the responses cannot be independently verified due to the very nature of subjectivity. Furthermore, the rich experiences of human interactions confound

a rigorous analysis of specific questions. The use of model paradigms, i.e., well-controlled specific tests of learning and memory, has therefore formed a keystone of cognitive neuroscience. Although most knowledge gained from these paradigms has derived from animal experimentation, many of the results have been verified in humans and have led to successful therapeutic treatments for the amelioration of impairments due to aging and disease. The most commonly used paradigms include eyeblink conditioning, fear conditioning, spatial navigation, and object recognition. These paradigms have been successful due to exquisite control of the stimuli, precise measurement of behavioral responses, and the use of adequate control groups. These reductionistic models offer the opportunity to localize the site or neural network that underlies cognition.

Eyeblink conditioning and fear conditioning are the two paradigms for which there is the most complete understanding of the required neurobiological mechanisms for acquisition, retention, and extinction of the task. The two paradigms are behaviorally very similar in that a neutral conditioning stimulus (CS) is paired with, and predicts, the presentation of an unconditioned stimulus (US) that evokes an unconditioned response (UR). The study participant eventually learns the association and exhibits a conditioned response (CR) to the CS after having experienced the paired presentations of the CS and US. The number of exposures required for an individual to exhibit CRs depends on the difficulty, or cognitive load, of the task and on the age of the individual. An advantage of these conditioning paradigms is that the stimuli can be specified precisely. A tone, for example, can be characterized by its frequency, volume, and duration; a shock can be characterized by its magnitude in amps, frequency, and duration; and a puff of air can be characterized by its pressure and duration.

Eyeblink Conditioning

Eyeblink conditioning typically pairs a tone (100–1000 ms) with a brief (100 ms) puff of air to the cornea (similar to that of a glaucoma test) or a mild shock to the side of the eye. The study participant initially has no response to the CS but blinks in response to the US. After the CS and US are repeatedly paired, the individual starts to respond prior to the onset of US such that the peak of the UR is often at the onset of the US. This is dramatic evidence that the individual has learned the temporal relationship between the two stimuli. An example can be seen in Fig. 1. The learning is relatively fast when the CS and US coterminate, and there is strong evidence, especially from Richard Thompson and colleagues, that acquisition of this task is critically dependent only on the cerebellum. For example, decerebrated animals, which have their forebrain disconnected from the brain stem,

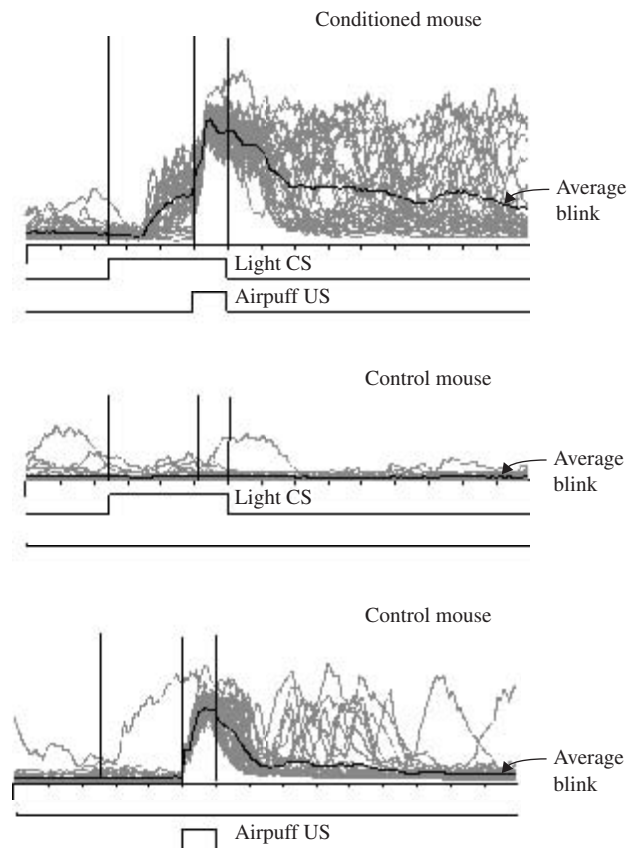

Figure 1 Mice were randomly assigned to either a conditioned or a control group (CS, conditioned stimulus; US, unconditioned stimulus). Conditioned mice were presented with a light pulse followed by a puff of air to the eye. Control mice received the same number of light pulses and puffs of air, but their stimuli were explicitly unpaired and randomly presented. The conditioned mice showed a high percentage of conditioned responses (those that start before presentation of the airpuff). Control mice responded to the light pulse with few blinks, but with robust blinks in response to the airpuff. The average blink is plotted for all of the recorded data for each trial.

can still learn the association, whereas rabbits with cerebellar lesions as small as 1 mm³ are unable to learn the association when the lesion is placed properly.

The cerebellar dependence of simple conditioning may suggest that the task is not cognitive in nature. However, as shown by John Disterhoft and colleagues, when the CS and US are separated in time, a memory trace of the CS must be formed to interact with the effect of US. The simple manipulation of introducing a trace interval between the CS and US appears to make the task more cognitive in nature, because the forebrain is required to learn trace eyeblink conditioning when the stimuli are separated in time beyond some critical interval. This interval may be species specific, but a trace interval of only 500 ms appears to be sufficient to require the activity of the hippocampus and forebrain for

learning to occur in rabbits and humans (250 ms is sufficient for rats and mice).

Another manipulation that is often used to make the task more cognitively demanding is discrimination conditioning. This paradigm uses two different conditioning stimuli such that one CS predicts the US, and the other CS is never paired with the US. An individual that learns this task will respond to the CS+ (the stimulus that predicts the US) but not to the CS− (the stimulus that is not associated with the US). Although this task does not require the hippocampus or forebrain to be learned, an animal with such a lesion will not be able to inhibit CRs when the stimulus contingencies of the experiment are switched, i.e., the old CS+ is now the CS− and vice versa. Learning the reversal of the stimulus contingencies seems to require a flexibility of associative learning that appears to be cognitive in nature and requires that the hippocampus and associated circuitry be engaged for successful acquisition.

Fear Conditioning

Fear conditioning typically pairs a tone (3–8 sec) with a brief shock to the feet in order to evoke a fear response. The fear response of rodents appears as the cessation of normal exploration and grooming such that respiration is the only movement observed. After the two stimuli are paired together in time, the subject freezes in response to the CS. A considerable amount of evidence from investigators such as Michael Davis, Michael Fanselow, Joseph LeDoux, and Stephen Maren indicates that the association of the two stimuli is critically dependent on the amygdala, a part of the brain that is involved in modulating autonomic responses. Like eyeblink conditioning, fear conditioning can also be made more cognitively demanding by separating the tone and the foot shock in time by a stimulus-free trace interval. The presence of the trace interval adds the additional requirement of hippocampal functioning for animals to learn the association of the tone and the foot shock.

Although the two conditioning paradigms may not appear to be inherently cognitive in nature, several methodologies (e.g., neuronal recordings and lesions) indicate that those paradigms require and activate higher order brain structures that are associated with cognition. Two other widely used behavioral paradigms that also seem to be cognitive in nature are spatial navigation and object recognition.

Spatial Navigation

Spatial navigation requires the integration of numerous multimodal stimuli in order to acquire a flexible cognitive map of the environment, so that a study participant can self-direct to a goal, regardless of the starting point

location in a known environment. The most widely used spatial navigation paradigm is often referred to as a Morris water maze, after Richard Morris, who developed the use of the maze. The maze, typically a pool about 6 feet in diameter, is filled with opaque water (the water is made opaque by adding either nontoxic paint or milk powder). The water serves to distribute any olfactory cues that may have been left along the swim path, and it hides a small escape platform that is submerged just below the surface of the water. The water is relatively cool, to encourage even good swimmers, such as rodents, to actively search for an escape route. Rodents typically find the escape platform in a relatively short amount of time; the platform is fixed in place relative to the visual and other contextual cues within the room. The rodents are returned to their home cage after they find, or are directed to, the escape platform and have had time to observe the room from the platform. It is during this time that they appear to form a flexible cognitive map of the room, such that they can find the escape platform from any release site. A few trials are also given with a moveable platform that is marked with a visible flag. These trials are used as a sensorimotor control to confirm that any rodent unable to locate the platform with extramaze cues (due to aging or hippocampal dysfunction) is able to swim to the goal using visual guidance. The rodents typically show a decrease over trials in the time and distance required to find the hidden platform. An example can be seen in Fig. 2. The latency and path length scores are used to assay learning.

Other motivated spatial navigation tasks include the radial arm maze and the hole-board. Those tasks are appetitive rather than aversive in nature, and rely on food or water rewards to motivate the subject to navigate the maze to find the rewards. An example of a simple maze that does not require external motivation is the Y maze. This maze is shaped as its name implies and reveals that rodents tend to alternate spontaneously their selection of which arm to explore, i.e., they tend to explore new places. Because spontaneous alternation indicates that the subjects do

Figure 2 Rats learn the location of a submerged escape platform in a pool of opaque water by forming a cognitive map of their environment. Subjects were given four trials per session for four sessions. Each trial started from a different quadrant of the maze (chosen in random order). The single trial of each session that started from the “north” position (black dot is the target) is shown. Learning is indicated by the gradual decrease in the path length. Figure courtesy of A. Kuo with permission.

not explore randomly, they must be cognizant of their surroundings and remember where they have been.

Object Recognition

Object recognition is the ability to recognize a previously experienced object as familiar. This familiarity can be measured by recording the amount of time that a study participant appears to spend attending to the object. The object can be inanimate, or it can be another study participant, in which case the task is referred to as social recognition. Primates are often used to study object recognition, especially the task referred to as delayed non-matching to sample. This task has trials that are separated by a delay of several seconds and the primate is rewarded for picking one of two objects that was not picked on the previous trial. This task takes advantage of the fact that primates naturally prefer to explore new objects. This task is impaired by lesions of the hippocampus and seems cognitive in nature.

Model Systems

Except for the swimming maze and hole-board, all of the paradigms discussed so far have been used with humans. However, the use of animal model systems has led to the greatest understanding of the neurobiological mechanisms that underlie the different tasks. Eyeblink conditioning was originally done with humans starting in the 1920s. The task was adapted for rabbits by Isidore Gormezano and colleagues in the 1960s. The rabbit was selected due to its tolerance for restraint and the lack of many spontaneous eyeblinks. The rabbit is also a good size for neurophysiological experiments because it can support the hardware necessary for extracellular recordings of neural activity from multiple sites. The disadvantage of the rabbit as a model system is that it has few other behaviors that can be utilized by cognitive neuroscientists, and it has a relatively long life span, impeding research on the effects of age on cognition.

More comprehensive descriptions of cognitive behaviors, including eyeblink conditioning, were attempted by adapting the eyeblink paradigm for rats. This was done by using a tether to connect the equipment to the rat so that it could move about relatively freely. The rat-based model allowed an analysis of age-related impairments and a comparison of multiple tasks such as eyeblink conditioning, fear conditioning, and water maze learning. A combination of tasks is invaluable for validating general properties of cognitively demanding tasks.

Most recently, the eyeblink conditioning paradigm was adapted for the mouse in order to determine the effects of specific genes on learning, memory, and cognition. The shift from rat to mouse is technically rather

straightforward, but the selection of the conditioning stimulus needs to be considered carefully because inbred strains can be insensitive to a particular stimulus modality, such as light, or can suffer from age-related sensory impairments, such as hearing loss. Some of these details have been determined for the common C57BL/6 mouse, including the necessity of the hippocampus for trace eyeblink conditioning.

Behavioral Measurements

Eyeblink Conditioning

The parameters and methodologies used to measure cognition vary with the task being used. Eyeblink conditioning, as the name implies, relies on detecting movement of the eyelids. Many investigators who use rabbits will, however, use extension of the nictitating membrane (NM) as a measure of the response, although both responses are often collectively referred to as eyeblinks. The nictitating membrane, found, for example, in rabbits and cats, acts as a third eyelid. Animals with this membrane also have an extra set of extraocular eye muscles (the retractor bulbi muscle) that acts to withdraw the eyeball into the socket. The membrane normally rests within the inner corner of the eye and passively extends as the eyeball is retracted during a blink. Extension of the NM is often measured with either a minitorque potentiometer or a reflective sensor.

Minitorque Potentiometers

The potentiometer is usually stabilized above the head of the animal and the rotating arm of the potentiometer is connected to a loop of silk that is sutured to the distal point of the NM. This transducer can be calibrated so that there is a direct conversion of volts to millimeters of NM extension. Some researchers have also used this transducer in humans by connecting the rotating arm of the potentiometer to the eyelid with a lightweight adhesive.

Reflective Sensors

The other common method of measuring eyeblinks is to use an infrared reflective sensor that measures changes in reflected light as the NM extends and withdraws across the eye. This device combines an infrared light-emitting diode (LED) and a phototransistor into one package. The LED is used to aim invisible infrared light at the cornea and the phototransistor is aimed to detect the reflected energy. This device does not require any physical attachment to the NM or eyelids, and is often calibrated in terms of volts per maximum blink. Newer models of the minitorque potentiometer are also based on a reflective sensor, rather than wire windings, so that movement of the potentiometer spins a polarizing filter relative to

a fixed polarizing filter, and the amount of light that passes through the set of polarizing filters is proportional to the movement of the potentiometer arm.

Eyeball Retraction

Because eyeball retraction is the primary mover for NM extension, it may be a more sensitive measure than NM extension is, and may be useful when looking for subtle changes in the system. This was the case when Disterhoft and colleagues determined which eye muscles regulated the conditioned response. They fitted the rabbit with a contact lens that had a thin filmstrip protruding from it. The filmstrip had an optical density grating that moved freely between an LED and a phototransistor. The output of the device was then calibrated for volts per millimeter of retraction.

Electromyographic Activity

The potentiometer and reflective sensors work well for animals that tend to be stationary. The recording of electromyographic (EMG) activity from the eyelids was introduced when freely moving rats were being used for conditioning studies. The activity can be recorded from thin, sterile wires that are implanted in the eyelid, or temporarily pasted next to the eye in the case of humans. In either case, the wires are led to an amplifier and filter so that blinks can be recorded. The EMG activity associated with a blink tends to be a very sensitive and short-latency indicator of a response, and highly correlated with simultaneous measurements using a reflective sensor. An example from studies of rabbits, rats, and humans can be seen in Fig. 3. The EMG signal is often rectified and integrated in order to produce an analog signal that can be analyzed in the same way as signals recorded from the other devices.

Fear Conditioning

As stated previously, the fear response of rodents is apparent in the cessation of normal exploration and grooming, such that respiration is the only movement observed. This measure was originally recorded with a stopwatch by trained observers. The time spent in a freezing posture relative to the total time of observation would yield a score of percent freezing. Better learning was indicated by a greater percent of freezing to the conditioning stimulus. More recently, computer software has been developed to detect movement either by video tracking or by comparisons of adjacent video frames (if the two frames are identical, there is no movement). The computer system has the advantage of being objective, extremely sensitive to small movements, vigilant in detection, and able to record and store the data accurately.

Another technique to assess fear conditioning has been to detect changes in heart rate activity. This involves the

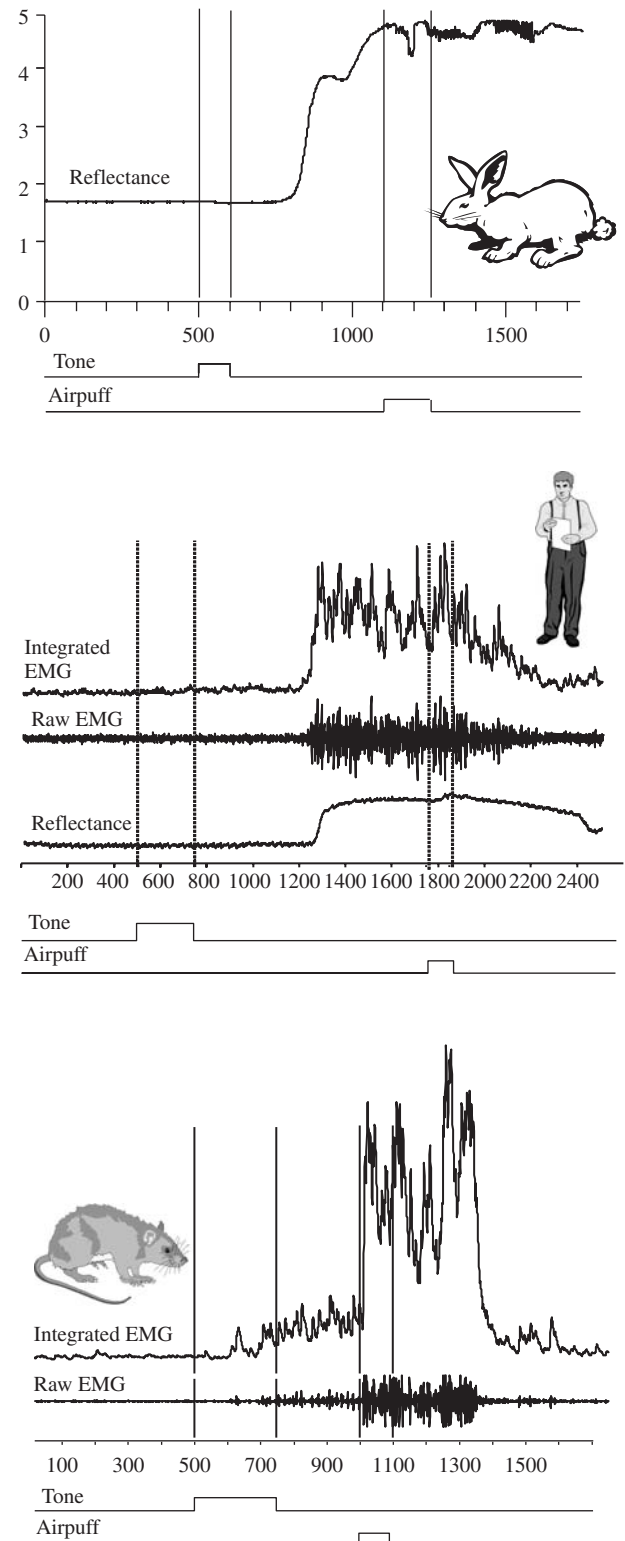

Figure 3 Examples of eyeblink data recorded with electromyographic (EMG) electrodes and infrared reflective sensors. Similar equipment can be used across species for a comparative analysis of learning using model systems. The horizontal axis represents time in milliseconds. Figure courtesy of J. Power with permission.

implantation of two subdermal electrodes. The study animal is connected by wires during each training or testing session. Heart rate measurements are especially useful for animals that have few baseline movements, such as rabbits or aged rodents. Heart rate activity can be easily recorded and presentation of the fear-eliciting stimulus is often accompanied by a transient decrease in heart rate. More recent procedures involve telemetry systems that receive a signal from a surgically implanted transponder. There are no leads connected to the animal with this system.

Fear conditioning experiments have also been done with human study participants. The individuals are usually told that they will be presented with tones and a mild shock, but they are not told that the tone predicts the onset of the shock some seconds later. They can also be instructed to use a dial to indicate their ongoing expected probability of being shocked. This methodology has been used by Fred Helmstetter and colleagues, who find that the study participants quickly learn to expect the shock at the appropriate interval after the conditioning tone. Behavioral measurement of fear conditioning in humans is done with the galvanic skin response (GSR), which is also used in lie detector tests.

Spatial Navigation

As mentioned previously, the most widely used task for spatial navigation is the water maze. Learning in this task was originally measured with a simple stopwatch, i.e., the time it took for the animal to find the escape platform was recorded. Decreases in this latency indicated learning and an awareness of the environment. Computer software that has since been developed utilizes video tracking. These computer systems not only record the time for the animal to find the target, but they also record and measure the path that the animal took to get to the target. This allows an analysis of path length, speed, and latency, as well as measures of proximity to the target. The path length measure has been a valuable tool to discriminate differences due to motor/swimming abilities from differences due to the formation of a cognitive map of the environment, i.e., recognizing the location in the environment. Many investigators will also introduce a “probe trial,” in which the escape platform is removed in order to try and determine how well the location of the platform was learned.

Electrophysiological Measures of Learning

Electrophysiological correlates of learning have been sought in order to locate the sites and processing of activity that might mediate cognition. The general idea is

that brain regions that exhibit task-related activity must be mediating the task. However, this is not always true, because some regions show correlated activity even though the task can be acquired after lesions of the specific region. The hippocampus provides an excellent example because it exhibits neuronal activity that is correlated with simple conditioning, even though the task can be learned after the hippocampus is removed. This finding raises the question of which regions are necessary for a task rather than just activated by the task. The answer requires either permanent or temporary inactivation of a structure to determine if the activity is essential to the function of the network. Investigations of the cerebellum provide an excellent example. Recordings from neurons within the eye zone of the cerebellar interpositus nucleus (an output of the cerebellum) during eyeblink conditioning exhibit activity that is highly correlated with the conditioned response in terms of timing and amplitude of response, and lesions of this area prevent new conditioning and abolish established conditioning.

Extracellular Recordings

The first experiments to detect electrophysiological correlates of learning and cognition used microelectrodes with an exposed tip about 0.5 mm in length. These electrodes recorded the extracellular electrical activity of numerous neurons within the vicinity of the recording tip. The activity would typically be gathered by setting a threshold and recording a time point whenever the activity crossed the threshold. This technique works well when the neuronal population is homogeneous in function, but the activities of individually isolated neurons are necessary to understand the function of a region with heterogeneous responses. Consider an example in which there are two different cell types with responses in opposite directions, i.e., one type shows increased activity and the other shows decreased activity. The net sum of this activity as recorded with a multiunit electrode would indicate no response, when in fact both cell types were responding. The solution to this problem is to record the activity of single neurons. This type of analysis often reveals that a population of neurons has heterogeneous responses, and the different response types can be quantified in terms of percent representation.

The activity of single neurons is now recorded by using electrodes or microwires with much smaller exposed tips (0.05 mm or less) or by using waveform identification techniques to cluster the activity according to groups with similar waveforms. This technique is based on the idea that each neuron exhibits a characteristic waveform based on its biophysical properties and its distance from the electrode; an analysis of subthreshold activity requires intracellular recordings (see later). More recently, a stereotrode, or closely spaced pair of electrodes (or

tetrode, four closely spaced electrodes), has been used to triangulate on the activity of simultaneously recorded neurons. This technique was developed by Matthew Wilson and Bruce McNaughton. The technique increases the ability to distinguish different neurons with fairly similar waveforms, especially when recording from a region with a high density of neurons.

The characterization of large numbers of single neurons within a nucleus is necessary to gain an understanding of the function of a nucleus. Another important clue to determining the function of a nucleus is to compare the activity patterns of the main input and output of the region. This, of course, requires a knowledge of anatomical connections so that the main input and output of a region can be analyzed. This technique considers the nucleus of interest as a “black box” that converts the input function into the output function. The transformation of the signal that must have occurred identifies the function of the nucleus. This type of analysis is critical for a systems-level model of behavior.

Intracellular Recordings

Electrophysiological recordings can also be made from individual neurons by either penetrating the neuron with a sharp micropipette electrode or by attaching the tip of a micropipette to the surface of a neuron with slight suction. A few researchers use this technique in living animals. They rely on coordinates and characteristic electrophysiological signals to indicate when the electrode is near a target. A sudden drop in noise and a recorded voltage near the resting potential of neurons (about -65 mV) indicate when the electrode has penetrated a single neuron. However, most studies with intracellular recording have been done using *in vitro* brain slices. These are slices of tissue that have been cut from an extracted brain and stabilized in laboratory containers with appropriate physiological buffers. These slices remain viable for several hours under proper conditions.

In vitro slices are often used to study the hippocampus because it is involved with memory functions and because its network properties can be isolated within a single slice (consider a banana, and how each slice is similar to another). The advantage of intracellular recording is that it allows measurement of subthreshold changes in voltage or current, and the electrode can be aimed at either the soma or a dendrite when the slice is visualized with an appropriate microscope and the electrode is advanced with a micromanipulator (see Fig. 4). Furthermore, the results from these “slice” experiments can be interpreted as being intrinsic to the structure being studied because it is physically disconnected from the rest of the brain. This also applies to studies on the effects of drugs, i.e., any effect of the drug must be acting on

Figure 4 Intracellular recordings can be made to observe biophysical changes related to learning. (A) The photomicrograph shows two pyramidal neurons from a slice of the hippocampus. A patch pipette was attached to the neuron on the right in order to record activity. (B) The two traces show that the afterhyperpolarization following a burst of evoked action potentials is reduced in rats trained with trace eyeblink conditioning relative to rats that are given explicitly unpaired presentations of the tone and airpuff. Figure courtesy of E. Sametsky and A. Kuo with permission.

hippocampal circuits because it is the only structure in the dish.

In vitro recordings from the output neurons of the hippocampus proper (area CA1) have yielded considerable insight into the mechanisms that are associated with learning and age-related impairments. John Disterhoft and colleagues discovered that the biophysical properties of individual hippocampal neurons change with learning such that the neurons become more excitable. Normally, a neuron initiates an action potential, which is a sharp rise in membrane potential followed by a sharp fall that actually exceeds the original resting potential. This afterhyperpolarization (AHP) is reduced with learning so that the neuron requires less input to respond with another action potential. This change is specific for animals that are trained on a learning task (eyeblink conditioning or water maze), because animals given control conditions do not show the increase in excitability. An example can be seen in Fig. 4. The AHP of hippocampal neurons increases with age so that neurons from aging animals are less likely to respond to a given input. This may partially explain why older subjects are slower to learn some associative tasks. Furthermore, several studies have shown that drugs (nimodipine, *d*-cycloserine, metrifonate, CI-1017, and galanthamine) that facilitate learning also reduce the AHP of hippocampal neurons, i.e., they become more excitable.

The combination of data from extracellular recording experiments and intracellular recording experiments has provided considerable insight into the mechanisms and systems-level interactions that are likely to underlie cognitive processes. A disadvantage of the techniques is that data are slowly acquired from confined regions and large numbers of neurons are necessary to make meaningful conclusions. These techniques are also only realistic if there is an *a priori* expectation for the involvement of

a region in the task being studied. This information typically comes from data arising from either lesion studies or anatomical studies of neuronal interaction. The only other electrophysiological option is one of brute force mapping of the entire brain. This is sometimes referred to as a “fishing trip.”

Imaging Cognition

A “fishing trip” through the brain in search of cognition could be avoided if some sort of “radar” was available to narrow down the target area. This so-called radar is now available in the form of different neuroimaging techniques. The technique that presently has the greatest spatial and temporal resolution is functional magnetic resonance imaging (fMRI), which relies on differences in the magnetic susceptibility of oxygenated and deoxygenated blood. This blood oxygen level-dependent (BOLD) response can be followed in time while a subject learns or performs a task. The response can then be superimposed on a detailed image of the brain so that functional activity (increases or decreases in the BOLD response) can be localized. The technique is most often used with human study participants because they can keep their head very still, follow directions, give verbal feedback, and indicate responses with some sort of detector (e.g., a keystroke). Some experiments have been done recently with monkeys, but they are rather precious and require lots of training, some sedation, and extreme care to maintain in good health.

A simple animal model for neuroimaging of cognition is again based on the rabbit. Alice Wyrwicz, John Disterhoft, Craig Weiss, and colleagues took advantage of the rabbit’s natural tolerance for restraint and adapted the eyeblink conditioning paradigm for the MRI environment. This paradigm allows the detection of functionally active regions throughout most of the brain while the rabbit is awake, drug free, and learning a new task. The results so far have confirmed the involvement of the hippocampus and cerebellum in simple delay conditioning, and have revealed specific regions that should be explored more carefully with electrophysiological techniques to understand fully the neural mechanisms that mediate cognitive processes. An example of activation in the visual cortex and hippocampus can be seen in [Fig. 5](#).

Awareness and Cognition

Although the use of the eyeblink conditioning task with animal model systems has been emphasized, the goal has always been to understand the mechanisms of human cognition. A major advantage of using humans in cognition studies is that the experimenter can get verbal

Figure 5 Functional magnetic resonance imaging of the awake rabbit brain during eyeblink conditioning. The left image shows the statistically significant blood oxygen level-dependent response to the visual stimulus during explicitly unpaired control presentations of the light and airpuff. The right image shows the activity in response to the same visual stimulus alone after the rabbit had reached a level of 80% conditioned responses on trials with paired presentations of light and airpuff. The difference in activations, especially in the visual cortex and hippocampus, represents learning. Figure courtesy of B. Tom and A. Wyrwicz with permission.

feedback about the experience. The postsession interview technique has been quite revealing about interactions between awareness and conditioning. Larry Squire, John Disterhoft, Kevin LaBar, and colleagues from their laboratories have utilized questionnaires to determine whether human participants were aware that the conditioning stimulus (tone) predicted the unconditioned stimulus (airpuff). Individuals were also asked questions about the content of a silent movie that they were watching (the movie was used to keep subjects awake and alert during the experiment). All of the individuals accurately answered questions about the content of the movie, but some, especially older people, were unaware of the predictive value of the conditioning stimulus. The striking result was that only those who were aware of the stimulus contingencies exhibited conditioned responses during trace conditioning. This is strong evidence that awareness or cognition is necessary for, or occurs simultaneously with, higher forms of conditioning such as trace conditioning.

Cognitive Psychology

Johan Wagemans

University of Leuven, Leuven, Belgium

Glossary

architecture of cognition The basic components of the cognitive system in terms of the representations and computations that are used in the different mental functions.

behaviorism Psychology as the science of behavior, limited to observable entities such as stimuli and responses, and their associations.

brain imaging The technique to visualize localized brain activity corresponding to particular mental processes.

cognitive neurosciences The multidisciplinary consortium of sciences devoted to mind–brain relationships.

cognitive sciences The multidisciplinary consortium of sciences devoted to the understanding of the mind and the mental functions.

computational (information-processing) approach The attempt to understand mental functions (e.g., perception) as processes (computations) on internal (symbolic) representations.

ecological approach The attempt to understand mental functions (e.g., perception) without intermediate processes but in relation to the behaving organism with its natural environment.

functionalism The philosophical view behind the information-processing approach, positing that mental processes can be understood at a functional level, detached from their hardware implementation in the brain.

neural network models Models of mental functions that rely on the properties of the brain as a huge network of highly interconnected simple units.

Cognitive psychology is the area of specialization within psychology that is concerned with human cognitive processes such as memory, language understanding, problem solving, thinking, and the like. This definition entails two aspects. First, cognitive psychology is

a particular theoretical framework in psychology developed in the 1960s and 1970s, and is currently being subsumed under larger multidisciplinary sciences such as the cognitive sciences and the cognitive neurosciences. Second, the domain of cognition can be sketched, both in its narrow sense, including strictly cognitive phenomena, and in its broader sense, including also other phenomena such as attention and performance, perception and action, and emotion and motivation.

Origins and Rise of Cognitive Psychology

Psychology has been defined in many different ways in the past, from the science of the mind to the science of behavior and back again to the science of the mental life. The most widespread view today is that psychology is concerned with observable behavior as well as with its determining factors, both external (in the environment) and internal (within the person). Psychologists want to understand and explain why people behave the way they do. These causes are currently believed to depend on a complex interplay between external events and subjective factors such as the personal history, the desires, and the style of thinking of an individual. This has not always been acknowledged in the history of psychology.

Before Cognitive Psychology

In the early days of psychology as an independent discipline, the internal processes were studied by means of introspection: Trained observers were asked to report the contents of their own thoughts and the dimensions of their own subjective experiences. However, this method was

severely criticized for its limitations: People were often not fully aware of the driving forces and internal mechanisms behind their own behavior, and even trained observers could not agree about basic aspects such as the number of dimensions that should be distinguished to describe properly the subjective experience. As a result of this, introspection was abandoned and internal processes were banned from psychology's scope.

Behaviorism defined psychology as the science of behavior. It restricted the domain of study to external factors only, which could be observed and described objectively. Psychology was thus limited to the study of stimuli (S) and responses (R) (i.e., S–R psychology), and all intermediate processes within the organism (O) were locked up in a “black box.” All psychological phenomena were explained in terms of S–R connections. For example, learning was understood as the establishment of associations between stimuli and responses. In classical conditioning, Pavlov's dog started to salivate on the sound of a bell because the sound always preceded the food, the natural stimulus for the salivation response. In operant conditioning, small animals such as rats and cats learned to press a lever because this (initially random) response was rewarded by food or freedom (i.e., the opening of the cage). Skinner taught pigeons to play table tennis by sophisticated reward schemes, starting from the animal's natural repertoire of behavior and gradually shaping it into the desired behavior.

The Cognitive Revolution

By the late 1950s, psychologists became convinced that much of human behavior could not be explained in S–R terms only. Most everyday behavior is not guided by stimuli as such, but by an understanding of the stimuli. When a person smells smoke, they will not shout “fire!” if they also see their neighbor lighting a cigar; when others hear someone shouting “fire!,” they will not run out of the building if they are in a movie theatre watching actors in a fire scene. In striving for objectivity, behaviorists excluded invisible entities such as understanding (and beliefs, preferences, desires, plans, strategies, and the like) from a scientific explanation of behavior, but in doing so their explanations failed to capture the real causal mechanisms behind behavior. Behaviorism thus declined and a new alternative emerged. Three interrelated factors gave rise to the so-called cognitive revolution in psychology in the 1960s. The first was definitely the widespread dissatisfaction with behaviorism's limitations, which became strongly articulated in Chomsky's vehement attack (in 1959) on Skinner's book on verbal behavior. Chomsky argued that, in principle, language cannot be explained as purely verbal behavior, determined by S–R connections. Human language production and understanding must include mental processes and representations to capture

their essential characteristics of syntax and semantics, and the productivity and creativity in their usage. Language conveys meaning and meaning implies world knowledge, which is stored in memory and is activated appropriately in both the speaker and the listener. Initial behaviorist attempts to include hidden chains of S–R connections to replace the O within the black box could never solve these basic problems.

The second historically important trigger for the shift in thinking in psychology was the increased need to understand the functioning of human operators in the context of industrial processes (factories, aircraft control, telecommunication, and the like). Many instruments or machines did not function optimally or led to serious accidents because of failures at the operator level: Warning signals were missed because of limitations of attention, or were misinterpreted because of incorrect cognitive assumptions; appropriate actions were not taken because of capacity limits on short-term memory or mistakes against the principles of logical reasoning. A great deal of pioneering work was done on these topics in the 1950s. For example, Broadbent introduced the notion of a filter to understand the role of attention and selection in perception (in his 1958 book, *Perception and Communication*); Miller quantified the capacity limit of short-term memory as the “magical number seven plus or minus two” (in a famous paper, published in *Psychological Review* in 1956); and Bruner and colleagues studied thought processes by innovative experimental techniques, leading to their 1956 book, *A Study of Thinking*.

The third factor, the computer revolution in the 1950s and 1960s, provided an excellent metaphor to develop alternative theories of what happens in human language production and understanding, as well as in the case of man–machine interactions. People process information in roughly the same way as computers do: they receive and encode messages, derive their meaning by relating it to knowledge stored in memory, make decisions by following certain algorithms, and send commands to trigger appropriate responses. The information-processing stream between input (S) and output (R) devices appeared similar in the 1950s and 1960s in both cases; the underlying processes of encoding, decoding, data storage, retrieval, and transfer were considered to be at least analogous in humans and computers. The internal representations and symbol manipulations performed by the computer were considered good models of the human mind.

In 1967, Neisser wrote *Cognitive Psychology*, the first book in which this new theoretical framework was spelled out systematically. In the early 1970s, journals such as *Cognitive Psychology* and *Cognition* were initiated, and somewhat later, traditional journals were renamed to reflect a similar transition (e.g., *Journal of Verbal Learning and Verbal Behavior* was changed to *Journal of Memory and Language*). A new field was born.

The Core Program of Cognitive Psychology

Core Concepts: Internal Representations and Operations

Cognitive psychology, as an alternative approach to behaviorism and as a scientific paradigm to study mental processes, comes in different versions when applied to a variety of topics. However, all of these cognitive theories and models share a number of essential ideas. The core concept is that of internal representations and internal operations. In a classic study (reported in *Science* in 1966), S. Sternberg demonstrated that people can scan their internal representation of a stimulus display, briefly stored in so-called short-term memory, in order to find a specific target. In another *Science* paper (in 1971), Shepard and Metzler showed that the response times to determine whether two block figures are identical, despite a different orientation in space, increase linearly with the angular separation between the two images. They took this as experimental evidence for a mental rotation process, operating on the internal representations of the stimuli, analogously to the physical rotation, which would be needed to align the solid block figures in space. In 1972, Craik and Lockhart argued that what is done to the incoming information determines how well it is remembered. They provided evidence in favor of their “levels of processing” framework, when they showed that subjects who were oriented toward “shallow” aspects of the stimulus (e.g., those who were asked whether the letters of a word are printed in lowercase or uppercase letters) remembered fewer items when prompted unexpectedly in a later stage of the experiment, compared to subjects who were oriented toward “deeper,” more semantic aspects of the stimulus (e.g., those who were asked to make a sentence with the word).

Core Business: The Architecture of Cognition

Theoretical and empirical research in this tradition then consists of identifying the characteristics of these internal operations, the different kinds of representations, the different stages and levels of processing, how they relate to one another, how they interact, etc. For example, classic work has divided memory into three different stages, each with its own specific properties: (1) a sensory buffer, with a very large capacity but very brief duration, which uses a veridical code, with no translation of the input format (e.g., retinal image); (2) a short-term memory system, with a very limited capacity (7 ± 2) and relatively short duration, using a phonological code (i.e., sound) to assist the internal rehearsal process that avoids the decay of the

trace over time (e.g., when whispering a telephone number between hearing it and dialing it); and (3) a long-term memory system, with an unlimited capacity (lifelong learning!) and unlimited duration (reactivation of apparently forgotten material often appears possible), which is mostly based on a semantic code (i.e., the meaning is stored, not the details). A second example of this type of research concerns the format of the internal representations. This issue has given rise to one of the classic controversies in cognitive psychology, known as the “mental imagery debate.” One position holds that there is a single, universal representation format for all kinds of information (i.e., encoding all information in a propositional format or “language of thought,” to borrow a term introduced by Fodor in 1975). The alternative view (defended strongly by Kosslyn and Paivio) proposes that visual information is not recoded as propositions but is maintained in an analogue representation format, giving rise to the idea of “mental images” inspected by the “mind’s eye” (e.g., mental rotation).

Another issue that has attracted a lot of interest and research effort is whether certain internal operations are performed sequentially (in serial stages) or simultaneously (in parallel). This type of research has led to a wide variety of “box-and-arrow” models of the intermediate mental processes in-between input stimuli and output responses. All of these can be taken as attempts to carve up the mind into its basic building blocks or “modules” (to borrow another term introduced by Fodor, in 1983), or, more generally, to discover the basic “architecture of cognition” (i.e., the title of the 1983 book by J. R. Anderson, one of the champions of this approach).

The problem with this whole approach is, of course, that none of these cognitive mechanisms can be observed directly. Researchers must design clever experiments, with well-chosen experimental and control conditions, as well as manipulated and registered variables, to derive the internal representations and processes from observable responses such as response times and error rates. These “chronometric explorations of mind” (the title of a book by Posner in 1978) have had some success in some domains, but it is not the case that universally accepted “unified theories of cognition” have resulted from this endeavor (despite valuable attempts in that direction by pioneers such as Newell, in his last book in 1990).

Core Assumptions: The Functionalist Philosophy behind the Approach

The general theoretical framework behind most of the work in cognitive psychology is the so-called information-processing approach, that is, the notion that the human mind performs mental operations when processing the meaning of the incoming sensory signals (i.e., input)

and when deciding to perform certain actions (i.e., output). In-between these peripheral input and output devices are central cognitive mechanisms that operate on internal representations. A critical assumption of this approach is that these internal representations and processes can be understood at the functional level, without consideration of the hardware level (i.e., the neural mechanisms implementing them).

This assumption constitutes the heart of the so-called computational approach to cognition, which is the idea that cognition is, literally, computation (defended strongly by Pylyshyn in his 1984 book). This approach thus goes beyond the computer metaphor in claiming that all cognitive processes can be understood as computations on internal, symbolic representations. At the functional or software level, the human mind works in just the same way as the computer; it is only at the hardware level that they differ, but that is essentially irrelevant to their operation as information processors. This philosophical position, known as functionalism (i.e., a modern version of mind–brain dualism), has implications for the relation of cognitive psychology to artificial intelligence and its position within the cognitive (neuro)sciences (see the section below).

