Editor Biography

Dr. Kempf-Leonard is Professor of Sociology, Crime and Justice Studies, and Political Economy at the University of Texas at Dallas. Prior to her appointment at UTD in 2000, she was Associate Professor and Graduate Director of Criminology and Criminal Justice at the University of Missouri at St. Louis. She also served for ten years as a gubernatorial appointee to the Missouri Juvenile Justice Advisory Group. She received her Ph.D. at the University of Pennsylvania in 1986; M.A. at the University of Pennsylvania in 1983; M.S. at the Pennsylvania State University in 1982; B.S. at the University of Nebraska in 1980. Her book *Minorities in Juvenile Justice* won the 1997 Gustavus Myers Award for Human Rights in North America. Her publications have appeared in: *Criminology, Justice Quarterly, Journal of Criminal Law & Criminology, Crime & Delinquency, Journal of Quantitative Criminology, Advances in Criminological Theory, Punishment & Society, Corrections Management Quarterly, the Journal of Criminal Justice, Criminal Justice Policy Review, The Justice Professional, Youth and Society, The Corporate Finance Reader*, and *The Modern Gang Reader.*

Editorial Board

Foreword

Not long ago, and perhaps still today, many would expect an encyclopedia of social measurement to be about quantitative social science. The *Encyclopedia of Social Measurement* excellently defies this expectation by covering and integrating both qualitative and quantitative approaches to social science and social measurement. The *Encyclopedia of Social Measurement* is the best and strongest sign I have seen in a long time that the barren opposition between quantitative and qualitative research, which has afflicted the social sciences for half a century, is on its way out for good. As if the Science Wars proper—between the social and natural sciences—were not enough, some social scientists found it fitting to invent another war within the social sciences, in effect a civil war, between quantitative and qualitative social science. Often younger faculty and doctoral students would be forced to take sides, and the war would reproduce within disciplines and departments, sometimes with devastating effects. This, no doubt, has set social science back. We cannot thank the editors and contributors to the *Encyclopedia of Social Measurement* enough for showing us there is an effective way out of the malaise.

This volume demonstrates that the sharp separation often seen in the literature between qualitative and quantitative methods of measurement is a spurious one. The separation is an unfortunate artifact of power relations and time constraints in graduate training; it is not a logical consequence of what graduates and scholars need to know to do their studies and do them well. The *Encyclopedia of Social Measurement* shows that good social science is opposed to an either/or and stands for a both/and on the question of qualitative versus quantitative methods. Good social science is problem-driven and not methodology-driven, in the sense that it employs those methods which for a given problematic best help answer the research questions at hand. To use a simple metaphor, asking whether social science is best served by qualitative or quantitative methods is about as intelligent as asking a carpenter whether a hammer or a saw is the better tool.

So far every effort has been unsuccessful in the social sciences at arriving at one canon for how to do science, most conspicuously the attempt at emulating the natural science model. Different explanations exist of this phenomenon, from Anthony Giddens' so-called double hermeneutic to Hubert Dreyfus' tacit skills argument. It is a great strength of the *Encyclopedia of Social Measurement* that it stays clear of the unity of science argument for social science, and of any other attempts at imposing one dominant paradigm on what social science is and how it should be conducted. The editors and most of the contributors have rightly seen that success in social science and social measurement lies with the type of methodological and epistemological pluralism, which is a distinguishing feature of the encyclopedia. Together with its impressive substantive breadth—covering the full range of social measurement from anthropology, sociology, political science, economics, and business administration over urban studies, environment, geography, demography, history, criminology, and law to neuroscience, biomedicine, nursing, psychology, linguistics, and communication—this healthy pluralism will prove the *Encyclopedia of Social Measurement* to be a robust and indispensable companion to all working social scientists for many years to come.

BENT FLYVBJERG
Professor of Planning,
Department of Development and Planning,
Aalborg University, Denmark

Preface

> *Methodology . . . [has] developed as a bent of mind rather than as a system of organized principles and procedures. The methodologist is a scholar who is above all analytical in his approach to his subject matter. He tells other scholars what they have done, or might do, rather than what they should do. He tells them what order of finding has emerged from their research, not what kind of result is or is not preferable. This kind of analytical approach requires self-awareness on the one hand, and tolerance, on the other. The methodologist knows that the same goal can be reached by alternative roads.*
>
> (Lazarsfeld and Rosenberg, 1955, p. 4)

In the social sciences we use methodology to try to answer questions about how and why people behave as they do. Some types of behavior are very common or routine, while others happen rarely or only in certain situations. When you realize that every conceivable type of behavior is within the realm of possible subjects for us to study, you can begin to appreciate the scope of social science. Beyond identifying human activities and the boundaries in which they occur, social scientists also want to explain why behaviors happen. In looking for causes, social scientists pursue all dimensions of the social world. We look at personal traits of individuals, characteristics of interactions between people, and contextual features of the communities and cultures in which they live. We study people who lived in the past, try to improve the quality of life today, and anticipate what the future will hold. It is difficult to think of a topic that involves people for which a social scientist could not investigate.

Given all we do, it is good that there are so many of us. You will find social scientists in university departments as professors of sociology, psychology, anthropology, political science, and economics. You will also find professors of geography, history, philosophy, math, management, planning, finance, journalism, architecture, humanities, and art who are social scientists. Even this multidisciplinary list is not exhaustive. There are important and prevalent social science investigations that influence decision-making in the world outside of universities too. Social scientists are world-wide and work in all branches of government, large and small organizations, and many types of businesses. Daily life for most people is influenced by social science research in marketing, insurance, and government. However, not everyone in these positions is a social scientist; the distinction involves scientific inquiry, or the approach used to try to answer questions about behavior. As the definition cited above conveys, good science includes tolerance and appreciation for many methodological paths. This encyclopedia of social science methodology provides 356 entries written by social scientists about what they do.

The entries in this encyclopedia cover many forms of measurement used by social scientists to study behavior. Eleven substantive sections delineate social sciences and the research processes they follow to measure and provide knowledge on a wide range of topics. The encyclopedia has an extensive index too, because many topics include issues that are relevant in more than one section. From many perspectives and strategies, these volumes describe the research questions social scientists ask, the sources and methods they use to collect information, and the techniques they use to analyze these data and provide answers to the important questions.

Each section includes entries that address important components of quantitative and qualitative research methods, which are dissected and illustrated with examples from diverse fields of study. The articles convey research basics in sufficient detail to explain even the most complicated statistical technique, and references for additional information are noted for each topic. Most entries describe actual research experiences to illustrate both the realm of possibilities and the potential challenges that might be encountered. Some entries describe major contributions and the social scientists who made them. The authors are accomplished methodologists in their fields of study. They explain the steps necessary to accomplish the measurement goals, as well as provide their practical advice for ways in which to overcome the likely obstacles.

Collectively, the entries in this encyclopedia also convey that no single approach, type of data, or technique of analysis reigns supreme. Indeed, plenty of disagreements exist among social scientists about what constitutes the "best" measurement strategy. Often distinctions are made between quantitative and qualitative methodologies, or are

discipline-specific. Some preferences can be linked to a specific field of study or research topic; others, related to time and location, coincide with how new ideas and advances in technology are shared. Sometimes we don't even agree on what is the appropriate question we should try to answer!

Although our views differ on what is ideal, and even on what are the appropriate standards for assessing measurement quality, social scientists generally *do* agree that the following five issues should be considered:

1. We agree on the need to be clear about the scope and purpose of our pursuits. The benchmarks for evaluating success differ depending on whether our intent is to describe, explain, or predict and whether we focus extensively on a single subject or case (e.g., person, family, organization, or culture) or more generally on patterns among many cases.
2. We agree on the need to make assurances for the ethical treatment of the people we study.
3. We agree on the need to be aware of potential sources of measurement error associated with our study design, data collection, and techniques of analysis.
4. We agree it is important to understand the extent to which our research is a reliable and valid measure of what we contend. Our measures are reliable if they are consistent with what others would have found in the same circumstances. If our measures also are consistent with those from different research circumstances, for example in studies of other behaviors or with alternate measurement strategies, then such replication helps us to be confident about the quality of our efforts. Sometimes we'd like the results of our study to extend beyond the people and behavior we observed. This focus on a wider applicability for our measures involves the issue of generalizability. When we're concerned about an accurate portrayal of reality, we use tools to assess validity. When we don't agree about the adequacy of the tools we use to assess validity, sometimes the source of our disagreements is different views on scientific objectivity.
5. We also agree that objectivity merits consideration, although we don't agree on the role of objectivity or our capabilities to be objective in our research. Some social scientists contend that our inquiries must be objective to have credibility. In a contrasting view of social science, or epistemology, objectivity is not possible and, according to some, not preferable. Given that we study people and are human ourselves, it is important that we recognize that life experiences necessarily shape the lens through which people see reality.

Besides a lack of consensus within the social sciences, other skeptics challenge our measures and methods. In what some recently have labeled "the science wars," external critics contend that social scientists suffer "physics envy" and that human behavior is not amenable to scientific investigation. Social scientists have responded to "anti-science" sentiments from the very beginning, such as Emile Durkhiem's efforts in the 19th century to identify "social facts." As entertaining as some of the debates and mudslinging can be, they are unlikely to be resolved anytime soon, if ever. One reason that Lazarsfeld and Rosenberg contend that tolerance and appreciation for different methodological pathways make for better science is that no individual scientist can have expertise in all the available options. We recognize this now more than ever, as multidisciplinary teams and collaborations between scientists with diverse methodological expertise are commonplace, and even required by some sources of research funding.

Meanwhile, people who can be our research subjects continue to behave in ways that intrigue, new strategies are proffered to reduce social problems and make life better, and the tool kits or arsenals available to social scientists continue to grow. The entries in these volumes provide useful information about how to accomplish social measurement and standards or "rules of thumb." As you learn these standards, keep in mind the following advice from one of my favorite methodologists: "Avoid the fallacy fallacy. When a theorist or methodologist tells you you cannot do something, do it anyway. Breaking rules can be fun!" Hirschi (1973, pp. 171–2). In my view nothing could be more fun than contemporary social science, and I hope this encyclopedia will inspire even more social science inquiry!