Current Domains within Cognitive Psychology

Cognitive psychology is not only a particular theoretical approach within psychology; it also entails a particular substantive area of research, a set of phenomena that would be called “cognition” even if there were no agreement concerning all of the theoretical positions and assumptions of cognitive psychology as an approach. In a strict sense, cognition concerns only the central types of representations and processes, at the highest level of the system (using “central” as opposed to “peripheral” input and output mechanisms). However, in many textbooks of cognition (and corresponding courses within academic teaching programs), “cognition” is sometimes used in a much broader sense, implying all of the internal mechanisms (even the more peripheral ones).

Central Cognition

Problem Solving, Decision Making, and Reasoning

In their highly influential book on this topic, Newell and Simon studied human problem solving by asking people to think aloud while solving problems and by attempting to reproduce the results and the processes in computer simulations. They introduced the notion of a problem space, consisting of the initial state of the problem,

the goal state, all of the intermediate states, and all of the possible operations involved in moving from one state to another. To select one of these operations, to move in the right direction in the problem space, the cognitive system relies on a means–ends analysis and other heuristics or rules of thumb (to be contrasted with algorithms, which are sequential procedures that are more complex but guaranteed to produce the correct outcome when followed accurately).

Heuristics and biases are also used quite frequently in human decision making under uncertainty. These have been studied in a flourishing line of research by Tversky and Kahneman (e.g., papers in *Science* in 1974 and 1981). Despite the fact that they sometimes introduce mistakes, these heuristics and biases also contribute to the speed and flexibility that are characteristic of human thinking but are difficult to reproduce in computers. In contrast, computers are better at applying rigid algorithms, detached from common sense and intuition (see also Dreyfus' 1972 book *What Computers Can't Do*).

Mistakes against logic are also found commonly in other forms of reasoning, such as deductive reasoning (e.g., conditional reasoning, syllogistic reasoning). Following the rules of logic, a deductive inference produces a correct conclusion if the premises are correct. According to one type of theory of deductive reasoning (e.g., that of Braine), humans use mental logic, a set of abstract, formal rules, very much like the rules of logic. According to an alternative approach, humans do not use the formal rules of logic but they represent, in so-called mental models, the different possible states of the world corresponding to the premises. Johnson-Laird is the most famous representative of this mental model approach to deductive reasoning. The latter approach has the advantage that it incorporates more of what is known of other mental processes, such as working memory and language understanding.

Memory and Language

The concept of a “working memory” was introduced by Baddeley to reflect the active, coding, and control processes in short-term memory. It is more a “workspace,” to keep the code active, than a passive “warehouse” for information. It consists of a central executive system, which allocates resources to two independent subsystems, the articulatory or phonological loop and the visuospatial sketchpad (for verbal and visuospatial information).

Other memory systems have been added to the three memory systems in the traditional stage model. For example, Tulving introduced the notion of episodic memory, which encodes, stores, and retrieves facts from personal life (e.g., a person's first party or first day at college or university). This type of memory seems to operate differently than does so-called semantic memory, which stores meaning in a more abstract way, in the sense

that it does not retain the spatiotemporal details of where and when the stored information was encountered. These concrete aspects of the encoding circumstances do matter for episodic memory. Semantic memory is often conceived as a network of concepts with attached properties (e.g., as slots in frames), sometimes with the nodes at different levels in a hierarchy but always with connections between the nodes. For example, in the so-called spreading activation theory of semantic processing, knowledge that is needed to answer questions such as “Can a robin fly?” or “Is a penguin a bird?” is retrieved from such a network by activating the two nodes and having the activations spread between them until they meet. These models can capture prototype effects (reported by Rosch in a famous 1973 paper in *Cognitive Psychology*) by including shorter connections between a superordinate category such as “bird” and more typical exemplars such as “robin” and longer ones for less typical exemplars such as “penguin.”

Within semantic memory, a distinction is often made between declarative memory (for facts that can be stated in simple sentences, such as “Brussels is the capital of Belgium”) and procedural memory (for procedures such as how to tie one’s shoes). Other relevant divisions are between intentional and incidental learning (at the encoding stage), or between implicit and explicit memory (at the retrieval stage). This last dissociation has attracted a lot of interest because patients with amnesia appear to perform well on so-called implicit memory tests, in which they do not have to search in a controlled fashion for the information in long-term memory but are given the opportunity to reactivate this information automatically (e.g., in a word-fragment completion task or in a priming paradigm). This distinction between controlled and automatic processes has also been made in other contexts (e.g., expertise, attention, and performance).

In some cognitive theories, these different memory systems are made to work together. For example, in J. R. Anderson’s theory of expertise, called adaptive control of thought (ACT), declarative and procedural memory are interconnected by a working memory system, which performs operations on the concepts and rules that are retrieved from the long-term memory systems. A crucial aspect of expertise development or skill acquisition in this view is knowledge compilation, a progressive shift from the use of declarative memory (serially retrieving facts) to the use of procedural knowledge (routines that can be run more automatically).

Human language is also such a complex, multileveled phenomenon, requiring the consorted activation of different subsystems and representations. On the one hand, it is useful to distinguish between syntax and semantics, and to introduce purely syntactic concepts such as a phrase structure (a tree diagram to capture the different syntactic building blocks of a sentence) and to rewrite

rules (telling which components can be put together to have grammatically correct sentences). This is needed to be able to assess the grammaticality of meaningless sentences such as “Colorless green ideas sleep furiously,” one of the famous examples by Chomsky, who did pioneering work on syntactic structures and on aspects of the theory of syntax and thus contributed strongly to the cognitive revolution in the 1950s and 1960s (see above). On the other hand, everyday language understanding implies the interactive activation of syntactic and semantic components from the language system. When people listen to a few sentences, they automatically draw inferences from the intended meaning. They often generate a schematic representation of the scene or scenario from their long-term memory and use that to interpret (and perhaps disambiguate) the incoming information. Making use of so-called scripts, Schank and Abelson have contributed to the construction of artificial systems for language understanding. (This work has been taken as typical for so-called strong artificial intelligence. As a consequence, it has been criticized by opponents of this type of artificial intelligence, such as Searle, in his famous Chinese room though experiment, published in a widely discussed paper in *The Behavioral and Brain Sciences* in 1980; see further discussion below.)

More recent models of text comprehension (e.g., Kintsch’s “construction-integration model” published in *Psychological Review* in 1988) go even further and make use of a complicated scheme of different representations (e.g., sentence level, propositional network, and text representation) and cognitive systems (e.g., production system and semantic and episodic memory system). Likewise, Levelt’s theory of speech production entails the parallel and interactive activation of representations of meaning and grammatical structure (semantics and syntax), as well as morphemes and phonemes (basic word forms and basic units of sounds).

Other Domains within “Cognition” in the Broad Sense

Attention and Performance

To the extent that information processing in complex tasks consists of different operations performed in different subsystems, an important question is how to make these subsystems work together properly. This is the issue of the control of information processing. One type of control is provided by so-called production rules. These are “if–then” rules, which automatically initiate a certain cognitive operation (or sequence of operations) when a particular stimulus triggers a particular representation in long-term memory (because they are internal, they should not be confused with behaviorist S–R connections). These production rules, which are

quite central in the work of Newell and Simon and of J. R. Anderson, are rather automatic processes, but there are also more controlled ways of strategically selecting operations and assigning cognitive resources to different subsystems. These control operations are said to depend on a so-called central executive system, a kind of “big boss” that makes all the “slaves” or “assistants” do the real work (see Baddeley’s model of working model, previously mentioned). One problem that has attracted a lot of attention is how to avoid the problem of infinite regression with such a command system: Who or what controls the operation of this homunculus (“little man in the head”)? Another homunculus perhaps? But who controls this one then?, etc.

Control can thus be automatic and strategic. Experimental research by Shiffrin and Schneider (in a set of twin papers in *Psychological Review* in 1977) has shown that learning has strong effects on these control processes. Car driving, for example, is a complex task that requires the coordinated activity of many subsystems. Experienced drivers become so highly practiced in executing these different operations in particular sequences that they no longer require strategic control; they become automatized and the previously required resources can now be used for other tasks, such as listening to the radio or engaging in a nice discussion with another passenger. When experienced drivers need to explain all the steps to a novice whom they are teaching to drive a car, they often make mistakes because the automatized routines must now be decomposed again (which requires strategic control again). These issues also play a role in a variety of other activities such as skilled typing and piano playing. Motor control can also shift from slow and laborious complex planning to fast and automatic execution of sequential procedures.

Assigning resources is also of central importance in the domain of attention. The central processing mechanisms (e.g., short-term memory) have only a limited capacity, so a selection at the input stage is needed to avoid overload. It is not possible to pay attention to all the stimuli that are available simultaneously in a complex everyday environment. Studies of the necessary filter mechanisms were quite instrumental in the rise of cognitive psychology in the 1960s. A popular experimental paradigm to study these issues is dichotic listening with a shadowing task. In these experiments, subjects receive two different messages in the two channels of a headphone and they have to repeat the message in one (i.e., to “shadow” that target channel). They appear to be able to ignore the other (distracter) channel better when the selection is supported by acoustic or semantic differences between the channels (e.g., male versus female voice, news versus commercial). Anecdotal evidence as well as experimental results demonstrate that this selection is not always absolute; for example, while one person is listening to another

person during a conversation at a cocktail party, the listener can block out effectively all of the background noise (enhancing the strength) until he/she hears his/her own name being mentioned in another group of people standing a bit further away in the room. This so-called cocktail party phenomenon implies that the background stimuli have been processed at least unconsciously, perhaps even up to the semantic level. Where exactly in the processing stream selection takes place, early or late, is one of the major distinctions between different theories and models of attention. Attention is still a very active area of research nowadays, probably even more than ever. Attention is also one of the factors that introduce a distinction between sensation and perception.

Sensation and Perception

Although sensation and perception are more peripheral functions than are attention and performance, they deserve to be covered in an overview on cognitive psychology for two main reasons. First, regardless of the theoretical approach taken, sensation and perception are the input channels through which the cognitive system acquires information about the environment and is able to behave in a well-adapted manner. Second, cognitive psychology is one of the dominant approaches of studying and understanding perception.

According to the standard view, sensation is basically the registration of stimuli from the environment, whereas perception implies the further processing of the sensations until they provide meaning. For the visual modality, the sensations are the retinal images; the perception of objects, scenes, and events in the environment strongly depends on retinal images, but is not uniquely determined by them. The same distinction applies also to other modalities such as audition (hearing), olfaction (smelling), haptics (touching), etc.

According to the standard view, incoming information is too poor to explain the richness of experience, so perception consists of the elaboration and enhancement of the stimuli by means of intermediate processes. A typical example of the poverty of the stimulus is the fact that retinal projections are two-dimensional snapshots interrupted by eye blinks and eye movements, whereas a stable, three-dimensional world is perceived. Typical examples of intermediate processes include unconscious inferences, problem solving, hypothesis testing, and memory schemata. Unconscious inference (i.e., automatic deductive reasoning) was proposed by the 19th-century physiologist and physicist Helmholtz to explain how humans recover a constant object size from the variable retinal sizes at different viewing distances. Cognitive psychologists proposed that the incoming data (i.e., the retinal images) are processed by relying on schemata in memory, which activate world knowledge in the form of hypotheses, to be tested further by checking whether the

incoming data agree with them. This approach strongly defends the role of top-down processing—that is, from high-level world knowledge to low-level sensory data. Typical representatives of this cognitive approach are Gregory (*The Intelligent Eye*) and Rock (*The Logic of Perception*).

In a series of books published in 1950, 1966, and 1979, all with a strong impact on the field, J. J. Gibson revolted against this traditional view. In normal ecological circumstances, he argued, the available information is much richer than assumed in the classic, cognitive approach. When perceivers are allowed to look with their two eyes, to move their head, and to move around in their environment, new sources of information become available (e.g., retinal disparity, motion parallax, and optic flow), which often allow disambiguating the reduced projection in a single retinal image at a single instance in time. In fact, Gibson claims, perception can then be direct in the sense that no intermediate processes are then needed to further process the information (in contrast to the classic, indirect approach). The higher order invariants in this stimulation specify the surfaces, objects, and events in the world in a one-to-one fashion. The perceptual system is then required only to pick up this information or to resonate to these invariants in a direct manner, without internal representations or computations. Hence, the burden of the research is to describe and analyze the available information as such (which requires a new approach, called “ecological optics”), rather than the psychological processes. The leitmotiv here is “do not ask what is inside the head but what the head is inside of.” This position has, of course, caused a great deal of controversy in the domain of perception. In fact, it has had a much larger impact than on perceptual psychology only, because this so-called ecological approach has also been applied to other domains, such as perceptual learning and development (in a 1969 book by J. J. Gibson’s wife, E. J. Gibson) and coordination of motor behavior (in a 1968 book by Bernstein). Strongly influenced by J. J. Gibson’s work, Neisser (one of the founders of cognitive psychology) revised his view on attention, perception, and cognition in *Cognition and Reality*, less than a decade after his first book, which had defined the domain and approach of cognitive psychology. Traditional distinctions such as those between sensation and perception, between stimuli and responses, and between perceptual and motor systems all disappear when the behaving organism is studied in relation to its environment (i.e., as an integral ecosystem).

Despite the apparent incommensurability of the different world views underlying the indirect and direct approaches, a third way has been proposed in the so-called computational approach by Marr (in his 1982 book, *Vision*). Marr acknowledges Gibson’s discovery and analysis of the richness of the visual stimulation, while at the same time arguing for the need to describe and analyze the

processing mechanisms that are involved. When computer or robot vision and natural or biological vision are investigated (as Marr does), it becomes immediately clear that the issue of intermediate mechanisms that detect and process the incoming information is far from trivial. The computational approach is a bottom-up approach, starting from the information, extracting as much as possible from it by some well-chosen algorithms, and representing the results in intermediate representations, before reaching the final stage of conscious perception of meaningful objects, scenes, and events. Research has shown that a whole series of intermediate processes and representations are needed to achieve tasks such as object recognition.

This comes back again to the notion of “information processing,” as in traditional cognitive psychology, but with two important differences: (1) the mechanisms are now spelled out in much more detail (they are written as algorithms, implemented in a computer, to be simulated and tested as models for human vision) and (2) world knowledge stored in memory comes into play only as late as possible. In light of these similarities and differences with standard cognitive psychology, it is clear that important issues of empirical research are (1) to test the psychological plausibility of these algorithms (see Palmer’s *Vision Science: Photons to Phenomenology*) and (2) to investigate when cognition penetrates perception (see Pylyshyn’s paper in *The Behavioral and Brain Sciences* in 1999).

Emotion and Motivation

Emotion and motivation are normally not included as core domains within cognitive psychology, but it is useful to point out that they, too, have cognitive aspects. What humans feel is at least partly influenced by what they know, and mood has well-known influences on memory and thought processes. Regarding motivation, it is clear that knowledge is quite important in regulating and planning behavior in trying to reach goals, both lower level, physiological goals (such as satisfying hunger or sexual appetite) and higher-level, cultural goals (such as establishing a successful career and marriage, or enjoying a great novel, movie, theater play, or opera). Schank and Abelson’s 1977 book (as mentioned earlier in) includes quite a bit of interesting cognitive psychology on this topic.

The Current Position of Cognitive Psychology

Within Cognitive Science

Cognitive psychology has always been a key player in the multidisciplinary cluster of sciences known as “cognitive sciences,” from its emergence in the 1950s and its establishment in the 1970s (with its own journal and

society starting in 1977) until today (e.g., *The MIT Encyclopedia of the Cognitive Sciences* in 2001). Along with cognitive psychology, there exists a variety of disciplines, some of which are associated also with the early pioneers of cognitive science (names in parentheses): cybernetics (Wiener), computer science (Turing, von Neumann), artificial intelligence (Newell and Simon, Minsky, McCarthy), neural networks (Hebb, McCulloch and Pitts, Rosenblatt), linguistics (Chomsky, Lakoff, Jackendoff), philosophy (Putnam, Fodor, Dretske, Dennett), cognitive anthropology (Dougherty, D'Andrade), and cognitive ethology (Griffin, Allen and Bekoff). Because cognitive psychology is a behavioral discipline, with a subject belonging to humanities but a research methodology, which is at least partly inspired by the natural sciences and engineering, it has fulfilled an important bridging function within this consortium. The functionalist philosophy and the computational framework behind most of the work in cognitive psychology have provided the foundation for this crucial role within this network of interdisciplinary collaborations.

Beyond Traditional Cognitive Science

It is fair to say that the present situation within cognitive psychology (and, in fact, cognitive science as a whole) is no longer as bright as it was in the 1980s. The past decade or so has been characterized by two tendencies, one “downward into the brain” and one “outward into the environment.” These tendencies have revealed the limitations of the symbolic approach of information processing based on algorithmic computations and symbolic representations, as well as of the underlying functionalist assumptions. These tendencies have also inspired novel approaches, providing some new building blocks waiting to be integrated in a newly emerging multidisciplinary science.

Downward into the Brain

Two developments have given rise to the gradual breakdown of the functionalist assumption that mental functions can be studied independently of their hardware implementation in the brain. First, the symbolic approach, developed in collaboration between cognitive psychology and artificial intelligence, was found to miss some essential aspects of the flexibility of human intelligence. Exceptions to the cognitive models could always be found when tested experimentally, and seemingly successful computer models could not be made to generalize beyond their initial conditions (i.e., the frame problem). As mentioned earlier, Searle criticized the symbol manipulation approach for its lack of true intelligence with meaning and intentionality derived from real contact with the world. For him, applying formal rules on symbols is just like juggling with Chinese characters without understanding Chinese. Researchers started to realize that the brain's

properties did matter after all. The brain is a huge network of millions of highly interconnected neurons, which are simple computational units. Early attempts to incorporate these properties into neural network models of the human mind (e.g., Hebb's 1949 book, *The Organization of Behavior*, and Rosenblatt's 1962 book, *Principles of Neurodynamics*) had lost their attraction after Minsky and Papert had criticized the limited computational powers of one-layered neural networks, known as “perceptrons” (in their 1969 book with that title). In the 1980s, however, these limitations could be solved because the computational powers emerging from large-scale networks with simple units were demonstrated (in a 1982 paper by Hopfield, a physicist) and because it was discovered how multilayered neural networks could be trained (i.e., by back-propagation, as shown in a 1986 article in *Nature* by Rumelhart and colleagues). Although neural network modeling had, in fact, always continued on a low-profile scale (e.g., Grossberg's adaptive resonance theory models), it was only with the publication (in 1986) of the two books by the parallel distributed processing research group (headed by Rumelhart, McClelland, and Hinton) that this approach, also known as the subsymbolic approach, or connectionism, emerged as a crucial and respectable player again. The properties of the brain as a dynamical system are also being taken seriously now.

The second event giving rise to breakdown of the functionalist assumption was the development of new brain imaging techniques (such as positron emission tomography and functional magnetic resonance imaging). This new technology could yield vivid images of localized brain activity corresponding to particular cognitive operations, which seemed quite attractive to a large number of cognitive psychologists for examining the brain mechanisms corresponding to their putative cognitive mechanisms. Indeed, some of the foremost cognitive psychologists from the 1970s were also pioneering these brain imaging techniques in the late 1980s and early 1990s (e.g., Posner and Kosslyn).

Thus developments in neural networks and imaging gave rise to the cognitive neurosciences, a new multidisciplinary science that has witnessed enormous growth within a rather limited period of time. Cognitive psychology now develops alongside the neurosciences, although some people fear that cognitive psychology will simply “evaporate” as a result of this, both for scientific and socioeconomic reasons (because the brain is supposed to be the real “stuff” behind the more elusive “mind” and because of the abundant funds going to the neurosciences compared to psychology).

Outward into the Environment

The tendency to break out of the laboratory into the natural environment was started by J. J. Gibson and has continued with increasing force. Within artificial intelligence, it

gradually became clear that the analytic approach of decomposing intelligence into its basic building blocks and then putting the building blocks together in a computer model was doomed to failure. The radical alternative was to have “intelligence without representation” (as Brooks called it in an influential paper in *Artificial Intelligence*) or to let intelligence grow into more natural circumstances by building small, insectlike robots and studying, from a more synthetic approach, how they develop survival strategies and solve realistic problems, in interaction with their environment. In other words, rather than isolating the mind from the brain, and the cognitive system from its environment, intelligence became embodied again and cognition became situated in its context again. In artificial intelligence, this new trend has led to the emergence of a new field called “artificial life.” It appears that cognitive psychology will have to collaborate more with social scientists and biologists than with computer scientists.

Conclusion

It may appear that the pendulum has started to swing back again in the direction of less internal cognition and more externally guided action, after almost half a century of dominance of cognitivism over behaviorism. However, with the experience of the disadvantages of the one-sided exaggerations of both approaches, it should be possible to achieve a better synthesis. Finally, with the increased understanding of the brain mechanisms, which mediate all of the interactions between the mind and the world, cognitive theories can now be built on firmer ground. Scientists from all of the contributing disciplines, including the social scientists, should work together to try to understand human cognition in its broadest possible sense.

Cognitive Research Methods

David B. Kronenfeld

University of California, Riverside, Riverside, California, USA

Glossary

computational Describing types of models or approaches based on actually implemented computer programs, whereby the formal representation is embodied in the computer program and the output of computer runs can be compared with empirical data.

ethnoscience Early cognitive anthropology, focused on studying the semantics of folk knowledge systems with a methodology from structural linguistics.

formal (models, features, or descriptions) Entities or statements that are explicitly and precisely specified, often via mathematical representations.

instantiation The application of an abstract but well-defined plan (such as a computer program) to a particular concrete situation (cf. “realization” in linguistics, which refers to a filled-out concrete instance of an abstract category).

kinship terminological system The kinship terms of a language, organized and analyzed as a distinct system.

reference and contrast An assessment in which “reference” refers to the semantic relationship of words or cognitive categories to phenomena in the world that the words or cognitive categories represent; “contrast” refers to the semantic relationship of words or cognitive categories to other words or categories.

semantic component A dimension of contrasting attributes, whereby the attributes distinguish members of one semantic category from another.

similarity matrix A matrix of values that represent the similarity of each item on a list to each other item. If similarity is taken as symmetric (as it usually is), then the information is all contained in half of the matrix (a half-matrix).

triads test A way of arriving at a similarity matrix by constructing a list of all possible triples from the list of items, and then having informants for each triple indicate which two out of the three items are most similar. Summing the pairwise similarity scores across triples produces a similarity matrix. Balanced block designs have been constructed that allow use of only a subset from the list of

all possible triples—needed because the number of possible triples rises geometrically with the number of items on the list.

Psychology and psychological methods are basic to any study of cognition, but the shared or distributed cognition that underlies, or is embedded in, any social system presents special problems and responds to special constraints because of its extraindividual nature. Cognitive anthropology has been the research tradition most concerned with collective cognitive structures and systems, and it is work in this tradition that is emphasized herein. Cognitive anthropology initially developed, as “ethnoscience,” out of an attempt to apply descriptive and analytic insights from structural linguistics—developed there for the study of phonology, morphology, and syntax—to the study of semantic systems.

Background

The study of cognitive anthropology first emerged in 1956 when Ward Goodenough challenged John Fischer’s description and analysis of household composition patterns on the island of Truk. Fischer had used traditional anthropological definitions of concepts such as “matrilocal” and “patrilocal” residence (based on whether a new couple were living with the wife’s or husband’s parents), while Goodenough argued that, for the Trukese whose land and houses were owned by corporate matrilineal descent groups, one could understand residence decisions only in terms of the options Trukese faced and the rights that created these options (i.e., in effect, with whose matrilineage the new couple lived). Goodenough argued that Trukese decisions could be understood only in terms of

the categories (and entailments of categories) they recognized as part of their language and culture. Goodenough's goal was one that goes back to Boas and his students, but his approach represented a radical departure. This approach was based on the linguistic insight most forcefully driven home by Edward Sapir (in articles on "Sound Patterns in Language" and "The Psychological Reality of Phonemes") that effective descriptions of languages (e.g., ones unknown to the linguist or the linguistic community) had to be based on the phonological (sound) and grammatical categories and distinctions used by speakers of that language, as opposed to external categories based on the linguist's own language or on some abstract or philosophic standard. The distinguishing of the "phoneme," the minimal cognitive unit of sound in a language that distinguishes one meaningful unit (e.g., word) from another, from a "phone type," a physical sound unit that linguists use to describe the sounds of a language, had an importance for linguistics comparable to the importance for physics of the distinction of "mass" from "weight"; it allowed a compact, formal, systematic characterization of the sounds of a language, and thus of the constraints on their patterning and combining into larger units. Goodenough argued that cultures, like languages, were systems that could be understood only via an analysis that was built on the conceptual units used by their members.

In linguistics, the analysis in terms of phonemes of the sound system used by speakers of a language was called "phonemic," whereas the description or analysis of a language's sounds in terms of some external classification scheme, such as the International Phonetic Alphabet (IPA), was called "phonetic." Those terms and the distinction they imply had already been generalized to culture by Kenneth Pike in 1954 as "emic" and "etic," and analyses such as that advocated by Goodenough came to be spoken of as "emic." In Pike's linguistically derived sense, "emic" referred to an analysis of knowledge and/or behavior that was structured by the categories that native participants used in making their decisions regarding distinctions or actions, whereas "etic" referred to an analysis structured by categories brought by the describer from outside the given system; the anthropologist Marvin Harris much later introduced a different and confusing—but ultimately more widely known—interpretation of the terms in which "emic" referred to a folk theory and contrasted with an "etic" or scientific theory.

The goal of the approach that grew in response to Goodenough's discussion of "residence rules" was an emic approach to the description and analysis of culture. Development of the approach began with the area of shared knowledge closest to linguistics, that of the overlap between language and culture—the semantics of word meanings. Groups of semantically related words (or the conceptual universe they referred to) were spoken of as

"domains." The major structuring devices for domains were Saussure's relations of contrast (X vs. Y) and inclusion (M is a superordinate category that includes both X and Y); these semantic structuring relations were in turn to be related to the pragmatic relations among the entities the labels referred to (what X looks like, how it works, what it does, etc.). "Frame eliciting" is an ethnographic descriptive heuristic device for finding and describing emic units and emic relations among these, whereas componential analysis is an analytic heuristic for finding emic units from a pattern of etic descriptions.

Frame Eliciting

In frame eliciting, native statements on some topic of ethnographic interest are elicited, and then sentences from the statements are turned into frames by replacing meaningful entities in them with blanks; lists of potential culturally appropriate fillers of the blanks are then elicited. These statements typically came from a record of less formal questioning involving versions of "what's that?," "what is it used for?," "who does it?," and so forth. A statement such as "X is a kind of M" would then be turned into a question, as in "Is ____ a kind of M?," where other elicited entities (such as Y, C, D, etc.) would be used in the blank. Often taxonomic questions would also be involved, such as "what kinds of X are there?" and "what is X a kind of?," and sometimes attribute questions, such as "how do you tell X from Y?" or "what is the difference between X and Y?." Categories with similar privileges of occurrence are grouped together and the features on which they contrast with one another are examined, as are their differential implications for further associations or actions. Similarly, the relations between superordinate and subordinate categories (in terms of inclusion relations) are explored. The method is best described by Frake in his "Notes on Queries in Ethnography" article.

Componential Analysis

In componential analysis, an exhaustive set of referents of each of a set of contrasting terms (a domain) is assembled. Each referent is characterized on a list (ideally, a complete list) of attribute dimensions that seem relevant. The classic example was in kinship, wherein the contrasting terms were "kinterms" and the referents were "kintypes"—genealogical strings connecting "ego" (the reference person) and "alter" (the relative of ego's labeled by the kinterm); attribute dimensions included information such as "sex of alter," alter's "generation" relative to ego, and lineality (alter on, next to, or off ego's direct line of ancestors and descendants); this is discussed in Wallace and Atkins' "The Meaning of Kinship Terms." Relevance can be assessed on the basis of prior comparative experience,

pertinent *a priori* assumptions, informant information, serendipity, etc. Then the analyst experiments to find the smallest set of attribute dimensions with the fewest distinctions per dimension sufficient to distinguish all of the items in the domain from one another. Those attribute dimensions are interpreted as the semantic components that structure relations among the terms in the domain. An alternative approach is to ask informants to describe the difference between one term and another or one subset of terms versus another, and build up a set of potential semantic components that way. Originally it was thought that the attribute dimensions had to come from some universal, etically specified set (modeled on a misunderstanding of the status of the IPA)—spoken of as an “etic grid”—but it has become clear that potential attributes can come from anywhere, as long as they are well defined. Within the particular domain of kinship terms, more formally explicit inductive procedures have been designed for automating the production of a componential analysis from sets of genealogically specified referents, but these methods seem specific to kinship terminologies and to depend on special, unique features of that domain.

Data Structures

Paradigmatic Structures

A componential analysis aims at producing one kind of cognitive structure, a “paradigm.” Paradigmatic structures are composed of a set of terms (or categories), all contrasting with one another at a single level of contrast (like opposites, but with the possibility of being multinary); the terms are distinguished from one another by a set of cross-cutting semantic dimensions (i.e., sets of contrasting attributes, as in Fig. 1: m : m_1 vs. m_2 , x : x_1 vs. x_2 , y : y_1 vs. y_2). A paradigmatic structure is like a “cross-tabulation” in statistics. In principle, each dimension is relevant to each term. Figure 1 shows the actual structure, but the information can also be presented in tabular form, as in Table I.

Both Occam’s razor and relevant psychological studies suggest that each of the categories in a paradigmatic structure should be conjunctively defined, but for folk categories the mechanism that produces conjunctivity is a probabilistic one depending on “cognitive ease,” which does allow for the possibility of some disjunctivity where there exists a good functional reason and there is sufficient effort invested in relevant learning (as, e.g., with “strikes” in baseball). Cognitive ease refers in a general and loosely defined way to the mental work involved in learning and using (in this case) a category, and “conjunctivity” is one well-defined version or aspect of it. Conjunctivity refers to the intersection (as opposed to sum) of

Figure 1 An abstract paradigmatic structure. Key: A through G are categories (terms), m , x , and y are dimensions of contrast, and m_1 , m_2 , x_1 , x_2 , y_1 , and y_2 are defining attributes on the given dimensions.

Table I Tabular Presentation of a Paradigmatic Structure

Term	Dimension ^a		
	m	x	y
A	m_1	x_1	y_1
B	m_1	x_2	y_1
C	m_2	x_1	y_1
D	m_2	x_2	y_1
E	m_1	x_1	y_2
F	m_1	x_2	y_2
G	m_2	x_1	y_2
H	m_2	x_2	y_2

^a As defined in Fig. 1.

values on relevant dimensions; thus, taking “red” vs. “green” and “boxes” vs. “circles” as relevant dimensions for a restricted domain of figures, “red things,” “boxes,” or “red boxes” would be conjunctively defined categories, whereas a category made up of anything that was either “red” or a “box” would not be conjunctive and hence would be disjunctive.

Kinship terminological systems and pronominal systems have provided the clearest and most complete examples of semantic domains with paradigmatic structures, though cultural artifact domains (such as automobile types) can tend toward paradigms. The simplest example of a paradigm is a set of two terms contrasting with each

other on a single two-valued semantic dimension (as in “black” vs. “white”).

Taxonomic Structures

Another kind of structure is a “taxonomic” one. Taxonomic structures are composed of a set of terms at different levels of inclusion, related to one another by a hierarchy of contrast (e.g., “cat” vs. “dog”) and inclusion relations (“cats” and “dogs” are both “carnivores”) (see Fig. 2). Such structures have a head term, which includes some number of subordinate terms, which in turn may each include terms at still lower levels of contrast. Dimensions of contrast are not normally repeated; successive dimensions subdivide (rather than crosscut) prior or higher level ones. Each semantic dimension (in Fig. 2: m : m_1 vs. m_2 , x : x_1 vs. x_2 , y : y_1 vs. y_2) is only pertinent to the node at which it occurs in the system—that is, to the subset of items covered by the superordinate term it subdivides (e.g., whatever it is that distinguishes “cats” from “dogs” is irrelevant to “horses” vs. “cows”). Figure 2 shows the actual structure, but the information can also be presented in tabular form, as in Table II.

The clearest examples of taxonomies in the literature have been ethnobotanical and disease domains. The minimal example of a taxonomy is a set of two terms contrasting with one another under a single head term. Taxonomic categories, like other folk categories, should in the normal course of events be conjunctively defined, and the conjunctivity constraint can be a powerful tool when attempting to analyze and understand systems of folk categories.

Figure 2 An abstract taxonomic structure. Key: A through D and X, Y, and M are categories (terms), m , x , and y are dimensions of contrast, and m_1 , m_2 , x_1 , x_2 , y_1 , and y_2 are defining attributes on the given dimensions.

Mixed Structures

Mixed structures are possible; either of the preceding kinds of structure can, in principle, be embedded as a node in the other. That is, an item in a taxonomy could expand multi-dimensionally (instead of as the normal simple contrast), whereas an item in a paradigm could be the head term for a taxonomy. A fruitful research area concerns the combination of cognitive conditions, conditions of use of the terms, and nature of the pragmatic phenomena being categorized by the terms in question that lead to one or the other kind of semantic structure. Psychological issues, including concept formation strategies and constraints, short- vs. long-term memory, rehearsal time and learning, and so forth, seem relevant to the issue.

Marking

Taxonomic semantic structures are relations among named entities. But sometimes one name or label will operate at more than one level of contrast. For instance, “cow” can be opposed, as a female, to the male “bull,” but “cow” can also be the cover term for bovines that includes both “cows” and “bulls.” The relation between the words “cow” and “bull” is an example of a contrast between an “unmarked” term (“cow”) and a “marked” term (“bull”), whereby the unmarked term is both opposed to the marked one and included by it. Such marking relations can be joined into more extensive “marking hierarchies,” as “man” vs. “animal,” whereby “man” includes “man” vs. “woman,” which, in turn, respectively include “man” vs. “boy” and “woman” vs. “girl.” The unmarked member of such an opposition represents a kind of default value for both members of the opposition when the feature on which they contrast is neutralized. For cows, the functional basis of the default is simple: the great number of cows for each bull in a dairy herd. For men and women, the basis is perhaps more interesting: having to do with women’s long-time lack of civil and other rights and privileges. Marking is extensively seen in ethnobiological classifications, and indeed, according to Brent Berlin,

Table II Tabular Presentation of a Taxonomic Structure

Term	Dimension ^a		
	m	x	y
A	m_1	x_1

^a As defined in Fig. 2.

provides a major mechanism via which such systems develop (a taxonomic term is used not just for its primary referents—its unmarked sense—but also as a generic cover term for other similar items; if the other items have their own specific labels, these will be rarer marked alternatives to the unmarked default, on the model of “bull”). Marking was first worked out for phonological systems by N. Trubetsky in 1939 and translated as *Fundamentals of Phonology* in 1969, and then broadly extended by J. Greenberg 1966 to other linguistic phenomena; marking seems to show up widely, as well, in shared nonlinguistic cognitive systems. It offers a mechanism by which an existing cognitive category can be used as a kind of generic to include novel referents, and thus by which simple systems of classification can evolve into more complex ones, as the novel referents eventually get their own specific category under the older generic.

Semantic Extension

Marking provides examples, as just seen, in which not all referents of a term (or of a nonverbal cognitive category) may be equally central for their users, or as well understood. In general, for word use at least, a great amount of our usage is of words for referents that are not the primary referents of the words. A normal process in word use is “semantic extension,” whereby entities (objects, actions, attributes, etc.) that do not have their own special labels are spoken of via the label of some similar entity; the choice of label depends on how the oppositional structure of the semantic domain chosen matches the relations between the target entity and other entities from which it is being distinguished. Such extension can be denotative (based on attributes of form or appearance), connotative (based on functional attributes—what makes the category useful), or figurative (metaphoric, metonymic, etc.). The referent to which the label primarily “belongs” is spoken of variously as the “focal,” “core,” “kernel,” or “prototypic” referent. Prototypicality seems to be a result of a combination of frequency of usage (what referents learners most frequently encounter) and functional fit (what referents best fulfill, whatever it is that makes the category important enough to get its own unit or label). For instance, in English, the term “uncle” prototypically refers to a parent’s brother, but it also—entirely literally and correctly—can be used for an aunt’s husband (and, sometimes, as an unmarked term for a “great uncle,”—i.e., grandparent’s brother). It can be used connotatively for other close males with whom there is interaction in the way interaction should occur with an uncle; these can include (depending on context and situation) a parent’s cousins, family friends of the parents’ generation, and so forth. Such usage is not considered “technically” correct, as can be demonstrated methodologically

via native speaker use of linguistic “hedgies” (such as “well he’s not *really* my uncle but . . .”). Figurative usage, as when we speak of the United States government as “Uncle Sam,” happens when it is not the specific functions (for uncles, avuncular behavior) that are at issue, but some more general attitude. In figurative usage, the choice of domain/paradigm (say, kinfolk in the case of “uncle”) conveys something (say, for our uncle example, a close personal, solidary, and noncontingent relationship) and then the particular choice of term within that paradigm provides more specific guidance concerning what is meant (“uncle” vs. “father” signifying an affective rather than authority or provisioning emphasis; “uncle” vs. “aunt” signifying a male; “uncle” vs. “brother” signifying relative seniority).

Componential structures of relations among conceptual categories, the “defining features” of categories, in this extensionist approach apply necessarily only to the focal members or referents of categories (versus to the full ranges of members or referents); they may well apply as well to other members, but they also may not. For example, in English, a “mug” is a kind of “cup.” Among other things, a prototypic mug is an extended referent of the “cup” category. English speakers also recognize that there exist some kinds of beer steins that can be called “mugs” but that these do not fall into the denotative range of the “cup” category. As this cup/mug example exemplifies, the core/extension approach applies to taxonomic structures as well as to paradigmatic ones. Basic early examples were Lounsbury’s 1964 work on Crow- and Omaha-type kinship terminologies and Berlin and Kay’s 1969 study of basic color terms. Eleanor Rosch, in psychology, elaborated a general descriptive model of word meanings from the Berlin and Kay base. Kronenfeld has elaborated a fuller semantic theory of extension. Marking and semantic extension are methodologically important because they strongly affect the interpretation of verbal interaction both within the study population and between the researcher and the study population. There is reason to think that nonverbal concepts might well operate in a similar manner.

Universal (cross-cultural and cross-language) patterns have been used by students of shared cognitive structures to demonstrate the force of specific kinds of cognitive patterns in the domains of color and kinship. But the universal issue has ebbed in importance. The kinds of patterns involved in marking and extension do appear to be both general and universal, but that apparent universality is a matter of form rather than of content, and depends more on general properties of human thought, memory, and communication than on any specific properties of any particular domain in which the patterns are seen; there exist particular reasons for the specific content universals that have been found in the domains of color terms and kinship terms, but marking and extension occur

as well in domains that lack these particular characteristics (such as cups and glasses, pens and pencils, books, religious controversies, political factions, and men's vs. women's work in American households).

Types of Models

Taxonomic and paradigmatic structures emerged in early semantic studies as ways of descriptively organizing chunks of folk knowledge. There was and still is discussion of the psychological status of such descriptions: to what degree, or in what senses, are they to be considered psychologically "real"? The debate about psychological reality was inherited, along with the previously mentioned methodology, by cognitive anthropology from structural linguistics. When the discussion was broadened to include actual psychological data (as opposed to simple reasoning), the issue quickly became one of "real" "in what sense" and/or "under what conditions." This methodological advance was introduced by Romney and D'Andrade in 1964 in "Cognitive Aspects of English Kin Terms" (reprinted in 1969 in Tyler's *Cognitive Anthropology*). Variant versions of psychological reality emerged, *inter alia*, among folk definitions of categories, folk understandings of the connotations or implications of category membership, of differing contexts of definition and application, etc. For kinterms in particular, actual folk definitions (as in the "because he's my mother's brother" answer to "how do I know X is my uncle?") were found to be quite different in form from the definitions implied by componential analysis ["first generation, ascending, colinear (or collateral), male, kinsperson"]. On the other hand, there was found strong psychological evidence for native use of something like componential structures to reason about the attitudes and behavior that pertain to various classes of kin. (This was learned through answers to questions such as "Describe an uncle," "Why are uncles important?," "How should you treat your uncle?," etc.) Studies aimed at distinguishing psychologically "real" from unreal componential structures (among those that did the basic job of distinguishing the categories from one another reasonably succinctly) in kinship showed that interviewees were capable of applying a range of different models in different contexts, even if some models appeared more generally salient than others.

Formal Models of Cultural Knowledge Systems

Attempts to organize and formalize the description of folk definitions of kinterm categories led to a different kind of modeling and a different kind of research methodology. It was found (particularly by S. H. Gould in 2000 and by

F. K. Lehman and D. Read; their articles appear in Kronenfeld (2001) that the folk definitions of different kinterm categories were systematically related to one another, and could be formally modeled as an algebraic system—i.e., via a small set of axioms and derivations from these. This breakthrough raised the possibility that other "cultural knowledge systems" (as, for example, ethnobiological classifications and kinds of property rights) could be similarly amenable to formal modeling (El Guindi and Read offered an early instance in 1979 in *Current Anthropology*). And it raised the question of whether there might exist some common properties that might run across the full set of such knowledge systems (or at least substantial subsets of them).

With the emergence of successful formal models of cultural knowledge systems, it became clear that such systems were used more for reference and communication than for actually planning or interpreting action. They were shared systems of classification and organization. They were productive systems of reasoning that could be applied by someone to new events or entities in a way that others in the culture could easily understand. They had to be fairly easily learned (because many or all members of a given culture would know them) but without being explicitly taught. They had to be structured in such a way that consistent changes in their application by users could feed back into changes in the structures. One active area in cognitive anthropology involves the construction and exploration of models of such cultural knowledge systems.

"Cultural Models" as Models of Behavioral Patterns or Interpretation

As the nature of cultural knowledge systems is better understood, it is becoming clear that there has to exist at least one other kind of culturally shared cognitive structure, which might be called a "cultural model." The term, and the kind of approach, emerged as anthropologists, on the model of schema theory in psychology and of attempts in cognitive sciences to model routine behavioral situations (such as Schank and Abelson's 1977 simulation of conversations about restaurant behavior), tried to summarize and model regularities in culturally standardized behavioral patterns or behavioral interpretations (important examples are in 1987 and 1992 collections by Quinn and Holland and by D'Andrade and Strauss; the work is summarized in D'Andrade's *The Development of Cognitive Anthropology*). The modeling task seemed to require some consideration not only of the classification of cultural entities (types of people, situations, means, etc.) but also of actors' goals and values, of understood or presumed community standards, of actors' emotions, of the aspects of situations that were understood to trigger

various emotional responses (in terms of both kind and intensity), and of the cues that actors used to recognize what was in other actors' minds. The underlying task was not that different from the traditional task of ethnography, but the methodological means was radically new, based as it was on a theory of effective cognitive structures. The methodological mechanism involves constructing a model (ideally one that is computational) of the hypothesized behavioral entity, and then examining how well the model's output matches verbal data or other observations.

Individual vs. Shared Structures

Early attempts to construct such cultural models, though convincing as metaphoric accounts, seemed difficult to represent with any precision. Several different kinds of problems have emerged and are gradually being addressed. On the one hand, actual psychological schemas are dynamic structures existing only in individual minds; they are constantly adapting in response to feedback from the social and physical environments. Yet, on the other hand, cultural models are seen as shared and thus relatively stable entities that no one person can alter. Sharing and the conditions of learning a stable, shared system seem to place very different kinds of formal constraints on cultural models, compared to the constraints that shape individual schemas. Individual schemas are seen as direct producers of action, whereas cultural models, as something external to the personal psyche, have to be adapted and applied by their users. The application of cultural models to specific situations seems mediated by a number of considerations, such as whether self-behavior is being constructed or the behavior of someone else is being interpreted, how the outcome is to be interpreted, what knowledge of what set of alternative cultural models the actor or interpreter ascribes with what certainty to other relevant participants, and so forth.

Shape, Boundaries, and Content

Another kind of problem involves the shape, including, form(s), boundaries, and structure, of cultural models. Actual ethnographic conversations with interviewees suggest, on the one hand, the existence of well-known and well-shared cultural models, at least for important areas of culture (such, for example, as love and marriage). On the other hand, those conversations suggest a lot of variation in detail from one application of a given cultural model to the next, similar variance in nuances of interpretation, and a real, fuzzy line (regarding content) between where the standardized cultural model ends and where the details of some particular cognitive instantiation of it begin—and then, in turn, where the actual details of given real world events enter in. One question concerns whether cultural models are to be understood as applying directly to behavior or as providing a more abstract template, which is then used to construct a more ad hoc filled-out model

(a kind of instantiated model). If the latter, then it seems possible that people have in their learned cultural repertoire not only sets of cultural models but also, perhaps, representations of the commoner instantiations of salient cultural models. Another question concerns whether cultural models are to be understood as defining complete whole classes of situations to which they apply (in the manner described earlier regarding paradigmatic definitions of semantic referent sets) or as defining prototypic situations, which then are extended by users to some variety of actual situations. If the models are prototypic, the question arises as to how much (and what kind of) detail is to be included in the prototype. The question also arises whether such included material is to be limited to what is essential to the operation of the model or, alternatively, should include as well the more common accidental attributes of typical application situations or instantiations.

Decision Theory—Models of Routine Decision Making

A third category of models of social cognition, somewhat predating the other two, was the construction (by Hugh and Christina Gladwin, James Young, Naomi Quinn, and others) of ethnographic models of routine decision making. Decisions studied included whether to fertilize fields, what kind of fertilizer to use, which market to attend for selling fish, and what kind of health care to select. This approach was based directly on Goodenough's study of residence rules. Such models differed from cultural models because their target issues came not out of the culture, but out of some externally generated conceptualization, problem, or theory, often from either standard economic theory or applied anthropological issues. The approach was limited to routine decisions for which there existed a backlog of cultural experience, clear benefits for a better vs. worse decision, and some reasonable set of alternatives from among which a choice had to be made (and any of which, in one or another context, might be best). The approach was built on insights from cognitive psychology concerning information-processing constraints. Such constraints might include overall complexity, difficulty of statistical calculations, continuous vs. discrete n -chotomous variables, or simultaneous consideration of multiple variables vs. seriatim consideration of one or two at a time. Attention was paid to standard devices for getting around those limitations. There was an attempt to develop a list of consistent attributes of such decision processes. The list included the role of preattentive processing, the use of "elimination by aspects" (in which attributes were considered sequentially in their order of felt importance, to eliminate less desirable alternatives), the conditions that determined whether decision

problems were broken down into attribute-structured pieces or taken as whole gestalts, the use of “rules of thumb,” and the relationship of rules of thumb to systematic framing variables (such as economic constraints, economic strategies, etc.). The ethnographic approach produced a descriptive model of actual behavior, the structure of which could then be examined for the analytic principles that structured it.

A variant of the decision-making approach was developed by Robert Randall in his 1977 dissertation, combining it with a hierarchy of decisions starting with basic cultural needs (such as “making a living”) and building in marking defaults at all levels. Its organization came much closer than did other decision-making approaches to using internal (to the culture) issues to structure the decision universe. By using higher level cultural goals to define lower level goals and tasks, Randall’s system paralleled Frake’s approach to Subanun “Religious Behavior” (reprinted in Tyler’s *Cognitive Anthropology*). Together they represented an important return to the original ethnoscience aim of describing cultures in their own terms. It was then possible to consider what universal or comparatively useful elements fell out from comparisons of such descriptions. This was an approach that had to be largely hypothetical until the emergence of modern computers and the modeling within modern cognitive sciences of emergent systems. This larger, integrated approach to cultural systems provides a frame within which cultural models can be considered, and offers an approach in which cultural models can be seen as hierarchically arranged such that more general ones include more specific ones. The cognitive sciences approach—especially the “agent-based” version—offers a way (see later) by which cultural models can be represented and evaluated for the effectiveness with which they account for relevant behavior (including conversations, actions, and interpersonal coordination).

Methods and Techniques

As indicated, frame eliciting has been a basic technique for eliciting self-conscious cultural knowledge systems (such as kinship and ethnobiological ones), and finding structure in such knowledge. Such knowledge is shared and explicit: it is what native members of the culture talk about, define for each other, use in reasoning, and so forth. The technique involves systematic exploration of statements concerning the entities in question. Relevant statements include ones involving semantic relations of contrast and inclusion and ones involving pragmatic relations such as parts and wholes, sequences, task- or context-related clusters, uses of objects, effects of actions, and so forth. The analyst then assembles the information thus gained into structures that seem of interest and that

seem implicit in the data; these can be semantic structures (involving, say, the meanings of words such as “red” or “yellow”) or various kinds of pragmatic ones (involving, say, the perceived structure of the interrelations among the actual hues).

One issue of debate has concerned whether the structures thus derived (for example, a taxonomic “tree diagram” derived from informant statements that C and D are kinds of Y, A and B are kinds of X, and X and Y are kinds of M) are to be ascribed to native cognition or just treated as summaries of regularities in native understanding as expressed in discussions (see Fig. 2). Because, either way, native speakers have the relevant information available to use in conversations and reasoning, the issue may not have much immediate practical importance; but the debate points up the difficulties in understanding exactly what is meant by structure, and thus in being able to consider what might constitute relevant evidence. For some kinds of structures under some conditions, as Romney and D’Andrade showed for kinterms, multidimensional scaling (MDS) of inter-item similarity data can help.

Free-Listing “Snapshots”

One kind of information that is sometimes desired about a group involves what ideas or thoughts or concerns, etc., and maybe what linkages among these, are most salient in the group in one or another context. One way of getting a quick sketch of such salient notions is to give informants a short free-listing task (e.g., “list five thoughts that come to mind when you think of ‘anthropology’”) or sketching task (“sketch an American high school”); it is then possible to form a composite list or picture based on responses produced by more than one or two people (used tellingly by Kevin Lynch in his 1960 *Image of the City*). The composite can be ordered so that answers produced by more people are more saliently displayed, compared to those produced by fewer people. Because the task is open-ended, and because specific responses are being counted (rather than sorted into categories or ratings), repeated answers can only represent items that are saliently associated with the stimulus concept in the relevant cultural community; the odds of two people coming up with the same response by chance (i.e., where there is no relevant shared linguistic and cultural community understanding) is exceedingly low, given the size of people’s vocabularies and the varieties of ways available for describing and talking about even commonplace items. The high-frequency items provide a kind of “snapshot” of where the collective attention is directed. Such a snapshot can be used as a starting point for more careful and expensive research regarding the given issues. A comparison of such snapshots for two contrasting communities can focus a researcher quickly on salient cognitive (or behavioral) differences. The relevance of the snapshot(s) to

a particular research problem is determined by the nature of the stimulus, but because the technique is inexpensive to implement, different stimuli can be experimented with in order to see what makes a difference and what responses are robust enough to come through the variants. This technique is a way of measuring collective or shared salience of concepts in some context; it does not distinguish beliefs from knowledge from incidental rumor and it does not speak to any kind of truth or falsity. Free-listing tasks can also be used for a variety of other cognitive purposes, including exploring semantic structure (as seen in Romney and D'Andrade's article in Tyler's 1969 book); Bernard (2002) has provided a useful overview.

Multidimensional Scaling

Multidimensional scaling, like factor analysis, is a computational method for taking a matrix of pairwise similarities or dissimilarities for a list of entities (e.g., color terms, kin terms, diseases, or roles) as input and finding the arrangement of points representing those entities in a space of a specified dimensionality such that the rank order of interpoint distances best matches the rank order of interentity dissimilarities. The measure of this match is called "stress." The lowest dimensionality for which the stress is still low is looked for by running the procedure for a sequence of dimensionalities. If stress gradually increases as dimensionality decreases, it suggests that the data have no clear dimensionality; on the other hand, if the stress stays more or less constant and low, down to a certain dimensionality, but spikes up below that dimensionality, it suggests that the data arrangement really has that intrinsic dimensionality. An example is the basic six primary color terms in English (with similarity measured via a triads test), whereby from 5 down through 2 dimensions stress is low, but whereby it spikes up in one dimension; an examination of the arrangement reveals the familiar red–orange–yellow–green–blue–purple color circle, sometimes with some extra distance between the cool colors and the warm ones, and sometimes with the warm colors a little more spread out than the cool ones.

MDS then offers a way of getting a metric spatial model out of ordinal (or interval) data. If the fit of the picture to the input data is good, as it was with Romney and D'Andrade's kinship data, then it suggests that the MDS spatial model is a reasonably good representation of the model that natives are using to generate the inputted similarity data (of the sort shown in Fig. 1). The picture comes in the form of a list of points with their coordinates in the given dimensional space; the axes are arbitrary in terms of the research problem, though some programs can orient them so that the first accounts for the greatest amount of interpoint distance, the second the next amount, and so forth. The analyst needs to scan

the pattern of points and recognize or guess at the picture that the pattern represents. Four-dimensional pictures are hard to treat this way, and higher dimensional ones are impossible, so for higher dimensional pictures the picture has either to be simplified, by pulling out sets of points that seem odd, or indirect interpretative devices must be used. It is worth noting that, as the number of dimensions approaches the number of entities being scaled, the constraints that make the technique work break down.

Factor Analysis

Factor analysis does much the same task, but is a mathematical algorithm that generates a best arrangement of the points in relation to the inputted data. It requires ratio data. Unlike factor analysis, MDS uses a heuristic technique that can get locked into a relatively good solution while missing the optimal one, but requires only ordinal data. One by-product of the ratio/ordinal difference is that when imperfect ratio data are fed into factor analysis (as is typically the case with similarity measures), each irregularity in the data forces some extradimensionality in the picture. The effect is that factor analytic pictures can never be interpreted by direct examination of the pattern of points in the space, but always have to be attacked via indirect means, usually some attempt to orient the axes of the space (as in a "varimax" rotation) such that the resulting axes become interpretable as meaningful variables or scales.

One common data type involves a matrix of cases by data measurements, whereby data measurements are, for example, a question (e.g., "do you give money to?," "do you show respect to?," etc.) by topic (e.g., "father," "father's brother," "friend," etc.) matrix for each of a set of informants, and whereby similarity (question to question, topic to topic, or informant to informant) can be measured by correlation coefficients or by measures of the proportion of measurements (or questions), over all pairs, for which each of a pair of topics elicited the same measurement (or response) from the same informant. Another common data type is based on rating tasks (from psychology), such as paired comparisons or triads tests.

Hierarchical Clustering

Hierarchical clustering (HC) programs use the same kinds of similarity data as those used by MDS to produce hierarchical tree (or dendrogram) structures. Cladistic analysis in biology is based on such a procedure. The aim of the program is to find the best or most efficient branching structure starting with each entity separate from all others and gradually cumulatively joining entities

into clusters (each new clustering being a node on the tree), until all of the entities are together in a single cluster (represented by the single apical node of the tree), with the level of similarity indicated at the point at which each new cluster is formed (i.e., previously separate clusters joined together into a new node on the tree) for each node, such that the inputted similarity values match (as well as possible) the values of the nodes on which the pair of items are split apart. Where the detailed data are less than totally or absolutely consistent with a dendrogram structure—that is, where members of one cluster have differing similarities to items in other clusters—different programs use different means of either averaging the similarity within clusters or picking the value that controls when the two clusters join. Such choices should be made in terms of an assessment of what kinds of distortions the given types of data (relative to a theory) are liable to be most vulnerable to, but commonly choices are made more capriciously. The programs thus produce tree structures even if the inputted data are to a greater or lesser degree inconsistent with such a structure. The validity of the resulting structure depends on the combination of analytic goals and the interpretative assumptions that are brought to the enterprise, and that are used to account for the inconsistent data, and on the fit of these assumptions with the method used for merging clusters. The degree to which the inputted data actually fit a tree structure can be examined by comparing the trees produced by maximal overlap and minimal overlap criteria (regarding similarity values of the separate items in the one cluster relative to items in the other cluster) for merging two clusters into a new cluster.

Both HC programs and MDS programs will produce pictures for any inputted similarity matrix. But the specific data structures they produce are logically incompatible with one another; MDS represents a many-to-many mapping of data interrelationships whereas HC represents a cumulation of many-to-one mappings, which means that they cannot both accurately represent the structure underlying the same data at the same time. But neither type of program comes with any really effective goodness-of-fit measure that tells in absolute terms how well it did.

It should be noted that MDS represents a mechanism for finding dimensional pictures (based on cross-cutting global variables) in data that look like the paradigmatic structures produced by componential analysis, hence Romney and D'Andrade's use of MDS in their test of alternative componential analyses of a set of kinship terms. On the other hand, HC programs offer a mechanism for pulling out of data tree structures that have a shape similar to that of taxonomic structures (though usually without the labeled nonterminal taxa that characterize a true taxonomy),—hence the use of such programs for cladistic analysis in biology. The intersection of cross-cutting variables, which produces

a paradigm, cannot be directly represented in hierarchical structures, whereas the successive subdivisions of higher level categories by lower level features that produce a taxonomy cannot be directly represented in paradigmatic structures.

Consensus Measures

A comparable but different approach exists for evaluating answers to questions that have “right” and “wrong” answers—the consensus theory approach worked out by Romney and Batchelder. They have developed a statistical technique that can take informants' answers to a set of questions and determine whether the spread of answers to a given question represents differing degrees of knowledge about a single “correct” answer or the presence in the target community of different “correct” answers, or the lack of any consensus. When there is a single “correct” answer, the technique can tell the analyst what that answer is. “Correct” here can refer to actual facticity—say, the date on which the U.S. Civil War ended—or to a cultural consensus about what might even be a factually incorrect answer—as in beliefs in some communities about who “really” blew up the World Trade Center. Diverse “correct” answers, based on different knowledge, can be, for instance, the distinction between interpretations of ritual by priests and by laity, or the distinction for some cultural sequence, such as the “cargo system” in one Mexican pueblo (shown by Cancian in 1963), between the actual noncanonical path that some know “Joe” to have taken and the canonical path that others presume “Joe” to have taken). The method is similar to the free-listing snapshot one in that it assumes that shared answers must have a basis in shared knowledge, whereas uninformed guesses are going to be idiosyncratic. In both cases, the analyst is taking advantage of the fact that communities are characterized by shared knowledge, and thus that there are ways of pulling inferences out of shared responses from community members that could not be pulled out of answers produced by a random cross-section of strangers; the two methods represent different ways of getting at shared cognition.

Anthropology has progressed from a mechanistic view of culture in which culture was seen as unitary, whole, shared, and canonical. Formerly, everybody, at least in allegedly “simple” cultures, was presumed to know and do the same thing as everyone else, except for some variation according to age and sex. It is now realized that the kind of diversity known and experienced within our own culture characterizes the makeup of other cultures as well (even if the amount of variation is in part a function of size and contextual diversity). It is now known that the division of labor in society involves distributed knowledge as well as distributed economic activity; we are beginning to understand something of how the shared frame works that

enables the coordination of diversity in everyday, un-self-consciously constructed sociocultural systems. All levels of society involve some mix of shared cultural content and diverse content, where “content” refers to some mix of knowledge, values, goals, etc. In all levels, there is a mix of enough sharing to allow coordination (whether cooperation, collaboration, competition, or avoidance) and enough diversity to provide a real division of labor. The consensus approach does not represent or entail any commitment to the monolithic view of culture; it does provide a tool for measuring some of the sharing. So far, our ways of looking at the diversity are still less formal.

Implicational Analysis

Joseph Greenberg’s 1968 exploration of implicational universals in linguistics has been carried over into anthropology by Roy D’Andrade and Michael Burton, L. Brudner, and Douglass White (see below). A table is constructed showing the interaction of the presence or absence of one variable with the presence or absence of another, and then a “zero cell” is looked for in the table—that is, a logically possible combination that no empirical cases fall into (see Table III). The zero cell, if the other numbers in the table are large enough to make it statistically significant, means that there exists a logical implicational relationship between the two variables; in the example here, it means that the presence of Y implies the presence of X, but not vice versa—that is, X must be present before Y, or the presence of X is a necessary condition for the presence of Y. Depending on the data, these implicational relationships can be chained (as $W \rightarrow Y \rightarrow X \rightarrow Z$) to produce, for instance, a kind of scale on which the sexual division of labor in different societies can be ranked (in Burton *et al.*’s 1977 example) or the cumulation of symptoms that go into native speakers’ narrowing disease diagnoses (D’Andrade’s example) or the structure of Navajo attitudes toward conditions involved in relocation (Schoepfle *et al.* in Gladwin (1984)). Such chains, based on comparisons among systems, can also provide insight into how conceptual systems can and cannot change over time (as Greenberg

has shown for structural aspects of language and as Per Hage has shown for kin terminologies).

Network Analysis

Network analysis, though not directly cognitive, does offer considerable insight into the ways in which shared cognitive structure and content spread and into the social conditions that affect such spread. It can also provide some insight into the actual makeup of the social entities to which various shared cognitive structure or content inheres—because collective cognition, by definition, has to inhere in some social entity (whether formal or informal) and has to achieve its collective sharing, complementarity, predictability, etc. through patterns of interactions among community members. Network analysis is concerned with who communicates with whom within a group and with the analytic insights that come from considering the overall pattern of linkages within that group.

Systematic Patterns of Recall Errors

Systematic patterns of errors in informants’ recall of systematic events or in calculations, when available, can be informative regarding the cognitive presuppositions shared by members of some informant community. An informant account of some event—say, who attended a particular seminar (in a 1987 study by Freeman, Romney, and Freeman) or what someone’s “cargo system” trajectory in some Mexican village was (Cancian in the example mentioned earlier)—that is accurate does not necessarily speak to any underlying cognitive system; the informants could just have good memories. An erroneous account by some single given informant may not mean much—it could be bad memory, bad understanding, an attention lapse, or just plain cussedness. But any errors repeated by several informants become quite interesting, particularly in regard to what explains their agreement. Because the accounts are counterfactual, memory of what actually happened can be ruled out as an explanation for the sharing. If the questions were asked in some way such that collusion among interviewees (and picking up cues from the question or questioner) can be ruled out, then the explanation has to lie in some general knowledge that the informants bring to the question-answering task. Such general knowledge has to represent some kind of cultural/community norm or presupposition, some piece of shared cognitive structure. Thus patterned errors in responses of members of a group can give researchers a special window into the shared cognitive structures associated with group members.

Table III A Two-by-Two Table, with a Zero Cell Implicational Relationship^a

X	Y	
	Present	Absent
Present	Exist cases	0: no cases (hence: $Y \rightarrow X$)
Absent	Exist cases	Exist cases

^a X and Y are features that are either present or absent in each case; “exist cases” means that there are cases in the given cell.

How Models and Structures Get Used in Research

Verbal Models

Models of cultural knowledge systems and cultural models are not only goals of analysis, but can also (even when tentative, partial, or informal) play a useful heuristic role in research and a useful summarizing and organizing role in ethnographic reporting. Tentative and preliminary work on characterizing, for example, American student cultural models relating to love and marriage has played an important role in helping researchers to conceptualize empirical issues. These may include presentation of self, positively or negatively valued profiles or role instantiations, senses of means—ends connections, participant vs. observer perspective effects, the logic of reasoning about causality, morality, and inferential evidence, and so forth. By trying to organize their interview findings and behavioral observations into functioning agent-based (i.e. actor-oriented) models (even if still only loose verbal characterizations of such models), researchers have been led to consider questions and interrelationships that would not have occurred in more traditional ethnographic approaches.

Similarly, from the perspective of more abstract cultural descriptions, even merely verbal attempts at framing cultural categories, structures, and structural relations in terms of how native users see and reason about them (as in Frake's description of Subanun religious behavior) enable a much more coherent approach to cultural functioning than do more traditional overviews.

Formal (Explicit) Models

The next step up from verbal models is the construction of formally precise models. These can show not just classifications and strong logical entailments, but also “native” reasoning about the likely import of evidence relative to competing claims, “native” presuppositions about goals and motivations, and so forth, as in Hutchins' 1980 study of Trobriand litigation. Such explicit models allow researchers to evaluate empirically their effectiveness at accounting for data (actions, decisions, justifications of action, etc.). They allow the design of indirect psychological tests (of the sort used by Romney and D'Andrade to evaluate proposed models of kinterm systems of cultural knowledge). And they enable experimentation with realistic possible empirical situations that have not (yet) been observed but about which informants can be asked.

Formal Computational Models

Formal computer models—that is, formal models that have been implemented in computer programs, which

then have been actually run—have been used in several different ways in the study of collective cognition. One of these ways is to try to model some worked out chunk of the world, including not only the relevant cognition but also the physical and social world on which the cognition is working. An example is Schank and Abelson's 1977 modeling of conversations about restaurants (including aspects that depended on knowledge of the physical world, the cultural organization of different kinds of restaurants, necessary and optional activities, and so forth); Read, in a 1998 article in the electronic *Journal of Artificial Societies and Social Simulation*, offered another example based on birth spacing decisions and marriage patterns among the !Kung san, a hunter—gatherer group in southern Africa. Other variants include attempts to model the full details of specific traffic flow patterns in specific big cities. Such models can, as in the traffic flow models, provide platforms for systematic experimentation with the effects of different arrangements, different motivations and attitudes, and so forth. They are usually too heterogeneous to constitute any coherent modeling of an actual structure. The restaurant model was systematically constructed on clear principles, knowledge structures, and reasoning processes, and so did constitute a test of the adequacy (though not the necessity) of those principles, structures, and processes for producing the behavior in question. But the complexities of interactions among simulation elements make experimentation on specific mechanisms tricky, certainly for those outside of the study group. Both kinds of simulations require major efforts by large teams, and so are not easily embarked on, nor easily criticized by outsiders.

A variant is the simulation of a single frame within which actors operate, as in Plattner's simulation of stall operation in St. Louis' Soulard market. The simulation is straightforward enough and simple enough that outsiders can consider and evaluate its actual operations, and it has a clear behavioral target that it is trying to match (the pricing decisions of stall operators). Plattner's example additionally illustrates three other important uses of such computer models. First, by bringing his informants into the development process—by trying versions out on them—he was able to use both early successes and early failures as extended ethnographic techniques for helping to raise to consciousness (both informant consciousness and researcher's consciousness) previously unrecognized aspects of the behavior being studied. Second, the developed model, once properly calibrated and accurate, became an important ethnographic tool by allowing Plattner to stop the action at key moments to discuss with informants what was going through their minds at the time, which was impossible in the hurly-burly of actual activity during active actual market operations (and which were lost from memory by the time things were quiet enough for interviews and conversations) and to experiment with

novel market conditions. Third, the developed model has served as a valuable teaching tool, enabling students to get hands-on experience regarding the operation of market systems, including both the principles that drive them and the cognitive pressures that shape actor performance in them. This simulation was simple enough for one person to develop and straightforward enough that it could be examined and understood by potential critics and borrowers.

Another variant of the simulation idea involves simulating an analytic procedure used by anthropologists to make inferences from their data. In this case, the goal is to determine how well defined and complete is the given procedure, to raise to consciousness (and then include) any parts of the procedure that the analyst appears to rely on but that are not in the overt procedure, to discover any gaps in the procedure, and to look for improvements or shortcuts. An example of such a simulation was Kronenfeld's 1976 computer implementation of Romney's procedures for implementing Lounsbury's approach to the analysis of kinship terminological systems.

A very different kind of simulation involves a focus not on an output situation but on some particular (simple) mechanism. The goal is not to replicate any rich or full "reality" for some ethnographic data set, but only to implement some proposed mechanism in the context of that data set. How much of the target "reality" the given mechanism can produce can then be seen without added assumptions or mechanisms. An example of such a simulation is the 1993 *Journal of Quantitative Anthropology* article by Kronenfeld and Kaus, in which a set of computer "critters," created within a space that contained "food," were allowed to move randomly while "searching for food"; they consumed food they landed on. Parameter values included how far they could "see" food, how fast they could move, whether they could tell if another "critter" saw food, and whether they each were tied by a "leash" to the rest of the flock. One goal was to see whether a bunch of separate, independent "agents," each acting on its own, but each responding to the behavior of others (a feedback mechanism), could produce a system that clearly exhibited Durkheimian "emergent properties." A parallel goal was to evaluate the foraging effects (efficiency of cleaning out the environment, distribution of food consumption across the population, etc.) of different food distributions and different combinations of the other parameters, especially the "leash" parameter that produced the emergent system.

Algebraic Models

For systems that are well understood, and for which variability and systematicity have been well explored, the possibility arises of producing algebraic models with axioms that are clear entities and operations, and for which different ethnographic examples can be derived

from such axioms. Such models are rare in anthropology, but have been constructed at least for kinship terminological systems (as in the different though not deeply dissimilar systems of Gould and Read and Lehman). Algebraic representations of other systems of cultural knowledge are perhaps in the offing. However, our understanding of cultural models seems still too rudimentary for such; for these, the logically looser, though still explicit, approach involved in experimental computer modeling seems much more likely to be useful.

Conclusion

Cognitive research methods offer a particularly useful approach to an understanding of the nature of culture (and thus of society) and how it works. But such usefulness will depend on significant improvements both in our empirical knowledge of cultural models and in our ability to formally represent this knowledge. Agent-based computational models seem to offer one very promising method for addressing such goals. Our understanding of how cultural systems change and adapt will benefit from further study of the interaction of individual cognitive properties (including capabilities, constraints, mode of operation, and so forth) with shared cognitive structures (including cultural knowledge systems, cultural models, and whatever other kinds of shared cognitive structures future work may turn up).

Commensuration

Mitchell L. Stevens

New York University, New York, USA

Wendy Nelson Espeland

Northwestern University, Evanston, Illinois, USA

Glossary

commensuration The comparison of different objects, attributes, or people according to a common metric.

cost-benefit analyses Decision-making techniques in which the benefits and costs associated with a course of action are calculated.

incommensurable Something that is not amenable to any common measurement; something unique, incomparable.

metric Any standard of measurement.

Commensuration is the expression or measurement of different entities according to a common metric. Utility, price, and cost-benefit ratios are prominent examples, but commensuration encompasses all human efforts to express value quantitatively. Commensuration entails using numbers to create relations between things, where difference is expressed as magnitude, as a matter of more or less rather than of kind. The quantitative relationships that commensuration accomplishes create new distinctions as they eliminate old ones. The logic of commensuration is built into virtually all facets of government and economic practice as well as scientific inquiry. Censuses, financial instruments such as stocks and futures, surveys, scales, and rankings all are instances of commensuration.

Theories of Commensuration

The promise and limits of commensuration have engaged thinkers since ancient times. According to Martha

Nussbaum, the relationship between measurement and control, counting and knowing, has deep roots in Greek thinking about cognition.

Platonic ethics understands commensuration as essential to the determination of the “Good,” which was best achieved by making all values commensurate and then prioritizing them in order to make the wisest choices. Plato believed that commensuration could simplify even the most complex ethical questions, while at the same time eliminating biases of passion from decision making. Aristotle took a contrary view, arguing that the values that make up a good human life are practical, plural, and not reducible to a common standard. For Aristotle, an ethical life requires that we attend to the distinctiveness of values, to particular cases over general rules. Living well depends on appreciating the intrinsic value of different kinds of commitments, but doing so leaves us more vulnerable to luck and passion. For Aristotle, this is the sacrifice that living in a far richer world requires.

Commensuration is a central theme in Max Weber’s investigations of rationalization, which echo the dialog between Plato and Aristotle on the virtues and threat of reason rooted in calculation. For Weber, the expanding role of calculation as a strategy to manage uncertainty and make predictions was a central feature of Western rationalism and crucial for the development of capitalism. Decision making based on numbers, rather than duty, magic, or custom, represented a radically new orientation toward business. Weber argued that the development of capital accounting depersonalized business relations and fostered an objective stance toward business choices. Weber’s emphasis on calculation is grounded in the

technical advantage it confers to those who use it. Those who calculate more accurately or more thoroughly will outcompete those who calculate less well or less often.

The cash nexus is perhaps the most ubiquitous instance of commensuration. The rise of universal currencies both fascinated and worried many critics of modernity, who repeatedly described the relationships between money's ability to commensurate all values and human alienation. For Karl Marx, the cash nexus facilitated the appropriation of labor by capitalists by severing the natural relationship between workers and the products of their labors. For Georg Simmel, the universality of monetary valuation contributed to "the calculating character of modern times," in which people become obsessed with "measuring, weighing and calculating" while their emotional faculties wither.

More recently, rational choice theory in its various guises (game theory and utility theory are prominent examples) extends the Platonic project. Rational choice theory models all facets of human behavior on the presumption that individuals and groups calibrate their preferences and choose courses of action which maximize self-interested outcomes. Rational choice frameworks are appealing for their analytic clarity and for their generality. Scholars such as Gary Becker and Richard Posner, for example, have brilliantly applied the premise that people make choices on the basis of rational calculation to such intimate questions as how people choose mates and opt to have children. But other scholars have taken more an Aristotelian view, citing the wealth of historical and ethnographic evidence demonstrating that people often value things (such as lovers, children, or a native country) because of their singularity—that is, in qualitative rather than quantitative terms.

Commensuration as a Practical Accomplishment

Commensuration is not inevitable. It typically requires considerable human effort, political power, and large resource outlays to accomplish. The discipline, coordination, and technical expertise that commensuration demands often take a long time to establish. This partly explains why commensuration thrives in bureaucracies. Because commensuration obscures distinctive characteristics, it is also a powerful strategy for producing the impersonal authority that is the hallmark of bureaucracies. Before metrics can be used they must be invented, and some instances of their creation stand among the most enduring and consequential artifacts of human civilization. Money economies are prominent examples.

The recent transition of many European Union (EU) nations to a common currency aptly demonstrates the amount of effort required integrate disparate value systems according to a common metric. The move to

the euro was in the planning stages for years and took enormous political effort to assure compliance throughout the EU. Literally all components of economic life on continental Europe had to be recalibrated to the new currency, a truly massive organizational feat. Media stories about the transition have ranged from the euro's affect on global financial markets to the Herculean task of reprogramming thousands automated teller machines, to the efforts of social workers to teach blind consumers the distinctive feel of the new bills and coins.

The rise of cost-benefit analysis in U.S. public policy provides other examples of the work commensuration requires. As Theodore Porter demonstrates, even before the Flood Control Act of 1936, when federal law first required that the benefits of federally subsidized water projects exceed their costs, bureaucracies were using cost-benefit analysis. Spurred by law and conflict, agencies invested more heavily in development of cost-benefit analysis; over time, the procedures were standardized, regulated, and eventually incorporated into economic theory. Attendant professional groups of econometricians, statisticians, and decision theorists emerged to do the job of measuring and comparing the value of such disparate objects as riparian habitats, natural vistas, flood control, Indian land claims, and revenue. Commensurative expertise became institutionalized as distinctive careers and elaborate professional industries. As a commensuration strategy, the reach of cost-benefit analysis extended far beyond decision making. It shaped what information was incorporated, how internal units interacted, relations with other agencies and with constituents, and even the terms under which government projects could be challenged or supported.

Commensuration and the Constitution of Social Things

Commensuration often creates what it purports merely to measure. But the constitutive power of commensuration is potentially threatening because its authority often hinges on its claims to be a neutral measure of existing properties. Commensuration is especially good at creating new types of people. As Ian Hacking shows, enumeration demands classification; creating new categories of individuals can fundamentally affect how we understand ourselves and others. Governments typically are key players in this creative process. Porter has noted, for example, how census officials, survey researchers, and activists have over time created "Hispanics" by aggregating people of Puerto Rican, Mexican, Cuban, Iberian, and Central and South American descent. Despite the vast cultural and historical differences represented by the peoples in this aggregate, the designation "Hispanic"

has shaped the self-understanding, collective memory, and politics of millions of Americans.

Some of our most basic social units are products of commensuration. John Meyer and his colleagues have documented how the production of elaborate censuses, health-and-welfare statistics, and economic output measures do much to constitute the very idea of the modern nation-state. The global spread of standardized methods for producing these statistics has helped transform subjects into citizens and disparate peoples into comparable political entities. National measures of such attributes as infant mortality, literacy, telephone service, and GDP—easily comparable with the figures of other countries—often serve as proxies for the nation itself in global conferences and associations. Provided it has the symbolic trappings to go along with them (a flag, an anthem, a traditional costume, and a written national history), in the milieu of global diplomacy the nation *is* its numbers. Whether what emerges from commensuration is “the best colleges,” “the average voter,” “national productivity,” or “developing economies,” commensuration creates fateful categories that become embedded in institutions and acquire powerful constituencies.

Incommensurables

Incommensurables are things that are regarded as unique in ways that make them inimical to quantitative valuation. Children are perhaps the most prominent example. Feminist legal scholars have made articulate arguments against the development of markets in children and have raised concern about the rise of quasimarkets in international adoption, in which hopeful parents pay large sums to intermediate firms for the transfer of infants across national borders. Central to the feminist concern is the notion that the singular value of human life is eroded when it meets the cash nexus too directly. How to manage adoptions in a manner that sufficiently honors human integrity, alongside very real financial incentives for biological parents and the practical organizational costs of adoption transactions, remains a controversial legal and ethical question.

Sometimes people invest such singular value in particular objects that to commensurate them is tantamount to destroying them. Joseph Raz calls such objects “constitutive incommensurables.” Wendy Espeland argues that for the Yavapai Indians of the U.S. Southwest, land is a constitutive incommensurable. When federal agents sought to purchase Yavapai land for a large water reclamation project, the Indians argued that their land was a part of their identity as Yavapai and so should not be the object of commensuration. In a more recent example, several member countries of the EU have refused to adopt the euro, citing the intimate relationship

between national currency and national identity. These cases reveal the paradoxical way in which commensuration systems themselves can serve as constitutive incommensurables when they are imbued with singular meaning.

Commensuration Politics

Commensuration is rarely a politically neutral process because it transgresses cultural boundaries and reconfigures values in ways that variably privilege different parties. The long-standing legal debate over comparable worth pay policies, in which the pay scales of predominantly female occupations are rendered commensurate with predominantly male jobs, is a clear example. Proponents of comparable worth argue that women are systematically disadvantaged by a labor market that channels them into occupations that pay less than ostensibly equivalent jobs that are predominantly male. But the comparable worth movement has been stymied by two formidable obstacles: the expense to employers of adjusting female pay scales upward and the stubborn cultural presumption that the jobs men and women do are essentially different.

Another broad instance of commensuration politics involves the national debate over the role of standardized tests in college admissions. College entrance exams such as the SAT purport to commensurate all college-bound students with a common yardstick of college readiness. SAT scores are closely correlated with race, however. Asians have the highest average scores and African-Americans the lowest, with those of Whites and Hispanics in between. SAT scores also vary by social class. These unsettling relations are hard to reconcile with those who interpret the test as a measure of individual merit. At issue in the debates over comparable worth and the validity of test scores is the quintessential American question of how to commensurate opportunity—a political and ethical problem as well as a technical one.

Commensuration is so ubiquitous, we often fail to notice it. Yet commensuration is crucial for how we implement our most cherished ideals. Values expressed through commensuration are often associated with precision, objectivity, and rationality. Democracy has become synonymous with voting and polls. Standardized tests identify merit, assure competence, and hold educators accountable. Cost-benefit analyses evaluate efficiency. Risk assessments reassure us about uncertain futures. As a vehicle for assembling and sorting information, commensuration shapes what we attend to, simplifies cognition, and makes a complicated world seem more amenable to our control.

Communication

Ayo Oyeleye

*University of Central England in Birmingham,
Birmingham, United Kingdom*

Glossary

communication Definitions vary according to theoretical framework and focus. Media theorist George Gerbner defined the term as “social interaction through messages.”

decoding The process of interpreting and making sense of the nature of messages.

discourse analysis A method for analyzing the content of mass communication; seeks to explain the ways that mass media texts are used to convey power and ideology to readers or audiences.

encoding The process of communicating through the use of codes (aural, visual, etc.) that are deemed appropriate for the objectives of the sender of a message.

group dynamics The scientific study of the behavior and interactions of people in groups.

interaction The mutual relations between people in a social context.

sociogram A chart used for illustrating the interrelations among people in groups.

sociometry A technique for identifying the structure of ties in a group based on affective interaction, as opposed to role expectations.

The term communication covers a very broad range of concepts concerned with interactions, and an enormous amount of research activity and interest is devoted to the study of the nature of communication. The focus here is the study of human communication in terms of levels of communication. This approach is useful for delineating types of communication as well as for mapping the field in terms of the subject focus and the theoretical and methodological applications entailed. Measurement and analysis of human communication encompass both scientific and humanistic traditions of inquiry and a wide range of research methods, including laboratory experiments,

surveys, content analyses, semiology, discourse analyses, hermeneutics, and ethnography.

Introduction

The origin of the word “communication” has been traced back to the Latin word *communicare*, which means “to impart,” i.e., to share with or to make common such things as knowledge, experience, hope, vision, thought, opinion, feeling, and belief. This historical link can be seen in the way that many contemporary dictionaries define the words “communicate” and “communication.” Central to the various definitions are expressions such as “to share,” “to make known,” “to bestow,” or “to reveal,” thus conveying the concepts of imparting information and having something in common with another being. In communication studies, however the word takes on a rather more complex guise and, as such, it is not easy to offer a single definition that will encompass the various perspectives that communication scholars hold on the concept. Indeed, scholars such as J. Corner and J. Hawthorn argue that such a task is neither necessary nor desirable. They contend that the study of communication should be undertaken by reference to its essential characteristics as constituted by a variety of ideas and methods in the arts and social science disciplines. The often conflicting and contentious ideas about the nature of communication must not be seen as a drawback. Rather, they should usefully encourage students of communication to develop a critical awareness of the relative status of all contending ideas about the nature of the subject, while also engendering a sense of challenge to participate in the ongoing efforts to explore and enunciate the nature and elements of communication.