In preparing this encyclopedia the goal has been to compile entries that cover the entire spectrum of measurement approaches, methods of data collection, and techniques of analysis used by social scientists in their efforts to understand all sorts of behaviors. The goal of this project was ambitious, and to the extent that the encyclopedia is successful there are many to people to thank. My first thank you goes to the members of the Executive Advisory Board and the Editorial Advisory Board who helped me to identify my own biased views about social science and hopefully to achieve greater tolerance and appreciation. These scientists helped identify the ideal measurement topics, locate the experts and convince them to be authors, review drafts of the articles, and make the difficult recommendations required by time and space considerations as the project came to a close. My second thank you goes to the many authors of these 356 entries. Collectively, these scholars represent well the methodological status of social science today. Third, I thank the many reviewers whose generous recommendations improved the final product. In particular I extend my personal thanks to colleagues at the University of Texas at Dallas, many of whom participated in large and small roles in this project, and all of whom have helped me to broaden my appreciation of social

measurement. Finally, I thank Scott Bentley, Kirsten Funk, Kristi Anderson, and their colleagues at Elsevier for the opportunity and their encouragement when the tasks seemed overwhelming. Scott's insights to the possibilities of a project such as this and the administrative prowess of both Kirsten and Kristi helped make this a reality.

Good science is a cumulative process, and we hope this project will be ongoing and always improving. Despite our best efforts to identify topics and authors, sometimes we failed. If you have suggestions, criticisms, or information worth considering, I hope you will let me know.

Paleodemography

James W. Wood
Pennsylvania State University, University Park, Pennsylvania, USA

Glossary

age-at-death distribution The distribution of individuals in a sample (e.g., a skeletal sample) by known or estimated ages at death. The empirical age-at-death distribution provides the fundamental data for paleodemographic analysis.

age mimicry A statistical bias whereby the estimated age-at-death distribution of a target sample (q.v.) tends to reproduce the known age-at-death distribution of whatever reference sample (q.v.) was used to generate it. This bias can be eliminated with the proper statistical methods.

ancient DNA (aDNA) Genetic material (mitochondrial or nuclear DNA) recovered from archaeological or paleontological samples using the polymerase chain reaction. In paleodemography and paleopathology, the aDNA of interest may be that of the actual humans being investigated or may be that of the pathogens infecting them or food remains associated with them.

demographic nonstationarity The failure of a population to conform to the theoretical ideal of a stationary population, i.e., one which is closed to in- and out-migration and has an intrinsic rate of increase equal to zero, age-specific schedules of fertility and mortality that are unchanging over time, and the equilibrium age distribution uniquely determined by those age-specific birth and death rates. In the presence of demographic nonstationarity, age-specific mortality rates cannot be estimated unless the effects of population increase are removed statistically.

paleopathology The branch of osteology concerned with the identification and classification of disease-related features in ancient tissues, especially in bone but also in dry soft tissue. The ultimate goal of paleopathology is to make inferences about disease frequency and health in ancient populations, concerns that also fall under the heading of paleoepidemiology.

reference sample A sample of skeletons with documented ages at death whose characteristics are used as a standard for estimating unknown ages in a target sample (q.v.). The documented ages are usually treated as known without error, which is probably never strictly the case and is sometimes very far from the truth.

taphonomy The study of the formation of paleontological or archaeological samples, including the processes of deposition, preservation, and recovery. Several biases in paleodemography are taphonomic in nature, including the tendency for skeletons of the very young to be underrepresented because of poor preservation.

target sample A sample of skeletons of unknown ages at death, usually from an archeological site, whose ages are to be estimated as a first step in paleodemographic analysis.

Paleodemography is the branch of biological anthropology devoted to the reconstruction of past populations using skeletal samples from archaeological excavations. Skeletons may be studied at the time of (or soon after) excavation, or may sit in museum collections for many years before being examined. In either case, paleodemographers use data on the distribution of skeletons by age at death and sex to reconstruct general population characteristics, especially mortality patterns. Paleopathological data on bony lesions indicative of growth faltering, infections, or chronic illness may provide supplementary information on individual-level health. Although serious methodological problems have dogged the field from its inception, recent advances hold promise that paleodemography will become an important and reliable source of information on the many populations in the past that did not leave more conventional demographic records.

Introduction

Paleodemography attempts to reconstruct past population structure using samples of human skeletons from archaeological excavations. Its chief claim to legitimacy

is that it provides demographic information—albeit of a limited, indirect, and uncertain sort—about the many human populations in the past that left no written records. In principle, it also allows reconstruction of demographic trends over time spans unattainable by any other branch of population science. Because of persistent methodological problems, however, paleodemographic analysis has achieved limited credibility among mainstream demographers. Yet while it is fair to say that past paleodemographic analyses were often too crude to be believable, it is also true that methodological advances over the past decade or so—advances with which most demographers are unfamiliar—have done much to place paleodemography on a firm scientific footing. The most important advances have been in the areas of age estimation, mortality analysis, adjustments for the effects of demographic nonstationarity on skeletal age-at-death distributions, and corrections for biases in the distribution of pathological lesions caused by selective mortality.

Age Estimation

Osteologists have made great progress in identifying reliable skeletal markers of age. Information on age at death is provided by such things as dental development, annual increments in dental cementum, closure of long-bone epiphyses and cranial sutures, and changes in the articular surfaces of the pelvis. Ages based on such features are subject to differing degrees of error arising from the inherent variability of the underlying processes of maturation and senescence; juveniles can be aged much more reliably than adults, and younger adults more reliably than older adults. But all paleodemographic age estimates are inherently error-prone and always will be. No matter how much osteological work is done to reduce the error and identify new age indicators, a large degree of aging error will always be a part of paleodemography. The deepest problems of paleodemographic age estimation are thus statistical rather than purely osteological.

In addition to a target sample (the archaeological skeletons whose ages are to be estimated), the paleodemographer needs access to a reference sample of skeletons whose ages at death are known (or at least documented, which is not always the same thing). Several well-known reference samples—for example, the Hamman-Todd and Terry Collections—provide reasonably accurate data on the joint distribution of c and a, where c is a vector of skeletal traits that provide information on age and a is age itself. For the target sample, however, we know only the marginal distribution of c, from which we hope to estimate the marginal distribution $\Pr(a)$ of ages at death. One of several parametric or nonparametric methods can be applied to data from the reference sample to estimate the conditional probability density or mass function $\Pr(c \mid a)$. If these estimates are to be used in aging archaeological skeletons, we need to make an invariance assumption that the joint distribution of c and a is identical in the two populations from which the reference and target samples were drawn. It is by no means clear that this assumption is warranted for many skeletal traits, and an ongoing goal of paleodemography is to identify indicators that are both informative about age and reasonably invariant across human populations.

Insofar as the invariance assumption is correct, it would seem to make sense to combine data on $\Pr(c)$ in the target sample and the joint distribution of a and c in the reference sample to estimate $\Pr(a \mid c)$ for each individual skeleton. But according to Bayes' theorem,

$$\Pr(a \mid c) = \frac{\Pr(c \mid a)\Pr(a)}{\int_0^\infty \Pr(c \mid x)\Pr(x)\, dx},$$

where $\Pr(a)$ is the age-at-death distribution in the target sample, which is unknown. Müller *et al.* have recently suggested using the marginal distribution

$$\Pr(c) \int_0^\infty \Pr(c \mid a)\Pr(a)\, da$$

as a basis for maximum likelihood estimation of $\Pr(a)$. If we provide a parametric specification for $\Pr(a)$—for example, as a Gompertz-Makeham, bi-Weibull, or Siler function—we can estimate the parameters of the age-at-death distribution by maximizing the likelihood function

$$L = \prod_{i=1}^{n} \Pr(c_i) = \prod_{i=1}^{n} \int_0^\infty \Pr^*(c_i \mid a)\Pr(a \mid \theta)\, da,$$

where n is the size of the target sample, c_i is the vector of skeletal characteristics observed in the ith skeleton in the target sample, θ is a set of parameters for the parametric $\Pr(a)$ model (to be estimated), and the asterisk denotes an empirical estimate from the reference sample. Once the parameters of $\Pr(a \mid \theta)$ have been estimated, the expected ages of individual skeletons can be found by a straightforward application of Bayes' theorem. This approach to age estimation is now called the *Rostock protocol* because it grew out of a series of workshops held at the Max Planck Institute for Demographic Research in Rostock, Germany, although significant parts of the protocol were anticipated in the earlier work of Konigsberg and Frankenburg.

It will seem strange to orthodox paleodemographers that they need to estimate the entire age-at-death distribution before they can estimate individual ages—the reverse of their usual procedure. But the Rostock protocol actually solves a number of problems that have long plagued paleodemography, including the problem of so-called age mimicry (the tendency of the estimated age-at-death distribution to be biased in the direction

of the age distribution—often highly unusual—of the reference sample) first noted by Bocquet-Appel and Masset. In addition, the method can be used to obtain, not just point or interval estimates of age, but the entire error structure of the age estimates. There are important statistical problems that remain to be solved, such as whether to use discrete categories or "staged" traits versus more continuous age indicators and how best to use multivariate skeletal data when traits are correlated in their age trajectories. But these problems can all be attacked within the framework of the Rostock protocol.

Mortality Analysis

For years paleodemographers have used skeletal age-at-death data to compute life tables based on some simple modifications of conventional life-table techniques originally developed by Acsádi and Nemeskéri. Though this approach is still a common one, the paleodemographic use of life tables can be criticized on several grounds. First, paleodemographic studies do not produce the kinds of data needed to compute life-table mortality rates using standard methods—specifically, the numbers of deaths among people at each (known) age and the number of person-years of exposure to the risk of death at that age during some well-defined reference period. Second, the use of fixed age intervals in the life table implies that the ages of all skeletons are known within the same margin of error, including those of fragmentary skeletons that exhibit only a few, unreliable indicators of age. Third, the life table is a wasteful way to use the small samples typical of paleodemographic studies—samples that are often on the order of a few dozen or a few hundred skeletons. In computing a life table we need to estimate one parameter (an age-specific mortality rate) for every age × sex category in the table. Few paleodemographic samples will support such an extravagant approach to estimation.

The Rostock protocol supports an alternative approach to paleodemographic mortality analysis. If unbiased estimates of the parameters of $\Pr(a \mid \theta)$ can be obtained for the target population of interest, and if the effects of demographic non-stationarity can be removed (see below), the parameter estimates can be used to derive the survival function, age-specific hazard of death, life-expectancies, and anything else we might hope to learn from life-table analysis.

Demographic Nonstationarity

Another shortcoming of traditional paleodemographic life-table analysis is that it assumes that the population under investigation was stationary—that it was closed to migration and had an intrinsic rate of increase equal to zero, age-specific schedules of fertility and mortality that were unchanging over time, and an equilibrium age distribution induced by those age-specific birth and death rates. Only in this special case is the empirical age distribution of skeletons expected to have a simple, straightforward relationship to the cohort age-at-death column in the life table.