Defining Communication

Over the years, communication scholars have developed a number of definitions for communication that tend to reflect the particular perspective from which they are working. Such definitions can serve the useful purpose of providing a starting point for framing inquiries into some aspect of communication, or they can show the perspective from which scholars are studying communication. A definition of communication as framed by Berger and Chaffee, for example, inscribes it within the tradition of scientific inquiry thus: "Communication science seeks to understand the production, processing, and effects of symbol and signal systems by developing testable theories, containing lawful generalizations, that explain phenomena associated with production, processing, and effects."

Not all communication concerns or inquiries fall within this rubric, however, and as McQuail has noted, the definition represents only one of several models of inquiry into communication—an empirical, quantitative, and behavioral paradigm. In order to make some sense out of the fragmentation and coalescence that have characterized the development of communication as a field of studies, especially from the 1960s, scholars have continued to classify communication studies according to theoretical approaches, methods of inquiries, levels of communication, and so on. For instance, Sven Windahl and Benno Signitzer have identified two broad approaches to the definition of communication. There is a transmission approach whereby communication involves a sender/message/channel/receiver model. Proponents of this approach, which is also referred to as a linear model, attempt to show how an idea, knowledge, emotion, or vision is transferred from one person to another. Thus, George and Achilles Theodorson define communication as the "transmission of information, ideas, attitudes, or emotion from one person or groups to another (or others) primarily through symbols."

The second approach described by Windahl and Signitzer is one characterized by "mutuality" and "shared perceptions." This approach is referred to variously as the interactional, ritual, or humanistic model. In this approach, there is recognition that communication entails the active engagement of both the communicator and the receiver. Indeed, the proponents of this approach prefer to blur the distinctions between the roles of the communicator and the receiver of messages, stressing instead the interchangeable nature of both roles. In this regard, Gerbner defined communication as "social interaction through messages." Similarly, Wilbur Schramm, in a later review of his earlier view of communication, offers this transactional definition: "Communication is now seen as a transaction in which both parties are active. The

parties are not necessarily equally active—that is more likely in the case of interpersonal communication, but less so in the case of mass media and their audiences—but to both parties the transaction is in some way functional. It meets a need or provides a gratification. To a greater or lesser degree information flows both ways." Another author has described a ritual model as one in which words and phrases such as "sharing," "participation," "association," "fellowship," and "the possession of a common faith" are linked with communication. A ritual view of communication is concerned with its role in the maintenance of society in time, rather than with the extension of messages in space.

These two broad perspectives on communication are crucial in their implications for framing the distinctive ways that scholars approach the study of communication, the sorts of questions that they pose for research exploration, and the methods used in their inquiries into the nature of communication.

The Process of Communication

From the early attempts to develop and formalize the study of human communication, scholars have conceptualized it as a process. The idea of communication as a process has come to be seen by many scholars as a crucial part of its definition. A process is an activity that has no beginning or end. It is an endless continuum with only a forward motion. That is, every new act of communication is a further development on that which it precedes. For example, news stories, by definition, are reports on new occurrences, but in many cases they are also reports of developments on previous accounts of an event. Every new account takes the original story further, to newer resolutions or developments. Likewise, in interpersonal relationships, people are always developing newer acts of communication, even when the conversation is about past events or conversations. Conversations always have a history and rarely begin from scratch. A common maxim for exploring this notion is "people cannot not communicate." They cannot "uncommunicate" either. The very attempt to not say something in a given social context does actually communicate something—a limited knowledge of the topic, a lack of interest, shyness, dislike, defiance, and so on. There is a useful Yoruba (Western Nigeria) saying that captures this forward and irreversible motion of communication so well: "A word is like an egg. Once broken, it cannot be put back together again!"

Not all communication scholars like the idea of describing communication as a process, however. Their main objection is that this view renders communication a mere product of causality, which therefore rules out the

possibility of choice. Communication can be the result of both intentional and unintentional actions. Heath and Bryant have contended that the key to understanding communication does not lie in attempts to determine whether communication is intentional or unintentional, but in recognizing that communication is an endless process. One implication of seeing communication as a process is that individual events occur over time in a fairly but not totally predictable manner. Communication develops from a series of events that relate to one another for many reasons. These include causality, rule compliance, randomness, covariance, or strategic choices by each participant.

A process view of communication recognizes the twin properties of communication as a motion and an action. As motion, communication issues from linear causation, not from will or chance. As action, communication is the result of human deliberation and intentions. It is not difficult to understand these twin properties of communication if we look at our own experiences. Many human communication efforts are motivated by the need to participate in an ongoing process—at work, at home, at school, etc. This is the linear causality element of communication. Communication precedes us, it was around before we were born, and will still be there when we are gone. People participate in communication as a way of plugging into the stream of human history. Preexisting communication engenders further communication in a never-ending, forward motion. Communication is not, however, about some kind of preprogrammed reaction to events. It can also be random or unplanned. Many will recall the numerous occasions when they have said things they wish they had not said, or said things in a way that they did not intend. The extent to which communication is deliberate and intentional or spontaneous and unplanned is a key issue for scholars in all areas of communication research.

Levels of Communication

In the attempt to make sense of the expansive body of work that constitutes the communication field, a less contentious analytical approach is to distinguish between different levels of the communication process. This approach allows us to see the different communication processes involved at different levels. It also helps to map the field of human communication study in terms of the research concerns and focus, as well as the various concepts and theoretical and methodological traditions deployed for its study at each level. This explains why the study of human communication is characterized by a multidisciplinary mode of inquiry.

There are two broad categories of communication. The first concerns the locus of communication activity and the

second concerns the number of people involved at any given time. The locus of communication is about whether communication takes place within a person (intrapersonal communication) or outside, i.e., between two or more people (interpersonal communication), or among a number of people linked by a form of technology (such as broadcasting) that enables the distribution of information to a large group (mass communication). When communication is classified according to the number of people that may be involved at any particular time, the individual or small groups or masses of people may be involved. The two broad categories (the locus of activity and the number of people involved) thus can be filtered into four levels of communication: intrapersonal, interpersonal, group, and mass communication.

Intrapersonal Communication

The study of intrapersonal communication involves attempts to understand how people make sense of the world around them and how this in turn impacts the way people react to the world around them. Thirteen properties have been proposed to be involved in the process of intrapersonal communication. These include perceptions, memories, experiences, feelings, interpretations, inferences, evaluations, attitudes, opinions, ideas, strategies, images, and states of consciousness. The study of intrapersonal communication draws on theoretical and methodological practices from cognitive, behavioral, and social psychology. Key questions that researchers working at this level of communication try to find answers to include how people's perceptions, feelings, and understanding affect their interaction with the world around them; how people respond to symbols; and how people store and retrieve information.

Communications scholars working at the intrapersonal level aim to understand the place of the individual in the communication process. Intrapersonal communication has been defined as "communication within the self, and of the self to the self." Communication begins and ends with the self. The individual is the basic unit of any social formation and, as such, there are important insights to be gained on the nature of human communication from understanding the role of the individual in this complex process. The self can be understood as composed of different elements. First, there is the inner self, which is made up of a number of elements such as self-perception, self-evaluation, and personality. Second, surrounding the inner self are other elements such as needs, which generate the drive to communicate with others and to interpret communications. Third, there is the element of cognition, which allows us to make sense of the external world and the communication coming from it. Because the self is a very dynamic entity that is in constant interaction with the external world, it has a fourth crucial

element, a monitoring capacity that gauges the reactions of others to our communication, thus allowing us to modify our communication constantly in relation to the different contexts in which we find ourselves.

Intrapersonal communication can be said to entail two active elements, encoding and decoding. Encoding can be understood as the process by which an individual translates his/her thoughts into communicative signs (such as speech or writing) for others to interact with, or not. Decoding, by the same token, can be understood as the process of receiving signals from external sources and attempting to make sense of them.

Measurement of Intrapersonal Communication

Communication scholars working at this level are interested in finding answers to a number of questions about how communication takes place inside an individual, and how this has implications for wider concerns about human communication. The concern could be, for instance, about how individuals make sense of communication from others and what factors hamper or facilitate the process. Or it could be about understanding the factors that govern individual differences in their communicative competences.

Two fundamental properties of communication, impact and intersubjectivity, have been identified, and there has been an attempt to locate the place of the individual in the broader communication process. Impact is by far the most commonly associated property of communication. There is a huge interest, both academic and nonacademic, in the possible impact of communication (on an individual, on small or large groups of persons, on an organization, on a society, etc.). An act of communication does not necessarily guarantee an impact. Likewise, the impact of communication can range from none to total control. As such, it has been suggested that adequate accounts of human communication must identify the mechanisms that generate the degree of impact that one person's behavior has on another person's behavior or cognitive/emotive state. The contention is that such an account is necessary for communication scholars to be able to specify boundaries for their discipline.

Intersubjectivity is also an essential property of human communication. Intersubjectivity emerges out of the shared knowledge possessed by participants in a social interaction. It is based on common experience and communication. It is what makes communication between people possible, because it allows them to presume that there is a common perspective on how an event can be understood. Without the presumptions that come with intersubjectivity, communication will be frustrating or practically ineffective. In a similar vein, the existence of a shared knowledge among social actors affords them the opportunity to construct a common

“world” of interconnected beliefs and inferences. Well-known communication phenomena such as coordination, coorientation, misunderstanding, emotional empathy, and identity negotiation are grounded in intersubjectivity. Because intersubjectivity exists in degrees, an adequate account of human communication must identify the mechanisms that generate degrees of intersubjectivity. Otherwise, communication scholars will be unable to explain problems associated with misunderstanding and its impact on relational definition, conflict, the sources of deception, and the lack of coordination. Conversely, by understanding the mechanisms that generate degrees of intersubjectivity, communication scholars are able to intervene and correct misunderstandings in social interactions. A good case in point is the application of social judgment theory to the study of real conflicts that have emerged from misunderstanding among social actors. By basing the method for this on an understanding of the mechanisms that generate degrees of intersubjectivity, it is possible to identify sources of misunderstanding as well as to explain the persistence of misunderstanding, even when one or both parties have sought to address the sources of that misunderstanding.

Approaches to Measuring Intrapersonal Communication

Communication scholars have developed several approaches to study communication problems. Three in particular—trait, transindividual, and cognitive/interpretive approaches—stand out for their potential for understanding the problems and measurements of intrapersonal communication.

Trait Approaches Trait approaches locate the core of communication in the individual and his/her predisposition to initiate action or to respond to behavior. Traits are understood as a stable predisposition to behavior, and, as such, trait approaches treat human beings as a complex of predispositions that are stable over long periods of time and over various contexts. Although traits are treated as constant and predictable, the behaviors they give rise to are often varied. The trait approach has been used widely to predict social behavior.

Transindividual Approaches These approaches take communication, particularly its regular features, as deriving from the evolving and ritualized practices of social aggregates such as dyads, groups, organizations, culture, and so on. Scholars working in these approaches tend to locate the center of communication away from the individual and place it instead on social collectives. They tend to place emphasis on the role that the context of communication plays in the communication process, rather than the individual. The transindividual approaches use context to explain communication behavior in two

ways: behavioral contingency and conventionalized versions. In behavioral contingency, the research focus is on analyzing or measuring the interactions between individuals or among members of a group that is sufficiently stable to have a pattern. The emphasis is not on any attributes that the individuals bring to the interaction, but on the communicative acts that evolve from such interactions. The focus here is on analyzing how communication between individuals is contingent on the behavior of those individuals involved in an interaction. This approach entails the use of “relational analysis” that begins at the level of the dyad rather than at the level of the individual.

In the conventionalized versions approach, just as in the behavioral contingency approach, emphasis is on the context of communication. In this approach, emphasis is on the shared attributes of members of a linguistic community, such as knowledge of contexts, knowledge of communicative forms, and knowledge of the appropriate interpretations for them. The assumption of a communal pull of cultural resources for communicating and making sense of the world taken by this approach leads scholars away from focusing on the individual and instead, to focusing on the context of interaction. If all members of a linguistic community are assumed to share a common knowledge of communicative competence and performance, then they are culturally interchangeable. These two models within the transindividual approaches thus place emphasis on the nature of human communication as social interaction. However, these models are not very good at explaining the extent to which a message might impact on another person’s behavior or state of mind, because they fail to identify the mechanisms by which such impact might occur. When such attempts have been made, they reveal the need to recognize the role of the individual in the communication process.

Cognitive/Interpretive Approaches Like the trait approaches, the cognitive/interpretive approaches are more focused on the role of the individual in the communication process. Trait approaches do this by analyzing the predispositions and peculiarities of individuals that govern the initiation of or reaction to communication. By contrast, the cognitive approaches focus on individual differences in cognitive structures that lead to differences in message interpretations and behaviors. As such, the emphasis of the cognitive approaches is on the innate, psychological processes that individuals deploy to tasks of interpretation and production of messages. The cognitive/interpretive approaches attempt to account for how individuals react subjectively to messages and behaviors. They seek to explain the degree of competences that individuals have in social interactions involving message acquisitions, such as how they tease out information

from messages, how they retain and transform such information, and how they act on it.

A method of research commonly used in this area of work is discourse processing. This seeks to explain the cognitive processes and knowledge structures that individuals use to interpret and produce texts. This research method seeks to explore the ways that people in a social interaction accommodate each other’s communication competences through adaptive techniques in their production and interpretation of messages. There are many approaches to the study of discourse, and the term has had a checkered history in terms of how it is defined and used in academic disciplines. Suffice it to note here that to the extent that discourse processing entails the study of the psychological processes that people deploy to communicative interactions, it can be said to be rooted in the level of intrapersonal communication. That is not to say, however, that the method of discourse processing treats messages as solely governed by psychological processes, because a considerable amount of attention is also paid to contextual factors. Work in discourse processing shows how intrapersonal communication involves a complex cognitive system that underpins the ability to interpret and produce messages in social interactions. Although much communication is social and interactional, an explanation of the mechanisms by which the twin essential elements of communication, impact and intersubjectivity, take place must incorporate an understanding of the processes that occur at the intrapersonal level (see Fig. 1).

Interpersonal Communication

Following from the work of Herbert Mead, in 1934, which showed that communication is central to the capacity of

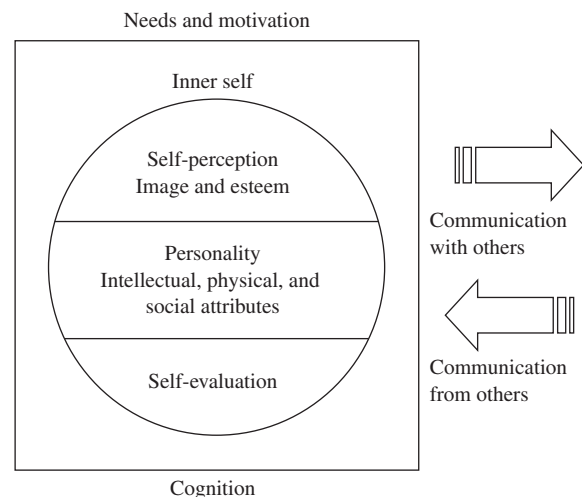

Figure 1 A model of the intrapersonal communication process.

people to grow in personality and relationships, scholars have been interested in the analysis of interpersonal communication. At the heart of the inquiry into the subject of interpersonal communication is the interest in the quality of relationships among people—loves, family, couples, peer groups, work mates, and so on. Heath and Bryant have identified four central themes among the broad range of topics that research into interpersonal communication addresses. They are (1) quality of relationships, (2) social conflict, (3) accuracy with which people understand one another, and (4) communication planning and competence. The study of interpersonal communication aims, among other concerns, to determine the variables that account for the differences in relationships. Heath and Bryant defined interpersonal communication as a “dyadic interaction in which people negotiate relationships by using communication styles and strategies that become personally meaningful as the persons involved attempt to reduce uncertainty (about themselves, their partners, and their relationships), to be self-efficacious, and to maximize rewards through interaction.” They further observed that when the action or words of one person has an effect on another person, interpersonal communication can be said to have taken place.

There are two major perspectives on the motive behind interpersonal communications and relationships: uncertainty reduction and rules-based approach. Uncertainty reduction involves attempts to develop an understanding of other people, and of ourselves, by seeking and sharing information that will enhance our intelligence. Such intelligence also includes an understanding of (or a best estimate of) the communication competence of the parties involved in a relationship. In this vein, it has been pointed out that psychology, rather than sociology or culture, is the main character of interpersonal communication. By this is meant that the knowledge that people have of each other derives mainly from experiencing each other’s behavior. As such, in order to understand the nature of interpersonal communication, research must examine the impacts of what people say and do during interaction, and not focus solely on the content of conversations. When people understand interactions and the relationship variables that affect their quality, they may be better able to predict how to influence relationships and to make them more rewarding. The underlying assumption of this perspective on interpersonal relationship is that it is primarily motivated by a need to reduce uncertainty in any given interaction.

By contrast, there is a rules-based approach in which participants are motivated to follow a mutually agreed interactional convention in order to achieve desirable communication outcomes. However, even in this approach, participants often break the rules in order to gain rewards, thus suggesting that perhaps uncertainty

reduction is a stronger motivation for people during interpersonal communication.

Rosengren has suggested that the study of interpersonal communication must involve at least two lines of inquiry—a study of its general characteristics and how it varies according to the other known variables that come into play. He identified seven key variables: age, gender, personality, education, occupation, social class, and nationality. These variables often overlap and work in combination to influence the types of roles that people play in social interactions.

Measurement of Interpersonal Communication

Interpersonal communication research is based on the assumption that the nature of interaction between social actors derives from their mutual perceptions of words and actions. Interpersonal communication thus entails all behavior, verbal and nonverbal, that takes place during interaction. The key element in interpersonal communication is interpersonal relationship and the central focus of study in interpersonal relationship is the nature and quality of interaction between participants. Interaction is a process that develops over time and entails practices such as turn-taking, interruptions, topic shifts, disclosures, and confirmations. The quality of interaction in a given situation may be enhanced or hampered by variables such as complementarity (a reciprocal interaction in which the actions and words of one interactant suit or help to complete those of the other), divergence (whereby interaction orientates toward separate directions), convergence (whereby interaction orientates toward coming together), compensation (whereby interaction involves interactants filling in gaps, or making up for the failings of the others).

Key among the many concerns of researchers working at the level of interpersonal communication are attempts to understand the effect of the aforementioned variables on interactions and on interpersonal communications, and how each variable may enhance or hinder relationships. Some researchers focus on matters of social cognition and seek to understand the way people develop a knowledge of one another, as well as the level of communication competence that people bring to relationships and how this impacts on the quality of relationship that develops.

Group Communication

Research into the study of group influence on human behavior can be traced back to the 1950s through the work of the social psychologist Muzafer Sherif. Another social psychologist, Solomon Asch, worked on the pressures and conformity that the group can exert on individuals. A major strand of the work in group

communication is that associated with Kurt Lewin and his study of group dynamics. Also, in the 1940s, Paul Lazarsfeld and his colleagues researched the influence of the group on the way that people form political attitudes and make voting decisions.

Severin and Tankard have identified three significant types of groups, primary, reference, and casual. A primary group usually comprises two or more persons in a long-standing relationship that also involves a close, face-to-face interaction. Examples of such primary groups are families, religious/social groups, work groups, teams, fraternities, classroom cohorts, military units, and so on. A reference group is a standard-bearer for the person who has so associated with such a group. A person will not necessarily belong to such a group but would have identified with the group because of some qualities, values, or principles that the group possesses, or that the person believes the group possesses. A casual group offers the loosest form of association, involving usually a grouping of people who have come together in pursuit of similar goals. Such goals may include taking a bus ride, being in an elevator, or being a spectator at a sporting event. Membership in a casual group is usually by chance, and members seldom think of themselves as belonging to any such group.

Communication processes at the level of the group are about relationships rather than attributes. The measure of communication at the group level focuses not on individual attributes, but on the relationships that emerge from the interactions of two or more people. At the heart of studies on group communication is the age-old belief that human beings are social animals, and, as such, are strongly influenced by the groups to which they belong. This belief has been reinforced by modern psychology by showing that our attitudes, behaviors, and perceptions are often strongly influenced by other people. The likelihood of being influenced by other people depends on the kind of relationship we have with those other people. As social animals, people tend to live, work, and play in groups, and it is those groups to which we belong that are more likely to influence us the most. It must be clear from the onset, therefore, that research into group communication is based on the study of relationships.

The central research activity on group communication concerns observing and analyzing what goes on in groups and how these relationships affect the nature of communication in a group. Four conceptual properties that define the nature of relationships in group communication have been identified. First is the number of people involved in the relation. The smallest number of people that can constitute a group is two. This is known as the dyad, and such a relation is referred to as dyadic. A group made up of three people is a triad, and when a communication relation involves three people, it is triadic. Although higher order relations are possible, they are rarely studied

in network research. Importantly, the number of people involved in the relationship is not the same as the entire number of people that make up a group or network.

Strength or intensity of relations is the second conceptual property. Strength is the amount of interaction between the people involved in group communication. Traditionally this is measured by a binary method defined basically in terms of “present” or “absent.” A recent development, however, recognizes the need to measure strength of relations in terms of the variability in the amount of interaction between pairs of people.

The third property of relations is symmetry and the fourth property of relations is transitivity. Symmetry refers to the direction of communication flow in relationships. A symmetric flow occurs when communication is equal between the people involved. There are situations when the flow of communication may be coming from only one source, or when it may be one-sided and thus asymmetric. Transitivity describes different possibilities of relationships that can occur in a group situation (see Fig. 2). In the first case, if person A is related to person B and person B is related to person C, then, by implication, person A is also related to person C. In this scenario, the relation between person A and person C is, by implication, through the relations of person A to person B, and person B to person C. In an intransitive relation, person A communicates with person B and person B communicates with person C, but person A is not, by implication, in communication with person C.

Rosengren also described the complexity that develops in groups, as the size of the group increases, by comparing a dyad to a triad. He noted that whereas in absolute terms the difference between the two is quantitatively small (being just one), in relative terms a triad is 50% larger than a dyad. This difference is qualitatively significant because a triad makes possible the formation of three coalitions within the group. This is illustrated with a scenario in which one member in a group lets slip to outsiders a secret shared by the group. In a dyad, it would be easy for both members to know who had leaked the secret, because it can only be one or the other member of

Figure 2 A model of transitive and intransitive relations in group dynamics.

the dyad. In a triad, however, only the guilty party would know who had leaked the secret. Each of the other two members would be suspicious of the other members of the triad. Thus, group membership beyond a dyad introduces increasing complexity to the relationship within such groups.

Measurement of Group Communication

A number of methods for measuring and analyzing group interaction have emerged over the past 50 years. All of the methods in use cannot be covered in detail here, but several are briefly described. The main focus here is on highlighting the key issues that the analysis of group communication raises for researchers working in this area. Two main approaches have been identified. The first is based on observation and classification of the manifest behavior of each individual member of a group. The second is based on extensive interpretation of what transpires in the relations among group members.

There are three ways in which the manifest behavior of members of a group can be measured. The most basic method simply measures the participation of group members. For instance, a group interaction can be observed with the aim of counting the number of times that each member of the group speaks. A more sophisticated method would be to measure not only the interaction between group members but to also record the actual verbal exchanges between specific members of the group. This type of analysis is useful for revealing the structure of a group, particularly in terms of differences among members. Such differences can give rise to the formation of cliques and alliances within a group. This method of measuring group dynamics uses a technique called sociometry, and the results are often presented visually as sociograms. Sociograms are diagrammatic representations of the preferences and interactions of all members of a group. In Fig. 3 for instance, the basic sociogram reveals the number of times each group member has exchanged communications, and further analysis of this pattern might lead to the observation that the pattern of exchange among the group members is uneven. This might prompt further questions: Why is there no direct communication between person A and person C? Why is it that only person C and person D have an equal amount of exchange between them? Why did person A not respond to person E?

The third method by which manifest behavior of members of a group can be measured, credited to Robert Bales, is interaction process analysis (IPA). Bales proposed three ideas about groups: first, that the small group is a social system; second, that there are fundamental problems that every group must resolve; and third, that group behavior can be observed and classified in relation to these problems. Bales distinguished between two key categories of acts, both verbal and nonverbal, that group

Figure 3 Participation process in a group. Arrows indicate group interaction and the number of times members spoke to each other.

members perform—the socioemotional area and task area. He further split these into two subcategories, distinguishing between positive and negative socioemotional acts and information-giving and information-seeking acts. In all, Bales identified 12 types of problems or acts that he ordered into a system for observing the behavior of members in a group. Bales' IPA has been widely used in a variety of situations, but the method has prompted discussion of a number of issues regarding its limitations for understanding what goes on in groups beyond the overt acts of group members. Some of these limitations include the problem of measuring intensity of behavior; the broad categories, which may not always distinguish between acts that ought to be treated separately; and the problem of interpreting nonverbal acts, especially with the possibility that a live coding and a video-recorded session may yield different results for the coders.

Mass Communication

Morris Janowitz defined mass communication in 1968 as “the institutions and techniques by which specialized groups employ technological devices (press, radio, films, etc.) to disseminate symbolic content to large, heterogeneous, and widely dispersed audiences.” Building on the original (1959) work of Charles Wright, communication scholars have identified other characteristics of mass communication over the years:

- Mass communication involves a large, anonymous, and heterogeneous audience.
- The sources of mass communication are institutions and organizations that are primarily driven by a profit motive.

- The flow of mass communication is one-way, from the source to a multitude of receivers, with little or no opportunity of interaction for audiences.
- The content of mass communication is formulaic and standardized.
- The relations between the senders and receivers of mass communication are marked by anonymity and remoteness.

Many of these characteristics are changing, however, as a result of new communication possibilities enabled by technological innovations, changes in production practices within the media industries, different audience demands, changes in the characteristics of audiences, and other wider social changes. Thus many forms of mass communication are becoming increasingly interactive, as well as yielding more control to audiences to define the terms of their engagement with the media. As the mass media audience has become fragmented and less monolithic, media companies are tailoring their content to meet the needs of more specific groups of audiences. The new media technologies have made possible a shift from limited media sources (such as radio and television channels) to an ample supply of sources, bringing about multichannel broadcasting and other possibilities. There is also an increasing convergence of media forms and technologies, and traditionally distinct media in print, radio, television, film, music, graphics, etc. are merging on a single multimedia platform.

Mass communication media are still essentially characterized by an ability simultaneously to send either a uniform or tailored message to a large number of widely dispersed people. Also, mass communication activities are largely undertaken by large, centrally organized, and highly bureaucratic organizations. These organizations, especially in this age of globalization and conglomeration, do command a huge amount of resources, as well as economic, cultural, and political clout, which impacts on other social institutions and on the wider society. For these reasons, mass communication tends to be seen as a society-wide process. DeFleur and Ball-Rokeach have identified three critical questions entailed in the inquiry about the nature and influence of mass communication:

1. What is the impact of a society on its mass media?
2. How does mass communication take place?
3. What does exposure to mass communication do to people?

This set of questions is useful for exploring mass communication as a society-wide process, but it certainly does not exhaust the range of pertinent questions that can be asked about the nature and role of mass communication in society. A glaring omission, for instance, is a question about what people do with the media. How do people use the media and for what purpose? The study of mass

communication, which began earnestly in about the 1940s through the pioneering work of Paul Lazarsfeld and his colleagues, has developed and spread out way beyond the initial preoccupation with an instrumentalist orientation, which sought to understand the effects of mass communication on people. One of the earliest attempts to define the nature and scope of mass communication was by Harold D. Lasswell. In a seminal article published in 1948, Lasswell offered this definitional statement about mass communication: “A convenient way to describe an act of communication is to answer the following questions: Who? Says what? In which channel? To whom? With what effect?” This came to be popularly known as the “Lasswell Formula” and it has been put to various applications. It has also been criticized for its limitations for understanding what mass communication entails. The main criticism of the Lasswell Formula is that, in describing the process of communication, it offers too simple a model for what is essentially a complex set of activities. Whereas this definition offers both a description of the nature of mass communication as well as a description of its scope, Lasswell seemed to have used it to describe the field in terms of the different research inquiries happening at the time, or as a prescription of the areas that research activities needed to cover. This approach, with some modification, is still useful for mapping research activities in mass communication today. The key elements in a communication process that Lasswell identified remain relevant today, even though the range of questions, and the research focus that scholars are dealing with in relation to each of them, have expanded significantly. In using his formula to describe the research activities in the field of mass communication, Lasswell identified each of the elements in his formula with a specific kind of research inquiry (see Fig. 4).

There was an attempt in 1958, by another researcher, to improve on Lasswell’s original formula by adding two further questions: “Under what circumstances?”

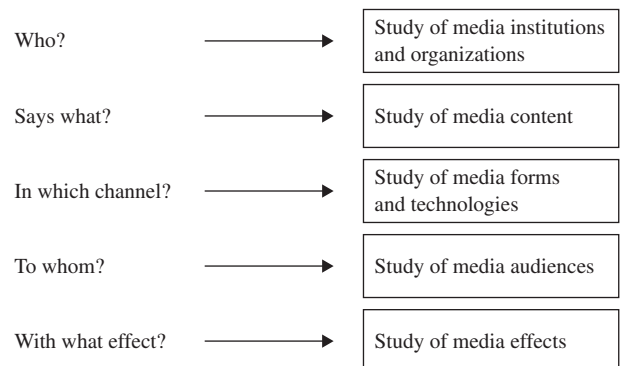

Figure 4 An adaptation of Lasswell’s communication formula for mapping key research activities in the study of communication at the level of society.

(is a message sent) and “For what purpose?” These two additional questions help to refine Lasswell’s original formula and can be related to both the sender and the receiver of mass communication.

Measurement of Mass Communication

Control Analysis Control studies engage with matters of organization, ownership, and regulation of the mass media, set within the broader context of the media institution. Other types of inquiry within control studies include matters of professional values and work ethics of workers in the various media industries. Scholars working in this area are interested in understanding issues such as how institutional factors shape media content, the impact of the media institution on the wider society in which it operates (as well as the impact of society on its media institution), the impact of the media institution on other social institutions (and vice versa), the internal dynamics of media organizations (particularly the relations between the various sectors inside a media organization), and how these impact on the production of media culture. Generally, control studies aim to find out how, and to what extent, these kinds of institutional factors serve to control the production of media culture. This type of study tends to involve the use of humanistic research methods such as participant observation, depth interview, and documentary analysis.

Content Analysis The study of media content emerged partly as an offshoot of the earlier preoccupation with media effects in the study of mass communication. The logic of this connection is straightforward: if the media are supposed to be able to influence audiences that are exposed to their messages, then a better understanding of how and why such effects happen can be obtained from a systematic study of media content. The need to also understand the appeal that various mass media content holds for audience members is another impetus for the development of research interest in the content of the mass media. With regard to the connection between content study and media effects, the early studies held a set of assumptions about media content:

- Media content reflect the intentions and values of those who originated them.
- Meanings encoded into messages are equally decoded by receivers of such messages.
- Once we understand the encoded meanings in media messages, we can predict the effects they will have on receivers of the messages.

Another line of inquiry into media content stemmed from the assumption about the connections between media content and dominant social values and ideology. This view holds that media content, by and large, reflects the values and preferences of dominant groups in society,

leading to contentions about whether the media adequately reflect, or should reflect, social reality. Inquiries of this nature also raise critical issues with the media for being the carriers of dominant ideological values along the lines of class, race, gender, ethnicity, nation, sexuality, and so on. Media content has been studied with a variety of methods of inquiry. Lasswell referred to this area of study as content analysis, which incidentally also happens to be the title for a specific social science research method. In 1952, Bernard Berelson defined the method of content analysis as “a research technique for the objective, systematic and quantitative description of the manifest content of communication.”

Scholars studying media content within the humanistic tradition have tended to use methods such as semiotics, discourse analysis, narrative analysis, genre analysis, and other methods of literary criticism. Humanistic research tends to place emphasis on the “textual” nature of media content, and the meanings that audiences get out of media texts. The word “text” suggests something that media audiences engage with, rather than something that they passively absorb. Audiences, therefore, “read” media texts, and are capable of deriving all sorts of meaning from them that are different from those intended by the producers of the texts.

Media Analysis The research tradition that comes under the media analysis section of Lasswell’s formula is represented by the work of scholars such as Harold Innis and Marshall McLuhan in the 1950s and 1960s, and Alvin Gouldner, Altheide and Snow, and Eisenstein in the 1970s. Although this tradition of inquiry has a lot of internal diversity, concerning the research interests of these scholars in mass communication technologies, they are united, according to McQuail, by their emphasis on the potential of communication technology to bring about social change. Harold Innis laid the foundation for this line of inquiry in mass communication when he founded the Toronto School in the 1950s. In developing his thesis about the importance of communication technology, Innis, basing his thesis on the study of ancient civilizations and their relationship with the prevailing dominant communication technology, established the proposition that communication technologies play a crucial role in social change. This happens in two key ways, through what Innis referred to as “communication bias” and through the benefits accruing from a monopoly control of a prevailing communication technology by a dominant social group or class. He argued that communication technologies had an innate bias in relation to the dimensions of time and space, because they favor one or the other. According to this contention, a prevailing communication technology such as stone is more biased toward time and therefore allowed the Egyptian empire to exist over a long period of time. By the same token, the

invention of papyrus, a much lighter substance to carry about, afforded the ancient Roman Empire to extend itself over a large territory. Also, social groups tend to fight for control of the prevailing communication technology until one ends up monopolizing its use. Because such control is essential for the production and distribution of knowledge, it also provides the group or class with power.

McLuhan extended Innis' idea about the significance of communication technology by exploring the linkages between our experience of the world and the communication technology that we use to experience it. His underlying argument here is that different communication technologies will give us different experiences of the world, hence his popular phrase that "the medium is the message." These pioneering studies, although often characterized as technological determinism, laid the foundation for contemporary inquiry into the new media technologies and their impact on existing communication and social relations.

Audience and Effects Analysis The studies of mass media audiences and effects represent two sides of a coin, and are interrelated in obvious ways. Although some effects studies relate to the impact of the mass media institution on society as a whole, or on other social institutions, much of the work in this area of media research (and the controversies it engenders) has been in relation to media audiences. Notions of a powerful media effect tend to imply a weak, malleable audience. Conversely, conceptions of a weak or limited effect of the media tend to relate to conceptions of the audience as active, obstinate, and creative. Nevertheless, the realization that media effects are not nearly as predictable as was once thought, and that the meaning of a media message cannot be predetermined at the source, led usefully to the development of audience study as an independent subject of inquiry in its own rights. This development has yielded a number of insights on the nature of the mass media audience that has enriched our understanding of mass communication.

The study of mass media effects has been a recurrent feature of theoretical and research activities in mass communication scholarship right from its inception. Although much of the body of work that constitutes the effects research is more representative of North American communication research tradition, it is only one (and for that matter a small proportion) in a wider range of subject interests covered by this tradition. Severin and Tankard identified four reasons for the continued interest in the subject of mass media effects:

1. Continued concern of the public. The widespread availability of mass media in various forms throughout the 20th century, both nationally and internationally, has meant that the public is always concerned about how

some aspect of the available symbolic content will affect a section (usually children and teenagers) of the audience. Every new form of mass communication tends to engender its own public concern about its possible effect on people. Thus, in the past, such concerns had been expressed about comic books, cinema, television, radio, and popular music. Arrival of the Internet has predictably raised some concerns as well. Concerns about these media include issues about the portrayal of screen violence, bad language, explicit and gratuitous sex, and promotion of antisocial or harmful behavior.

2. The organizations that produce mass communication messages are interested in the effects of their efforts, not least because they have invested a considerable amount of time, skill, and money in producing the messages. The activities of the advertising and marketing industries are a good example of this.

3. The desire to understand causes and effects is a fundamental human trait that offers a vital source of knowledge. Such knowledge allows humans to control events and to master their environment.

4. Analysis of mass communication in terms of causes and effects is compatible with the scientific tradition of inquiry (one of the major approaches used by scholars in the field).

Jack McLeod, Gerald Kosicki, and Zhogdang Pan have characterized the media effect approach as having its primary focus on audiences; as attempting to specify the nature of influence in terms of changes or prevention of changes in the audiences in relation to other relevant variables; as aiming to locate the source of influence or effect in a particular area of the media, such as a media message system, medium, type of content, or individual message; as using the terminology of variables (e.g., independent, dependent, or intervening) as well as different notions of causality to describe the process of effects and the conditions under which they are likely to occur; and as tending to formulate propositions about effects in ways accessible to empirical testing. Denis McQuail has identified four phases in the checkered history of effects research: powerful effects (short-term, immediate effect of media), limited effects, return of powerful effects (long-term, cumulative effect of media), and negotiated media influence.

The powerful effects phase McQuail locates this phase historically between the start of the 20th century up to the late 1930s. It represents the phase when a lot of power was attributed to the mass media. The mass media were thought to be able to shape public opinion and belief and to change the behavior of people as desired and designed by those who controlled the media and their content. Crucially, McQuail noted that this phase was not marked by any actual research into the way media

works and that the notions about the power of the media were based mostly on observation and speculation.

The limited effects phase This phase witnessed the arrival of empirical research into mass communication as exemplified by the Payne Fund studies in the United States in the early 1930s, and principally the work of Paul Lazarsfeld *et al.*, from the 1940s onward. This era, according to McQuail, lasted until the 1960s and involved a large amount of research into various aspects of media content and form, films, programs, political campaigns, public communication campaigns, advertising, and other marketing campaigns. The research efforts of this period were largely aimed at understanding how specific media form and content can be used to persuade or inform the public and to assess any negative effects of media that might then lead to measures to control the media. Notable among the studies of this period are Carl Hovland's study of attitude change among soldiers in the U.S. Army during World War II in the 1940s and 1950s, which showed that orientation films were not effective in changing attitudes. There was also the research by Eunice Cooper and Marie Jahoda in 1947 on the "Mr. Biggott" cartoons, which showed that the factor of selective perception could actually reduce the effectiveness of a message; Lazarsfeld also did a study of voting behavior, which showed that people were more likely to be influenced by others around them than by the mass media.

The return of powerful effects phase This phase was characterized by a shift in research focus from investigating short-term, immediate effects on individuals to investigating long-term, cumulative effects on a large number of people. Writing in defense of the research focus of this phase, Gladys and Kurt Lang argued that the conclusion about a "minima effect" of media represents only one particular interpretation, which had gained currency in media scholarship at the time. They continued: "The evidence available by the end of the 1950s, even when balanced against some of the negative findings, gives no justification for an overall verdict of 'media impotence'." Also at this time, key among the studies that attributed powerful effects to mass media are Elisabeth Noelle-Neumann's spiral-of-silence theory, which argued that three characteristics of mass communication (cumulation, ubiquity, and consonance) gave them powerful effects on public opinion. According to this theory, the opinions that people hold on any matter of significance can be influenced through a perception of such opinion as representing a minority view. People hold back on their opinion when they perceive it to be a minority one, for fear of isolation. This withholding of opinion then influences others to do the same thing, thus creating a spiral of silence. The media are said to be a major source of defining majority views. George Gerbner's cultivation theory also ascribed a powerful influence to the mass

media in terms of the effect of heavy viewing on people's perception of real conditions in the world around them. Gerbner and his associates sought to explain the effects of television viewing on people's perceptions, attitudes, and values using the survey method to explore people's view on a range of social issues, and cross-referencing these views against heavy and light viewing habits of respondents.

Negotiated media influence phase McQuail describes this phase as one characterized by an approach that saw the influence of the media in terms of their ability to "construct" social reality. By this view, the media outlets construct meanings about various aspects of the social world and present these in a systematic way to audiences. This phase is also characterized by a shift in methodological application from quantitative to qualitative methods. This phase of media effects study incorporates a view of both media power and audience power. The audience is active and participatory in a process of meaning construction that involves a continuous negotiation between the audience's worldview and the meanings offered in the mass media. In her study of the rise of the women's movement in the Netherlands, Liesbeth van Zoonen sought to assess the contribution of the media to the events. She commented that "the media image of the movement is the result of an intricate interaction between movement and media," which led to a kind of public identity and definition. It is worth noting that the latter of McQuail's four phases tend to build on, rather than cancel out, the previous ones, and that the sheer diversity of research interests in the field means that all these phases are still represented in the works of various scholars in the field.

Comparative Sociology

John R. Hall

University of California, Davis, Davis, California, USA

Glossary

analytic element A distinctive aspect of social phenomena, deemed to vary across cases.

indirect method of difference John Stuart Mill's analytic strategy based on comparison of two or more groups of cases that differ in the occurrence of basic propensities.

method of agreement John Stuart Mill's analytic strategy based on identifying propensities always found together in otherwise diverse cases.

practice of inquiry A research methodology typified on the basis of how it combines more elemental forms of discourse, including value discourse, narrative, social theory, and explanation or interpretation.

qualitative comparative analysis Charles Ragin's Boolean-algebra and fuzzy-set-theory approach to comparative analysis of potentially multiple causal configurations in a set of cases.

Comparative sociology encompasses a range of practices that focus on the juxtaposition of cases or aspects of cases, either to induce or to test theoretically derived hypotheses, to apply social theory, or to produce bounded generalizations and "rules of experience."

Introduction

Comparison occurs in social inquiry whenever observations about one or more aspects of a given case are considered in relation to observations about other cases or theoretical models. Comparisons may be formulated either by analyzing relationships among variables for multiple cases or by investigating the parallels and differences among cases. Yet similar social phenomena are often genetically connected to one another. Comparative sociology thus encounters

basic issues concerning selection of cases, measurement across cases, independence versus mutual influence of cases, and logics of inference. Comparison, then, is an Archimedean point for inquiry. Issues concerning it are relevant to both quantitative and qualitative research, and to both comparisons of cases and comparisons focusing on variables. Conventionally, comparative sociology addresses similarities and dissimilarities across cases, and this article explores the issues within this domain.

Despite precursors, comparative inquiry is especially a product of modernity. Perhaps the greatest study of comparative sociology, Alexis de Tocqueville's *Democracy in America*, preceded the modern scientific delineation of comparative logic by John Stuart Mill. During the latter part of the 19th century, the *Methodenstreit* (methodological conflict) in Germany centered on issues about generalization versus the uniqueness of culture and history, and whether the natural and cultural sciences differ from one another so radically as to require different epistemologies. Max Weber developed the most influential solution. In the formative institutional developments of modern social science during the first half of the 20th century, questions about the epistemology of comparison were pushed aside. Then, beginning in the 1960s, comparative sociohistorical research underwent concerted development. Today, comparative research takes place within a broader domain of sociohistorical inquiry characterized by "integrated disparity": diverse practices invoke radically alternative logics of analysis, while nevertheless retaining sufficient points of mutual articulation to permit theoretical and substantive dialogue among them.

Classic Approaches

One enduring problem of comparative sociology concerns how to construe the object of inquiry to be studied. On

the one hand, scientific positivism and, later, analytic realism suggest that research should seek to identify and study objectively discernible phenomena. Alternatively, the neo-Kantian legacy suggests that whatever the status of reality as such, investigators bring phenomena into distinctive focus by their frames of analytic interest. From these two alternatives radiate an array of issues and problems of comparative sociology that are parsimoniously framed by the contrast between two classic approaches, i.e., the scientific comparative method of John Stuart Mill and the interpretive, or *verstehende*, comparative practice of Max Weber.

Mill's Scientific Method

Overall, Mill's 1843 philosophy of scientific method structures comparisons across cases on the basis of their variable attributes. Mill specified two methods of research, both relevant to nonexperimental comparative analysis—the “method of agreement” and the “indirect method of difference.”

According to the logic of the method of agreement, if two features co-occur under otherwise diverse circumstances, these features are likely to be somehow processually connected with each another. With random sampling, the very diversity of cases on other dimensions enhances the argument that similarities are patterned by whatever shared dynamic is identified. For instance, if patron–client relationships occur in the most diverse social settings, but wherever they occur, there are substantial resource inequalities, the method of agreement will produce the inference that resource inequality is somehow connected to the occurrence of patron–client relationships.

The indirect method of difference involves searching for contingent co-related variations. It is as though two different findings derived from the method of agreement were placed side by side. If a particular propensity is found only in the presence of another propensity, and never when the second propensity is absent, Mill reasoned, the propensities are causally connected. Thus, if a study of postcolonial nation-states finds that a propensity toward a particular type of state formation occurs only in former plantation slavery colonies, whereas diverse non-plantation former colonies lack the propensity, plantation slavery colonization may be identified, in Mill's words, as “the effect, or the cause, or an indispensable part of the cause.”

Weber's *Verstehende* Methodology

Whereas the logic of Mill yielded a nomothetic search for general principles, an alternative, idiographic view suggests that the special character of sociohistorical phenomena makes them necessarily the subjects of a different

kind of inquiry, namely, a cultural science based on understanding unique social meanings and actions. This was the central issue of the German *Methodenstreit*.

Max Weber sought to resolve this conflict by acknowledging the meaningful and cultural bases of both social life and inquiry, while retaining a rigorous method of analysis. His approach depended on two central assertions: first, that infinitely varying sociohistorical phenomena become objects of inquiry through cultural (value) interests in them, and second, that because values cannot be warranted scientifically, the objects of sociohistorical inquiry cannot be scientifically determined, even though, once determined, they may be studied by way of scientific methods. Weber thus adopted an almost heroic stance, embracing “value neutrality” as an ethical obligation, while engaging in “science as a vocation” in a way that warrants pursuit of contextualized truths.

Weber's approach was both comparative and based on the principle of *Verstehen* (interpretive understanding). Seeking a middle ground between generalization and historicism, he combined explanation and understanding by using ideal types that would be “adequate on the level of meaning” (that is, incorporate specifications of structured cultural meanings and meaningful actions). Such ideal types—what Guenther Roth calls “sociohistorical models”—serve as meaningfully coherent analogues to empirical cases, yet allow for hermeneutic and causal comparison beyond particularities.

Comparison thus becomes a multifaceted enterprise: a given case may be compared with various sociohistorical models, either to explore the degree to which one or another model subsumes the case within its explanatory orb, or to pursue refinement of the model. In addition, multiple cases may be compared with one another in relation to one or more models. Finally, models may be compared, whether they are framed at a substantive level of analysis (e.g., religious ethics of salvation in Christian Europe) or a purely conceptual one (e.g., instrumental-rational versus value-rational action).

Contemporary Issues

In the 1960s, comparative sociology began to flourish. Partly, the impetus came from increased interest during the Cold War in cross-national comparison, and partly it came from neo-Weberians, neo-Marxists, and other historically oriented social scientists interested in alternatives to social systems theory, functionalism, and positivism, which they regarded as incapable of critically engaging issues about alternative historical trajectories. Various kindred practices also took hold (initially, social science history, and later, an efflorescence of interdisciplinary research in the human sciences, broadly conceived). By the beginning of the 21st century, researchers

and methodologists had confronted a set of linked problems concerning case definitions and measurement, study design, and interdependence of cases and possibilities of generalization.

Defining Cases and Constructing Measurements

Comparison requires the existence of multiple cases that bear some formal equivalence, at least in the aspects being compared. Thus, the most general methodological problems concern the grounds on which cases can be deemed sufficiently similar constellations of social phenomena, such that knowledge could reasonably be developed through comparison.

The Ecological Fallacy Controversy

On the face of it, case definition would seem bound by some basic rules. Organizations should not be compared to people, or people to administrative governmental units. This approach posits multiple “levels of analysis” and holds that comparison must treat cases on the same level—persons with persons, organizations with organizations, and so forth. This standard of comparison is necessary, it has been argued, to avoid the “ecological fallacy,” an example of which would include inferring relationships between attributes of individuals (income and political conservatism) on the basis of aggregate relationships between those same attributes found in more encompassing units (such as provinces). Recently, efforts to come to terms with the problem have yielded some fruitful procedures of ecological regression, even if the precept of avoiding inferences across levels remains a useful initial rule of thumb.

Yet there are two further issues. First, certain considerations may call for a different methodological strategy than one that defines analysis in relation to “levels.” Put simply, there is no epistemological guarantee that studying cases at a given level of analysis captures the relevant social processes in a given social phenomenon. Second, as Georg Simmel pointed out long ago, a given social form (e.g., conflict) can manifest at quite different scales and within different structures of social organization. These two points imply, respectively, that comparisons may analyze cases defined as wholes that transcend levels, and that cases at radically different levels of analysis may be compared, providing there is a good theoretical rationale for doing so. Indeed, this possibility has been explicitly theorized by Charles Tilly.

Case Definition

Apart from the ecological issues, there is a wider debate, both about what constitutes a case and about whether cases are the appropriate objects of comparative

sociological analysis. Sociologists are no longer so taken by the kind of “grand theory” entailed in any effort to subsume individual cases in all their nonincidental explanatory aspects within a single framework. War, for example, may involve the most diverse social processes concerning ideology, military assets, geopolitical strategies, popular mobilization, social movements, and so on. Although it is possible to compare wars with one another as “historical individuals,” or wholes, there are at least two alternatives. First, “war” may be theorized as a domain so broad that it encompasses disparate subtypes that need to be compared to one another by way of alternative sociohistorical models. Second, Stinchcombe’s proposal for the development of “theoretical methods” of sociohistorical analysis holds that the search for broad causal equivalences across cases is too crude; researchers are likely to achieve greater success in theorizing parallel patterns by looking for “deep analogies” about how things happen in various social phenomena that, on the face of it, might not even be considered as members of the same set. Here, comparison is not of cases, but of theoretically equivalent social processes, wherever they are found.

These considerations warrant a more general point. Contributors to Ragin and Becker have argued that “cases” come into focus on the basis of theoretical or substantive interests, and that on occasion, only during the process of research does what the case is a case of become evident. In other words, case selection is necessarily a reflexive process bound up with other research activities.

Sampling on the Dependent Variable

A connected issue about cases concerns their relation to a presumed wider universe of phenomena. Within the particular logic of variable-oriented analysis that is oriented to explaining variation across cases in outcomes measured by a dependent variable, cases need to be selected without regard to their outcome; that is, research must avoid “sampling on the dependent variable.” On its face, this precept makes sense. Comparison of cases with outcomes deemed equivalent may reveal conditions necessary to the outcome, but research cannot effectively probe what conditions are sufficient for an outcome to occur unless it includes comparisons with cases that lack that outcome. To be sure, Mill’s method of agreement focuses on co-occurrences of two features across cases that are otherwise diverse. But Mill’s indirect method of difference has to be judged more robust, because the method of agreement provides no way of evaluating whether an outcome would occur in the absence of a putative cause.

However, as reasonable as the rule of thumb against sampling on the dependent variable seems for certain kinds of analysis, comparison with “negative” cases of a phenomenon needs to be carefully thought through.

Consider “war” again. If the analytic interest is in explaining war as an outcome, it makes obvious good sense to compare conditions under which wars occur with those in which they do not occur. However, spatially, if not temporally, “nonwar” is something of a default condition, and a question arises as to which nonwar cases to sample. Comparison of most nonwar situations with war is unlikely to be very enlightening. The goal, instead, is to include cases in which war is a serious possibility but does not occur. In this example and more generally, then, the task is to define a population broader than those with a certain value on the dependent variable but narrow enough to permit relevant comparisons of meaningfully different cases.

Moreover, how a dependent variable is defined is an open question, and explanations may be proffered even without comparison to cases in which a phenomenon is absent. Continuing with the example of war, the analytic interest may be in explaining variations across wars, rather than explaining whether war occurs. Given this interest, the dependent variable will be defined in a way that makes the exclusion of nonwars irrelevant. In short, whether sampling on the dependent variable is problematic depends on the goals of research, and whether such sampling occurs depends on how the dependent variable is defined.

Measurement across Cases

More generally, case selection is inextricably bound up with measurement. Comparisons across cases will typically take the form of noting differences and similarities in relation to certain attributes of interest (that is, “analytic elements”). The degree to which such comparisons are formalized depends on the methodology. At one extreme, a historian investigating a single case may still bring in a series of ad hoc comparisons in order to illustrate key commonalities or differences. At the other extreme, a formal methodology of comparison will require the construction of an at-least two-dimensional matrix of cases by analytic elements, or variables.

Whatever the degree of formalization, valid comparison depends on a basic assumption, namely, that a given analytic element can be meaningfully described in relation to the cases. The cultural turn in sociohistorical inquiry has brought this issue into sharper focus. To take one construct, whatever the analytic reality of “class” in material terms, it also entails a phenomenon of social construction, both of those who participate in its “making” (e.g., in E. P. Thompson’s *The Making of the English Working Class*) and of sociohistorical analysts after the fact. The implications are several and significant. First, any conceptualization of class will be but a pale shadow of the phenomenon as it obtains in social processes. Analysts are thus faced with a trade-off between providing rich “measurements” of class that make comparisons across

multiple cases increasingly complex, or offering relatively spartan conceptualizations that facilitate comparison, but at the expense of nuance. Second, even spartan conceptualizations will have to acknowledge different sociohistorical constructions of class, e.g., in industrializing France versus industrializing England. Third, in a postpositivist understanding of inquiry, measurement is not posited as theory free; thus, the analyst has to consider the ramifications of a particular conceptualization relative to various salient theories of a phenomenon. And fourth, even a relatively spartan approach to measurement confronts the historicity of measurement. Comparing class formations cross-nationally, for example, depends on utilizing statistical series that are products of their times, both in the definitions of occupations and in the ideas and interests that drive constructions of measures in the first place. In this instance and more generally, research is necessarily engaged in activities of “translation”—between different empirical phenomena and their historical social constructions, which may involve not only a methodological but also a social effort to establish commensuration, or equivalence among measurements of phenomena, within one or more research studies.

Advances in Study Design

The classic foundations of comparative sociology trace to positivist and *verstehende* logics of comparison. Starting in the 1960s, comparative and historical sociologists began to propose alternative methodologies across this range. During the early phases, this discussion was framed largely through reference to exemplary studies by scholars such as Reinhard Bendix, Barrington Moore, Charles Tilly, and Immanuel Wallerstein, and through inductive descriptions of institutionally established approaches, such as the *Annales* school. But no widely shared interdisciplinary enterprise emerged. Instead, practitioners operated under a mélange of competing labels such as “comparative history,” “historical sociology,” “social science history,” and “world systems analysis,” even though these labels do not identify either coherent methodologies or effectively self-contained agendas of inquiry.

How are diverse methodological practices to be construed within an overall domain of sociohistorical inquiry? One account, by Peter Burke, defines the realm as a continuum between history and social theory. Two other descriptions—those of Theda Skocpol (originally, with Margaret Somers) and of Charles Tilly—displace the idea of a continuum by specifying alternative types of interdisciplinary inquiry. Skocpol and Somers identify three alternative logics of “comparative history.” One involves the “parallel demonstration of theory” in different contexts, a second approach involves a single phenomenon (such as democratization) that is studied

through the “contrast of contexts” in different cases, and a third strategy, “macro-causal analysis,” is concerned with testing hypotheses through comparative analysis.

Charles Tilly has taken a different tack, theorizing a two-dimensional typology that differentiates alternative kinds of propositions studied through inquiry. On the first axis, propositions about a given phenomenon (e.g., class struggle) may range in application from one to multiple forms of the phenomenon (worker resistance, social movement, or electoral politics). On the second axis, for any given form, propositions about a phenomenon could be directed to anywhere from one to all instances. Four kinds of propositions can thereby be delineated: (1) “individualizing” propositions concerned with only one instance of one form (that is, a unique case), (2) “encompassing” comparison, dealing with multiple forms of a single overall instance (such as the world economy), (3) “universalizing” analysis intended to cover all instances of a single form of a phenomenon (such as a general model of all developmental economic growth), and (4) “variation-finding” analysis that seeks to uncover the patterns of a phenomenon for all cases, whatever their alternative forms.

The other major development in methodology involves not the description of alternative types of inquiry, but the formalization and extension of one particular type, what Skocpol and Somers term macro-causal analysis. Charles Ragin uses set-theory Boolean algebra to consolidate Mill’s methods of difference and agreement within an overall methodology simultaneously keyed to general problems of logic and the particular problems of socio-historical inquiry. Ragin’s qualitative comparative analysis (QCA) marks an important advance over Mill’s and other formulations of comparative logic, by identifying multiple configurational patterns within an array of systematically described cases. Ragin is thus able to provide analytically for the possibility that different sets of prior conditions or conjunctures of causes may yield the same outcome. Ragin’s method also may reveal “contradictory” combinations of circumstances (A, B, and C) for which a particular outcome, O, occurs sometimes but not always. This implies that general causal factor patterns do not explain everything; when they do not, their use can help focus residual puzzles to be addressed through detailed historical comparison of alternative unique outcomes. In a subsequent elaboration, Ragin confronts the problem that many social variables (e.g., ethnicity) do not have strong categorical boundaries, by developing a procedure based on the recognition of fuzzy boundaries. This modification moves the comparative method beyond restrictive classification assumptions that were poorly aligned with even the most basic social ontology.

Finally, uses of theoretical models in comparative research have been elaborated. Hall shows how theoretical sociohistorical models such as ideal types can be

incorporated into even formalized comparative methodologies. In a different vein, Geoffrey Hawthorn has developed Weber’s logic of the “mental experiment” into “counterfactual analysis,” a procedure that sharpens the specification of conditions under which empirical cases may be compared to purely hypothetical ones. Hawthorn holds that the comparative consideration of hypothetical scenarios can deepen an analysis if the counterfactual hypotheses are neither so distant from the course of events to be irrelevant nor so unstable in their dynamics as to make prediction unreliable.

Key Issues in Contemporary Methodologies

In relation to study design, two issues that become especially important concern whether cases can be considered causally independent of one another and the relation between sample size and logic of analysis.

Independence, Genealogy, and Diffusion

One of the most formidable and intractable problems facing comparative sociohistorical inquiry concerns whether cases can be considered causally independent of one another. Any methodology that seeks to identify common patterns amenable to general explanation either has to assume independence or it has to provide a method for ascertaining the character and significance of influence across cases. Specifically, if a researcher employs Mill’s “method of agreement,” inquiry must assume causal independence of cases because the method cannot differentiate between independent cause–effect relationships, versus genetic or mutual influences that produce parallel outcomes. Suppose, for example, that a study of 60 panics associated with satanism in the United States showed that they developed in quite similar ways. The parallel event structures might seem to suggest a causal theoretical explanation, but alternative explanations cannot easily be excluded, because the satanism scares could have occurred through diffusion and imitation. What is the solution to this problem? In circumstances where case independence cannot be assumed (e.g., state formation in Europe, as studied by Reinhard Bendix), comparative inquiry is still possible, but it has an alternative rationale, of identifying genealogies, mutual influences, and patterns of diffusion. In such research, comparative analysis can address whether commonalities are shaped by nonindependence, and if so, how.

Number of Cases and Generalization

The other issue concerns sample size. Assuming that the problem of independence can be resolved, formal methods can be employed for comparing large numbers of cases. But Stanley Lieberson is less sanguine about

using formal methods of comparison in studies with small numbers of cases, both because this situation precludes probabilistic arguments and because the number of variables of interest may overwhelm the cases analyzed. However, even if analyzing a small number of cases may not be an appropriate basis for drawing causal generalizations, it may nevertheless offer a valuable way to understand social processes in themselves and *in situ*.

The problem of sample size is most exacerbated under conditions in which the sample size is one, a situation that historians often take as their point of departure and that is also faced by world-systems theorists, i.e., when they posit a single overarching totality, the modern world system. Under these conditions, if comparison is to be maintained as a methodological enterprise, it must either compare the totality to a nonempirical sociohistorical model, or the analysis can proceed by a series of nested internal comparisons, paralleling the theoretical search for “deep analogies” proposed by Stinchcombe. The most elaborate effort in this direction for world-systems theory is “incorporated comparison” as proposed by McMichael.

Alternative Practices

By the end of the 20th century, there had been substantial development of comparative methods. Yet the differences—between inductive and deductive historical sociologists, between those interested in causal explanation versus interpretation, between historical sociologists whose methodologies are explicitly comparative and historians using comparison only implicitly—often threaten to divide practices of inquiry that nevertheless share substantive interests. It is thus important to theorize the overall domain of sociohistorical inquiry within which comparative analysis is practiced. For this project, Hall identifies the ways in which alternative “practices of inquiry” bring together various “forms of discourse,” discourses that constitute interrelated moments of analyzing sociohistorical phenomena.

Four formative discourses (value discourse, narrative, social theory, and explanation or interpretation) are typically implicated both in comparative inquiry and in case studies often drawn on in comparative research. Each of these formative discourses is capable of serving as a dominant discourse that orders relations among all four discourses through internal subsumption and external articulation of them, thus consolidating a meaningfully coherent practice of inquiry. For example, if narrative discourse predominates, it will order the articulation among all four discourses in one distinctive practice of inquiry, whereas the predominance of social theory will order an articulation of discourses that constitutes an alternative practice.

In turn, generalizing versus particularizing orientations make a difference in how inquiry works. Thus, each dominant discourse, such as narrative, orders the four formative discourses in one distinctive practice when the goal is general knowledge, and a different one when the goal is detailed knowledge of a distinctive phenomenon. Given four alternative ordering discourses and two (generalizing versus particularizing) orientations of inquiry, it is possible to identify eight ideal typical practices of inquiry. In these terms, the three methodologies identified by Skocpol and Somers, theory application, contrast-oriented comparison, and analytic generalization, are the central comparative practices.

Theory Application

In the practice of theory application, the analyst seeks to bring parallel phenomena into view via narratives that apply a particular theoretical lens to the analysis of cases. The particular social theory dictates the central issues of comparative plot analysis for the narratives, and explanation (or interpretation) centers on differentiating theoretically informed versus nontheoretical accounts, and on determining whether the nontheoretical accounts require modification or disconfirmation of the theory, or are simply matters that lie outside the theory’s domain. The emphasis on close and careful comparison of a small number of cases offers bases for deepening theorization of explanatory accounts and refining theory, but generalization typically is undermined by the small number of cases.

Analytic Generalization

Analytic generalization encompasses the formal methods formulated by Mill and elaborated by Ragin. Here, the researcher empirically tests or develops hypotheses deduced from theories or induced from observations. Narrative is structured to offer the basis for adjudication of hypotheses in relation to theories, and the evaluation of alternative explanations and interpretations mediates the process of theoretical adjudication. The rigor of this practice approximates the intent of positivism, but problems of measurement equivalence and sample size, discussed previously, can threaten validity.

Contrast-Oriented Comparison

Explanation and interpretation are the central discursive concerns that order inquiry oriented to the production of bounded generalizations and “rules of experience” through contingent and idiographic analysis of sociohistorical phenomena deemed kindred in relation to a theoretical theme. The focus is on how a particular social phenomenon (e.g., proletarianization, fundamentalism)

plays out in different sociohistorical contexts. Narrative is used to trace the relations between contexts, processes, and outcomes. Because causal independence of cases is not assumed, analysis of genealogies, diffusion, and mutual influence is readily incorporated into comparative analysis.

Theory application, contrast-oriented comparison, and analytic generalization are part of a wider array of practices of inquiry, including a fourth generalizing one, “universal history,” that persists despite postmodern condemnation of “metanarratives,” and four particularizing practices (situational history, specific history, configurational history, and historicism) especially oriented to case studies. All these latter practices produce research that is implicitly comparative and that may be drawn on in comparative analysis. However, one, configurational history, is of particular importance to comparative historical sociologists.

Configurational History

The configurational history methodology operates by theoretically identifying the elements, conditions, and developments necessary for a particular (“configurational”) social phenomenon to occur, e.g., modern capitalism, or a particular technology of power. The theoretically defined configuration is then used as a basis for generating questions of historical analysis about the fulfillment of conditions, creation of elements, etc. This strategy is not inherently comparative in the conventional sense, but it involves a strong use of social theory in relation to historical analysis, and is thus favored by historical sociologists (e.g., Max Weber and Michael Mann) who seek to develop sociologically informed explanations of distinctive historical developments.

The cultural turn in epistemology, especially as underwritten by Foucault, has created conditions of substantially increased sophistication about comparative research. Once methodologies of inquiry are understood via a typology that traces their alternative relationships to more elemental forms of discourse (narrative, social theory, etc.), comparative research becomes located in relation to a broader domain characterized by a condition of “integrated disparity,” in which diverse practices invoke radically alternative logics, while nevertheless retaining sufficient points of mutual articulation to permit

theoretical and substantive dialogue and translation among them. Thus, although comparative research continues to be shot through with tensions between science, relativism, and constructivism, researchers may find conditions ripe for a new era in which they find themselves mediating among diverse comparative and other practices of inquiry. But to consider those possibilities would move into the realm of as-yet contingent possibility.

Complexity Science and the Social World

Will Medd

University of Salford, Salford, Greater Manchester, United Kingdom

Glossary

complex systems Emergent open systems that are far-from-equilibric, having nonlinear and self-organized behavior.

complexity science A multidisciplinary field concerned with the analysis of complex systems.

emergent dynamics Those dynamics with properties qualitatively different from the properties of the component parts.

far-from-equilibric A state in which there is continual flow and change and yet which enables an overall structure to form and be maintained.

nonlinearity In nonlinear systems, the output of the system cannot be calculated by the sum of the results of interactions. This means that small changes within the system over time can lead to large-scale, often unpredictable, transformations in the system.

open system A system that is open to interaction in terms of the exchange of information or energy with its environment.

self-organization Emergent dynamics that are the consequence of interaction through positive and negative feedback not fully determined by the early phase of system development, the intentions of the interaction parts, nor external forces.

This article is an overview of the recent development of approaches within social sciences that understand social phenomena through the lens of complexity science. Complexity science, comprising a range of work spanning many disciplines, explicitly aims to understand the dynamics of complex systems that are open and far-from-equilibric, displaying emergent, self-organized, and nonlinear behavior. The significance of complexity science is the way it brings to the fore the interrelationships between order and chaos, stability and instability, and continuity and change. Social scientists have sought to develop the application of complexity science to social

phenomena, which raises fundamental questions about what “the social” is and what are the limits to our knowledge of it.

Complexity Science

The term “complexity science” can be misleading because it implies a unified body of science. There are attempts to generate such unification, exemplified by the work of the Santa Fe Institute and more recently the United Kingdom Complexity Society. Indeed, for some, it is precisely the possibility of unification between disciplines that has generated the interest in complexity science, exemplified by the 1996 Gulbenkian Commission on Restructuring the Social Sciences. While the idea of a unified science has been very prominent in representations by popular science writers, within social science strong claims have also been made about the potential of complexity science for such unification. Social science writers argue that, now that the inherent complexity and unpredictability of nonlinear natural phenomena have been revealed, the complexity of the social world can no longer be seen as distinct due to its complexity. Both the natural and social world can, they propose, display similar complex dynamics, requiring, therefore, similar explanation according to the properties of complex dynamical systems. Though there are disputes about just what complexity science is (for example, whether it is a science of modernity or a postmodern science), there is nonetheless a shared concern, developed in recent decades, that phenomena characterized by emergent, self-organized, and nonlinear behavior share similar characteristics that render traditional linear methods of understanding limited.

Whereas there had been much initial interest in the application of chaos theory to social science during the early 1990s, interest in the implications of nonlinearity became consolidated through the notion of complexity

science. Complexity science brought a focus on nonlinearity, with the limits of knowledge being understood as a consequence of the character of systems, rather than a problem of knowledge generation. Because complex systems could not be broken down into their component parts, the parts could not be analyzed to explain the whole and predict future states. Complex systems have emergent characteristics that are qualitatively different from those of their parts. Complexity science therefore incorporates an interest in understanding the emergent patterns of system behavior and in developing models that can be applied to a whole host of phenomena. It is the apparent ubiquity of the characteristics of models of complexity science that has generated the interest in complexity science, as a new science that can integrate different disciplines.

Key features can be identified to describe complex systems:

1. **Self-organized emergence.** Emergent dynamics typify those complex systems having properties that are qualitatively different from the properties of the component parts of the system, so that the whole is not reducible to the sum of its parts. Complexity science has been interested in how such dynamic emergence comes into being, given that such emergent differences are not inherent in the early phase of system development, nor the intentions of the interaction parts, nor is it predetermined or predictable from external forces impinging on the system. Rather the emergence is self-organized through the positive and negative feedback relationships between interacting parts, the emergent dynamics, and those parts.

2. **Nonlinearity.** Important to the interest in self-organized emergence has been recognition of the significance of the nonlinearity of these dynamics, in which small changes in a system over time can be iteratively amplified so that they do not necessarily lead commensurately to small effects. In nonlinear systems, recursive relationships open up the possibility that small changes over time can lead to large-scale, often unpredictable, transformations in the system. In other words, small-scale local change, in both “natural” systems and complex social or cultural fields, can lead to large-scale global transformation of the entire system. Nonlinear systems dynamics can therefore become very sensitive to the initial conditions of the system, rendering problematic specific prediction.

3. **Self-organized criticality.** Complexity science has a particular interest in the role of self-organized nonlinear emergence for understanding life and its evolution. The quest has been to explore how systems maintain themselves in optimum states for survival—that is, how they maintain appropriate stability, continuity, and order while at the same time nurturing the capacity for local forms of instability, change, and disorder. Particular attention has been given to systems maintaining themselves at

critical points, at which they maintain an appropriate equilibrium between order and chaos (or as sometimes referred “far-from-equilibrium”), ensuring both continuity and adaptability.

4. **Evolutionary dynamics.** Complex systems emerge through processes that involve exchanging information and energy with their environments. Survival of the system depends on being able to learn to select and adapt to the changing environment. Such learning requires memory and therefore history. Hence, two similar systems placed in the same environment might respond in very different ways because the history of the system is important in determining the future of the system in dynamic relation to its environment. Change occurs, then, through both internal organization and an ability to take advantage of external perturbations, sometimes inducing an evolutionary leap. This means that complex systems are essentially historical and also contingent in nature.

5. **Attractor states.** Through the “mathematics of complexity,” methods have been used to describe and visualize complex systems in “phase space.” Phase space is an abstract multidimensional space with coordinates for all the variables of the system. Each point in phase space represents the system at any possible point in time. Introducing time into the system enables exploration of the system trajectory. Attractor states refers to trajectories that tend to be restricted to (attracted to) particular parts of phase space. Thus, a shift in system dynamics will often be described in terms of a shift of attractor state, i.e., a shift from one attractor to another. Such a shift can be described qualitatively.

6. **Interdependent systems.** Finally, to understand the dynamics of complex systems, it is important to understand their interdependence with other systems. Hence, any optimal point is subject to continual change in processes of coevolution. A related point here is the importance of scale. Patterns of system dynamics are repeated through different scales, often referred to in terms of self-similarity, and understanding their dynamics requires understanding that there are systems within systems.

Complexity Science and the Social World

Complexity science has been applied across the social sciences, including, for example, politics, economics, psychology, sociology, international relations, and organizational and management studies. The rise of complexity science across such a broad range of areas of science can be attributed to different factors, and, indeed, combinations of factors. Different extremes can be identified. For example, an essentially realist account would suggest that complexity science has gained attention because it represents a better account of the world than we have

previously had—in other words, because it is right. Alternatively, an emphasis can be made on shifts in our cultural condition, in which many areas of life are becoming destabilized and hence we have developed more sensitivity toward approaches that explore instability, chaos, and change. This debate is significant for understanding the development of the application of complexity science to the social world, and gains increased prominence in the context of the infamous “Sokal” affair, in which social scientists were accused of misusing metaphors from within the sciences. That said, however, within those extremes, the strength of complexity science can be seen in terms of its ability to offer better accounts of the world in relation to shifting concerns about instabilities humans now face. Importantly then, “complexity social scientists” have wanted to do more than just use the metaphors of complexity science to describe the social world. They have wanted to show how social science can contribute to complexity science and how complexity science, applied and developed for the social world, can illuminate real processes of social dynamics, even if that knowledge is always local. The problem has been how to do this. In relation to the concerns of social measurement, are three particular areas of attempts to achieve this: mathematical modeling, simulation, and reinterpreting quantitative measurement.

Applying Nonlinear Mathematics

Though mathematicians such as Poincaré had previously considered the possibilities of nonlinear behavior, it was the advent of computer technology that really brought to light its significance. Computer technology enabled mathematicians to solve nonlinear equations numerically (by trial and error) rather than analytically (finding a formula to a solution). These new methods of numerically solving nonlinear equations enabled analysis of more complex behavior by including the possible interactive affects that linear analysis breaks down. This enabled the discovery and confirmation (for some) that ordered patterns could be hidden within what could appear quite chaotic behavior, and that ordered behavior could lead to quite chaotic outcomes. That mathematics was now recognizing the significance of nonlinearity, instability, and uncertainty and was developing techniques to understand this was particularly important to social scientists such as Kiel and Elliott writing in the mid-1990s. Previous writers had applied chaos theory to specific examples, but the edited collection of Kiel and Elliott marked an attempt to bring together the use of nonlinear techniques to the social sciences more broadly.

The core issue in these techniques was to examine graphic representations of time series data in order to expose “attractors,” or forms of underlying order, pattern,

and structure. The technique involved representing the system dynamic within an imaginary space called “phase space.” Phase space is a multidimensional space with x number of coordinates to represent the many different aspects of the systems. A single point in phase space represents the system state at a particular point in time. Overtime, the trajectory of the system can be mapped and the emergent patterns, if, indeed, there are any, can be analyzed. Within phase space, systems that are not entirely chaotic (i.e., displaying no patterns of behavior) tend to be “attracted” to particular dynamics. The analysis of phase space enables the identification of such attractors. Whereas “point attractors” in phase space indicate a stable equilibrium and “cyclical attractors” demonstrate a stable periodic oscillation between the same points, it is “strange attractors” that researchers were interested in. Strange attractors were significant because they indicated that though the trajectory of the system never reached the same point twice (and was not therefore cyclical), an ordered pattern nonetheless emerged. Further, at particular points in time (bifurcation points), the system would suddenly switched from one side of the attractor to the other, thus generating a figure-eight pattern. Hence, though the data may appear disorderly, the geometrical representation of the data in phase space may demonstrate forms of stability. Thus, the discovery of order within chaos.

There has been much interest in the dynamics of systems in strange attractors; however, identifying that social systems are operating within strange attractors is problematic. Indeed, though the interest in nonlinearity and the language of attractor states has been quite popular, a number of problems with the application of nonlinear mathematics have meant this has remained quite marginal in the social sciences. There are three particular difficulties. First, such analysis requires large amounts of time series data that are consistent and reliable, which is difficult to achieve in the social sciences. Second, some of the emergent patterns are as much a function of the nonlinear equation as they are of the particular data being explored. Third, equations assumed deterministic relationships in their structure, meaning that the structure of the equation does not evolve; this is problematic for social analysis because underlying social structures may change in ways that the equations supposedly representing them cannot. These challenges led to much debate about the role of modeling. It was clearly the case that the models could not provide objective viewpoints of the social world, and would therefore become by necessity tools in the social world.

Developing Simulation

While computer technology led to a new interest in nonlinear equations, computer technology also enabled the

emergence in the 1990s of methodologies using computer simulation. Most interest for social science has been the development of “agent-based” models for simulation. In relation to complexity science, these are models in which agents interact at the local level, producing emergent, self-organized behaviors at the collective global level. In such simulations, the agents are therefore set up to act as if they are social agents, insofar as they can process and react to information in relation to their environment. The researcher is then interested in the self-organized patterns that emerge in running the simulation, including the emergence of individual behaviors of the agents. These patterns are self-organized because they are neither the consequence of the intention of the agents nor some external force, and yet they seem to evolve in ways that are neither entirely ordered nor entirely chaotic. Indeed, some complexity scientists talk of systems at the “edge of chaos.” They are emergent because the self-organized behavior displays properties that are qualitatively different from the properties of the agents and cannot be explained by aggregation of the individual agents.

Simulation has been subject to criticism. One area of criticism is that the simulations are always too simplistic—that simulation requires a simplification of the agents to rule-based behaviors, of the agents interacting in particular ways, and of what is seen as important in the environment. The problem is that when dealing with complex systems, the implication of complexity is that we do need to pay attention to detail in ways that we cannot predict. And yet simulation requires us to make various decisions about what is important. In response to this is the argument that simulation does not claim to be the real system, but instead provides a method for exploring possible dynamics that might be looked for in the real system. In this sense, certainly simulation models have brought attention to the ways in which even quite simple behaviors, distributed and recursively interacting within a system, can lead to quite complex emergent dynamics at the system level. A more problematic criticism, however, is that the problem of such simulations is that they may fail to capture a key aspect of the social world, namely, that in the social world, human beings may change their very behavior in unpredictable ways as a consequence of the emergent system. Though simulation studies have explored the adaptive behaviors of individuals in relation to the emerging system, such simulation always requires some form of programming of agent behavior or learning.

(Re)interpreting Quantitative Data

Though there have been some questions about the limits of applying nonlinear mathematics to the social world, and

concerns about the extent to which simulation can capture the very complexity that complexity science is interested in, an alternative avenue of research has explored the extent to which complexity analysis can be used to interpret social science data. Particularly influential in this area of work is David Byrne, who engages with the ontological implications of complexity science for the social sciences. In particular, he built on Reed and Harvey’s work, arguing that complexity science offers a definitive ontology for critical realist analysis. Byrne develops his argument through analysis of a range of phenomena, including urban dynamics, planning, health, and education. For Byrne, the implication was a call to rethink the social science agenda, and particularly the value of quantitative methodology.

The argument put forward is that the implication of complexity is a reconsideration of how we understand what we are measuring, and the key to this is “death of the variable.” The notion of the variable is seen as misleading because it tends to then be taken as something that exists. Complex systems are emergent, and this means that they do not have parts that can be represented in this way. However, drawing on the notion of multidimensional phase space, in which different coordinates of the system can be represented, it becomes possible not to think of measurements as representing variables of the systems, but, instead, as representing variate traces of the underlying systems dynamic in order to identify classes of system and systems behavior. The term “variable” then comes to be used as a word referring to things outside of the system, or inputs from the environment.

The importance of this move to talk of variate traces concerns the implication of how we understand and interpret the system we are exploring. Recognizing our measurement as a trace keeps open our sensitivity to the inherent complexity of complex systems. It keeps open that within complex systems are further complex systems, nested in complex hierarchies and networks. Interpreting the system then involves exploring combinations of traces, exploring the shifting implications of different parameters of the system, and exploring subsets of relationships within the system. It represents a shift from measurement of the system to classification of systems states and of system types.

Challenges for Measuring Social Complexity

The most difficult challenge posed by complexity science for social measurement is that of complexity itself. In the case of applying nonlinear mathematical models to the social world, the difficulties of establishing determinate sets of relations to represent complex social

interactions are raised. Developing simulation models requires an assumption that the boundaries of the social world under question can somehow be established, such that the interactions of agents within the simulation are clear. And in reinterpreting quantitative data, we are faced with the challenge of what counts as a variate trace and how different would the system appear if alternative measurements had been made. All of these approaches have shed light on our understanding of social measurement, and the implication is that social measurement must be undertaken as an exploratory task because modeling can never be complete. To conclude, there are two key challenges that such exploration must continue to examine, namely, the problem of the boundaries and the limits to knowledge.

First, the problem of boundaries refers to asking a pertinent question: What is the system that we are looking at? This can mean asking what are the agents of the system to include in a simulation, as well as what traces of the system we might want to measure. Similarly, this can also mean exploring the question of what constitutes the boundary of the system. Traditionally, these sorts of questions are often answered through particularly disciplinary lenses. However, in attempting to transcend disciplines, complexity science suggests that social measurement needs to involve opening up our assumptions of what is in and out of a system, to explore the processes of emergence, as well as interaction between systems and their environment (which includes other systems). Complexity science is about understanding systems as both open and closed and exploring how boundaries between the system and the environment are constituted. Particularly in a global and increasingly technological context, these questions are becoming especially pertinent and, in theory, appear to be most appropriate for the application of complexity, as exemplified in the work of John Urry.

The question of how to establish the boundaries of the system under question is significant to the second challenge, that of the role of social measurement and knowledge of the future. In establishing the boundaries of the system and hence of social measurement, we are also establishing what we assume to be the internal and external dynamics to the system. Complexity science recognizes that absolute prediction is not possible. What is less clear is the extent to which it becomes possible to shape future scenarios—that is, in complexity language, to shape the likely, desired, attractor-state of the system. If it is the case that those boundaries are

dynamic, then this suggests the need for continued adjustment of interventions. One implication is that when considering strategies or planning, for example, the message is to see these as processes that are continually reflexive, in order to be adaptive to changing internal and external environments. Another implication is that it becomes necessary to involve different forms of knowledge throughout the system. For these reasons, many involved in complexity research work with those engaged in the world, exemplified by the notion, for example of “integrative method.”