As demographers have long realized, the age structure of a nonstationary population (and thus the number of its members at risk of death at each age) is more sensitive to changes in fertility than to similar changes in mortality. Thus, age-at-death distributions from different populations are at least as likely to reflect fertility differences as genuine differences in mortality. This incontrovertible fact of mathematical demography has given rise to the odd notion that paleodemographic age-at-death estimates are more informative about fertility than mortality. In fact, all we can ever hope to estimate about fertility from such data is the crude birth rate, which is scarcely a measure of fertility at all. But if we could correct for demographic nonstationarity, we could extract quite a bit of information about age-specific mortality from skeletons, and perhaps even estimate the population's growth rate.

Let $f_0(a)$ be the expected age-at-death distribution for a single birth cohort in the target population. If the target population was stationary, the same distribution holds for all deaths occurring in the population. But even if we cannot take it for granted that the population was stationary, it may be reasonable to assume that it was stable. That is, we may be able to make all the assumptions listed above for the stationary population, except allowing for the possibility of a nonzero growth rate. (The assumption of stability is much less restrictive than that of stationarity: even when fertility and mortality rates are changing and migration is occurring, most human populations still closely approximate a stable age distribution at any given time.) In a stable but nonstationary population, the age-at-death distribution is only partly a function of age-specific mortality; it is also influenced by the number of living individuals at risk of death at each age, which is influenced in turn by population growth. More precisely, the probability density function for ages at death in a stable population with growth rate r is

$$f_r(a) = \frac{\mu(a)S(a)e^{-ra}}{\int_0^\infty \mu(x)S(x)e^{-rx}\,dx} = \frac{f_0(a)e^{-ra}}{\int_0^\infty f_0(x)e^{-rx}\,dx},$$

where $\mu(a)$ is the force of mortality and $S(a)$ is the survival function at age a. This expression also applies to all the skeletons accumulated by a stable population over some more or less extended span of time—for example, the period over which skeletons were deposited in a particular cemetery. In principle, then, we can treat $f_r(a)$ as the $\Pr(a \mid \theta)$ function in the Rostock protocol and

estimate r as an additional parameter of the model, if we can assume that the population was stable. If it was not stable, at least approximately, we have probably reached the limits of what we can ever hope to learn about age-specific mortality from skeletal samples.

Selective Mortality and Paleopathological Analysis

When trying to interpret the mortality patterns of past populations, it would seem to make sense to use the information on individual-level health provided by the kinds of bony lesions studied by paleopathologists. Such lesions include marks in bones and teeth indicative of stress-related periods of growth faltering during preadult life, other dental and bony lesions caused by undernutrition (both general protein-calorie malnutrition and deficiencies of specific micronutrients), changes in the structure of bones caused by infection, and signs of chronic conditions such as arthritis and certain malignancies. Since most paleodemographers are also paleopathologists, the two kinds of analysis almost inevitably go together. There are, however, important problems in interpreting paleopathological findings at the population level that have received too little attention in the past.

The most obvious of these problems are the poor sensitivity and specificity of osteological indicators of health and disease. Most disease processes affect bone only in rare and unusually advanced cases; hence, bony lesions do not reveal most cases of the associated disease. In addition, specificity is poor because several unrelated disease processes can induce indistinguishable changes in bone. These problems are aggravated by the fact that most common diseases of the preindustrial past cause no bony changes whatsoever and thus go unmarked in the skeletal record. Much work needs to be done to develop more general osteological indicators of health and disease. One recent development that holds some promise is the extraction of microbial DNA from ancient bone, making it possible to detect the presence of infections that do not cause gross histological changes.

A deeper problem has to do with a form of selectivity bias that is inherent in the formation of skeletal samples. (This bias is quite distinct from the common taphonomic biases caused by differential burial and preservation.) All the individuals represented in a skeletal sample share one important characteristic: they are dead. As such, they are unlikely to be representative of the living community from which they were drawn. People who die at any given age presumably have characteristics that differentiate them from the larger group of living people originally at risk of death at that age. In particular, they are more likely to have pathological conditions, some of which may leave bony markers. In short, mortality is selective with respect to the very features of interest to the paleopathologist. While it is true that everyone dies eventually and (in theory) becomes available for paleopathological examination, it is also true that those who die are likely to have conditions, perhaps acquired soon before the time of death, that distinguish them from surviving members of their cohort.

Because of selective mortality, the frequency of pathological lesions in a skeletal sample is generally a poor reflection of the prevalence of the associated disease process in the living population. To understand the relationship between the two, it is necessary to model the process of selective mortality itself. This requires us, at a minimum, to model the individual-level distribution of risks of developing the pathological condition and the influence of the condition on the relative risk of death at each age. Recent work in this area has drawn upon models of heterogeneous frailty developed by mathematical demographers over the past two decades. While this work is promising, the problem of selective mortality is still a profound one for paleopathological analysis.

Prospects

During the past decade, the most important developments in paleodemography have been methodological, not substantive. But now that paleodemographic methods have become more sophisticated, there is every reason to expect that important empirical results will be forthcoming in the near future. It is likely, too, that the findings of paleodemography will be strengthened by the study of DNA extracted from ancient bones—a field that is already starting to provide insights into the ancestry and kinship structure of past populations, as well as the pathogens that infected them. There is also a new and encouraging movement to bring archaeological settlement studies—long an established approach to past population dynamics—into the purview of paleodemography. While mainstream demographers were once justified in dismissing the field of paleodemography, it may be time for them to rethink their skepticism.

Glossary

dichotomous scoring The use of two ordered categories to record the outcome of an individual's interaction with an item (usually "Right"/"Wrong").
objective comparison The possibility of comparing the locations of two parameters on a measurement variable independently of all other parameters and through two alternative observable events.
ordered response categories A set of ordered alternatives for recording the outcome of an individual's interaction with an item.
partial credit scoring The use of more than two ordered categories to record the outcome of an individual's interaction with an item (usually to recognize degrees of correctness or completion).
Rasch model A model for measuring based on the principle of objective comparison.

The partial credit model is a statistical model for the analysis of tests and questionnaires that provide several ordered response categories for each item. Examples of such items are test and examination questions that award part marks for partially complete or partially correct answers, rated student performances, and graded essay questions. The partial credit model is used to calibrate items of this general kind and to measure respondents along a latent measurement variable. The model is best understood as Rasch's model for dichotomies applied to adjacent pairs of response categories in an ordered sequence of categories.

Introduction

It is common in the social and behavioral sciences to use ordered response categories to record individuals' responses to measurement items. For example, respondents may be asked to indicate the frequency with which they engage in a particular activity by choosing one of several ordered time periods. They may be asked to indicate the strength of their agreement or disagreement with a statement by choosing from a set of ordered alternatives on a Likert scale. Or they may be asked to record their response by choosing one of a number of points on a provided scale (e.g., semantic differential).

In addition to measurement instruments that provide respondents with ordered response alternatives, many other instruments require judges to evaluate individuals' responses and to assign them to one of several ordered categories. For example, a psychologist may rate an aspect of a child's language development or the child's performance on a psychomotor task using a set of ordered rating points. In educational contexts, many areas of learning require judgments of the quality of students' responses to tasks, including instrumental music, dance, drama, written expression, art portfolios, research projects, oral language, computer programming, and technology (food, metals, ceramics, etc). In these areas of student learning it usually would be inadequate to record a response as either right or wrong. Judgments must be made of the quality of students' responses and work, and these judgments invariably are made and recorded against a scale of ordered possibilities. Points on this scale sometimes are labeled with letter grades (e.g., A to E) or numbers (e.g., 1 to 10).

In most systems of measurement, and certainly in the measurement of physical properties, individual instruments are calibrated against general measurement scales. The result is that measures such as 35 cm and 28°C have a meaning that does not depend on the particulars of the instrument used to obtain them. This characteristic is sometimes referred to as a distinguishing feature of measures.

Ordinary test, questionnaire, and examination scores do not have this property. A score of 35 items correct on a test does not have a general meaning; the ability required to score 35 will depend on the number and difficulties of the items on that particular test. The partial credit model is designed to convert performances on instruments measuring the same variable into numerical measures on a common scale. It is one of a number of statistical models developed to do this. The distinguishing properties of the model are that it can be used to calibrate items that provide multiple ordered response alternatives, and it belongs to the Rasch family of models.

Specific Objectivity

The partial credit model is a particular application of the model for dichotomies developed by Danish mathematician Georg Rasch. An understanding of the partial credit model thus depends on an understanding of Rasch's model for dichotomies, the properties of this model, and, in particular, Rasch's concept of specific objectivity.

Rasch used the term specific objectivity in relation to a property of the model for tests he developed during the 1950s. He considered this property to be especially useful in the attempt to construct numerical measures that do not depend on the particulars of the instrument used to obtain them.

This property of Rasch's model can be understood by considering two people A and B with imagined abilities θ_A and θ_B. If these two people attempt a set of test items and a tally is kept of the number of items N_{10} that person A answers correctly but B answers incorrectly and of the number of items N_{01} that person B answers correctly but A answers incorrectly, then under Rasch's model, the difference $\theta_A - \theta_B$ in the abilities of these two people can be estimated as:

$$\ln\left(\frac{N_{10}}{N_{01}}\right)$$

What is significant about this fact is that this relationship between the parameterized difference $\theta_A - \theta_{BAB}$ and the tallies N_{10} and N_{01} of observed successes and failures applies to *Any* selection of items when test data conform to Rasch's model. In other words, provided that the responses of A and B to a set of items are consistent with the model, the difference $\theta_A - \theta_{BAB}$ can be estimated by simply counting successes and failures without having to know or estimate the difficulties of the items involved. Any subset of items (e.g., a selection of easy items, hard items, even-numbered items, or odd-numbered items) can be used to obtain an estimate of the relative abilities of A and B from a simple tally table (Table I). The possibility of obtaining an estimate of the relative abilities of A and B that is not dependent on the details of the items used was referred to by Rasch as the possibility of specifically objective comparison.

Table I Tally Table

Person A \ *Person B*	*Wrong*	*Right*
Right	N_{10}	N_{11}
Wrong	N_{00}	N_{01}

Figure 1 Rasch's model begins with the idea of a measurement variable on which two objects A and B have imagined locations ξ_A and ξ_B.

Rasch's Model

In its most general form, Rasch's model begins with the idea of a measurement variable on which two objects A and B have imagined locations ξ_A and ξ_B (see Fig. 1). The possibility of estimating the relative locations of objects A and B on this variable depends on the availability of two observable events:

- An event X indicating that ξ_B exceeds ξ_A.
- An event Y indicating that ξ_A exceeds ξ_B.

Rasch's model relates the difference between objects AA and B to the events X and Y that they govern:

$$\xi_B - \xi_A = \ln\left(\frac{P_X}{P_Y}\right) \quad (1)$$

where P_X is the probability of observing X and P_Y is the probability of observing Y. Notice that, under the model, the odds P_X/P_Y of observing X rather than Y are dependent only on the direction and distance of ξ_B from ξ_A, and are uninfluenced by any other parameter. In 1977, Rasch described the comparison of two objects as objective if the result of the comparison was "independent of everything else within the frame of reference other than the two objects which are to be compared and their observed reactions."

An estimate of the difference between objects A and B on the measurement variable can be obtained if there are multiple independent opportunities to observe either event X or event Y. Under these circumstances, $\xi_B - \xi_A$ can be estimated as:

$$\ln\left(\frac{p_X}{p_Y}\right) = \ln\left(\frac{N_X}{N_Y}\right)$$

where p_X and p_Y are the proportions of occurrences of X and Y, and N_X and N_Y are the numbers of times X and Y occur in $N_X + N_Y$ observation opportunities.

Dichotomous Test Items

The most common application of Rasch's model is to tests in which responses to items are recorded as either wrong (0) or right (1). Each person n is imagined to have an ability θ_n and each item i is imagined to have a difficulty δ_i, both of which can be represented as locations on the variable being measured (see Fig. 2). In this case, observable event X is person n's success on item i, and observable event Y is person n's failure on item i, as shown in Table II Rasch's model applied to this situation is:

$$\tilde{\theta}_n - \delta_i = \ln\left(\frac{P_1}{P_0}\right) \tag{2}$$

If person n could have multiple independent attempts at item i, then the difference $\tilde{\theta}_n - \delta_i$ between person n's ability and item i's difficulty could be estimated as:

$$\ln\left(\frac{p_1}{p_0}\right) = \ln\left(\frac{N_1}{N_0}\right)$$

Although this is true in theory, and this method could be useful in some situations, it is not a practical method for estimating $\tilde{\theta}_n - \delta_i$ from test data because test takers are not given multiple attempts at the same item (and if they were, they would not be independent attempts). To estimate the difference $\tilde{\theta}_n - \delta_i$ from test data, it is necessary to estimate θ_n from person n's attempts at a number of items, and to estimate δ_i from a number of n's attempts at that item. In other words, the difficulties of a number of test items and the abilities of a number of test takers must be estimated simultaneously.

Comparing and Measuring Individuals

In the application of Rasch's model to tests, every person has an imagined location on the variable being measured. Two people m and n have imagined locations θ_m and θ_n (see Fig. 3). It follows from Eq. (2) that, if m and n attempt the same item and their attempts at that item are independent of one another, then the modeled difference between n and m is:

$$\tilde{\theta}_n - \theta_m = \ln\left(\frac{P_{10}}{P_{01}}\right) \tag{3}$$

where P_{10} is the model probability of person n succeeding but m failing the item, and P_{01} is the probability of person m succeeding but n failing that item.

It can be seen that Eq. (3) is Rasch's model, Eq. (1), applied to the comparison of two people on a measurement variable. The two observable events involve the success of one person but failure of the other in their attempts at the same item, as shown in Table III.

In this comparison of m and n, nothing was said about the difficulty of the item being attempted by these two people. This is because Eq. (3) applies to every item. The odds of it being person n who succeeds, given that one of these two people succeeds and the other fails, is the same for every item and depends only on the relative abilities of m and n.

Because the modeled odds P_{10}/P_{01} are the same for every item, the difference $\theta_n - \theta_m$ can be estimated as:

$$\ln\left(\frac{N_{10}}{N_{01}}\right)$$

where N_{10} is the number of items that person n has right but m has wrong, and N_{01} is the number of items that person m has right but n has wrong.

When test data conform to the Rasch model, the relative abilities of two individuals can be estimated in this way using any selection of items without regard to their difficulties (or any other characteristics). By making multiple pairwise comparisons of this kind, it is possible to estimate the relative locations of a number of people on the same measurement variable.

Comparing and Calibrating Items

In the application of Rasch's model to tests, every item has an imagined location on the variable being measured.

Figure 2 Each person n is imagined to have an ability θ_n and each item i is imagined to have a difficulty δ_i, both of which can be represented as locations on the variable being measured.

Figure 3 In an application of Rasch's model to tests, two people, m and n, have imagined locations θ_m and θ_n.

Table II Dichotomous Testing

$\xi_B - \xi_A$	*Observation opportunity*	*Observable event* X	Y
$\theta_n - \theta_i$	Person n attempts item i	1	0

Table III Dichotomous Testing, Comparing Individuals

$\xi_B - \xi_A$	*Observation opportunity*	*Observable event* X	Y
$\theta_n - \theta_m$	Individuals n and m independently attempt the same item	1,0	0,1

Figure 4 In an application of Rasch's model to tests, two items i and j have imagined locations δ_i and δ_j.

Table IV Dichotomous Testing, Comparing Items

$\xi_B - \xi_A$	*Observation opportunity*	*Observable event* X	Y
$\delta_i - \delta_j$	Items i and j independently attempted by the same person	0,1	1,0

Two items i and j have imagined locations δ_i and δ_j (see Fig. 4). It follows from Eq. (2) that, if items $i$and j are attempted by the same person and this person's attempts at items i and j are independent of one another, then the modeled difference between items i and j is:

$$\delta_i - \delta_j = \ln\left(\frac{P_{01}}{P_{10}}\right) \tag{4}$$

where P_{10} is the model probability of the person succeeding on item i but failing item j, and P_{01} is the probability of the person succeeding on item j but failing item i.

It can be seen that Eq. (4) is Rasch's model, Eq. (1), applied to the comparison of two items on a measurement variable. The two observable events involve the person's success on one item but failure on the other, as shown in Table IV.

In this comparison of items i and j, nothing was said about the ability of the person attempting them. This is because Eq. (4) applies to every person. The odds of success on item i given success on one item but failure on the other is the same for every person and depends only on the relative difficulties of items i and j.

Because the modeled odds P_{01}/P_{10} are the same for every person, the difference $\delta_i - \delta_j$ can be estimated as:

$$\ln\left(\frac{n_{01}}{n_{10}}\right)$$

where n_{10} is the number of people with item i right but j wrong, and n_{01} is the number of people with j right but i wrong.

When test data conform to the Rasch model, the relative difficulties of two items can be estimated in this way using any group of people without regard to their abilities (or any other characteristics). By making multiple pairwise comparisons of this kind, it is possible to estimate the relative locations of a number of items on the measurement variable.

Figure 5 When the model is applied to tests in which responses to items are recorded in several ordered categories labeled 0, 1, 2, . . . , K_i, each person n is imagined to have an ability θ_n and each item i is imagined to have a set of K_i parameters δ_{i1}, $\delta_{i2}, \ldots, \delta_{iK_i}$, each of which can be represented as a location on the variable being measured.

Table V Dichotomous Testing, Ordered Categories

$\xi_B - \xi_A$	*Observation opportunity*	*Observable event* X	Y
$\theta_n - \delta_{ik}$	Person n attempts item i	k	$k-1$

Application to Ordered Categories

The partial credit model applies Rasch's model for dichotomies to tests in which responses to items are recorded in several ordered categories labeled 0, 1, 2, . . . , K_i. Each person n is imagined to have an ability θ_n and each item i is imagined to have a set of K_i parameters δ_{i1}, $\delta_{i2}, \ldots, \delta_{iK_i}$, each of which can be represented as a location on the variable being measured (see Fig. 5), where δ_{ik} governs the probability of scoring k rather than $k-1$ on item i, as shown in Table V.

The Rasch model applied to this situation is:

$$\tilde{\theta}_n - \delta_{ik} = \ln\left(\frac{P_k}{P_{k-1}}\right) \tag{5}$$

In polytomous test items, objective comparison (and thus objective measurement) continues to depend on the modeling of the relationship between two imagined locations on the variable and two observable events. This comparison is "independent of everything else within the frame of reference," including other possible outcomes of the interaction of person n with item i. The conditioning out of other possible outcomes to focus attention only on the two observable events that provide information about the relative locations of the two parameters of interest is a fundamental feature of Rasch's model.

The conditioning on a pair of adjacent response alternatives has parallels with McFadden's 1974 assumption that a person's probability of choosing to travel by car rather than by bus should be independent of the availability of other options (e.g., train). McFadden referred to this as the assumption of "independence from irrelevant alternatives." In a similar way, it is assumed in this application of Rasch's model that a person's probability of

choosing or scoring k rather than $k-1$ is independent of all other possible outcomes.

When a person responds to an item with several ordered response categories, he or she must make a choice, taking into account all available alternatives. The partial credit model makes no assumption about the response mechanism underlying a person's choice. It simply proposes that, if category k is intended to represent a higher level of response than category $k-1$, then the probability of choosing or scoring k rather than $k-1$, should increase monotonically with the ability being measured.

As for dichotomously scored items, if person n could have multiple independent attempts at item i, then the difference $\tilde{\theta}_n - \delta_{ik}$ could be estimated from proportions or counts of occurrences of k and $k-1$:

$$\ln\left(\frac{p_k}{p_{k-1}}\right) = \ln\left(\frac{N_k}{N_{k-1}}\right)$$

However, because multiple independent attempts at test items usually are not possible, this method is not feasible in practice.

Comparing and Measuring Individuals

In the application of Rasch's model to tests in which responses to items are recorded in several ordered categories, every person has an imagined location on the variable being measured (see Fig. 6). It follows from Eq. (5) that, if individuals m and n attempt the same item and their attempts at that item are independent of one another, then the modeled difference between n and m is:

$$\tilde{\theta}_n - \theta_m = \ln\left(\frac{P_{k,k-1}}{P_{k-1,k}}\right) \tag{6}$$

where $P_{k,k-1}$ is the model probability of person n scoring k but m scoring $k-1$, and $P_{k-1,k}$ is the probability of person m scoring k but n scoring $k-1$ on that item.

It can be seen that Eq. (6), which applies for all values of k ($k = 1, 2, \ldots, K_i$), is Rasch's model, Eq. (1) (see Table VI). If one of either m and n scores k on an item, and the other scores $k-1$, then the probability of it being person n who scores k is the same for every item and depends only on the relative abilities of m and n.

Figure 6 In the application of Rasch's model to tests in which responses to items are recorded in several ordered categories, every person has an imagined location on the variable being measured.

Because the modeled odds $P_{k,k-1}/P_{k-1,}$k are the same for every item, the difference $\theta_n - \theta_m$ can be estimated as:

$$\ln\left(\frac{N_{k,k-1}}{N_{k-1,k}}\right)$$

where $N_{k,k-1}$ is the number of items on which person n scores k and m scores $k-1$, and $N_{k-1,k}$ is the number of items on which person m scores k and n scores $k-1$.