Computer Simulation

Louis N. Gray

Washington State University, Pullman, Washington, USA

Glossary

choice point A location, usually within a program, that can branch in two or more directions. The direction chosen depends on the underlying program.

compile A procedure by which a program or subroutine is translated into “machine language” (the fundamental structure of the operating system; usually binary).

endogenous variables The variables on which a system focuses; they are interrelated and may change as processes evolve within a simulation.

exogenous variables The variables external to a system; they are ordinarily set prior to simulation and cannot be altered within the simulation.

falsifiability A property of a statement (proposition or hypothesis) that makes it possible to show that the statement is false. For example, the statement “I am six feet tall” is falsifiable (given measurement assumptions); the statement “Someone is six feet tall” is not falsifiable. In science, specific empirical statements depend on the availability and applicability of appropriate measurement techniques.

flowchart A graphic depiction of elements of a simulation, with specific attention to choice points.

isomorphism A feature of a model or program that operates conceptually in a manner identical to a feature identified among humans, social groups, organizations, or social institutions.

model world The statement of a theory as specified in a simulation. The statement includes all the choice points and processes for determining outcomes.

moment-generating function A mathematical function that, with appropriate variable substitutions, produces the moments (central or raw) of a defined distribution. These functions completely specify the characteristics of a distribution.

process A procedure involving a time dimension and, thus, can result in either stability or change under specified conditions.

program Sets of instructions that control the operation of a computer.

programming language A specific symbolic language that can be used to construct a simulation or its subroutines.

real (empirical) world The processes a simulation is designed to mimic. Though some output may be available, the true underlying processes are unknown and output may also be contaminated by measurement error.

statistical test A procedure for assigning a probability to a specific hypothesis on the basis of known or hypothesized criteria.

stochastic A term generally referring to probabilistic variables; most frequently used to refer to probabilistic variables involved in processes or systems with a time dimension.

subroutine A segment of a program that performs a specific function. Subroutines are often compiled in languages different from that of the main program.

Historically, the term simulation has been used to describe procedures that attempt to mimic systems believed to exist in nature. Theory-based, simulated “model” systems must be distinguished from empirical (real-world) systems, the output of which is observable. Simulation techniques have come to replace the closed-form mathematical approaches once used to examine model systems. In particular, computer simulation forces examination of a theory in detail and requires addressing potential alternatives.

Introduction

Closed-Form Mathematics

Closed-form mathematical solutions are those that permit unique solutions to equations or systems of equations. The variables in the equations can be either exogenous or endogenous, but attention is centered on

the endogenous variables. Though closed-form solutions are still sometimes preferred, they are limited in their ability to deal with large numbers of variables and/or processes involving multiple complex stochastic elements. Further, their solutions often serve to limit research questions to those that are answerable by the mathematical approach used, rather than including questions of the greatest theoretical importance. These kinds of limitations on theoretical models are removed as computer simulation techniques progress.

Early Simulation Techniques

Early techniques involved mechanical or paper-and-pencil operations that, it was hoped, behaved isomorphically with the target system as it moved from state to state. Prior to the ready availability of personal computers, a variety of procedures for randomization and for evaluating outcomes were employed. Unfortunately, these approaches were limited in their applicability due to logistical requirements and the inevitable problems with implementation.

Computer Simulation

Current simulation techniques involve the computer programming of processes analogous to those believed to characterize social systems. The speed of modern computers makes it possible to develop virtual representations of processes involving many variables and extended time periods. To some extent, computer simulation has replaced the “thought experiment” as a way of constructing, understanding, analyzing, and testing theories about social processes.

Computer Simulation Defined

Computer simulation can be defined as a program of instructions implemented by a machine that is intended to be isomorphic in output (graphic, numeric, or both) to measurement of a real or hypothetical social process.

Process The process can be one that is believed to exist or one whose existence is in question, but with implications that are being addressed. In either case, there is a theoretical assertion that the process defined in the model world “works” as if the hypothesized process was operating in the empirical world (see Fig. 1). The process may involve transitions between states of a system (as in discrete-time Markov processes), the temporal course of a system (as in continuous-time Markov process), or any alternative the theorist can envision and program. The hypothetical process, for example, may involve feedback-control processes subject to stochastic input that cannot be easily addressed in closed-form mathematics. The process is usually outlined in a flowchart.

Figure 1 The relation between the empirical world and the model world. In the empirical world, operationalizations generate observations. In the model world, the program/theory generates output. In a perfect simulation, the empirical observations and simulation output should appear identical.

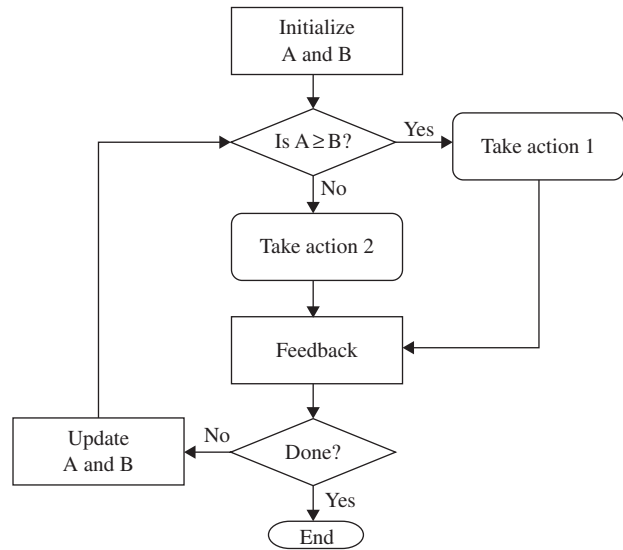

Figure 2 A generic flowchart with two registers and an undefined feedback process.

Flowchart A flowchart is a depiction of the general procedures in a simulation, including its choice points. Figure 2 provides a simple example.

Output Output refers to the kind of information that a researcher would look at (or would like to look at). For most researchers, this appears either as sets of numerical expressions or as graphical representations that depict the set of observations that could arise during, or as the result of, the hypothetical process (see Fig. 1). The range of included information depends on the focus of the research and the extent to which measurements on all aspects of the empirical process are available. The empirical or “measurement” model contains all the sources of error, known or unknown, that might be encountered. The theoretical model may, or may not, incorporate these sources of error.

Isomorphism Isomorphism refers to the extent to which a hypothetical process operates functionally as

the one that is of interest—that is, the degree to which each operation of a model has, symbolically, a parallel operation in the phenomenon of interest. The abstract principles of the simulation should be logically “identical” to those of the focal phenomenon, as Fig. 1 shows. Of course, no theory achieves this ideal state, but scientific techniques are designed to approach it. When using computer simulation, the extent to which an idealized model approximates, symbolically, the target behavior can be explored.

Some Examples The range of activities generally included in computer simulation is very large. No global attempt to cover this range is made here, but potentially social examples vary from neural processes in complex learning to transportation and air quality simulations (TRANSIMS; see <http://transims.tsasa.lanl.gov>) based on large-scale human activities.

Two Major Applications of Computer Simulation

There are two common situations in which computer simulation is used: (1) examination of abstract theoretical claims about processes for which sufficient data are unavailable (or unobtainable) and (2) examination of observed data as the output of specific, but unknown, processes. The first approach involves theoretical propositions and their plausibility (“what would happen if . . . ?”). The second situation is one in which computer simulation is used in the empirical testing of specific theory.

Examination of Theoretical Propositions

Sometimes social scientists have ideas about segments of society and their intersections that are too controversial, prohibitively expensive, or too vaguely defined to permit clear empirical examination and the collection of all relevant data. Computer simulation offers solutions to these kinds of problems, because the simulation can be constructed in a way that shows how observations might appear should they become available.

The Inevitable Problem

Computer simulation designed to test any complicated theory will normally progress until reaching a choice point that the underlying model does not completely address. This point, and others like it, may represent the most important contribution of computer simulation to the development of theory. If, at some point in program development, the underlying theory does not specify how the process is to proceed, the programmer/theoretician

is forced to make a decision unless the project is to be abandoned. Even if empirical information, or theoretical insight, is missing with respect to the choice point, the programmer/theoretician must still make a decision, or the program will not run. Before any of the other benefits of computer simulation can be realized, what may be its most important element must be noted: the programmer/theoretician must make decisions (address choice points) that may be ignored in the fundamental theory.

Unexpected Choice Points

Though theorists may believe they have fully explicated a theoretical position, it may be that they have not. In attempting a computer simulation of a set of theoretical propositions, it is usually found that there is some situation, logically arising within a computer program, that has not been addressed. It is always possible to employ a random device (e.g., a “coin-flip”) to resolve such difficulties, but often it is discovered that the decision point is one that had not been considered, even though it may now appear central to the theory. Thus, computer simulation forces examination of a theory in detail and requires addressing alternatives that would otherwise have been ignored.

A Fundamental Problem A fundamental problem and potentially negative side effect is that it may not be possible to address such choice points because of inadequate prior research and/or the emerging nature of a theoretical perspective. That is, the simulation may lack fundamental empirical support and may, thus, be entirely speculative.

Determining the Theoretical Value of a Simulation

The theoretical value of a simulation depends on the level of development of the theory it is designed to examine. Ordinarily, it should probably not be used just to see if there is an implementation that supports a given theory (because, eventually, one can be found). If the development of a simulation shows that important gaps exist in a theory, it seems that more empirical research is called for before a simulation can be of much scientific value or even taken seriously.

Examination of Empirical Data

Statisticians recognize that the power of a test (its ability to reject a false statistical hypothesis) is enhanced by the specificity of the theory. A theory that provides more information than another theory is, *ceteris paribus*, more powerful (and more easily falsifiable). Though researchers often concentrate on measures analogous to means and/or regression coefficients, it is also possible for a theory to specify information regarding variances

or standard deviations, and, perhaps, higher moments of a distribution or sets of distributions. The more additional information supplied by a theory, the greater the likelihood of rejection of that theory and the greater the potential for its modification in ways that improve its explanatory power.

Higher Moments

A complete explanation of any social process would specify all the moments of the distribution of outcomes. That would mean that variances, skewness, kurtosis, etc. could be estimated on the basis of theoretical propositions. A good approximation of the moment-generating function should be a potential outcome of the simulation. Given sufficient sample size, this additional information permits more complete testing of theoretical formulations and, if the results so indicate, increases confidence in their predictive ability. If such additional tests seem to fail or results are mixed, then there should be less confidence in the theory, leading to a search for ways in which to improve it. Of course, because the source of such failures is not necessarily known, it is not clear which part of the simulation might be at fault. It is always possible that the entire simulation is inappropriate and that the process should be reinitiated.

Appropriate Test Structure

A theory that generates expectations for several statistics permits simultaneous tests of those statistics or even more general tests of, e.g., a moment-generating function. For example, a theory that can estimate both the mean and standard deviation (or variance) of a distribution allows use of a z -distribution rather than a Student's t -distribution for the estimated mean, and use of a chi-square distribution for the variance, with more confidence than is sometimes the case. Such a theory should also reveal whether a mean and variance are independent, and how a simultaneous test of their estimated values might be constructed. Ideally, the theoretical statement would provide instructions for a simulation that would permit answers to these questions, though that is not often the case with current theory. Statistical methods for examination of large numbers of related outcomes are not clearly understood by many theorists/researchers, and a number of developments in these areas are anticipated.

A Caveat The more quantities that a simulation can estimate, the easier it is to falsify the underlying theory. It is almost inconceivable that a simulation that is not reducible to closed-form mathematics could successfully produce a moment-generating function that exactly matches any given set of observations. The more hypotheses that are simultaneously tested, the more likely the simulation is to fail, if only because no theory is likely to be

perfectly correct. Thus, it is necessary to restrict testing, at least at first, to those statistics that seem most important (e.g., the first raw and second central moments). As a simulation comes to satisfy these tests, then additional moments can be investigated.

Walking a Tightrope The point here is to make sure that a promising theory is not eliminated on the basis of tests beyond the initial interests. If the stance that any formulation is unlikely to be perfectly correct is adopted, it is also necessary to adopt a strategy that takes a middle ground. It is desirable to retain those theories that have the greatest chance of success, or modifications in them that can lead to such successes. As falsifiability is made easier, unfortunately, it is also more likely that promising models will be discarded. Because logic is pushing in two directions here, it is necessary to depend on those who use computer simulation to determine the dividing line between meaningful and meaningless levels of analysis.

Programming Languages

The programming language used for simulation requires at least two sometimes contradictory features: (1) it needs to be flexible enough to permit a variety of mathematical operations or their approximation and (2) it needs to be understandable to a focal audience of theorists and researchers without "black box" features that obscure its operation.

Flexibility and Scope

A programming language needs to have both flexibility, in terms of ease of completing operations, and scope, in terms of the range of operations it can carry out. Languages that have been used for simulation include several forms of Fortran, Basic, Pascal, C, C++, Java, and many others. Some simulations may use more than one language (e.g., compiled subroutines in C++ within True Basic) and some languages are easier to employ for some operations than others. Naturally, some languages make for efficient use of various unique computer properties and often are substantially faster than others (sometimes hours or even days faster). In addition to fundamental languages, there are also specialized languages focused specifically on simulation and related approaches. Examples of these are contained in several statistical packages plus focused software such as AMOS, GLLAMM, and Lisrel.

Programming in a Single Language

Programming completely within a language forces a programmer/theoretician to specify all the features of the simulation without resorting to any "black boxes" that

are compiled in other languages. Commercial packages often make simulation easier and faster, but often contain “black box” features whose nature is not necessarily apparent to the user (though their operation may be important to the output). Realistically, it may not be efficient to exclude subroutines in more efficient languages within a simulation. Such inclusions are only problematic when a programmer/theoretician is unaware of the internal working of these modules. The important point is that the simulation remains faithful to the process it represents and that the programmer/theoretician be sensitive to failures in this respect.

Clear Operation

For a simulation to be evaluated by other theorists, researchers, and/or programmers, it is necessary that all aspects of the simulation be understandable to as many potential users as possible. To the extent that a simulation contains some kinds of “magic” (i.e., a knowingly unrealistic component of a simulation), there should be skepticism about the results. If processes are involved in the simulation that are other than those imagined to operate, or are hidden from view in such a way that problems are suspected, then the usefulness of the simulation, either for the development of theory or for the analysis of data, is suspect. The notion that “faith” should be maintained is as foreign to a scientific use of simulation as it is to other applications of science. This is not to say that elements used in simulations cannot make use of simplifications or subcomponents that are compiled separately from the main code, just that there must be some point at which these elements are accessible and can be seen to represent currently understood or hypothesized processes.

Future Directions in Computer Simulation

The range of activities that future computer simulations might include is possibly broader than can be anticipated, but two can be predicted: (1) the growth of specialized languages and/or software and (2) increased blurring of the demarcation between simulation and empirical research.

Specialized Languages

As users seek increasingly rapid ways of anticipating research and policy outcomes, the development of software to fill those needs is likely. Generally, attempts to increase the ability to respond to requests for information in these areas should be welcomed, but care should be taken that the need for information does not result in incorporation of empirically insupportable processes. It is a very human

trait to take what we think we know as absolute truth, and computer simulation is no exception: The extent to which computer simulation can continue to aid us depends on our ability to represent in the simulation those features of social behavior and processes that are empirically supported. Processes that are in question need to be identified as such and their presence in simulated outcomes made clear to potential users. Fundamentally, useful simulations must be based on processes that can be empirically supported and on which there is substantial scientific agreement.

Demarcation of Simulation and Empirical Research

As empirical research expands, it is likely that various research endeavors will build on features of simulations to estimate quantities, develop measurements, or aid in quantitative analysis. As we move in these directions, the dividing line between empirical research (what we know) and our estimates of current states (what we think we know) will become increasingly blurred. As the question mark in Fig. 1 suggests, it is essential that theorists, researchers, and policymakers are clear about where the dividing line lies. In our haste to uncover solutions to real problems, we cannot afford to lose track of the difference between those things we understand and those things about which we speculate, however reasonable those speculations might be. Fundamentally, it is necessary to remember the principles of science and to refuse to be misled by technology that we may not entirely comprehend.

Computer-Based Mapping

Alberto Giordano

Texas State University, San Marcos, Texas, USA

Glossary

animated cartography The representation of movement or change on a map. An example is the representation of the path of a hurricane on a map, achieved by moving a dot across an area with velocities and directions corresponding to the ground speeds and directions of the eye of the hurricane at different times. In another example, consecutive maps of U.S. population by state at census years could be displayed at set time intervals (e.g., 10 years equals 5 s), allowing the viewer to detect change patterns. The most important aspect of an animated map is that it depicts something that would not be evident, or not as evident, if the frames were viewed individually: what happens between each frame is more important than what exists on each frame. The creation of animated (or dynamic) maps has become possible with the advent of computer cartography and the interactive map and during the 1990s dynamic maps came to be routinely used by cartographers.

computer-based mapping (computer cartography) The creation of maps with computers, made possible by specialized hardware (e.g., digitizers, scanners) and software applications. A fundamental characteristic of computer-based mapping is the separation between data management and display functionalities. This separation makes tasks such as the update and editing of maps easier than it is in traditional pen-and-ink paper cartography. Computer cartography has considerably extended the representational capabilities of traditional maps, for example, making it possible to create multimedia and animated maps. The World Wide Web has further revolutionized cartography, creating an entirely new distribution channel.

interactive map A type of computer-based map designed to allow user interaction and exploration. Functionalities implemented in interactive maps include pan, zoom in, zoom out, and the interaction with “hotspots,” symbols map users can click on to access additional information related to the spot. Additionally, by turning on and off different layers, users are often able to choose which information

they want displayed on the map. The interactive map is a prerequisite to the scientific visualization of cartographic data.

multimedia cartography The addition of text, images, sound, pictures, and video to the map. The creation of multimedia maps has become possible with the advent of computer cartography and the interactive map. Multimedia maps are becoming common, particularly on the Internet. For example, several tourism-related sites include maps with “hotspots” that users can click on to receive events information, see a video of the attraction, or check visiting hours.

scientific visualization In the cartographic context, the use of maps as tools for exploratory data analysis. Traditionally, maps have been used as tools for the communication of spatial information, but progress in computer-based mapping, geographic information systems technology, and spatial statistics has contributed to a shift in focus. Cartographers are becoming more and more engaged in scientific visualization, providing their expertise to other scientists to study such disparate phenomena as pollutant diffusion in a bay, environmental justice, or animal species distribution.

The introduction of computers in cartography has had profound effects on the way maps are designed, produced, distributed, and used. Maps have become easier to create and update and are more accurate. Using a computer, cartographers can easily and quickly try different cartographic designs and symbolization schemes. The World Wide Web has changed how many cartographic products are delivered to their intended final user. As a result of the introduction of computers, the distinction between mapmakers and map viewers has blurred and the roles are less defined.

Introduction

For most of its history, cartography was a highly institutionalized enterprise. Cartographers were often

university or government employees or worked for a commercial company. Making maps required a highly skilled labor force and the capital investments needed for the production, reproduction, and distribution of maps were not usually available to the general public. Maps were often classified materials and, at the extreme, state secrets.

Much of this has changed. The low cost of software and hardware has made it possible for individuals to make maps and distribute them via the Internet. Geographic databases are readily available online, so that one can—at least in the United States—produce fairly sophisticated maps with data publicly available on the Internet. This democratization of the mapmaking enterprise is one of the most important and probably long-lasting effects of the computer revolution in cartography. Alternative representations of the world have become possible, often in competition with official views. Individual citizens, non-profit organizations, and interest groups can make and distribute their own maps. On the other hand, professional cartographers often lament the poor quality of many productions, the dilettantism of several among the improvised mapmakers, and the lack of knowledge of basic cartographic principles. There is truth in these statements. Cartography is the art and science of communicating spatial information graphically and its rules, principles, and foundations should be learned and applied even by non-professional cartographers. For example, different cartographic projections have different properties that make them suitable for showing certain types of data and not others: an equal-area projection should be employed when representing density of population, an azimuthal projection should be employed when the map is being used for navigation, and so on. Another issue that has often surfaced concerns the reliability of the sources used in the compilation of many of the maps found on the Internet. It is often the case that these data are of uncertain origin or quality or it is not known how up-to-date they are. In other words, the maps have no reliable metadata (information about the data) or no metadata at all. In these instances, even professional cartographers might find it difficult to establish whether or not the data are fit for use. Unfortunately, the creation of metadata is often a neglected step of the cartographic process—albeit not only by the amateur cartographer.

In any case, the introduction of the computer has fundamentally changed the relationship between the map and its producer, who can more truly interact with the map, experimenting with design and symbology, modifying the map layout, and easily and readily changing scale, projection, center, and orientation. Often the map is linked to a database that can be queried by the user on the fly. Additionally, multimediality and animation have redefined the meaning of the term “map” itself. Maps have been combined with video, sound, text, and images to

enhance the representation potential of the graphic media. Dynamic—or animated—maps can be used to overcome one of the limitations of paper maps, that is, the fact that they are static. A sequence of maps can be used to show time changes or symbols can be rolled on the map to represent movement (e.g., the path of a hurricane). Finally, the Internet has revolutionized the distribution of maps. Anybody with Web access can make a map and publish it for all to see at no cost.

All these topics are discussed in the next sections. The objective is to convey the basic steps in the history of computer mapping, discuss its present state, and to speculate on its possible future.

Why Maps with Computers?

“Computer-based mapping” simply means making maps with a computer. The term is synonymous with computer cartography, computer mapping, computer-assisted cartography, and digital mapping. In computer-based mapping, specialized hardware and software are employed to display and analyze a particular type of data, i.e., geographical data. Geographical data (also called spatial data) are defined by having a positional component that is measured on a coordinate system. For example, the latitude and longitude of a mountain peak are stored in a computer database and are displayed using on a monitor using a cartographic symbol, such as a cross.

The history of computer cartography can be summarized in three distinct stages. In the beginnings—the 1960s and 1970s—the focus of computer cartography was map production. Essentially, cartographers and computer scientists were interested in how to automatically draw geographical features (e.g., cities, roads, lakes) on a piece of paper using points, lines, and polygons. Computers were extremely expensive, slow, and difficult to use. Progress in software design and new and improved hardware in the 1980s made it possible to focus on incorporating analytical functionalities (such as overlay, described below) in computer mapping systems. These advances contributed to the development of Geographic Information Systems (GIS) in the same years. Since the 1990s, computer cartography has undergone a major shift toward scientific visualization. Scientific visualization refers the use of maps as exploratory tools and relies on theoretical and technical advancements in multimedia design and animation and on the development of increasingly sophisticated spatial analytical techniques.

Computer cartography has, at least in the United States, a birth date many scholars agree on. In 1959, Waldo Tobler published a paper in the *Geographical Review* titled “Automation in Cartography.” In it, Tobler describes a system to automatically create map overlays. The concept of overlay is a fundamental one in spatial

analysis and cartography and it is founded on another important concept, that of layers. GIS and computer mapping systems break up maps into separate layers of geographical information (a layer containing all the roads, another with all the cities, and so on.) These layers are then combined, or overlaid, to create the map. The overlay function is an important one in spatial analysis and it is performed to create, among other types, suitability maps. These are maps that show how suitable places on a map are for a certain use. For example, by overlaying geology, hydrography, soil type, and topography layers, one could identify areas where timber can be harvested. The idea of separating layers of information predates the age of computers—originally layers were combined and inspected visually by plotting geographical features on transparent sheets—but the idea perfectly fits the logic of computer databases and especially of relational databases. In a relational database, each layer is a table and each table is composed of records (rows) and attributes (columns). Relationships between tables are explicitly coded by using attributes shared by the tables. For instance, a table showing the average personal income in the counties of California in 2002 could be linked to a table showing population in the same counties in the same year through the attribute COUNTY_NAME present in both.

One of the advantages of using layers in computer cartography is that they make updating a map a relatively easy task. For example, when new data for personal income and population in the counties of California are released, making a new map simply entails updating the values, displaying the map on the monitor, and printing it (or putting it on a Web site) if needed. Updating a paper map means redoing the map altogether.

This point highlights another major difference between computer mapping systems and traditional, pen-and-ink cartography. In computer mapping systems, and also in GIS, data and the representation of data are kept separated and are handled by different software components. The data are accessed by the database management system component and are displayed by the graphic rendering component, so that, for example, the record corresponding to income in a particular county is retrieved from the table and represented with a certain shade of red at a specific location on the map depending on its value in the table. It is this separation of the stages of data management and data display that makes updating a computer map a relatively easy task.

A Brief History of Computer Cartography

As already mentioned, the first examples of the use of computers in cartography were meant to aid map

production. In the *Bickmore Boyle System of Automatic Cartography*, developed in the early 1960s in the United Kingdom by D. P. Bickmore and R. Boyle, an operator would follow the coordinates of geographical features represented on a paper map and feed the coordinates to a magnetic tape. Information on the tape was coded into features such as rivers, coastlines, and contours. From the tape, the information was then plotted onto a table on which a projector was mounted. The projector would then plot the lines onto sensitized film. Worth noting is that the scale and projection could be changed by feeding the tape through a computer and that the drawing equipment was very accurate (0.07 mm). The Bickmore Boyle System is conceptually similar to a modern digitizer, a tool used to transfer geographical features from a paper map to the computer. Two other fundamental early examples of computer mapping systems were developed at the Royal College of Art in the United Kingdom and at the Harvard University Laboratory for Computer Graphics in the United States. The project developed by the Royal College of Art was to develop an automatic technique for presenting data in a cartographic form by means of a computer. It consisted of an electronic plotting table and a “lock-on” time follower, both connected to a computer. Lines traced from maps were converted into x, y coordinates and stored on magnetic tape. Later, the tape would be read to control the movement of a beam of light thrown onto photosensitive film, thereby redrawing the original. The system developed at Harvard University, called SYMAP (Synagraphic Mapping System), worked on a fundamentally different concept. In SYMAP, maps were produced by converting computer tabulations to graphic output on a coordinated basis, utilizing a grid and a standard lineprinter. The program could produce different types of thematic maps, such as contour maps to show elevations and choropleth maps to show quantitative values at specified areal units (e.g., household income in the counties of Massachusetts in 2002). These early efforts were followed by more experimental systems in the 1970s and even early 1980s, but high costs severely undercut any chance of widespread use. The cost of producing digital maps on mainframe systems such as those required by early computer mapping software often ranged from \$50,000 to \$100,000.

Computers have become of widespread use in cartography since the late 1980s. Lower costs and technical innovations are key factors. Inexpensive raster graphics devices, digitizers, and scanners gradually came into use. The introduction of the personal computer in the early 1980s started a revolution whose last chapters are being written by the introduction of handheld digital devices, such as palmtop organizers, digital cameras, and cell phones. Interactivity, the World Wide Web, and the integration of spatial analytical functions into computer

mapping systems are arguably the most important developments to occur in the field in the 1980s and 1990s. Multimediality and animation have further changed the face of cartography and will likely revolutionize the field in the future. These new developments are discussed in detail in the next sections.

Maps and Interactivity

The interactive computer as it is known today is a relatively new tool. From the 1950s until the late 1970s, computer mainframes were controlled through the use of punched cards containing instructions that were read and executed before a printout of the answers could be produced. Later, interaction with minicomputers and microcomputers occurred through a command line interface that required the use of a keyboard. In order for computers to really change the world of cartography, two major technical and conceptual advancement needed to occur: the WYSIWYG (What You See Is What You Get) principle and its implementation and the GUI (Graphical User Interface). Together, these two changed the panorama of computer cartography.

In computer systems designed according to the WYSIWYG principle, what the user sees on the screen is exactly what will appear on the paper when the document is printed. For example, a word processor software program will show formatting characteristics, such as spaces between lines, indentations, and font type, size, and style, on the screen exactly as they will be printed. The importance of the WYSIWYG principle for modern mapping systems cannot be understated. The ability to evaluate and, if needed, vary map design or symbolization choices is a very desirable function for a mapmaker. Cartographers can interactively choose the shape of a certain symbol and its size or choose where to locate a place name and immediately see on the screen how that symbol or label will look when printed or viewed on a Web site. However, the WYSIWYG principle is not fully implemented in cartography and limitations are evident, especially as concerns the use of color. This point is particularly worth discussing because it highlights one of the problems created by the use of computers in cartography. The problem lies in the difference between computers and printers when it comes to the way in which color is created. Color in computer monitors is created using light: red, green, and blue light is combined to derive all other colors in an additive process. In the RGB system, red, green, and blue are the primary additive colors. Secondary additive colors are magenta (blue plus red, with no green), yellow (green plus red, with no blue), and cyan (blue plus green, with no red). Mixing pure red with pure blue and pure green creates white. Printers create color in a very different way. The CMYK system is a subtractive

color process in which cyan, magenta, and yellow (the subtractive primary colors) inks are combined to create the subtractive secondary hues red (yellow plus magenta, with no cyan), green (cyan plus yellow, with no magenta), and blue (cyan plus magenta, with no yellow). Pure cyan plus pure magenta plus pure yellow is black. In practice, however, mixing cyan, magenta, and yellow inks does not yield a pure black but rather a very dark brown. For this reason, black ink is added to the three subtractive primary colors. The difference between the RGB and the CMYK systems has a very practical implication for cartographers, in that the color seen on the screen is unlikely to be identical to the color that will be created by the printer. Tables of correspondence exist between the CMYK and RGB systems but the match is far from perfect, at least in relatively inexpensive systems. In addition to differences in how color is created, another problem is created by the fact that a computer monitor is capable of producing far more different colors than a printer. A 24-bit monitor system, for example, can create over 16 million colors (16,777,216 or 2^{24}) and no ink combination can create as many different colors. And even if it could, no human is capable of discerning 16 million colors. This limitation notwithstanding, the WYSIWYG principle has been crucial to the diffusion and adoption of computer mapping systems.

Another innovation has played a fundamental role in the evolution of computer cartography: the adoption of a GUI as the standard method for human-machine interaction. A graphical user interface employs graphic tools such as menus, windows, pointers controlled by pointing devices (such as the mouse), icons to represent files or functionalities, and a desktop where icons are grouped. Microsoft Windows and the Apple Macintosh are examples of GUI. Interaction with a computer is easier with a GUI: users do not have to learn commands as in DOS or UNIX and the point-and-click type of interaction is more intuitive and natural. In the context of cartography, a GUI has made it possible to perform tasks that were impossible on a paper map. One such functionality is zooming in and out, which is equivalent to a scale change: users can zoom in on a particular portion of the map and see it in more detail. The most sophisticated systems allow cartographers to set the amount of information that users will see at a particular scale, so that, for example, all roads are shown at a larger scale and only interstate highways are displayed at a smaller scale. In general, interactivity in cartography has provided the user with more control over how the informative content of map is displayed: using the mouse, a user can click on a symbol and retrieve information on the geographical feature that that symbol represents. The user can also choose where to display a legend and how large it should be or even if a legend should be displayed at all. These examples highlight the importance of keeping cartographic representation functionalities

separated from cartographic data management functionalities. When a user clicks on a symbol, the information that pops up is retrieved from the database and displayed on the screen in a way that is similar to what was described earlier in relation to overlays. Interactivity and database connection have given the user significant freedom when it comes to making customized maps. For example, the online version of the *National Atlas of the USA* (available at <http://www.nationalatlas.gov>) lets the user make dozens of separate maps varying the geography and the variables mapped. This flexibility is typical of electronic atlases, a revisited version of traditional paper atlases that are becoming a prominent feature of government agencies' Web sites, especially in North America and Europe.

A final example of how computers have changed the way that users interact with the map is the case of choropleth maps. These are maps that portray the geographical variability of a quantitative variable by shading geographical units according to the value of the variable. For example, a cartographer might wish to create a map showing median household income in U.S. counties in the year 2000. The choropleth map is often used to display this type of data. Probably the most important decision a cartographer has to make when creating a choropleth map is how to subdivide the data in classes. Assigning a unique shade of color—for example, a shade of green—to all the over 3000 counties based on their household income would make it very difficult to extract information regarding individual counties from the map. A solution is to: (1) group the over 3000 values in, say, five classes ranging from the lowest to the highest value; (2) assign a shade of green from light to dark to each class so that the higher the income, the darker the shade of green; (3) color the counties a shade of green corresponding to the county's median household income. If one tries to create this same exact map at the U.S. Bureau of the Census Web site (available at <http://www.census.gov>) using Census 2000 data, the result is a choropleth map in which the five classes are subdivided as follows: (1) \$9243–\$23,750; (2) \$23,848–\$33,006; (3) \$33,026–\$41,183; (4) \$41,201–\$53,804; and (5) \$53,945–\$82,929. Looking at this map, the user will recognize that geographical patterns are present in the distribution of the value of median household income in the United States. For example, the corridor between Washington, DC and Boston, and the suburban counties around Atlanta, Minneapolis, Denver, and San Francisco are wealthy, with several counties in the fifth class. The southern states and parts of the southwest and the northwest have large numbers of relatively poor counties, with several counties in the first class. To obtain the five groups above, counties were first listed according to their median household income in ascending order and then grouped in five classes, each containing the same number of elements (approximately 600). This procedure is called

the “quantile” method for classifying data and is one of several available methodologies used to group data. Generally speaking, the choropleth map will look slightly different depending on the classification methodology chosen, even though it is hoped that similar patterns will appear no matter which one is chosen. Computer mapping systems usually allow users to vary the methods employed to derive classes, including their number, and expert users can take great advantage of this flexibility: by varying the procedure chosen to determine classes, one can evaluate the persistence of geographic patterns. In the example regarding household income in U.S. counties, should the same spatial pattern appear using the quantile, the equal interval, and the natural breaks methods, then it would be reasonable to conclude that the pattern is a real one and not an artifact of the classification method employed. Note that in this case, the cartographer is using the software to test whether the hypotheses formulated on the spatial distribution of income in U.S. counties are robust enough to be confirmed when the classification methods are varied. This is an example of the already mentioned “scientific visualization” approach to using maps: the database is explored and hypotheses are formulated and tested. With its computational power, computers can greatly facilitate these tasks.

The Functionalities of Computer-Based Mapping Systems

It has been mentioned already that in its early history, computer cartography focused heavily on the mapmaking process, even if its potential as a tool to aid the analysis of spatial data was recognized almost immediately and even if in a sense the concept of scientific visualization—a relatively new one in cartography—was already implicit in Tobler's 1959 description of a system for overlaying layers of geographic data.

In addition to spatial analytical functionalities, such as overlay and choropleth maps, computer-based mapping systems include a wide variety of cartographic functionalities. These functionalities constitute the core of the system and are discussed in the remainder of this section. Before moving on to review them, however, it is perhaps useful to explain that in computer mapping systems and in GIS, real-world features are conceptualized and symbolized as cells or as points, lines, and polygons. When cells (usually squares) are used, the system is raster-based. The key concept in raster systems is that of resolution. In raster systems, each cell corresponds to one and only one value (e.g., “water” or “not water” in an hydrology layer). In a layer containing elevations, each squared cell is assigned one value and the topographic representation will be as accurate as the level of its spatial resolution. For example,

an area of 10 by 10 km will contain 10,000 cells at a cell resolution of 100 m. So, each 100 by 100 meters cell is assigned one and only one elevation. If the resolution is increased to, say, 10 m, the resolution and the accuracy of elevation representation will increase and so will the size of the file (1 million cells). Vector systems work in a different way. Instead of being space-exhaustive as the raster systems, vector systems use points, lines, and polygons to represent real-world features. The prominent concept in vector systems is that of topology: in order to perform any cartographic or spatial functionalities, the relationships between points, lines, and polygons must be explicitly recorded. For example, a polygon is connected to other polygons by a common boundary and it is composed of a certain number of vertices or nodes. A line has an origin and an end and it might or might not cross a polygon. A point is identified by a set of spatial coordinates. The size of the files in vector-based systems is usually smaller than the size of those in raster-based systems. It is worth noting that three-dimensional representations are possible in both raster and vector systems and are generally used to show topography.

This premise is important because cartographic functionalities are implemented differently depending on the data model (raster or vector) used by the system, but in general both models include four main types of operations:

Generalization

These include functionalities to, for example, reduce the number of points in a line, smoothing its appearance, and reducing its size in bits; merging geographical units (e.g., create a map of the states of the United States from a map of the counties of the United States by merging all counties that belong to the same state); reducing the number of cities displayed on the map by using a population threshold (e.g., no cities with less than 1 million people).

Map Projections, Coordinate Systems, and Scale Transformations

This is one of the great advantages of computer mapping systems. The ability to change scale, projection, and coordinate system on the fly can be used by the cartographer to make maps that are specifically designed to fit an intended use. The example that was given earlier is that of employing an equal-area projection to show density of population. Another example would be using a conical projection with two standard parallels to represent landmasses that extend more in the East–West direction than in the North–South direction.

Cartographic Measurements

These operations include calculating the length of a line, the distance between points, the area and perimeter of a polygon, and so on. Vector and raster systems implement very different algorithms to take these types of measurements.

Symbolization

Computer-mapping systems are particularly powerful as tools to aid cartographic design. Especially in the most recent releases, cartographic and GIS software packages present the user with a wide choice of symbols and provide flexibility for designing or importing additional symbols from other sources and for varying the size, shape, and color of symbols. Additionally, the user can easily customize the layout of the map, changing the position and characteristics of the legend, the title, the scale bar, the neat line, and other cartographic elements.

However, it should be noted that there is one area in which computer-based mapping systems have thus far yielded disappointing results: the automated placement of text on a map. This is a challenging task because different and often contrasting needs must be reconciled when placing labels on a map. Text needs to be easily readable and so labels should be quite large, but at the same time space is often a scarce commodity, especially in general-purpose maps that aim at portraying all physical and human elements of a certain area. Also, labels need to be placed so that it is clear to which feature they refer to, but this is often difficult especially in areas where there are many symbols referring to the same class of features. For example, placing labels for cities in highly urbanized regions or labels for countries in Europe can be a very challenging task. The problem of automatically placing labels has been tackled in different ways. One approach that seems particularly promising is artificial intelligence, perhaps one of the future directions of development of computer-based mapping.

The Future of Computer Cartography: Animation, Multimedia, and the World Wide Web

It has been said that the largest producer of maps in the history of cartography is Mapquest (available at <http://www.mapquest.com>), because it delivers to visitors of its Web site several hundred thousands of customized maps each day. Granted, these are virtual maps—although they can be printed—but the number is impressive nonetheless. Mapquest and several similar sites are

examples of the revolution brought to the world of cartography by the World Wide Web. From the point of view of computer cartography, the revolution is one of distribution and of democratization, as already mentioned. To distribute a map to potentially millions of viewers, one simply need put it on the Internet. Compare this relatively simple action with the investments necessary to produce and distribute a map in the world of traditional print cartography. Ease of distribution has led to exponential growth in the number of maps produced and in the variety of their styles and designs and it has also facilitated the public exchange of competing views on the use of environmental and economic resources. Issues such as environmental justice and sustainable development are often discussed using maps as tools for scientific visualization.

On the other hand, the World Wide Web has not per se changed the way that maps are made. Multimedia and animated cartography, however, have. Animated cartography was pioneered by Thrower, who published a paper entitled "Animated Cartography," in a 1959 issue of *The Professional Geographer*, and by Tobler, who in 1970 developed a computer animation simulating urban growth in the Detroit region. The main advantage of animated—or dynamic—cartography is that it overcomes the traditional immobility of paper maps, in which time is kept constant (e.g., "Household income in U.S. counties in 2000"). Animated maps can show time changes, for example, by flashing a series of maps representing household income in 2000, 2001, 2002, and 2003. Animated maps can also represent another phenomenon that is problematic to deal with in traditional paper maps: movement. Traffic can be shown at different times of the day, a hurricane's path can be tracked in almost real time, and migration can be studied more effectively. When animation is combined with multimediality, the possibilities of traditional cartography increase exponentially. Multimedia cartography is the

combination of maps with text, images, video, and audio. One type of map that has successfully incorporated multimedia elements is the tourist map on the Internet. Typically, these are maps in which a user clicks on a particular spot and is presented with a wide array of information. For example, clicking on a park in a city map might bring up pictures, a schedule of daily events, opening hours, and maybe a video of the park's main attractions. Multimedia and animation are perhaps only a taste of what is to come in computer cartography: virtual reality, that is, the user *in* the map.

Computer-Based Testing

Richard M. Luecht

*University of North Carolina at Greensboro, Greensboro,
North Carolina, USA*

Glossary

automated test assembly (ATA) Involves the use of mathematical programming algorithms or heuristics to select optimal test forms that simultaneously meet statistical specifications as well as any number of content and other test construction constraints.

computer-adaptive testing (CAT) A test process that adapts in difficulty to the apparent proficiency of the test taker. CAT is usually more efficient than conventional fixed-item testing because it either reduces the number of items needed to achieve a prescribed level of measurement precision (reliability) and/or it achieves more precision across a broader range of the score scale with a fixed-length test.

computer-based testing (CBT) A test process delivered on a computer. Computer-based tests tend to differ in terms of the level of adaptation to the ability of examinees, the size of test administration units employed (items versus testlets), the type of connectivity required to interactively transmit data, the types of items supported, the test assembly methods employed, and the nature and extent of test form quality control mechanisms used.

multistage testing (MST) The administration of tests in stages. Multi-item modules called “testlets” are typically assigned to each stage. Examinees complete an entire testlet before moving on. Scoring and adaptive routing decisions can be employed between stages to achieve some degree of test adaptation.

test-delivery driver A software test administration application that typically performs six basic operations: (1) provides authorized navigation by the test taker, (2) selects the items to administer (fixed sequence, random, or heuristic based, such as a computer-adaptive test), (3) renders the test items, (4) captures responses, (5) timing (e.g., section time outs), and (6) real-time scoring, which may be needed for adaptive testing as well as final scoring, if a score report is immediately provided to the examinee.

testlet A collection of items administered together. Testlets are used in computerized mastery testing and can also be adaptively administered.

Large-scale computer-based testing technology is evaluated from the perspective of systems (hardware and software) and functions needed for implementation (related costs, security, and quality control). Popular computer-based testing delivery models are then defined; these include fixed forms, various computer-adaptive strategies, and multistage testing designs.

Computers in Testing

Computers have influenced almost every aspect of testing, from test development and assembly to administration, scoring, reporting, and analysis. The proliferation of personal computers (PCs), rapid improvements in network technology and connectivity, and new developments in adaptive testing technology and automated test assembly have made computer-based testing (CBT) a mainstay for virtually all types of testing, including educational tests, certification and licensure tests, psychological assessments, and even employment tests.

CBT Systems and Functions

Five core systems comprise most large-scale operational CBT systems: (1) item development and banking, (2) test assembly and composition, (3) examinee registration and scheduling, (4) test administration and delivery, and (5) postexamination processing. These systems, which are made up of hardware components, software, and

varying degrees of human intervention, provide most of the functionality in the overall CBT enterprise.

Item Development and Banking

Item development and banking involve building a database of test items. The item banking development and banking system include three primary subsystems. First, an inventory control and management subsystem is needed to track the demands for items over time and to schedule new item production. Second, item authoring and prototyping subsystems are needed to actually produce the items. Item authoring tools can range from simple word processing data to elaborate item composition applications that use templates and many automated features to compose new items. Finally, an item database is needed to store the item content (text, pictures, formatting specifications, pretest item statistics, content codes, etc.).

Test Assembly and Composition

Test assembly involves two steps: (1) selecting items from a large item bank or pool for each test form and (2) packaging or publishing the selected items in the appropriate format for administration on a computer. These steps may be done off-line (that is, test forms may be prepackaged before being administered) or they can be performed in real time, on-line. Computer-adaptive tests are constructed on-line while the examinee is taking the test.

Item selection can be accomplished by database queries, by stratified sampling of items within content categories or statistically determined “bins,” or by using formal item selection algorithms. CBT is gradually moving toward the latter approach, which is called automated test assembly (ATA). ATA involves the use of sophisticated mathematical optimization algorithms to select items from an item bank for one or more test forms. The ATA optimization algorithms are programmed into a computer and are used to select items from an item bank to meet large numbers of content constraints and statistical specifications for each test form. These same algorithms can be applied to many types of adaptive tests.

“Packaging” prepares the selected test items for delivery to the test takers on a computer—that is, the computerized test delivery driver administers the packaged test to the examinees. The packaging process varies for different types of CBT test delivery systems. In most CBT systems, packaging amounts to generating computer files in a data “markup” format (e.g., using a variation on the eXtensible Markup Language, or XML) that can be read by the test delivery software. Note that packaging may also include data encryption.

Examinee Registration and Scheduling

Examinee registration and scheduling are important operational activities for any CBT program. An eligibility and registration system ensures that the test applicants

are eligible to take the test (e.g., have met certain educational requirements) within prescribed time frames and that they pay any appropriate fees. Multiple application access modes can be used for eligibility and registration, including mailing in hardcopy applications, telephone access, and on-line Internet-based registration.

The registration and scheduling system also needs to locate an available computer “seat” for each examinee. Many of the commercial CBT vendors use dedicated test centers with a fixed number of test workstations. Therefore, the registration and scheduling system needs to find a location and time for each applicant to take the test. Many of the scheduling systems used by the major CBT vendors work in a similar way to an airline reservation system that reserves a particular seat for each passenger on a specific flight. Due to obvious capacity limitations in any fixed testing site network, there can be enormous competition for computer seats during certain times of the year—especially at the most convenient locations in major metropolitan areas.

Test Administration and Delivery

Taking a computer-based test once implied sitting in front of a “dumb” computer terminal connected to a mainframe computer and responding with the keyboard to a sequence of test questions. The rapid increase in availability of personal computers and improvements in connectivity, including networking technology and the emergence of the Internet, have led to ever-improving distributed models for testing. Modern CBT connectivity encompasses PC local-area networks running in dedicated testing centers, wide-area networks running in multiple locations, virtual private networks built on Internet technology, and even remote wireless networks capable of administering tests on handheld personal digital assistants, “pocket PCs,” and other small digital devices. Today, most computer-based testing—at least most high-stakes computer-based testing—is conducted at dedicated test centers. These testing centers have full-time test proctors and typically offer a secure, quiet, and comfortable testing environment. The actual test may be housed on a file server at the center, or the workstations at the center may connect directly to a central processing facility via the Internet or a private connection.

One of the most important components of any CBT test administration and delivery system is called the test-delivery driver, which is a software application that logs the examinee into the test, administers the test by presenting the items in some prescribed sequence, may allow the examinee to navigate around the test, carries out executive timing of the test sections, records appropriate actions or responses, and transmits the actions and responses to an appropriate storage repository. The test-delivery driver may also conduct real-time scoring and report the scores to the test taker. A test-delivery driver

needs to support multiple item types. Included are multiple-choice items, open-ended response items, essays requiring word processing, computational problems, items using interactive graphics, and custom computer-based work simulations. The test-delivery driver must also support multiple CBT delivery models, some of which require sophisticated item selection activities, including using automated test assembly. These latter types of models include computer-adaptive testing and adaptive multistage testing.

Postexamination Processing

Scoring and reporting are two of the most common postexamination processing activities for CBT. Very few high-stakes computer-based examinations immediately release scores to the test takers, even though that technology is rather trivial to implement. Instead, the response data are transmitted to a central processing facility for additional quality assurance processing and to ensure the integrity of the scores. Scoring and reporting to the examinees is done from that facility.

Postexamination processing also includes conducting many types of psychometric analyses, including item analysis, item calibration and equating, and research studies meant to improve the quality of the test. These types of studies are routinely performed by most major testing organizations.

Challenges for CBT

Building a CBT enterprise is an enormous undertaking. There are five challenges facing CBT: (1) systems development and reengineering, (2) costs of CBT seats, (3) dealing with increased item production needs under a continuous testing paradigm, (4) security, and (5) quality control of test forms.

Systems Development and Reengineering

As already noted, there are numerous component systems and procedures that need to be designed from the ground up, or at least must be reengineered from existing paper-and-pencil testing systems and procedures. Facing enormous systems development costs and time lines, many testing organizations opt to contract with commercial CBT vendors that offer various types of test delivery services—principally CBT item banking software, a test-delivery driver, and dedicated, proctored testing sites.

Costs of CBT Seat Time

Using commercial testing sites adds to the cost of “seat time,” at least when compared to paper-and-pencil testing. Many commercial test delivery vendors are for-profit corporations that charge premium rates for each hour of testing. For example, at \$15.00 per hour of testing, a program testing 10,000 examinees per year would

spend \$300,000 annually in seat time, assuming 2 hours of scheduled testing time per examinee. As a possible cost-saving measure, some testing organizations are exploring the use of proctored temporary CBT sites as a lower cost alternative to dedicated testing sites (e.g., temporarily converting a university or school-based computer laboratory in to a secure, proctored test site, using encrypted Internet data transmittal to and from the workstations).

Continuous CBT and Increased Item Production

Continuous CBT—that is, scheduling tests over time to accommodate large numbers of test takers within limited-capacity computerized test delivery centers—inherently creates an ongoing demand for large numbers of new, high-quality, pretested items. The item banks can quickly become compromised and the integrity of examination scores and decisions will become suspect, especially for high-stakes examinations. The obvious solution is to increase the number of test items in the bank and establish an item-inventory management plan for renewing, rotating, and replacing item banks over time. Stepped-up item production typically means periodically commissioning and training large numbers of item designers and item writers to compose new items to meet the demands. Items must also be pilot tested on a sufficiently large sample of motivated test takers to provide the statistical data needed to evaluate the quality of the items. Item statistics are also essential for test assembly. The practical challenges of building a steady-state inventory of high-quality, pilot-tested items cannot be trivialized.

Security

Security is an integral part of CBT. There are three aspects to security. Examinee security involves verifying the identity of the examinee, authenticating his or her data, and proctoring the examination to prevent cheating. Data security relates to encryption and secure transmittal of the data. Collaboration security involves monitoring and, ideally, detecting concerted efforts by examinees using the Internet or other means to memorize and share large sections of the test or test materials.

Most commercial testing sites offer a variety of examinee security measures, including double-entry password access to the test, digital photographs of the test taker at check-in, and proctoring services to monitor the examinees while they are taking the examination. Data security is primarily handled by applying multiple encryption layers to the data for transmission to/from and for storage at the testing center. It is more difficult to contend with collaboration security. A combination of statistical, website monitoring, and informant follow-up procedures is needed to detect and prosecute collaboration efforts by examinees or organizations to steal large portions of

an item bank through memorization and sharing of the item content.

Quality Control of Test Forms

Most of the early research on CBT and computer-adaptive testing viewed the challenges of CBT as strictly psychometric in nature, and almost exclusively focused on theoretical statistical issues related to measurement efficiency (issues such as achieving adequate levels of test score reliability using as few items as possible). However, testing professionals soon realized that statistical criteria and practical issues (such as overexposing test materials over time, guaranteeing content representation and test form quality for tests constructed by computers, and ensuring fairness in terms of access to and practice with CBT) were equally important; in some cases, practical issues were considered more important than statistical criteria were. With paper-and-pencil testing, content test committees functioned as the quality control (QC) experts, dealing with content-coverage issues, item or theme duplication, etc. In the CBT world, there are usually too many test forms and no opportunity for committees to review every test form before it is administered. Some CBT programs have begun to implement statistical QC and quality assurance (QA) procedures, much like those used in manufacturing and engineering. Some aspects of QC and QA can be automated (e.g., computing tolerances and flagging outliers); other aspects still require some degree of human review; carrying out test form quality checks can include a mixture of automated and human QC reviews.

CBT Delivery Models

CBT delivery models vary in the degree and nature of test adaptation provided, the type of connectivity required to transmit data interactively between testing stations or networks and central processing facilities, the size and types of testing units administered, the types of items supported, the test assembly methods employed, and the nature and extent of test form quality control mechanisms used. In most cases, a particular CBT delivery model will attempt to optimize one or two of these factors. However, there are almost always trade-offs because these factors tend to compete with one another. For example, a computer-adaptive test (CAT) almost exclusively focuses on maximizing the adaptability of the test to each test taker. There are sacrifices involved in adopting CAT, including reduced opportunities to carry out test form QC or QA, overexposure of “informative” items, and a possible degradation of system performance in large networks and Internet environments.

There are five broad classes of CBT delivery models: (1) preassembled, parallel, computerized fixed tests,

(2) linear-on-the-fly tests, (3) computer-adaptive tests, (4) CBTs using testlets, and (5) computer-adaptive multistage tests. On the surface, these models may appear to differ only with respect to their use of adaptive algorithms, the size of the test administration units, and the nature and extent to which automated test assembly is used. However, at a more detailed level of evaluation, they also differ significantly with respect to parsimony of design, system performance issues, measurement efficiency, and opportunities for quality control of test forms.

Preassembled, Parallel, Computerized Fixed Tests

The category of preassembled, parallel, fixed computer-based tests includes preconstructed, intact test forms that are administered by computer to large numbers of students. Different examinees may see different forms of the test, but all examinees administered the same form will see exactly the same items (i.e., the items are fixed for each form). These models are called computerized fixed tests (CFTs). In the typical CFT implementation, a number of fixed-length test forms are constructed for active use. When an examinee sits for the test, one form is randomly selected. The different forms are typically constructed to be parallel with respect to test content and are either formally equated for difficulty (using classical test theory or item response theory) or are assumed to be randomly equivalent. A CFT is directly analogous to having a fixed-item paper-and-pencil test (PPT) form. One advantage of a CFT over a PPT is that the presentation sequence for the items can be scrambled (i.e., randomized). Scrambling the item presentation sequence prevents certain types of cheating (e.g., coming in with an ordered list of illicitly obtained answers for the test). For multiple-choice questions, distractors may further be scrambled within each item as an added measure of security.

When properly implemented, the CFT model has several attractive features. First, test assembly is rather straightforward. That is, multiple test forms can be constructed to meet a common set of statistical and content specifications. Because the test assembly is done beforehand, extensive quality control procedures can be implemented to check every test form for content balance and other critical features, before release. Second, the CFT model is simple to implement in most CBT delivery systems because it does not require the on-line test delivery software to use any special type of item selection algorithms or scoring mechanisms. CFT therefore performs well in almost any testing network or web-based environment. One limitation of the CFT model is that it is not efficient from a measurement perspective. A second possible disadvantage relates to exposure risks. Unless automated test assembly (ATA) is used to

mass-produce many simultaneous CFT forms, with item overlap (exposure) controlled, there could be serious security risks.

Linear-on-the-Fly Tests

A variation on CFT is linear-on-the-fly testing (LOFT). LOFT involves the real-time assembly of a unique fixed-length test for each examinee. Classical test theory or item response theory (IRT) can be used to generate randomly parallel LOFT test forms. There are at least two variations of the LOFT model: a large number of unique test forms can be developed far in advance of test administration (which is a merely a special case of CFT, where ATA is employed, as noted previously) or test forms can be generated immediately prior to testing (i.e., in real time). A benefit of developing the test forms in advance is that content and measurement experts can review each form.

The primary advantage of the LOFT model is that numerous forms can be developed in real time from the same item pool. Furthermore, there is typically some overlap of items allowed across the test forms. When test forms are assembled just prior to administration, the current exposure levels of the items can be considered in the test assembly algorithm. At-risk items can be made unavailable for selection. For real-time LOFT, explicit item exposure controls can be used to limit the exposure of particular items, in addition to the random sampling scheme. The benefits of LOFT include all those associated with CFTs with the addition of more efficient item pool usage and reduced item exposure.

The disadvantages of LOFT are similar to those of CFTs (i.e., decreased measurement efficiency and exposure risks if test banks are relatively small, limiting the number of forms that can be produced). In addition, real-time LOFT may limit or altogether preclude certain quality controls such as test content reviews and data integrity checks. Although some quality assurance can be integrated into the live test assembly algorithm, doing so tends to complicate the functionality of the test delivery system and introduces additional data management challenges (e.g., reconciling examinee records). This latter problem can be slightly reduced in terms of risks to the integrity of the data by creative database management (e.g., using system-generated test form identifiers for every LOFT form).

Computer-Adaptive Tests

A computer-adaptive test adapts or tailors the exam to each examinee. Under the purest form of CAT, this tailoring is done by keeping track of an examinee's performance on each test item and then using this information to select the next item to be administered. A CAT is therefore developed item-by-item, in real time, by the test-delivery driver software. The criteria for selecting

the next item to be administered to an examinee can range from simply choosing items that maximize the reliability of each examinee's score, to complex heuristics using automated test assembly (ATA) processes. However, as noted earlier, the primary item-selection criterion in CAT is to maximize the measurement precision for the test and, correspondingly, minimize the measurement error of the examinee's score. Presently, several successful, large-scale CAT testing programs are in use. One of the oldest and most successful CAT programs is the Armed Service Vocational Aptitude Battery.

Test Adaptation and Measurement Efficiency

Computer-adaptive testing was developed for a singular purpose—to maximize testing efficiency. CAT obtains more accurate estimates of examinees' proficiency using fewer items than are typically required on nonadaptive tests. These gains in efficiency stem directly from the CAT item selection algorithm employed, which avoids administering items that are too easy or too hard for examinees. Therefore, CATs are often significantly shorter than their paper-and-pencil counterparts—typically about half as long as a parallel nonadaptive test. Figure 1 shows the efficiency gains of a hypothetical CAT, compared to a test for which the items were randomly selected. The plot shows the average standard errors of the estimated proficiency scores over 50 items. The standard errors are averaged for examinees having different proficiency scores. How the error functions plotted in Fig. 1 decrease over the course of the two tests can be seen specifically. It is important to realize that the errors decrease for a randomly selected set of items, too. However, CAT clearly does a better job of more rapidly reducing

Figure 1 Average standard errors for a 50-item computer-adaptive test (CAT) vs 50 randomly selected items.

the errors. For example, at 20 items, the CAT achieves nearly the same efficiency as the 50-item random test; at 50 items, the average standard error for the CAT is approximately half as large as for the random test.

Unfortunately, measurement efficiency has often been used as the sole criterion when evaluating different CBT delivery models. Instead, the importance weight given to efficiency needs to be carefully reviewed and applied in terms of concrete benefits, considered alongside the real costs associated with system design, implementation, and maintenance, as well as costs linked to generating test materials.

CAT Item Selection Algorithms

There are several types of CAT item-selection algorithms. Two somewhat traditional approaches that are cited in the psychometric literature include maximum information item selection and maximum information item selection with unconditional or conditional item exposure controls. An interesting CAT variation reformulates the usual sequential item selection problem in CAT as a series of optimization problems that allow complex test-level constraints to be readily incorporated into the test assembly process. The serialized test assembly problem can then be solved using formal mathematical optimization procedures that include network flow and linear and mixed-integer programming algorithms. This improved methodology has been called “shadow testing.” Under CAT with shadow testing, a complete test is reassembled following each item administration. This complete test, called the shadow test, incorporates all of the required content constraints and other constraints (e.g., cognitive levels, total word counts, test timing requirements, clueing across items), and uses maximization of test information at the examinee’s current proficiency estimate as its objective function. Shadow testing can further incorporate exposure control mechanisms as a security measure to combat some types of cheating. The shadow test model is a powerful means for balancing the goals of meeting content constraints and maximizing test information.

Limitations of CAT

Five limitations have been identified in the research literature relative to implementing CAT in an operational setting. First, when content constraints and conditional item exposure controls are incorporated into the item selection algorithm, much of the measurement efficiency gain associated with a CAT is lost. This is especially true for longer tests that must meet extensive content specifications, because the measurement efficiency gains due to the adaptive algorithm dissipate with increasing test length. Second, subject matter experts and psychometricians are unable to review a CAT form before it is administered to an examinee. Some test development experts question the “content validity” of test forms constructed entirely by

a computer algorithm, although using shadow testing and other content-balancing heuristics can mitigate some of this criticism. Third, examinees taking a CAT often complain about not being able to skip test items or review previously answered items. Using testlets (see later) helps alleviate most of these types of complaints. The final limitation relates to computer system performance issues specific to implementing CATs in Internet-based or intranet-based distributed CBT environments. A CAT is a very data intensive application and requires a fairly high degree of computation during the live test administration. When a CAT program is deployed in Internet-based testing (IBT) networks or wide-area network environments, where a central computer server needs to score and implement an item selection heuristic after every item and for every examinee, serious degradation in system performance can arise. As testing programs move toward using the Internet for real-time testing, these types of system performance issues will become more prevalent.

CBTs Using Testlets

The concept of a testlet was introduced to describe a subset of items, or a “minitest,” that could be used in either an adaptive or mastery testing environment. A testlet-based CAT involves the adaptive administration of preassembled sets of items to an examinee, rather than single items. Examples of testlets include sets of items that are associated with a common reading passage or visual stimulus, or a carefully constructed subset of items that mirrors the overall content specifications for a test. After completing the testlet, the computer scores the items within it and then chooses the next testlet to be administered. Therefore, this type of test is adaptive at the testlet level rather than at the item level. This approach allows for better control over exam content and can be used to allow examinees to skip, review, and change answers within a block of test items. It also allows for content and measurement review of these sets of items prior to operational administration.

Computerized Mastery Tests

An important variation on testlet-based CAT is computerized mastery tests (CMTs). Under CMTs, parallel testlets are preconstructed to provide optimal measurement precision in the region of a pass/fail cut score (i.e., the mastery point on the score scale). The preconstructed testlets are put into a pool and are then randomly selected for each examinee. After an examinee completes a minimum number of testlets, the answers are scored by the computer and loss functions associated with “pass,” “fail,” or “continue testing” are calculated. Both testlet-based CAT and CMT models offer a compromise between the traditional, nonadaptive format and a purely adaptive test delivery model. Advantages of CBT using testlets include increased testing efficiency relative to

nonadaptive tests, the ability of content experts and sensitivity reviewers to review the preconstructed testlets to evaluate content quality, and the ability of examinees to skip, review, and change answers to questions within a testlet or stage.

Limitations of CBT Using Testlets

One disadvantage of testlet-based CAT, relative to item-level adaptive tests, is that use of multi-item testlets sacrifices some amount of measurement precision insofar as the items are not being individually targeted to the examinees' proficiency scores. However, research suggests that the loss in efficiency may be minor, particularly in the context of classification testing such as placement, licensure, or certification. A secondary disadvantage is that testlets cannot contain any item overlap. That is, testlet-based CAT and CMT require the testlets to be unique because it is combinatorially not feasible to track testlet enemies (i.e., mutually exclusive testlets). This requirement may severely restrict the number of testlets that can be produced and may slightly increase exposure risks. A third limitation is that, despite the use of ATA to build the testlets, testlet-based CAT or CMT test forms may not meet all of the test-level specifications when various testlets are combined. Provided that all of the test specifications can be distributed at the testlet level, this is not a serious problem. However, various programs attempting to implement this model have encountered serious test form quality problems.

Computer-Adaptive Multistage Tests

Computer-adaptive multistage testing (CA-MST) is similar to testlet-based CAT, but is more structured and offers greater control over quality of the test forms and the testing data. Functionally, CA-MST can be used for adaptive testing applications or for mastery testing applications. CA-MST uses testlets as the fundamental building blocks for test assembly and test delivery. Testlets can range in size and may include discrete items, item sets that share a common stimulus (e.g., sets of 10 to 12 items, each associated with a particular reading passage), or even computer-based simulation exercises. The testlets are targeted to have specific statistical properties (e.g., a particular average item difficulty or level of precision) and all test-level content balancing is built into the test assembly process. Automated test assembly must be used to preconstruct all of the testlets so that they individually meet all relevant statistical and categorical specifications.

Computer-Adaptive Multistage Testing Panels

As part of the ATA process, the preconstructed testlets are prepackaged in small groups called "panels." Each panel

is essentially a self-adapting test form. A typical panel contains four to seven (or more) testlets, depending on the panel design chosen. Each testlet is explicitly assigned to a particular stage and to a specific route within the panel (easier, moderate, or harder) based on the average difficulty of the testlet. Multiple panels can be prepared with item overlap precisely controlled across different panels. This is an important distinction from testlet-based CAT and CMT, both of which cannot share items across testlets. In CA-MST, the overlap is conditioned into the ATA process and explicitly controlled across panels.

Figure 2 presents a 1-3-3 multistage panel design. One testlet (A) is assigned to Stage 1. Three testlets are assigned to Stage 2 (B, C, D) and three more testlets are assigned to Stage 3 (E, F, G). Examinees may review and change answers within each testlet. Once the examinee completes and submits each testlet, review is not allowed on the submitted materials. The examinee's cumulative score up to that point in the test determines which testlets are administered in Stages 2 and 3. The solid line arrows in Fig. 2 denote the primary adaptive routes allowed within the panel. The four dotted arrows denote secondary routes. Routing from Stage 1 to Stage 2 is based solely on the examinee's performance on Testlet A. Lower performing examinees are routed to Testlet B. Examinees performing moderately are routed to Testlet C and top-performing examinees are routed to Testlet D. Routing to Stage 3 (Testlets E, F, and G) is based on cumulative performance for all prior testlets. As Fig. 2 also indicates, multiple panels can be simultaneously constructed. A panel can therefore be randomly selected for any examinee from within the pool of active panels. Each panel is a formal data object that "knows" how to administer itself adaptively to the examinee. Each panel has testlets at multiple levels of difficulty. The prescribed difficulty for each testlet is controlled through automated

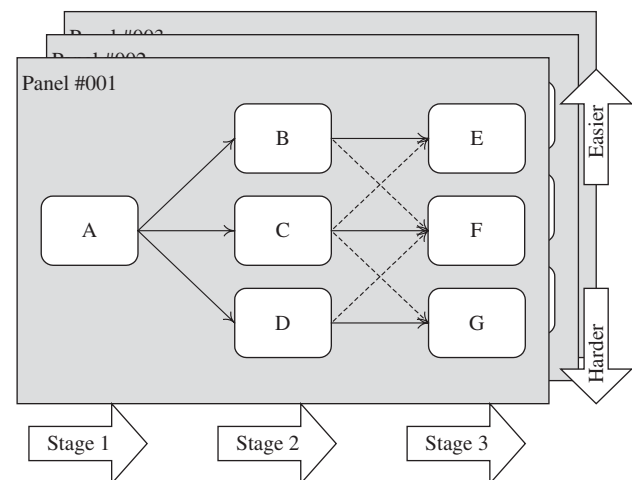

Figure 2 A sample 1-3-3 computer-adaptive multistage test panel configuration (showing three panels).

test assembly, using IRT test information functions to target the difficulty of each testlet to a specific region of the relevant score scale. This correspondingly targets the measurement precision where it is needed—achieving the same goal as CAT. There are seven explicit target test information functions underlying the 1-3-3 panel design shown in Fig. 2. There are seven viable pathways through each 1-3-3 panel: $A + B + E$, $A + B + F$, $A + C + E$, $A + C + F$, $A + C + G$, $A + D + F$, and $A + D + G$. Each panel is explicitly constructed so that any of those pathways provides a content-balanced test that meets all relevant test-level specifications (item counts, content balance, word counts, etc.). A large number of panels can simultaneously be constructed for operational use by mixing and matching items and testlets across panels.

In real-time, scoring and routing of the examinees within each panel can be greatly simplified by using cumulative number-correct scoring and score look-ups to mimic the maximum information criterion used in CAT. The number-correct cut-offs for each authorized route within the panel can be precomputed and packaged as part of the panel data. This feature simplifies the operational scoring and routing functionality needed by the test-delivery driver and potentially could improve performance of the test-delivery driver (i.e., involve less complex data processing and computational steps—especially in a web-enabled testing environment).

It is important to realize that the 1-3-3 panel design shown in Fig. 2 is merely one example of a CA-MST panel. Virtually any panel configuration can be custom designed to fit a particular assessment scenario by merely implementing a template for the desired configuration (number of stages, number of difficulty levels per stage, size of the testlets or modules within each stage, etc.). Some of the CA-MST panel designs proposed to date include the 1-3 (two-stage) design and the 1-2-2, the 1-3-4, the 1-3-4-5, and the 1-3-3-3 designs. More stages add to the adaptive flexibility.

The CA-MST test model is essentially a compromise solution that affords some degree of adaptation while ensuring adherence to the content specifications for every examinee as well as limiting any overexposure of the test items. Perhaps the greatest asset of CA-MST is that it contends with practical issues such as meeting test form review and other QC needs for test development, minimizing computational complexity for the test-delivery driver, and maximizing system performance by minimizing the amount of computing loads required by file servers and transmission channels.

Advantages and Disadvantages of CA-MST

CA-MST is designed to be parsimonious, to be reasonably efficient from a psychometric perspective, and to work well in most CBT environments—including

Internet-based applications. One of its chief advantages is that, by preconstructing the testlets and panels, it affords numerous opportunities to implement strong quality control procedures for test forms and testing data. CA-MST, like testlet-based CAT and CMT, is not quite as efficient as CAT is, but the differences seem negligible from a practical perspective. In any case, the increased control over content and overall test form content, the simplification of the unit selection and scoring functions that need to be built into the test delivery software, and the many other operational advantages that accrue from better quality control seem to offset any very minor efficiency loss.

Conclusions

CBT was once envisioned to make testing less complex and cheaper; but the opposite tends to be true. CBT systems are complex and expensive to operate. There are also many types of CBT delivery models to consider and, clearly, no singular CBT model is ideal for every testing program. But progress is being made and each new generation of CBTs seems to improve on the previous generation. Today, testlet-based CAT, CMT, and CA-MST have emerged as highly useful test-delivery models that have attempted to reconcile some of the shortcomings of CFT and CAT. In the case of CA-MST, the use of preconstructed testlets and highly structured “panels” yields distinct improvements in test form quality control, better security, more parsimony in data management, and important system performance advantages. Yet, there is room for improvement, and there will no doubt be new CBT technologies and delivery models, as well as new issues and perspectives that should be considered in evaluating those models.

Glossary

content balancing A set of one or more ancillary item-selection constraints based on content or nonstatistical item features.

conventional testing An approach to individual difference assessment whereby all examinees receive the same items, typically (but not necessarily) in printed mode.

exposure control algorithm An algorithmic enhancement to precision-based item selection that limits the usage rates of some highly informative items for the purpose of increased test security.

information A statistical concept related to the asymptotic variance of maximum-likelihood trait estimates; it can be expressed as the sum of individual item information functions, which can be evaluated at specific points along the trait scale.

item pool A collection of test questions and associated item parameters from which items are selected for administration by the adaptive item-selection algorithm.

item response function A mathematical function providing the probability of a correct response conditional on the latent trait level θ .

measurement efficiency The ratio of measurement precision to test length. One test or testing algorithm is said to be more efficient than the other if it provides more precise scores for a fixed test length, or if it achieves equally precise scores with fewer administered items.

measurement precision An index of the accuracy of test scores, often assessed by the average or expected squared difference between true and estimated trait parameters, $E(\theta - \hat{\theta})^2$.

stopping rule The rule used to determine when to end the test; typically based on the number of administered items (fixed length), or on the precision level of the estimated trait parameter (variable length).

trait A psychological dimension of individual differences; includes ability, aptitude, proficiency, attitude, or personality characteristics.

trait estimate A test score based on item-response theory; denoted by $\hat{\theta}$, the score is typically calculated by Bayesian or maximum-likelihood estimation approaches.

trait parameter The parameter θ , based on item-response theory; denotes the examinee's standing along the latent trait dimension.

Computerized adaptive testing is an approach to individual difference assessment that tailors the administration of test questions to the trait level of the examinee. The computer chooses and displays the questions, and then records and processes the examinee's answers. Item selection is adaptive—it is dependent in part on the examinee's answers to previously administered questions, and in part on the specific statistical qualities of administered and candidate items. Compared to conventional testing, whereby all examinees receive the same items, computerized adaptive testing administers a larger percentage of items with appropriate difficulty levels. The adaptive item selection process of computerized adaptive testing results in higher levels of test-score precision and shorter test lengths.

Computerized Adaptive Testing Response Models

Modern computerized adaptive testing (CAT) algorithms are based on concepts taken from item-response theory (IRT) and from maximum-likelihood and Bayesian statistical estimation theories. Early pioneers of CAT, including Frederic M. Lord and David J. Weiss (on whose work modern CAT algorithms are based) used item response functions (IRFs) as the basic building blocks of CAT.

These functions, denoted by $P_i(\theta)$, express the probability of a correct response for an item as a function of latent trait level θ . The trait estimated from adaptive testing can be a psychological (or other) dimension of individual differences, including ability, aptitude, proficiency, attitude, and personality. For ability measurement, IRFs are generally assumed to be monotonically increasing functions. Consequently, as θ increases, so too does the probability of a correct response.

One of the most commonly used mathematical expressions for an IRF is the three-parameter logistic (3PL) model:

$$P_i(\theta) = c_i + \frac{1 - c_i}{1 + e^{-1.7a_i(\theta - b_i)}}, \quad (1)$$

where the parameters a_i , b_i , and c_i denote the slope, difficulty, and guessing parameters, respectively, for item i . The 3PL is often used to model dichotomously scored responses from multiple-choice items. The two-parameter logistic (2PL) model (often used to model attitude or personality items) is a special case of Eq. (1), where guessing is assumed to be nonexistent (i.e., $c_i = 0$). The one-parameter logistic (1PL) model (where $a_i = 1$ and $c_i = 0$) is used in cases in which the IRF associated with item i is characterized by its difficulty parameter b_i ; all IRFs have identical slopes, and the probability of an examinee with infinitely low trait level correctly answering the item is zero. Other IRF models have also been used to extract information from incorrect options of multiple-choice items, or from other item-response formats (e.g., rating scales).

According to the assumption of local independence, the conditional probability of an observed response pattern is given by the product of item-specific terms:

$$P(u_1, u_2, \dots, u_n | \theta) = \prod_{i=1}^n P_i(\theta)^{u_i} Q_i(\theta)^{1-u_i}, \quad (2)$$

where u_i denotes the scored response to item i ($u_i = 1$ if item i is answered correctly; $u_i = 0$ otherwise), $Q_i(\theta) = 1 - P_i(\theta)$ (i.e., denotes the conditional probability of an incorrect response), and n denotes the number of answered questions. One implication of Eq. (2) is that the probability of a correct response to item i is independent of the response to item j after controlling for the effects of θ .

Another important property of IRT is scale invariance. The scale of measurement along which examinees are placed, the θ -scale, is defined independently of the statistical properties of the administered items. This invariance property does not hold for scales derived from classical test theory, which are founded on number-right or percent-correct scores. A percent-correct score of 75 on a test containing easy items has a different meaning than does a score of 75 on a test containing difficult

items. In contrast, an IRT-based test score (i.e., trait estimate $\hat{\theta}$) has the same meaning for tests containing either easy or difficult items (provided all item parameters have been transformed to a common scale). This IRT invariance property enables the comparison of scores from different or overlapping item sets. In the context of IRT, $\hat{\theta}$ test scores are all on a common measurement scale, even though these scores might have been estimated from tests consisting of different items.

Test Score Precision and Efficient Item Selection

Although the invariance property of IRT ensures that the interpretation of θ remains constant across tests consisting of different items, the precision with which θ can be estimated is very much dependent on the statistical properties of the administered items. Examinees with high θ -levels can be most accurately measured by tests containing many difficult items; examinees with low θ -levels can be most precisely measured by tests containing many easy items. This can be verified, for example, by an examination of the 1PL model, whereby the asymptotic variance of the maximum-likelihood estimator is given by

$$\text{Var}(\hat{\theta} | \theta) = \left[1.7^2 \sum_{i=1}^n P_i(\theta) Q_i(\theta) \right]^{-1}. \quad (3)$$

It can be seen from Eq. (3) that the smallest variance is obtained when $P_i(\theta) = Q_i(\theta) = 1/2$ for each item—any other values of these conditional response probabilities lead to a larger variance. From Eq. (1), for the 1PL, this optimal condition occurs when $b_i = \theta$, which is when the difficulty parameter of each item matches the examinee trait-level parameter.

One implication of Eq. (3) is that the optimal (i.e., most precise) testing strategy chooses items solely on the basis of the examinee's true trait-level θ . But obviously this is not possible, because θ is unknown prior to testing. (If it were known, testing would be unnecessary in the first place.) It is possible, however, to use an iterative adaptive algorithm, where an estimated trait-level $\hat{\theta}_k$ is obtained after each administered item $k = 1, \dots, n$, and the difficulty parameter of the next administered item b_{k+1} is matched to the current estimate: $b_{k+1} = \hat{\theta}_k$. In this sense, the difficulty of the next question, b_{k+1} , is adapted to the most up-to-date trait estimate, $\hat{\theta}_k$, of the examinee. By doing so, the precision level of the final estimate (obtained after the completion of the last item) is greater than that expected from conventional nonadaptive testing.

This idea of adapting the statistical properties of administered items based on responses to previous

items forms the basis of all CAT item-selection algorithms. However, commonly used algorithms differ along two primary dimensions: first, in the type of statistical estimation procedure used (maximum likelihood versus Bayesian), and second, in the type of item-response model employed (e.g., 1PL, 2PL, or 3PL).

Maximum-Likelihood Approach

The maximum-likelihood (ML) approach to CAT item selection and scoring is based on the log-likelihood function

$$l(\theta) = \ln \prod_{i=1}^n P_i(\theta)^{u_i} Q_i(\theta)^{1-u_i}. \quad (4)$$

The estimate $\hat{\theta}_{(ML)}$ is defined as the value of θ for which the likelihood (or, equivalently, the log-likelihood) function is maximized. Because no closed-form expression exists for $\hat{\theta}_{(ML)}$, it is typically calculated using an iterative numerical procedure such as the Newton–Raphson algorithm.

The estimator $\hat{\theta}_{(ML)}$ is asymptotically normally distributed with mean θ and variance

$$\begin{aligned} \text{Var}(\hat{\theta} | \theta) &= [-E(\partial^2 / \partial \theta^2) l(\theta)]^{-1} \\ &= \frac{1}{\sum_{i=1}^n I_i(\theta)}, \end{aligned} \quad (5)$$

where the information function for item i , denoted by $I_i(\theta)$, is

$$I_i(\theta) = \frac{[P'_i(\theta)]^2}{P_i(\theta)Q_i(\theta)}, \quad (6)$$

and where $P'_i(\theta)$ denotes the derivative of the item response function with respect to θ . For the one- and three-parameter logistic models, these derivatives are $P'_i(\theta) = 1.7P_i(\theta)Q_i(\theta)$ and $P'_i(\theta) = 1.7a_iQ_i(\theta)[P_i(\theta) - c_i]/(1 - c_i)$, respectively.

From Eq. (5), it is clear that the asymptotic variance of the ML estimate $\hat{\theta}_{(ML)}$ can be minimized by choosing items with the largest information values. If θ were known in advance of testing, then available items could be rank ordered in terms of their information values [Eq. (6)] at θ , and the most informative items could be selected and administered. Because θ is not known (to know or approximate θ is, of course, the purpose of testing), the most informative item can be selected using item-information functions evaluated at the provisional (most up-to-date) trait estimate, $I_i(\hat{\theta}_{k(ML)})$. After the chosen item has been administered, and the response scored, a new provisional estimate can be obtained and used to reevaluate item information for the remaining candidate items. These alternating steps of trait

Table I CAT Item-Selection and Scoring Algorithm

Step	Description
1. Calculate provisional trait estimate	Obtain a provisional trait estimate, $\hat{\theta}_k$, based on the first k responses
2. Choose item	Compute information $I_i(\hat{\theta}_k)$ for each candidate item by substituting the provisional trait estimate $\hat{\theta}_k$ (calculated in step 1) for the true parameter θ in Eq. (6); select for administration the item with the largest item-information value
3. Administer item and record response	
4. Repeat steps 1–3	Repeat until the stopping rule has been satisfied
5. Calculate final trait estimate $\hat{\theta}$	Based on all responses, including the response to the last administered item

estimation and item selection are repeated until a stopping rule (typically based on test length or precision) is satisfied. The adaptive item-selection and scoring algorithm is summarized in Table I.

Bayesian Approach

In instances when a prior distribution for θ can be specified, some test developers have opted to use a Bayesian framework for item selection and trait estimation. The prior density, denoted by $f(\theta)$, characterizes what is known about θ prior to testing. The most common approach to prior-specification in the context of CAT sets the prior equal to an estimated θ -density calculated from existing (or historical) examinee data. Then the assumption is made that future examinees (taking the CAT test) are independent and identically distributed, $\theta \sim f(\theta)$. Although in many cases, additional background information is known about examinees relating to θ (such as subgroup membership), this information is often ignored in the specification of individual examinee priors—to allow such information to influence the prior could lead to, or magnify, subgroup differences in test score distributions.

A Bayesian approach provides estimates with different statistical properties than are provided by ML estimates. In CAT, Bayesian estimates tend to have the advantage of smaller conditional standard errors, $\sigma(\hat{\theta} | \theta)$, but possess the disadvantage of larger conditional bias, $B(\theta) = \mu(\hat{\theta} | \theta) - \theta$, especially for extreme θ levels. Thus, the choice of estimation approach involves

a trade-off between small variance (of Bayesian estimates) and small bias (of ML estimates). Bayesian procedures do, in general, provide smaller mean-squared errors (MSEs) between θ and $\hat{\theta}$ (which is a function of both conditional variance and bias) than are provided by ML estimates. This suggests that Bayesian estimates can provide higher correlations with external criteria, and a more precise rank ordering of examinees along the θ -scale. Practitioners who are concerned about the effects of bias, or who do not have precise estimates of the trait distribution, tend to favor the ML approach. Conversely, practitioners whose primary objective is to minimize MSE or conditional variance have tended to favor Bayesian approaches.