Once again, when test data conform to Rasch's model—the relative abilities of two people can be estimated in this way using any selection of items. And by making multiple pairwise comparisons of this kind, it is possible to estimate the relative locations of a number of people on the measurement variable.

Comparing and Calibrating Items

In polytomous items, each item parameter δ_{ik} ($k = 1, 2, \ldots, K_i$) is a location on the variable being measured. The parameters δ_{ik} and δ_{jk} from two different items i and j can be compared on this variable (see Fig. 7). It follows from Eq. (5) that, if items i and $j$are attempted by the same person and this person's attempts at items i and $j$are independent of one another, then the modeled difference between parameters δ_{ik} and δ_{jk} is:

$$\tilde{\delta}_{ik} - \delta_{jk} = \ln\left(\frac{P_{k-1,k}}{P_{k,k-1}}\right) \tag{7}$$

where $P_{k,k-1}$ is the probability of the person scoring k on item i but $k-1$ on item j, and $P_{k-1,k}$ is the probability of the person scoring k on item j but $k-1$ on item i.

It can be seen that Eq. (7), which applies for all values of k ($k = 1, 2, \ldots, K_i$), is Rasch's model, Eq. (1) (see Table VII).

Table VI Dichotomous Testing, Comparing Individuals with Ordered Categories

		Observable event	
$\xi_B - \xi_A$	*Observation opportunity*	*X*	*Y*
$\beta_n - \beta_m$	Individuals n and m independently attempt the same item	$k, k-1$	$k-1, k$

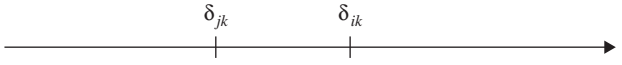

Figure 7 In polytomous items, each item parameter δ_{ik} ($k = 1, 2, \ldots, K_i$) is a location on the variable being measured. The parameters δ_{ik} and δ_{jk} from two different items i and j can be compared on this variable.

Table VII Polytomous Testing, Comparing Items

$\xi_B - \xi_A$	*Observation opportunity*	*Observable event* X	Y
$\delta_{ik} - \delta_{jk}$	Items i and j independently attempted by the same person	$k-1, k$	$k, k-1$

In this comparison of items i and j, nothing was said about the ability of the person attempting them. This is because Eq. (7) applies to every person. When a person attempts items i and j, the probability of the person scoring k on item i given that he or she scores k on one item and $k-1$ on the other is the same for every person.

Because the modeled odds $P_{k-1,k}/P_{k,k-1}$ are the same for every person, the difference $\delta_{ik}-\delta_{jk}$ can be estimated as:

$$\ln\left(\frac{n_{k-1,k}}{n_{k,k-1}}\right)$$

where $n_{k,k-1}$ is the number of people scoring k on item i but $k-1$ on item j, and $n_{k-1,k}$ is the number of people scoring k on item j but $k-1$ on item i.

When test data conform to Rasch's model, the difference $\delta_{ik}-\delta_{jk}$ can be estimated in this way using any group of people without regard to their abilities (or any other characteristics).

Comparisons with Other Models

The partial credit model is one of a number of models that have been introduced for the analysis of ordered response category data. To understand similarities and differences between these models, it is useful to identify two broad classes of models.

Models with Discrimination Parameters

In some models proposed for the analysis of test data, in addition to a location θ_n for each person n and a location δ_i for each item i, a discrimination parameter α_i is proposed for each item i. Among models for ordered response categories that include a discrimination parameter are Samejima's graded response model and Muraki's generalized partial credit model.

These models differ from the partial credit model in that they enable specifically objective comparisons, as described by Rasch. The reason for this can be seen most easily in two-parameter dichotomous item response theory (IRT) model:

$$\alpha_i(\tilde{\theta}_n - \delta_i) = \ln\left(\frac{P_1}{P_0}\right) \tag{8}$$

If we follow the steps outlined earlier and consider independent attempts of two people m and n at item i, then for the two-parameter IRT model we obtain:

$$\alpha_i(\tilde{\theta}_n - \theta_m) = \ln\left(\frac{P_{10}}{P_{01}}\right) \tag{9}$$

where P_{10} is the probability of person n succeeding but m failing item i, and P_{01} is the probability of person m succeeding but n failing.

It can be seen from Eq. (9) that the odds of person n succeeding but m failing, given that one of these two people succeeds and the other fails, is not the same for all items. Rather, the odds depend on the discrimination of the item in question.

To compare the locations of m and n on the measurement variable, it is not possible to ignore the particulars of the items involved and simply tally occurrences of (1,0) and (0,1). The comparison of θ_n and θ_m on the measurement variable is dependent not only on the two observable events (1,0) and (0,1) that they govern, but also on the details (the discriminations) of the items these two people take. For this reason, the two-parameter IRT model does not permit an objective comparison in the sense described by Rasch.

Models with Cumulative Thresholds

A second class of models for ordered response categories includes as parameters cumulatively defined thresholds. Each threshold parameter is intended to divide all ordered response alternatives to an item up to and including alternative $k-1$ from response alternatives k and above. L. L. Thurstone, who used the normal rather than logistic function to model thresholds referred to them as "category boundaries."

The threshold notion is used as the basis for Samejima's graded response model. Her model also includes an item discrimination parameter, but that is ignored here for the sake of simplicity. Samejima's model takes the form:

$$\theta_n - \gamma_{ik} = \ln\left[\frac{(P_k + P_{k+1} + \cdots + P_{K_i})}{(P_0 + P_1 + \cdots + P_{k-1})}\right]. \tag{10}$$

In this model, the item threshold γ_{ik} governs the probability of scoring k or better on item i.

Table VIII compares Samejima's graded response model with the partial credit model for an item with four ordered response alternatives labeled 0, 1, 2, and 3.

Table VIII Comparison of Samejima and Rasch Models for Polytomous Items

	Samejima	*Rasch*
Elementary equations (person n, item i, $K_i = 3$)	$\theta_n - \gamma_{i1} = \ln[(P_1 + P_2 + P_3)/P_0]$ $\theta_n - \gamma_{i2} = \ln[(P_2 + P_3)/(P_0 + P_1)]$ $\theta_n - \gamma_{i3} = \ln[P_3/(P_0 + P_1 + P_2)]$	$\theta_n - \delta_{i1} = \ln[P_1/P_0]$ $\theta_n - \delta_{i2} = \ln[P_2/P_1]$ $\theta_n - \delta_{i3} = \ln[P_3/P_2]$
Events being compared	Compound (e.g., response in category 1 or 2 or 3 rather than 0)	Simple (comparison of adjacent response categories)
Item parameters	Global/unconditional (each γ relates to all available response categories)	Local/conditional (each δ relates to adjacent response categories only)
Relationship of elementary equations	Dependent $(P_1 + P_2 + P_3)/P_0 > (P_2 + P_3)/(P_0 + P_1) > P_3/(P_0 + P_1 + P_2)$	Independent (e.g., odds of response in category 1 rather than 0 are independent of odds of response in category 2 rather than 1)
Implications for item parameters	$\gamma_{i1} < \gamma_{i2} < \gamma_{i3}$	δs are unfettered and free to take any value
Model for ordered categories	When brought together, the elementary equations provide a model for ordered response categories in which the person parameters cannot be conditioned out of the estimation procedure for the items	The elementary equations provide a model for ordered response categories in which the person parameters can be conditioned out of the estimation procedure for the items and vice versa
Specific objectivity	No	Yes

From Table VIII it can be seen that the observable events in this model are compound events, that is,

Event X: response in category 1 or 2 or 3
Event Y: response in category 0

The consequence is that the elementary equations in this model are not independent because $(P_1 + P_2 + P_3)/P_0 > (P_2 + P_3)/(P_0 + P_1) > P_3/(P_0 + P_1 + P_2)$. As a result, thresholds are not independent, but are always ordered $\gamma_{i1} < \gamma_{i2} < \gamma_{i3}$.

The elementary equations in Samejima's model lead to the following expressions for the probabilities of person n scoring 0, 1, 2, and 3 on item i:

$$P_{ni0} = 1 - \exp(\theta_n - \gamma_{i1})/[1 + \exp(\theta_n - \gamma_{i1})]$$

$$P_{ni1} = \exp(\theta_n - \gamma_{i1})/[1 + \exp(\theta_n - \gamma_{i1})] - \exp(\theta_n - \gamma_{i2})/[1 + \exp(\theta_n - \gamma_{i2})]$$

$$P_{ni2} = \exp(\theta_n - \gamma_{i2})/[1 + \exp(\theta_n - \gamma_{i2})] - \exp(\theta_n - \gamma_{i3})/[1 + \exp(\theta_n - \gamma_{i3})]$$

$$P_{ni3} = \exp(\theta_n - \gamma_{i3})/[1 + \exp(\theta_n - \gamma_{i3})]$$

It is not possible to condition one set of parameters (either the person parameters or the item thresholds) out of the estimation procedures for the other in this model.

In contrast, the elementary equations for the Rasch model (see Table VIII) lead to the following expressions for the probabilities of person n scoring 0, 1, 2, and 3 on item i:

$$P_{ni0} = 1/\Psi$$

$$P_{ni1} = \exp(\theta_n - \delta_{i1})/\Psi$$

$$P_{ni2} = \exp(2\theta_n - \delta_{i1} - \delta_{i2})/\Psi$$

$$P_{ni3} = \exp(3\theta_n - \delta_{i1} - \delta_{i2} - \delta_{i3})/\Psi$$

where Ψ is the sum of the numerators. In general, the partial credit model takes the form:

$$P_{nik} = \exp(k\theta_n - \delta_{i1} - \delta_{i2} - \cdots - \delta_{ik})/\Psi. \qquad (11)$$

It is possible to condition the person parameters out of the estimation procedures for the item parameters, and vice versa, in this model.

Other Rasch Models

As a member of the Rasch family of item response models, the partial credit model is closely related to other members of that family. In 1984, Masters and Wright described several members of this family and showed how each has as its essential element Rasch's model for dichotomies. Andrich's 1978 model for rating scales, for example, can be thought of as a version of the partial credit model with the added expectation that the response categories are defined and function in the same way for each item in an instrument. With this added expectation, instead of modeling a set of

m_i parameters for each item, a single parameter δ_i is modeled for item i, and a set of m parameters (τ_1, $\tau_2, \ldots, \tau_m$) are proposed for the common response categories. To obtain the rating scale version of the partial credit model, each item parameter in the model is redefined as $\delta_{ix} = \delta_i + \tau_x$. Wilson also has proposed a generalized version of the partial credit model in 1993.