The Bayesian approach to CAT item selection and scoring is based on the posterior density function,

$$f(\theta|u) \propto f(u|\theta)f(\theta), \quad (7)$$

where $f(u|\theta)$ is equivalent to the probability function [Eq. (2)], $f(\theta)$ is the prior distribution of θ , and $u = (u_1, \dots, u_n)$ is a vector of scored responses. Whereas the prior $f(\theta)$ describes what is known about θ before the data are observed, the posterior density function $f(\theta|u)$ provides a description of what is known about the examinee's trait level after the item-response data u have been obtained. Typically, summary statistics are used to characterize the posterior distribution: a measure of central tendency (such as the posterior mean or mode) is often taken as the trait point estimate, and the variance of the posterior distribution is typically taken as a measure of uncertainty. Small posterior variance values suggest that $\hat{\theta}$ has been estimated with a high degree of precision; large posterior variance values suggest otherwise.

One Bayesian approach to item selection chooses the next item to minimize the expected posterior variance, where the expectation is taken with respect to the yet-to-be observed response to the candidate item. This quantity is calculated by computing the values of the posterior variance if the candidate item is answered both correctly and incorrectly, and then calculating a weighted average of the two posterior variances, where the weights are equal to the probability of correct and incorrect responses based on the predictive posterior distribution. A less computationally intensive and more commonly used Bayesian item-selection method is consistent with a normal-based inference approach. According to this approach, the posterior distribution is approximated by a normal density,

$$f(\theta|u) = N(\hat{\theta}_{(\text{MAP})}, V), \quad (8)$$

with mean equal to the mode [maximum *a posteriori* (MAP)] of the posterior density, denoted by $\hat{\theta}_{k(\text{MAP})}$, and

variance based on the expected information evaluated at the mode:

$$\begin{aligned} V &= \frac{1}{\{-E[(\partial^2/\partial\theta^2)\ln f(\theta|u)]\}_{\theta=\hat{\theta}_{(\text{MAP})}}} \\ &= \frac{1}{\{1/\sigma^2 + \sum_{i=1}^n I_i(\theta)\}_{\theta=\hat{\theta}_{(\text{MAP})}}}. \end{aligned} \quad (9)$$

This approximation assumes that the prior is normal with variance denoted by σ^2 . The information function for item i , denoted by $I_i(\theta)$, is equivalent to the one derived for the ML case given by Eq. (6). It is clear from an examination of Eq. (9) that the administration of the item with the largest information value (evaluated at $\hat{\theta}_{k(\text{MAP})}$) will provide the greatest reduction in posterior variance V . As with the ML approach, the adaptive item-selection and scoring algorithm summarized in Table I is used, where the provisional trait estimate $\hat{\theta}_k$ is set equal to the posterior mode $\hat{\theta}_{k(\text{MAP})}$. Calculation of the mode requires the use of an iterative numerical algorithm to find the maximum of the log posterior density function, Eq. (7). Alternating steps of trait estimation and item selection are repeated until a stopping rule is satisfied. The posterior variance based on observed information,

$$\text{Var}(\theta|u) = \frac{1}{[-(\partial^2/\partial\theta^2)\ln f(\theta|u)]_{\theta=\hat{\theta}_{(\text{MAP})}}}, \quad (10)$$

is an often-used characterization of measurement precision.

Item-Selection Enhancements

Although the adaptive item-selection algorithms form an efficient basis for precise measurement, test developers have often found it beneficial or necessary to alter these algorithms. These alterations, or enhancements, include the specification of rules used to choose the first several items; the specification of rules used to stop the test; modifications to the item-selection algorithms, intended to reduce opportunities for test-compromise and to help achieve a more balanced item content; and the use of time limits.

Item Choice Early in the Adaptive Sequence

Most commonly used adaptive item-selection algorithms require the existence of a provisional trait estimate. This provisional estimate is used to evaluate the relative information contribution of candidate items, and is specified from the responses to earlier items. But how should the first item be selected? The choice of the first item and

other early items depends on the approach taken: ML or Bayesian.

ML approaches have adopted a set of heuristics for item selection early in the adaptive sequence. Typically, the first item selected is one of moderate difficulty relative to the population of examinees. If the first item is answered correctly, then a more difficult item is selected and administered; if the first item is answered incorrectly, then an easier item is selected. If necessary, selected items become successively easier or harder until at least one correct response and one incorrect response have been obtained. At this point, the ML function will typically possess a finite maximum, and the adaptive item-selection and scoring algorithm (Table I) can be used.

The Bayesian approach formalizes these heuristics by setting the initial provisional trait estimate equal to the mean of an informative prior trait density. The first item chosen is one with high, or highest, information at the prior mean. After the administration of the first item, the provisional trait estimation and item-selection algorithm (given in Table I) can be applied in a straightforward manner. Unlike the ML estimate, the provisional Bayesian estimate (taken as the posterior mean or mode) is defined for all response patterns, including those containing all correct or incorrect responses.

Stopping Rules

There are two common test termination or stopping rules used in CAT: fixed length and variable length. Fixed-length tests require that the same number of items be administered to each examinee. One consequence of fixed-length tests is that measurement precision is likely to vary among examinees. In contrast, variable-length tests continue the administration of items until an individualized index of precision satisfies a target precision level. These precision indices are often based on ML information [Eq. (5)] or Bayesian posterior variance [Eq. (10)] statistics.

Test developers have found that the choice of stopping rule is often highly dependent on the test purpose, item-pool characteristics, and operational constraints. In many instances, for example, equally precise scores among examinees are paramount, helping to ensure that decisions and interpretations made on the basis of test scores are equally precise for all examinees. In other instances, however, the occasionally long test lengths (possible with variable-length tests) might be judged too burdensome for examinees, and possibly for test administrators as well. To moderate some of the operational burdens, variable-length testing has been implemented with upper-bound constraints on the maximum number of administered items, and, in some instances, on the maximum amount of testing time allowed for each examinee. In other instances, test developers have opted for fixed-length

tests to help standardized testing conditions with respect to variability in testing time and related testing fatigue.

Test Compromise Safeguards

In some instances, examinees may attempt to misrepresent their performance. This is especially likely when the test scores on the exam are used as a basis for important decisions. With CAT, the same items are typically administered on multiple occasions (spanning weeks, months, or possibly years). This repeated-item use provides examinees with an opportunity to obtain information about the questions from others taking the test before them. In these instances, one or more compromise deterrents can be implemented.

The adaptive item-selection algorithm (Table I) provides highly efficient but deterministic item selection. Consequently, two examinees providing the same pattern of responses to a set of multiple-choice questions (e.g., A, D, C, A, B, C, D, . . .) will receive the same items and the same θ estimate. An examinee could be assured a high score by simply re-entering the response pattern copied from a high-scoring examinee. This strategy can be thwarted, however, by adding a stochastic component to the item-selection algorithm. Rather than matching the difficulty parameter b_i with the provisional trait estimate θ_k , the next administered item for the IPL model can be selected at random from among those items with difficulty parameters b_i falling in a narrow interval around θ_k (namely, the interval $\theta \pm \delta$, where δ is some suitably small constant). A strategy with similar intent designed for the 3PL model is based on the 5-4-3-2-1 algorithm, where the first item is selected at random from the five most informative items at the current provisional trait level, the second administered item is selected at random from the four most informative items evaluated at the current provisional trait estimate, and so forth. The fifth and subsequent items are chosen to maximize precision evaluated at the provisional trait estimate.

Although these strategies decrease or eliminate the gains associated with copied answer patterns, they do not necessarily limit the usage or exposure of the item pool's most informative items. That is, these strategies can still lead to instances in which some items are administered to nearly all examinees. An alternate method, referred to as the Sympon-Hetter exposure control algorithm, was designed specifically to place an upper ceiling on the administration rates of the most used items (typically, highly discriminating items of moderate difficulty). The Sympon-Hetter exposure control algorithm assigns an exposure control parameter, denoted by e_i , to each item i . These parameters are used in conjunction with the adaptive item-selection algorithm to screen items. For the selection of the k th item, candidate items are rank ordered by information level evaluated at the

provisional trait estimate $\hat{\theta}_k$. The item with the largest information is considered first. A random uniform number r (between 0 and 1) is drawn; the item either passes or fails the exposure screen. If $r \leq e_i$, then item i passes and is administered; otherwise it fails and is not considered again for administration to the examinee. If the first evaluated item fails the exposure screen, then the next most informative item is considered for administration. A new random number is drawn, and the exposure screen is repeated. This screening process is repeated until a candidate item passes.

The exposure control parameters e_i are specified prior to testing and are calculated through a series of computer simulations. The assigned e_i values are dependent on a target ceiling exposure value T , and on an assumed trait distribution $f(\theta)$. The use of the exposure control parameters ensures (in expectation) that the exposure rates of the most used items will not exceed the target ceiling rate T in a population with trait distribution $f(\theta)$. In practice, the target ceiling exposure rate T is often set to a value between 1/10 and 1/3, ensuring that the most used items are not administered to more than 1/10 or 1/3 of the examinee population.

A conditional version of the Simpson-Hetter approach has been suggested for use in situations when it is important to maintain a target ceiling exposure rate for homogeneous subpopulations of examinees. Over narrow ranges of θ , the unconditional approach can provide higher than desired exposure rates for some items, and higher than the target T specified for the overall population. The conditional approach remedies this problem by using a vector of exposure parameters for each item (e_{i1} , e_{i2} , . . .), where the exposure parameter used, e_{ij} , is specific to both the item i and to a narrow trait range indexed by the subscript j . This trait range is associated with the value of the provisional trait estimate. The conditional approach helps ensure that the exposure rates of the most used items do not exceed the target ceiling rate T ; this assurance is made without requiring any specific assumption regarding the form of the trait distribution $f(\theta)$.

Other methods intended to further reduce item exposure are commonly used in conjunction with the Simpson-Hetter exposure control method. Two such methods include the simultaneous and sequential use of multiple item pools. In the case of simultaneous item-pool use, examinees are randomly assigned to two or more distinct (nonoverlapping) item pools. These item pools serve the same function as served by alternate test forms in conventional testing. In the case of sequential item-pool use, the item pool is continuously updated or replaced over a period of days, weeks, or months, thus making sharing item content among examinees less profitable.

Inevitably, the choice of any CAT exposure control method requires a consideration of the effects on

measurement efficiency and test development costs. (Measurement efficiency is defined as the ratio of test score precision to test length.) In general, lower maximum item-exposure rates result in either lower measurement efficiency or in higher test development costs associated with larger or more numerous item pools. When making decisions about exposure control algorithms, including decisions about target maximum exposure rates and the number or size of simultaneous or sequential item pools, test developers have considered the unique compromise pressure placed on their exams. As part of the evaluation process, test developers typically perform extensive simulation analyses to examine the consequences of exposure control algorithms on measurement precision (for fixed-length tests), and on test lengths (for variable-length tests). These considerations have led some high-stakes developers to set low target maximum exposure levels at 0.10 and frequent item-pool replacement schedules (of just several weeks), and have led other test developers to use somewhat higher targets of 1/3 in conjunction with two or three simultaneous pools replaced at 5-year intervals.

Content Balancing

Test developers have been compelled in many cases to depart from strict precision considerations when designing and implementing CAT item-selection algorithms. These include cases, for example, in which the item pool consists of items drawn from different content areas of a more general domain (e.g., math items drawn from algebra and geometry). In such instances, item-selection algorithms that maximize precision may not administer properly balanced tests, resulting in test scores that have questionable validity. To help ensure adequately balanced content across examinees, constraints can be placed on the adaptive item-selection algorithms (e.g., constraints that ensure equal numbers of administered algebra and geometry items).

The most basic approach to content balancing spirals the sequence of item administration among key content areas. For example, math items would be administered in the following order: (1) algebra, (2) geometry, (3) algebra, (4) geometry, and so forth, where each item represents the most informative item (passing the exposure-control screen if used) at the provisional trait level among items in the given content (i.e., algebra or geometry) domain.

Although the spiraling approach is adequate for a small number of mutually exclusive content areas, this approach is poorly suited for situations in which more complex content constraints are desired. Consider the case, for example, in which items are classified along several dimensions simultaneously, and as a result do not fall into mutually exclusive categories. In such cases, methods such as the *weighted deviations* or *shadow testing* approaches can be used. These approaches are designed

to maximize precision while attempting (in the case of the former method) or forcing (in the case of the latter method) adherence to specified content constraints.

Test developers have placed different levels of emphasis on the issue of content balancing. Developers of licensure and certification exams, for example, have tended to produce CAT exams in which content targets and constraints heavily influence item choice. In these exams, the direct demonstration of the understanding of key facts and concepts is considered so important that it is not sufficient to infer mastery of one concept from the correct answers to items assessing more difficult concepts. In some instances, the balanced administration of items is so important that test developers have opted for a testlet-based approach, whereby balanced groups or sets of items are selected and administered. Within each group, items are balanced for content and span a relatively narrow range of difficulty. Thus, in the testlet-based approach, the difficulty level of the testlet item group (rather than the individual item) is tailored to the level of the examinee.

The issue of content balancing is complicated not only by the question of when to balance, but also by the question of how finely to balance. Inevitably, more detailed balancing constraints will lower the measurement efficiency of the adaptive testing algorithm, with some constraints having larger effects than others. For example, in a fixed-length test of high school math skills, the forced administration of a large number of calculus items (that happened to be difficult because of their advanced content) would degrade precision over the middle and lower proficiency ranges. Examinees in these ranges would be better measured by the administration of items of more appropriate difficulty levels, such as those taken from introductory or intermediate algebra. This example illustrates that the imposition of some content constraints may actually lead to a significant decrease in precision or measurement efficiency. Unfortunately, there are no universally accepted rules regarding the optimal balance between content and measurement efficiency considerations in the construction of item-selection algorithms. Rather, to arrive at a suitable approach to content balancing, test developers routinely weigh these trade-off considerations in the context of the specific exam and its intended purpose.

Time Limits

Because the effects of time pressure are not explicitly modeled by standard item-selection and scoring algorithms, the imposition of time limits can in some instances significantly degrade CAT measurement precision. Even in spite of this undesirable consequence, most high-stakes, high-volume testing programs have implemented overall test time limits for a number of reasons, including the desire to help reduce excessive test times. In instances

when time-limits have been imposed, most test developers have chosen to implement long time limits to provide most or nearly all examinees with an opportunity to answer all items without feeling rushed.

Although time limits might be desirable from an administrative standpoint, their use raises opportunities for gaming and test compromise in high-stakes testing. Low-ability examinees would be well advised to answer as few items as allowed. Under ML scoring, these low-ability examinees could capitalize on measurement error, which is greatest for short tests. Under Bayesian scoring, these same low-ability examinees could capitalize on the positive bias introduced by the prior, which is also greatest for short tests. To help discourage such test-taking strategies associated with time limits, test developers have implemented various scoring penalties applied to incomplete fixed-length tests. For variable-length tests, fair and equitable provisions must be made to help ensure that those requiring longer tests (to achieve the target precision level) are given sufficient time.

Item-Pool Development

Characteristics of the item pool (including size, item parameter distributions, and content coverage) directly impact CAT measurement efficiency and test score validity. Furthermore, particular characteristics of the adaptive algorithm (such as the stopping rule, number and type of content balancing constraints, and type and level of exposure control) can interact with key item-pool characteristics to further affect measurement efficiency and test score validity. These characteristics are listed in [Table II](#).

Large item pools are desirable from several standpoints. First, large item pools tend to contain a larger set of highly discriminating items, which in turn can provide greater measurement efficiency (i.e., greater precision for fixed-length tests and shorter test lengths for variable-length tests). Second, large pools are more likely to satisfy content balancing constraints, or to satisfy them without severely impacting efficiency. For fixed-length tests, large pools enable lower exposure levels (for the most used items) and can satisfy these levels without severely impacting precision. Many test developers have found that high precision levels can be obtained

Table II Factors Affecting CAT Measurement Efficiency

<i>Item-pool characteristics</i>	<i>Algorithm characteristics</i>
Size	Stopping rule
Item parameter distributions	Content constraints
Content coverage	Exposure control

with pools of a size that is about six to eight times the test length.

In principle, the ideal item pool contains items with difficulty parameters (b_i) values uniformly distributed throughout the θ range, and for the 3PL model, contains high discrimination parameters (a_i) values and low guessing parameters (c_i) values. In practice, these ideal parameter distributions are often difficult to achieve. For some tests, highly discriminating items may be rare, or may exist only for items with difficulty values that span a narrow range or for items of specific content areas. In these cases, CAT algorithms can be very inefficient, resulting in test scores that have low precision over some trait ranges (for fixed-length tests), or resulting in long test lengths (for variable-length tests). Consequently, test developers, when possible, have tended to write and pre-test large numbers of items in hopes of ending up with a sufficient number of highly discriminating items of appropriate difficulty and content.

Standard CAT item selection and scoring algorithms assume that the IRFs for all items are known in advance. In practice, these are estimated from examinee response data. For the 3PL model, large-scale testing programs have tended to use samples containing 500 or more responses per item to estimate item parameters. Programs that have based their item-selection and scoring algorithms on the 1PL model have typically relied on smaller sample sizes for IRF estimation. Test developers routinely use conditional (on $\hat{\theta}$) item-score regressions to check model fit. This model-fit analysis typically includes an additional check of dimensionality or local independence assumptions.

Many test developers have found it convenient, especially when developing the first set of pools, to collect calibration data in paper-and-pencil format. This mode of data collection is often faster and cheaper than collecting the same data by computer. In these cases, test developers have attempted to ensure that the use of item-parameter estimates obtained from paper-and-pencil data are adequate for use when the items are administered on computer in adaptive format. This assurance has been provided by several studies that have found inconsequential differences in item-response functioning due to mode of administration (computer versus paper and pencil).

Because of the complexity of the interactions between item-pool characteristics and adaptive testing algorithms, and the effects these have on measurement efficiency, test developers routinely conduct computer simulation studies to fine-tune the adaptive algorithms and to examine the adequacy of candidate item pools. These simulations take as input the item-parameter estimates of items contained in the pool (a , b , and c values), and if content balancing is proposed, the content classification of each item. Then, the consequences (on precision or test length)

of using the proposed adaptive testing algorithm can be examined for examinees falling at different trait levels. The outputs of these simulations are conditional (on θ) means and variances of the estimated scores, $\hat{\theta}$. These simulation studies allow the effects of different variations of the adaptive algorithms (i.e., changes in content constraints, pool size, stopping rule, target exposure level, etc.) to be examined and compared. The outcomes of these simulations are often used as a basis for determining the suitability of candidate item pools and adaptive algorithms.

Trends in Computerized Adaptive Testing

In recent years, research on item-selection and scoring algorithms has continued. This includes work on item-selection algorithms intended to provide greater measurement precision. One class of approaches addresses the uncertainty regarding the provisional trait estimates toward the beginning of the test. These approaches include methods such as the global information criterion, weighted-likelihood information criterion, a -stratified method, and fully Bayesian approaches. Research has also continued on improved exposure control algorithms to further guard against test compromise. Another class of item-selection approaches that has been developed to further increase the measurement efficiency of CAT in the context of multidimensional IRT modeling involves items that are selected to maximize the information along several dimensions simultaneously.

As more testing programs have considered the use of CAT, more attention has been given to its cost-effectiveness. In addition to the benefits of increased measurement precision and reduced test lengths, CAT offers a host of other benefits associated with the computerized administration of test items. These include immediate and accurate scoring, minimal proctor intervention, individually timed and paced test administration, standardized instructions and test administration conditions, improved physical test security (no hard-copy test booklets are available for compromise), and provisions for handicapped examinees (large print, audio, and alternate input devices). Many of these benefits, especially when considered alongside the key benefit of increased measurement efficiency, provide compelling incentives in favor of CAT. But several obstacles have prevented many test developers from adopting CAT. In addition to specialized software requirements (necessary for test development and administration), CAT also requires considerable resources for item-pool development and for the purchase and maintenance of computer test-delivery systems.

Compared to conventional testing paradigms, many high-stakes test developers have found that CAT requires more test items and greater data demands (for item calibration). These greater demands for items and data are due in part to requirements of the adaptive branching strategy, and in part to the change in testing schedule associated with the test delivery. Conventional exams administered in high- or moderate-stakes settings are often associated with periodic test schedules, whereby substantially different items (i.e., test forms) are administered on each testing occasion to help reduce instances of cheating. Because of the large item-pool development costs and the impracticality of administering a large number of computer-delivered exams on the same day (as is the case with periodic exams), CAT exams are administered exclusively using on-demand or continuous testing schedules. According to these schedules, the same items are used over an extended time period. These continuous schedules by their nature increase the opportunity for test compromise, which is most effectively countered by large numbers of items—either contained in a few large pools or contained in a large number of smaller item pools.

It is noteworthy that increased demand for items and calibration data has been minimal for at least one major high-stakes testing program that transitioned from paper-and-pencil format to CAT. This program, the Armed Services Vocational Aptitude Battery (ASVAB) program, differed from most programs in that its conventional test version was also given on-demand, and compromise was controlled through the simultaneous use of a large number of alternate paper-based test forms. It was found that a sufficient level of CAT precision and security could be achieved by the use of a small number of moderate-sized item pools. The ASVAB experience suggests that a large part of the increase in item/data demands typically associated with high-stakes CAT may be due to the change in testing schedule (from periodic to continuous), rather than to the demands of the adaptive item-selection algorithms.

Research has also intensified on item-pool data collection and maintenance procedures. Response data required for the calibration of new items can be easily obtained by administering these items along with the operational adaptive items. This method of seeding or interspersing helps ensure that examinees will provide high-quality motivated responses, and that the item parameter estimates obtained from these response data are appropriately scaled. Depending on the mixture of tryout and operational items presented to examinees, this sort of data collection design can raise special challenges for conventional item-calibration approaches. Research has also continued on approaches for phasing items in and out of item pools, and on the effects of these approaches on precision and other important item-pool qualities.

Developers have been sensitive to computer literacy levels among their test-taking populations, and in particular to the literacy levels of select (possibly economically disadvantaged) subgroups. In large-scale test development efforts, care has been taken to ensure that aspects of the computerized test-taking experience do not place particular subgroups at an unfair disadvantage relative to corresponding subgroups taking paper-and-pencil versions. Although no consistent subgroup/medium interactions along racial or gender lines have been identified, attempts have been made to mitigate any possible disadvantage among subgroup members by the use of simple item-presentation formats and by clear test-taking instructions. As computers become even more commonplace and ubiquitous among widely diverse segments of the population, this concern is likely to dissipate.

With the proliferation of computers in recent years, it would appear that one of the last major obstacles to CAT has been removed: the availability of computer platforms for CAT test delivery. However, many high-stakes test developers have been concerned about context effects associated with different hardware and testing environments, and possible interaction effects of these with test-delivery software. For paper-and-pencil tests, test performance can be affected by subtle differences in booklet font and layout, and by subtle changes to answer sheets. These concerns about context effects have caused at least some high-stakes test publishers to go to great lengths to standardize these and other aspects of the testing experience. In the first instances of large-scale high-stakes uses of CAT, this strict adherence to standardization carried over to computers, which were also standardized so that the computer hardware and software were virtually identical across test administrations for a given exam. This strict adherence to standardization meant that testing could occur only on specially designated computers. Consequently, their cost was factored into the cost of CAT testing.

If adaptive testing could be routinely conducted on computers used for other purposes (and this could be done without loss of precision or validity), then a primary impediment of CAT testing (i.e., hardware costs) could be substantially reduced. Some test developers are, for example, considering the administration of low- or medium-stakes adaptive tests over the Internet, thus enabling CAT to be administered on a wide variety of general-purpose computer platforms. Because of the important role computer hardware plays in both the economic and the psychometric viability of CAT, necessary research on context effects is likely to intensify in the coming years. This includes research on the aspects of the computer hardware that influence test performance, and on characteristics of the exam (such as speededness) and software interface that might interact with particular hardware characteristics. Progress in these and related

areas is likely to further increase the popularity of computerized adaptive testing.

Computerized Record Linkage and Statistical Matching

Dean H. Judson

U.S. Census Bureau, Washington, D.C., USA

Glossary

blocking field/strategy A way to limit the search space by forcing certain fields to match before considering whether to link two records. Pairs that do not match on one or more blocking fields are automatically not sent to be compared.

constrained matching In statistical matching, every record from both files must be matched one and only one time, as opposed to unconstrained matching.

database A collection of records laid out in fields.

false negative/false nonlink A nonlink between two records that is in fact not correct.

false positive/false link A link between two records that is in fact not a correct link.

field A datum about the object, sometimes called a variable (for example, first name, street name, street type, owner name).

labeled data Pairs of records labeled concerning whether they already have link or nonlink decision flags on them; otherwise, they are unlabeled.

link decision A decision to join two records; a decision to not join two records is a nonlink decision.

match Two fields (in two different records) that are considered the same or sufficiently similar; two records match if they refer to the same external object.

matching field/strategy For pairs of records that satisfy the blocking strategy, the matching strategy indicates how to compare matching fields so as to determine if the two records should be linked.

record A collection of data about an individual object (for example, a person, an address, a business entity).

search space The region in which the record of interest is sought, in either record linkage or statistical matching.

statistical match Two records from different databases that have been joined together, but are not believed to refer to the same external object.

training data set Pairs of records that have been labeled as either link or nonlink by a prior (often clerical) comparison of pairs.

unconstrained matching In statistical matching, a donor record may be used more than once if it is the closest record to a target record, as opposed to constrained matching.

Computerized record linkage refers to an attempt to take two databases, each of which has records on the same collection of objects (persons and addresses are typical examples), and link each record in one database with one or more records in the other database. Record linkage is sometimes known as entity identification, list washing, data cleaning, and merge/purge. Statistical matching refers to an attempt to augment a first database with fields from a second database by finding “similar-looking” records in the second database. Using person records as an example, record linkage means linking records on the same person, whereas statistical matching means linking records on two different people who happen to look alike on certain characteristics. In record linkage, the combined database contains more information than either database separately. In statistical matching, the combined database contains more variables.

What Is Computerized Record Linkage?

Why Link Data across Databases?

Among a variety of reasons to link records across different databases, four reasons are important: to evaluate

coverage overlap between two databases, to evaluate duplication in an existing database, to add new records and remove unused or unusable records, and to augment data in one database with data from another. To clarify the following discussions of database linkage, the first database will be referred to as database A, the second as database B (three-way links between databases are much less common, and typically they are composed of multiple two-way links).

Evaluating coverage overlap is important in population censuses. In censuses and vital registration (e.g., births, deaths) lists around the world, undercoverage (and occasionally overcoverage) is a constant concern. But how to evaluate undercoverage, when by definition undercoverage means that the people or addresses are missing from the list? A common solution is to use a dual system estimator, in which the census-taking organization takes the population census and follows up with a second enumeration attempt in a sample of areas. Thus, each person or address has two opportunities to be captured, and from these two captures an estimate of coverage (over or under) is constructed. But, in order to make the dual system estimate, the people and/or addresses in database A have to be linked to their equivalent record in database B. Because people write down their names, dates of birth, and their addresses with variations (e.g., William vs. Billy), linking equivalent records is not obvious.

Evaluating duplication is also important in vital registries, population censuses, marketing applications, and sample surveys. For example, immunization registries attempt to keep track of which persons have received which immunization. If the list contains duplicate records on a single person, it means that that person's actual immunization history is not accurately maintained. In vital registers, it is certainly not of demographic value to record duplicate births or to record deaths twice—both lead to estimation errors. Further afield, for direct marketing applications or sample surveys, duplication means that the household or person receives more than one solicitation, which is a waste of money at best and an annoyance to the recipient at worst.

Adding new records and removing unused or unusable records is important in list construction for sample surveys that use a list frame. In this case, database A represents the existing list, and database B represents a batch of new candidates for the list. Obviously, adding records that represent the same unit as one already existing on the database is creating duplication. Just as obviously, linking a candidate record from B with a record from A falsely, and not adding it to the list, is creating undercoverage. Thus, getting the link right is of crucial importance in list construction.

A final, important use for record linkage is to use data from database B to augment information in database A, if each database contains information not contained in the other (e.g., one is a credit card database, the other is a tax

assessor's database). If the databases contain most of the same people, for example, the ability to link two records together that refer to the same person allows the analyst develop a broader "picture" of who individuals are and what they do. This has been used to compare survey responses on income components with administrative records data on those same persons. In other studies, survey data have been linked with longitudinal data to determine if respondents and nonrespondents have different profiles.

Record Linkage Terminology

A "record" can be considered as a collection of data about an external object in the empirical world. "Fields" in the record refer to individual items of information about the external object (e.g., first name, sex, street name, Federal Information Processing Standards code). In the population of all possible record pairs, two records can be said to "match" if they refer to the same external object, even if they do so with error or variation (for example, "Dean Judson", "D. H. Judson," and "Dean Harold Judson, Ph.D." all refer to the same external object); otherwise the two records are a nonmatch. Two fields can also be said to "match" if they contain the same or sufficiently similar information. After analyzing a pair of records, the records are declared "linked" if they are most likely a match; "possibly linked" if they might be a match; and "non-linked" if they are most likely not a matched pair. (Note that this terminology distinguishes "matches" in the population from "link" and "nonlink" decisions, which refer to record pairs.)

Multiple Databases, No Common Identifier

In order to construct the single record for each object, a way must be found to associate that object in database A with the same object in database B. On the surface, if the databases contain identifier information, such as a Social Security Number (SSN), this problem appears to have a simple solution: merely merge the two databases, using the SSN as the merge field. However, studies have shown that anywhere from 1 in 10 to 1 in 20 SSNs is collected or recorded with some kind of error. That means that the SSN is stored incorrectly in one or more of the databases, so that the problem of finding a common link is more challenging. Another challenge occurs when linking identical SSNs but the names (or dates of birth or some other feature) are different. Which "person" has been found? Might it be a wife using a husband's SSN, or might it be an undocumented person fraudulently using an SSN? Or is it a data entry error? Now suppose further that each database does not contain a unique identifier—i.e., there is no SSN or comparable unique

identifier in each database. There are several fields that, when used together, might be sufficient to match a record uniquely in one database with the equivalent record in the other. For example, using first name, middle name, last name, and date of birth, and some geographical locator (such as an address, ZIP code, or census tract number), the pool of possible candidate records is reduced and it is likely that the two records can be linked.

False Positives and False Negatives

Unfortunately, data collection of identifying fields is never perfect. For example, consider two addresses: “2010 North Crater Road” (in database A) versus “2010 North Crater” (in database B). Are they the same address or are they different? Is “3-1402 Riverside Park Apartments, Alexandria, VA 22303” the same as “5840 Cameron Run Terrace #1402, Alexandria, VA 22303”? It is, but how is the computer to know that? Thus, the problem of false positives and false negatives must be faced. In short, there is a trade-off between being wrongly identified (a false link) and being erroneously not identified (a false non-link), which will be discussed further later.

Why Is Record Linkage a “Hard” Problem?

Classification Problem Similar to Cluster Analysis or Concept Learning

Record linkage is a special case of what are called “pattern classification” problems, which are well studied by both computer scientists and statisticians. The “record linkage as pattern classification” problem can be described very simply: given certain characteristics, should the object (a pair of records) be classified in the YES group (link them) or in the NO group (do not link them)? Consider a simplistic rule: Declare two (person) records “linked” if their first and last names match 100% on a character-for-character basis. Certainly this is a reasonable rule. However, consider the two (fictitious) records shown in [Table I](#). The proposed simplistic rule links these records, but this is clearly a “false positive.” Now consider the same rule using the records shown in [Table II](#): “Art” is, of course, just a nickname for “Arthur.” But now the

Table I Records That We Decide to Link (Under a Simplistic Rule)

<i>First name</i>	<i>Middle name</i>	<i>Last name</i>	<i>Suffix</i>	<i>Month of birth</i>	<i>Day of birth</i>	<i>Year of birth</i>
Arthur	F.	Jones	—	05	22	1971
Arthur	—	Jones	II	02	22	1988

Table II Records That We Decide Not to Link (Under a Simplistic Rule)

<i>First name</i>	<i>Middle name</i>	<i>Last name</i>	<i>Suffix</i>	<i>Month of birth</i>	<i>Day of birth</i>	<i>Year of birth</i>
Arthur	F.	Jones	—	05	22	1971
Art	F	Jones	—	05	22	1971

simplistic rule does not link these records and a “false negative” has been created.

Large Search Space, Small Target Subset

Record linkage is simply finding a subset (all the pairs that are declared “linked”) of a set (all possible pairs). However, record linkage problems are particularly challenging for three reasons:

1. As the number of records in either file increases, the number of possible comparisons increases as the product of the two file sizes. However, even ignoring duplication within a file, the number of matched pairs increases only as the minimum of the size of each file. Thus, for any reasonably sized record linkage problem, the size of the target subset becomes proportionally smaller and smaller relative to the size of the search space.
2. In practice, often there is no labeled training data set—that is, a collection of pairs of records that have been “hand coded” as either links or not links. This means that the problem is fundamentally a latent class problem, with the two latent classes being those pairs that indeed should be linked, and those that should not.
3. Finally, even records describing different people (or addresses) look quite a bit alike (as in [Table I](#)).

To illustrate the first reason, imagine two databases lined up in order, database A on the horizontal, database B on the vertical, as in [Fig. 1](#). Here, an M represents a match between records that should be linked. A blank means that two records should not be linked. The target subset is the diagonal of Ms, but as the table gets larger, it should be obvious that the search space (all pairs) is growing much faster than the target subset is. To illustrate the second reason that record linkage is a problem, simply mix up the data (just like real data) and remove the Ms (as in [Fig. 2](#)). In large databases, the search space is huge. To illustrate the third reason, consider the pairs of records shown in [Fig. 3](#); here the nearby records look a lot like matching records. Address one (101 Elm Street #1 97111) looks a lot like address two (101 Elm Court Apt.1 97111). But address two also looks a lot like address three, and, in fact, address three looks a lot like address four. But no one would like to link address one with address four.

Record #	1	2	3	4	5	...	<i>n</i>
1	M						
2		M					
3			M				
4				M			
5					M		
...						...	
<i>N</i>							M

Figure 1 Illustration of the space of all possible record pairs. Each M represents a match between records that should be linked; a blank means that two records should not be linked.

Record #	1	482	505	432	123	...	<i>n</i>
1							
142							
16							
4							
505							
...						...	
<i>N</i>							

Figure 2 Illustration of the space of all possible record pairs when the data shown in Fig. 1 are jumbled.

1	101 Elm Street #1 97111	vs.	101 Elm Court Apt.1 97111	2
2	101 Elm Court Apt.1 97111	vs.	101 Elm Street Apt.1 97111	3
3	101 Elm Street Apt.1 97111	vs.	101 Elm Street Apt.2 97111	4

Figure 3 Illustration of how “nearby” addresses look a lot like “matching” addresses.

Thus, in many cases, without a unique identifier, record linkage has been described as “searching for a needle in a haystack.” This metaphor is entirely misleading, however. The record linker is not searching for a needle in a haystack, but rather for a needle in a stack of needles.

How to Perform Computerized Record Linkage?

Parsing and Preediting

A necessary pair of steps to computerized record linkage is parsing the incoming data and applying any necessary

precredits. The complexity and importance of these steps are generally underappreciated; the programs needed to parse and interpret strings consistently are known as “standardizers,” and they are not easy to write. Consider, as an example, the strings “3-1402 Cameron Run Terrace” and “5840 Cameron Run Terrace # 1402.” Assuming that these each represent the same apartment in an apartment complex, which number in which position represents the apartment, and, more importantly, is it possible to write a computer program to pick out that number automatically? Further, can this standardizer pick out the apartment number correctly virtually every time? This is an area of very active research.

Character Matching

The most natural method of linking records, as already discussed, is some character-by-character matching of fields in the database. The primary weaknesses of character matching relate to inflexibility. Another type of weakness is nonuniqueness of the link/nonlink decision.

Sliding Windows

As an alternative to character matching, once a database has been parsed into fields, the database can be sorted according to different fields (for example, sort first by last name, then by first name, then by middle initial, then by year, month, and day of birth). Then, slide a “window” (of a predefined size) down the database, and compare all pairs of records within the window before sliding the window further.

Expert Systems

Character matching and “sliding windows” have the disadvantage that they rely only on the syntax of the fields, and not on their semantics. That is, when comparing “Arthur” to “Artie,” the character matchers do not use any special intelligence about the relationship between those two strings, rather, they “blindly” compare character to character. The sliding-windows approach, though using intelligence about the relative importance of fields, also does not use any special knowledge about the contents of the fields. An expert system attacks (and partially solves) this problem. Expert systems use collections of rules or clues designed by experts. These collections of rules can accumulate over time, providing locally specific rules to account for local conditions, special situations, and the like.

Fellegi–Sunter theory

In contrast to the previously discussed approaches, the Fellegi–Sunter model is a statistically principled approach to record linkage. This model is framed as

a “hypothesis test” when two records are compared. The separate fields are compared on a field-by-field basis, and the Fellegi–Sunter model uses information about the relative frequency of those fields to output one of three “decisions”: the records are declared to be a positive link, the records are declared to be a positive nonlink, or the decision “possible link” is returned. The “possible link” region is then sent to presumably expensive clerical review and resolution. If the positive link is (arbitrarily) labeled with 1, the possible link with 2, and the positive nonlink with 3, and the set A is considered to be all records in the first file, and the set B is all records in the second file, then the Fellegi–Sunter model is a function from the space $A \times B$ into the space $\{1, 2, 3\}$.

In the general Fellegi–Sunter model, the problem is framed as an ordering of configurations by their “weight.” For any collection of N individual fields \vec{x} , that configuration gets a ratio of match weight and nonmatch weight, $w(\vec{x}) = m(\vec{x})/w(\vec{u})$. The configurations are presumed ordered by this ratio (ties broken arbitrarily), indexed in order from highest weight to lowest weight, and cutoffs are chosen by defining a function $f(\vec{x})$ as follows (using the Fellegi–Sunter corollary 1 to ignore randomized choices falling exactly on a boundary):

$$f(\vec{x}) = \begin{cases} \text{Positive link} & \text{if index for } \vec{x} \geq \text{upper cutoff.} \\ \text{Positive nonlink} & \text{if index for } \vec{x} \text{ lower cutoff.} \\ \text{Possible link} & \text{if upper cutoff} > \text{index for } \vec{x} > \text{lower cutoff.} \end{cases}$$

The only remaining task is to define the weights w . In the standard Fellegi–Sunter model, denoting the event “the records are in fact a match” by M and “the records are in fact a nonmatch” by $\sim M$, these weights are defined as likelihood ratios, viz.,

$$w(\vec{x}) = \frac{P[\vec{x} \text{ configuration} | M]}{P[\vec{x} \text{ configuration} | \sim M]}.$$

The Fellegi–Sunter model demonstrated that these weights are optimal in the sense that, for a fixed false link rate α and fixed false nonlink rate μ , this decision rule, using these weights, minimizes the clerical review region. Typically, in practice, researchers make the “conditional independence assumption.” This assumption allows the weights in the preceding equation to be factored into

$$w(\vec{x}) = \ln \frac{P[x_1 = 1 | M]}{P[x_1 = 1 | \sim M]} \frac{P[x_2 = 1 | M]}{P[x_2 = 1 | \sim M]} \cdots \frac{P[x_N = 1 | M]}{P[x_N = 1 | \sim M]}.$$

When logarithms are taken, as is typically done in practice, this becomes a sum:

$$w^*(\vec{x}) = \ln \frac{P[x_1 = 1 | M]}{P[x_1 = 1 | \sim M]} + \ln \frac{P[x_2 = 1 | M]}{P[x_2 = 1 | \sim M]} + \cdots + \ln \frac{P[x_N = 1 | M]}{P[x_N = 1 | \sim M]}.$$

The term $P[x_i = 1 | M]$ is typically called a “match weight” or “ m -probability”, and the term $P[x_i = 1 | \sim M]$ is typically called a “nonmatch weight” or “ u -probability”; these terms are summed to construct a total score, compared to upper and lower (user-defined) cutoffs, and a decision is made.

Estimating these quantities is computationally intensive. In most applications, start values are provided by the analyst, and these start values are iteratively updated using a variant of the Expectation–Maximization (E–M) algorithm. Then, for candidate records pairs, the resulting weights are then summed and compared to the user-defined thresholds.

What Are Some Pitfalls of Computerized Record Linkage?