Substantive Calibration of Measurement Variables

When the partial credit model is applied, it provides estimates of the item parameters (δ_{i1}, $\delta_{i2}, \ldots, \delta_{im_i}$) for each item i. When these estimates are substituted into Eq. (11), the estimated probabilities of scoring $0, 1, \ldots, m_i$ on item i are obtained for any specified ability $\hat{\theta}$

Figure 8A shows the model probabilities of scoring 0, 1, 2, and 3 on a four-category item calibrated with the partial credit model. Notice that the maxima of the response curves are in the order $0 < 1 < 2 < 3$ from left to right. This is a basic feature of the model; the response curve maxima are always ordered $0 < 1 < 2 < \cdots < m_i$ on the measurement variable.

The item parameters (δ_{i1}, δ_{i2}, $\ldots$, δ_{im_i}) have a simple interpretation in this picture. Each parameter δ_{ix} corresponds to the position on the measurement variable at which a person has the same probability of responding in category x as in category $x-1$ (i.e., $P_{ijx} = P_{ijx-1}$). The parameter estimates for the item in Figure 8A are thus at the intersections of the response curves for categories 0 and 1, 1 and 2, and 2 and 3.

The person ability parameter θ_j in the partial credit model is the modeled location of person j on the variable being measured. For each item i scored $0, 1, \ldots, m_i$, the model defines a set of m_i item parameters. These parameters, all of which are locations on the measurement variable, can be used to map the qualitative meaning of the variable and to interpret person parameters.

In the case of items scored right or wrong, only one parameter is estimated for each item and these item difficulties mark out and give qualitative meaning to a variable. Levels of ability are differentiated in terms of the kinds of items likely to be answered correctly. By convention, "likely" means with a probability ≥ 0.5, although in some testing programs higher probabilities of success (e.g., ≥ 0.7 or ≥ 0.8) are specified.

Open-ended and performance tasks of the kind the partial credit model is designed to analyze are usually intended to be accessible to a wide range of abilities and to differentiate among test takers on the basis of their levels of response. Response categories for each item capture this response diversity and thus provide the basis for the qualitative mapping of measurement variables and the consequent interpretation of ability estimates. For items with more than two response categories, however, the mapping of response categories on to measurement variables is a little less straightforward than for right/wrong scoring.

As previously noted, because each item parameter in the partial credit model is defined locally with respect to just two adjacent categories (rather than globally taking into account all categories simultaneously), the item parameters in the model can take any order. For the item in Fig. 8A they are ordered $\delta_{i1} < \delta_{i3} < \delta_{i2}$. Because they have this property, these parameters may not, in themselves, be helpful in marking out regions of an underlying variable. Three useful alternatives are illustrated in Fig. 8A–C.

The first method, illustrated in Fig. 8A, identifies regions of single most probable response to an item. The three shaded regions at the bottom of Fig. 8A indicate the single most probable response (0, 1, or 3) for the range of abilities shown.

A disadvantage of this method is that, in this case, it defines no region for a score of 2. In fact, it gives the impression that category 2 has disappeared entirely.

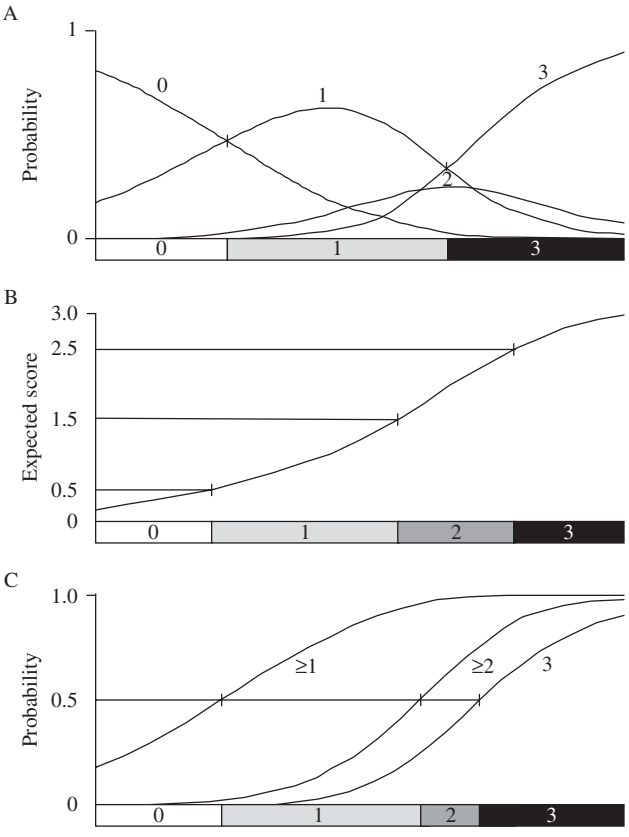

Figure 8 Probability and cumulative probability curves for the partial credit model.

This is not the case—a score of 2 on this item is a quite likely result ($p = 0.28$) for an ability at the junction of curves 1 and 3. When partial credit model item parameters are in the order $\delta_{i1} < \delta_{i2} < \delta_{i3}$, the parameters mark out regions of single most probable response for all categories. However, as can be seen from Fig. 8A, other orders of partial credit model item parameters are possible.

Some caution is required in the interpretation of "most probably" statements. Toward the far right of the shaded region labeled 1 in Fig. 8A, it is *not* the case that people will most probably score 1. Because the sum of the probabilities for categories 2 and 3 exceeds the probability of a response in category 1, people with abilities in this part of the continuum are more likely to score at least 2 than to score only 1. This observation makes it clear that the most useful method of mapping response categories onto underlying measurement variables is not obvious when items are scored in more than two categories.

The second method, illustrated in Fig. 8B, is based on the calculation of the expected score:

$$E_x = \sum_{h=0}^{m_i} hP_{ijh}. \tag{12}$$

In Fig. 8B, the abilities at which $E_x = 0.5$, 1.5, and 2.5 are identified. These are used to mark out an alternative set of response regions along the horizontal variable. An attraction of method B is that it is consistent with procedures for testing model-data fit that contrast a person's observed score on an item with his or her expected score. For expected scores between, say 1.5 and 2.5, the observed score that minimizes the observed-expected residual is a score of 2. In this sense, it might be argued that the 2 region of the measurement variable is best defined as that range of abilities for which the expected score is between 1.5 and 2.5. A disadvantage of this method is that it provides category regions that may seem implausibly wide.

The third method, illustrated in Fig. 8C, sums the curves in Fig. 8A. The curve labeled ≥ 1 is the result of summing curves 1, 2, and 3 in Fig. 8A. The curve labeled ≥ 2 is the result of summing curves 2 and 3. These cumulative ogives give the probability of scoring 1 or better, 2 or better, and 3 on this item. The abilities at which the cumulative probabilities equal 0.5 have been used to mark out a third set of regions. People with abilities in the 2 region in Fig. 8C will most probably (i.e., $p > 0.5$) score at least 2 on this item, but will most probably ($p > 0.5$) *not* score 3.

An attractive feature of this method is that it parallels the interpretation of variables constructed from dichotomously scored items. On a variable defined by dichotomous items, people's estimated location places them above items they will most probably pass ($p > 0.5$) and below items they will most probably fail ($p > 0.5$). Method C similarly interprets an individual's location by reference to thresholds they will most probably pass ($p > 0.5$) and thresholds they will most probably fail ($p > 0.5$).

Figure 8C also is helpful in distinguishing the partial credit model from models such as Samejima's graded response model. In the partial credit model, cumulative probabilities of the kind shown in Fig. 8C are not modeled directly but are the result of summing the category response functions in Fig. 8A, which in turn are the result of applying Rasch's model for dichotomies separately to each pair of adjacent categories. In the graded response model, cumulative probabilities *are* modeled directly. Thus, whereas the partial credit model gives the probability of person j scoring x on item i, the graded response model models the probability of person j scoring x or better on item i. As a result, the partial credit model is *not* a case of Samejima's graded response model (e.g., with equal item discriminations). This difference between the two models is sometimes misunderstood.

Parameter Estimation

Conditional and joint maximum likelihood procedures for estimating partial credit model parameters were described by Masters in 1982 and by Wright and Masters in 1982, who also describe a procedure based on the pairwise comparison of responses to items (PAIR) and a simplified procedure (PROX) based on the assumption that the effects of the person sample on item calibration and of the test on person measurement can be summarized by means and standard deviations on the variable. The essentials of the conditional and joint maximum likelihood procedures are summarized here.

Conditional Maximum Likelihood

The conditional maximum likelihood procedure begins with the conditional probability of the response vector (x_i) given test score r:

$$P\{(x_i); ((\delta_{ik}))|r\} = \frac{\exp\left(-\sum_i^n \sum_{k=0}^{xi} \delta_{ik}\right)}{\sum_{(x_q)}^r \exp\left(-\sum_i^n \sum_{k=0}^{xi} \delta_{ik}\right)}, \tag{13}$$

where $\delta_{i0} + 0$ and $\sum_{(x_q)}^r$ is the sum over all response vectors (x_q) that produce the score r.

The conditional probability of responding in category h of item i given score r is:

$$P^*_{irh} = \frac{\exp\left(-\sum_{k=0}^{h}\delta_{ik}\right)\sum_{x_q\neq i}^{r-h}\exp\left(-\sum_{q\neq i}^{n}\sum_{k=0}^{x_q}\delta_{qk}\right)}{\sum_{g=0}^{m_i}\left\{\exp\left(-\sum_{k=0}^{g}\delta_{ik}\right)\sum_{x_q\neq i}^{r-g}\exp\left(-\sum_{q\neq i}^{n}\sum_{k=0}^{x_q}\delta_{qk}\right)\right\}},$$
$$= \frac{\exp\left(-\sum_{k=0}^{h}\delta_{ik}\right)\gamma_{r-h,i}}{\gamma_r} \qquad (14)$$

where $\sum_{(x_{q\neq i})}^{r-h}$ is the sum over all response vectors $(x_{q\neq i})$ that exclude item i and produce the score $r-h$.

The conditional likelihood over N people with various scores is:

$$\Lambda = \prod_{j}^{N}\left[\frac{\exp\left(-\sum_{i}^{n}\sum_{k=0}^{x_{ij}}\delta_{ik}\right)}{\gamma_r}\right]$$
$$= \frac{\exp\left[-\sum_{j}^{N}\sum_{i}^{n}\sum_{k=0}^{x_{ij}}\delta_{ik}\right]}{\prod_{r}^{M-1}(\gamma_r)^{N_r}}, \qquad (15)$$

where $M = \sum_i^n m_i$ is the maximum possible score on the instrument:

$$\prod_{j}^{N}\gamma_r = \prod_{r}^{M-1}(\gamma_r)^{Nr}$$

and N_r is the number of people with a particular score r. The log likelihood can then be written:

$$\lambda = \log\Lambda = -\sum_{i}^{n}\sum_{k=1}^{m_i}S_{ik}\delta_{ik} - \sum_{r}^{M-1}N_r\log\gamma_r, \qquad (16)$$

where S_{ik} is the number of people scoring k or better on item i.

The estimation equations for the conditional maximum likelihood procedure require the first and second derivatives of the log-likelihood with respect to δ_{ih}. These are:

$$\frac{\partial\lambda}{\partial\delta_{ih}} = -S_{ih} - \sum_{r}^{M-1}\frac{N_r}{\gamma_r}\left(\frac{\partial\gamma_\lambda}{\partial\delta_{ih}}\right)$$
$$= -S_{ih} + \sum_{r}^{M-1}N_r\sum_{k=h}^{m_i}P_{irk} \qquad (17)$$

and

$$\frac{\partial^2\lambda}{\partial\delta_{ih}} = -\sum_{r}^{M-1}N_r\left(\sum_{k=h}^{m_i}P_{irk}\right)\left(1-\sum_{k=h}^{m_i}P_{irk}\right), \qquad (18)$$

where $\sum_{k=h}^{mi}P_{irk}$ is the probability of a person with score r scoring h or better on item i.

Joint Maximum Likelihood

The joint maximum likelihood procedure begins by modeling the likelihood of an entire data matrix (x_{ij}) as the continued product of the probabilities P_{ijx} over all people $j = 1, N$ and all items $i = 1, n$:

$$\Lambda = \prod_{j}^{N}\prod_{i}^{n}P_{ijx}$$
$$= \frac{\exp\sum_{j}^{N}\sum_{i}^{n}\sum_{h=0}^{x_{ij}}(\theta_j-\delta_{ih})}{\prod_{j}^{N}\prod_{i}^{k}\left[\sum_{h=0}^{m_i}\exp\sum_{h=0}^{h}(\theta_j-\delta_{ik})\right]}. \qquad (19)$$

The log-likelihood is:

$$\lambda = \log\Lambda = \sum_{j}^{N}\sum_{i}^{n}x_{ij}\theta_j - \sum_{j}^{N}\sum_{i}^{n}\sum_{h=1}^{x_{ij}}\delta_{ih}$$
$$-\sum_{j}^{N}\sum_{i}^{n}\log\left[\sum_{h=0}^{m_i}\exp\sum_{k=0}^{h}(\theta_j-\delta_{ik})\right],$$

which can be rewritten:

$$\lambda = \sum_{j}^{N}r_j\theta_j - \sum_{i}^{n}\sum_{h=1}^{m_i}S_{ih}\delta_{ih}$$
$$-\sum_{j}^{N}\sum_{i}^{n}\log\left[\sum_{h=0}^{m_i}\exp\sum_{k=0}^{h}(\theta_j-\delta_{ik})\right], \qquad (20)$$

where r_j is the score of person j on the instrument, and S_{ih} is the number of people scoring h or better on item i.

The first derivatives of λ with respect to θ_j and δ_{ih} are:

$$\frac{\partial\lambda}{\partial\theta_j} = r_j - \sum_{i}^{n}\sum_{k=1}^{m_i}kP_{ijk} \qquad j = 1,\ N$$

and

$$\frac{\partial\lambda}{\partial\delta_{ih}} = -S_{ih} + \sum_{j}^{N}\sum_{k=h}^{m_i}P_{ijk} \qquad i = 1,n,\ \ h = 1,m_i.$$

The second derivatives of λ with respect to θ_j and δ_{ih} are:

$$\frac{\partial^2\lambda}{\partial\theta_j^2} = -\sum_{i}^{n}\left[\sum_{k=1}^{m_i}k^2P_{ijk} - \left(\sum_{k=1}^{m_i}kP_{ijk}\right)^2\right]$$

and

$$\frac{\partial^2\lambda}{\partial\delta_{ih}^2} = -\sum_{j}^{N}\left[\sum_{k=h}^{m_i}P_{ijk} - \left(\sum_{k=h}^{m_i}P_{ijk}\right)^2\right].$$

With these results, the joint maximum likelihood estimation equations for the partial credit model are:

$$\hat{\theta}_r^{t+1} = \hat{\theta}_r^{(t)} - \frac{r - \sum_i^n \sum_{k=1}^{m_i} kP_{irk}^{(t)}}{-\sum_i^n \left[\sum_{k=1}^{m_i} k^2 P_{irk}^{(t)} - \left(\sum_{k=1}^{m_i} kP_{irk}^{(t)} \right)^2 \right]} \tag{21}$$

and

$$\hat{\delta}_{ih}^{t+1} = \hat{\delta}_{ih}^{(t)} - \frac{-S_{ih} + \sum_r^{M-1} N_r \sum_{k=h}^{m_i} P_{irk}^{(t)}}{-\sum_r^{M-1} N_r \left[\sum_{k=h}^{m_i} P_{irk}^{(t)} - \left(\sum_{k=h}^{m_i} P_{irk}^{(t)} \right)^2 \right]}, \tag{22}$$

where $\hat{\theta}_r^{(t)}$ is the estimated ability of a person with score r on the n-item instrument after t iterations; $\hat{\delta}_{ih}^{(t)}$ is the estimate of δ_{ih} after t iterations; N_r is the number of people with score r; and M is the maximum possible score on the instrument (i.e., $M = \sum_i^n m_i$).

Of these two procedures, the conditional maximum likelihood is preferable on theoretical grounds. The joint procedure has the advantage of being relatively easy to program, and for this reason it is widely used in practice. The estimates it produces, however, contain a bias. Through simulation studies it has been shown that this bias—which is greatest for instruments with small numbers of items—can be significantly reduced by multiplying the final item estimates by $(n-1)/n$. For typical data sets, these corrected estimates are equivalent to those obtained from the conditional procedure.

Participant Observation

Tamar Diana Wilson
University of Missouri, St. Louis, Missouri, USA

Glossary

advocacy The attempt to advance the interests and goals of the community or some of its members, often through networking them into services and goods provided by governmental or nongovernmental programs, agencies, and organizations.
cultural relativism The belief, ethical position, and approach that holds that cultures are diverse and unique in themselves and that behaviors and values must be understood in the cultural context in which they occur.
culture The shared patterns of thought, behavior, practice, lifestyles, and beliefs into which members of a society or community have been socialized; notably, cultures may be heterogeneous.
emic The insider or subjective viewpoint; emphasizes ideas and members' perceptions and interpretations of events, behaviors, relationships, and other phenomena of interest to the group or community.
ethnocentrism The assumption that the beliefs, practices, and lifestyle of the group to which one belongs are superior to those of other groups, who are consequently considered inferior.
ethnography The description and analysis of the culture or subculture (including behavioral patterns and lifestyles) of a group or community.
etic The outsider or objective viewpoint; emphasizes perceptions and interpretations of patterns of behavior and events using categories brought to the field by the researcher.
reciprocity The mutual exchange of goods and/or services and/or emotional support.
subculture The culture of a definable group or subsociety within a society or community.
work The generation of an income and/or the production or gleaning or processing of valued items for immediate use or sale.

Participation involves interacting, conversing, and sharing ongoing life experiences with members of a community. Observation of events, behavior, interactions, and conversations may be recorded in field notes or taped. Interviews may also be conducted and videos made. There are a number of continuums in the method, including that between observation and participation, that between passive participation and active participation, and that between active participation and advocacy/activism. Problems in participation—observation arise due to segregation along a number of axes in any given society and factionalisms that may divide it. Moving to insider status can involve essentialist characteristics of the researcher but also involves establishing commonalities and friendships, accepting fictive kinship designations, and participating in work and leisure activities with members of the community. Ethical issues include the principle of doing no harm, the necessity of being reflexive about one's impact and understandings gained, the importance of reciprocity relationships with community members, and the possibility of acting and advocating for the welfare of the community and its members.

The Method of Participant Observation

Development

Among the first to use participant observation as a data-gathering technique in anthropology were Bronislaw Malinowski in 1922 and Margaret Mead in 1928. Frank Cushing is also well credited with using the methodology, and even "going native" in his studies of the Zuni Pueblo in the 1880s. In the 1920s, the Chicago school, headed by Robert Ezra Park, sent sociologists into the field; they generated ethnographies on various aspects of the ethnically, occupationally, and socially diverse urban conglomeration of Chicago and elsewhere using methods of participant observation.

For most of the period following Malinowski and until the 1960s, participant observers stressed objective description and replicability, although subjective experience was sometimes taken into account and adopting a moral stance was not alien to early work. By the 1960s, emic and etic methods of approaching and gathering data had been elucidated and controversies arose regarding which was the best approach. In the 1980s, partially in response to earlier critical works, such as Vine Deloria's "Custer Died for Your Sins" and Edward W. Said's "Orientalism," as well as developing feminist critiques, ethnographers became more reflexive about their work and questioned the foundations and possibilities of complete "objectivity," often identifying its pursuit with colonialism, imperialism, gender discrimination, and ethnocentrism.

Definition

A working definition of participant observation as a methodology to gain information about and understanding of a group or community and create texts about their lives, behaviors, and beliefs (their "culture" or subculture) is as follows: Participant observation is (i) a qualitative methodology (which can put quantitative data into context and/or give it greater meaning); (ii) usually involving long-term research consisting of observing, interacting, conversing, sharing in work and leisure routines, and interviewing members of the community; and (iii) that takes an insider's (emic) point of view—often to build etic as well as emic models—to understand routine, everyday life or unique phenomena occurring within the setting(s) occupied by members of the group or community. In addition to utilizing a case study approach, participant observation consists of "a logic and process of inquiry that is open-ended, flexible, opportunistic, and requires constant redefinition of what is problematic, based on facts gathered in concrete settings of human existence" (Jorgenson, 1989, p. 14). An underlying assumption is that the researcher will be able to communicate with community members in their native language.

Participant observation is usually complemented by interviewing. Interviews can be unstructured, essentially guiding ordinarily occurring conversations toward topics of interest; semistructured, in which the interviewer openly suggests what he or she would like discussed; open-ended, with set questions designed to elicit a detailed response; or structured, in the form of a questionnaire administered to a sample of the population under study in a fixed format. This last form of interviewing may often lend itself to quantitative analysis. It also involves dialoguing with key informants—members of the community who lend themselves to supplying information about and interpreting local customs and perhaps attempting to socialize the researcher into meeting community expectations.

The results of participant observation are embodied in field notes, which document (i) the researcher's observations, conversations, interviews, interactions, and experiences as an insider or partial insider; (ii) emerging analysis and generalization; and, often, (iii) reflections on the researcher's role in and impact on the community and its members (reflexive ethnography). Field notes, once analyzed, form part of the basis of ethnographic understanding and are the foundation from which articles (or books) will be generated. Audio and video taping may also be used in capturing data.

Emics and Etics

Participation can lead to a greater emic (insider's, subjective, viewpoint) understanding; observation tends toward an etic (outsider's, objective, viewpoint) understanding. The emic point of view is concerned with the meaning the people ascribe to events, relationships, behaviors, and experiences. The etic point of view attempts to map patterns of behavior using categories identified not by insiders but through the perceptions and interpretations of the "outsider" often based on preexisting theory. Theoretical insights are thus brought to the field rather than being grounded in or "discovered" through the field experience. A completely emic view is often only an ideal because the researcher brings his or her own political and moral values into the field, which at a minimum will result in (unconscious) selective perception and recording of phenomena. Furthermore, hypotheses and categories for observation are often developed prior to entering the field, although they are subject to revision. On the other hand, a reliable and valid etic understanding, to not be ethnocentric, must take into account the emic viewpoint(s), which may be heterogeneous. (Viewpoints differ, for example, by gender, class position, or any number of achieved or ascribed statuses.) As Peter Berger pointed out in 1976, people can be assumed to be experts in their own lives and experts in defining the immediate problems (or joys and satisfactions) that confront them. Sometimes they even describe the larger context of their day-to-day problems: Etic approaches are useful in analyzing this context but may have already been appropriated by at least some members of the community; for example, the knowledge that the profit-making propensities of the factories they work for are responsible for their low wages or that Green Revolution packages are not adapted to the local agricultural regime.

In combating ethnocentrism, the belief in and ethical principle of "cultural relativism" is endorsed by most participant observers. There have been modifications in the theme of cultural relativism—which tends to reify "culture"—with the growing recognition (i) that behaviors, practices, norms, and values within any one culture may be heterogeneous due to differential access

to the means of production, power differences based on gender, ethnicity, and/or age and also the existence of subcultural groups; and (ii) that all cultures are and/or have been affected by world systemic processes (or processes of globalization), including colonialism, imperialism, capitalism, and consumerism.

Participant Observation Continuums

Some scholars equate passive participation with observation and distinguish three more interactive modes of participation: moderate (weighed toward observation and with only marginal membership), active (participation in as many events as possible with group or community members), and complete (becoming a full member of the group—"going native"). There are instances of all these modes of participation in ethnographies written by anthropologists and sociologists. However, degrees of participation/membership might also be conceived as occurring along three contiguous continuums. The first has as its poles "observation" and "participation" and runs from noninteractive "hanging out" and recording behavior one sees to participation as interacting, conversing, and interviewing with members of the community. The second continuum has as its poles "passive participation" and "active participation." Passive participation involves social interactions, dialoguing, conversing, and informal interviewing; active participation involves taking part in reciprocity networks, work routines, leisure activities, family and community events, and rites of passage and often being adopted as a core friend or fictive kinsman/kinswoman by one or more key informants. Active participation implies a greater socialization or enculturation into the society or subsociety under study. The third continuum runs from active participation to advocacy and activism. Advocacy and activism may involve independent input of effort and information, including networking community members into relevant government or nongovernmental organizations to help them or the community as a whole to obtain services or otherwise reach their goals (or even to envision new goals).

Problems Hindering Participant Observation

Segregation by Ascribed Status

Ascribed status includes gender, age, and ethnicity; they are considered essential and unchangeable characteristics of a person at any given point in time. They are unlike the achieved or acquired status of "college student," "warrior," or "engineer." Although assigning a role or a belief system to the holder of an ascribed status is considered essentialism, members of some groups and communities will do so. Some characteristics, such as marital status or parenthood, are on the ascriptive pole of an ascribed—acquired status continuum and are considered achieved statuses in others. Such characteristics can hinder (or help) access to people within a community who may conceive as oppositional statuses such as male vs. female, old vs. young, married vs. single, and so forth. It is well-known that within any given community male researchers may be denied access to women's spaces and activities, whereas female researchers may be blocked from entering men's spaces or watching men's activities. Even if the denial is not outright, the participant observer may be made to feel uncomfortable in settings reserved for the opposite sex. This is true not only in highly gender segregated societies, such as some in the Middle East, but also to some extent throughout the world (e.g., Australian women being expected not to enter men's segregated sections in public bars).

Many societies, especially tribal ones, are age graded as well. Informal segregation along the lines of same-aged peer groups is common in most societies. The participant observer may have easier access to people who are similar in age to his or her age. Martial status and parenthood may also affect the scope of interactions; some researchers have gotten more information and been more accepted by community members because they had children with them; others felt more restrained in the time they could devote to observation and participation because of child care responsibilities. Single researchers are often felt to be threatening and urged to find a spouse within the community. There are many instances, however, of ethnographers crossing into spaces normally segregated by age, gender, or any other ascribed (or acquired) characteristic.

Factionalism within the Group or Community

It has become well established that cultures are heterogeneous, dynamic, and changing, and that not all members of the community bearing the culture will have the same beliefs or habits. Within any community there may be opposing segments, parties, factions, or rivalries. Within the Mexican and Mexican American community of East Los Angeles, for example, neighborhood gangs may occupy streets that other gangs cross into only at risk. Political factionalism is common as well and can be found in such places as Mexican squatter settlements or rural population centers or in refugee camps throughout the world. Class factionalism is also common, whether in rural or urban communities. Often, the participant observer, because of the people he or she associates with or frequently interacts with, will be identified with the opposing faction and thus be denied access to or interactions with some people in the community.

Becoming an "Insider"

The Partial Insider

Partial insider is a rather essentialist term that has been used to describe a similarity of ethnicity or cultural background shared by the researcher and the people under study. On the one hand, the insider is only partially so due to differences in class (whether of origin or of actual class), work experience, education, overseas residence, urban or rural origin, gender, marital status, or sexuality. These differences may also cause the autoethnographer—the ethnographer studying his or her community of origin—to be a partial outsider as well, even being surprised by things that go on within his or her culture. This is specially true since (i) cultures are heterogeneous and (ii) and interpretations of events and behaviors in the same group can be highly variable, subject to change, and sometimes contradictory. On the other hand, commonalities may be established on the basis of any number of the many dimensions of ascribed or acquired status.

Establishing Commonalities

The ethnographer arrives in the field with a unique autobiography; over the life course the researcher has developed talents, acquired skills, and amassed bodies of knowledge and experiences that aid in adaptation to the field site and can be the basis for establishing communication though shared common interests and experience. The knowledge of wildlife, horticulture, livestock, boats, sports, mechanics, cooking, first aid, and so forth can aid in establishing rapport, facilitating discourse, and entering into reciprocity relationships with the community members.

There are at least five kinds of commonalities that ethnographers should seek in their fieldwork. First are the commonalities based on the hybridity, creolization, or interpenetration of cultures and the interconnectivity of the world. International migration has led to much primary interconnectedness as the mass media has led to much secondary interconnectedness. Thus, it would not be surprising, when doing fieldwork in North Africa, for example, if the researcher mentioned Paris, Marseilles, or Cadiz and a member of the community offered "I have a cousin in Paris" (or Marseilles or Cadiz) or even had been to one or more of these cities himself or herself. The same is true when mentioning Chicago, Los Angeles, or New York (among other places) in Mexico and Central or South America.

Second are commonalities based on ascriptive location (age, sex, race, and ethnicity) or personal situation (work, family, migration histories, marital status, and stage in the life cycle). Third are commonalities based on emotional experiences (joys and tragedies, celebrations and mournings, and births and bereavements). Fourth are commonalities that develop as the researcher is being socialized or enculturated into the community, as part of shared experiences. Fifth are commonalities based on sharing a common moral vision, what one can say "no" to; for example, torture, terrorism, and political repression; babies dying from lack of food or medical care; and children eating from garbage dumps. The establishment of such commonalities facilitates dialogue, conversation, interaction, empathy, and participation in events of importance to the researcher.

Friendship and Fictive Kinship

The researcher's presence is often considered intrusive and sometimes even "dangerous" to the normative order, especially since he or she is "out of place" in the sense of both not having a recognized status in the community and not knowing common courtesies, well-known social boundaries, or acceptable behaviors. Regarding the attempted normalization of "out-of-placeness," Freedman (1986, p. 54) recounts that upon her return as a widow to a village she had studied in Rumania, she was urged to remarry within the community because she was perceived as "a threat to the women and a temptation to the men."

People in a community may often try to regularize, tame, exorcise, or make sense of the anomalous role of the researcher by extending him or her the status of kinsman or kinswoman. The fictive kinship in which the researcher becomes involved may be *ad hoc* or a cultural institution, such as the practice of *compadrazgo* in Ibero-America as well as among other Catholic and some non-Catholic groups. In Latin America, becoming a godparent on the occasion of a baptism, a school graduation, a first communion, a coming out party, or a wedding (among other occasions) means that you have a responsibility for your godchild should his or her parents die, as well as reciprocal social and economic obligations with his or her parents, your compadres (coparents).

Male sociologists and anthropologists have been knitted into a community by members' informally adopting them as sons, brothers, fathers, or cousins and have been offered wives. Female researchers have been informally adopted as daughters and sisters and urged to find a husband with the group or community. Other researchers have gained entree into a community by being defined as a "friend" by a core member. Often, becoming friend or kin (however fictive) means becoming socialized into what are considered the site-specific or culturally unique requisites of such a role. In some cases, the researcher has found this to be a burden, and playing the kinship role correctly may limit access to other members of the community, especially of the opposite gender, or of antagonistic families. Such roles entail not only certain rights

but also obligations (including emotional upkeep), as do friendships and kinship ties worldwide.

Participation in Work and Leisure Activities

Commonalties can be established in the field by joining the work routines or play activities, including such sports as baseball or volleyball, fishing, dancing, horseback riding, and other pastimes that might fill part of the community members' leisure time. Working beside people can especially give knowledge into their daily lives and often opens up opportunities to know fellow workers and their families better. Fernández-Kelly worked in a *maquiladora* (an export-processing factory) in Cuidad Juarez, Chihuahua, Mexico, to gain insight into women employees' lives and to get to know them better. Kornblum worked in a steel mill, where many members of the South Chicago community he was studying (and living in) were employed. Phil DeVita established his credentials with the Acadian lobster fishermen through his mechanical and fishing abilities, part of the skills he brought into the field. Initially rejecting, community members eventually embraced him because of these abilities. In his words, "I became accepted as a mechanic and a fisherman, not as an anthropologist" (DeVita, 1992, p. 163). My work beside families of garbage pickers in Mexicali, corn farmers in Jalisco, and lettuce cutters in Salinas, California, gave me greater insight into the activities that occupied a good percentage of their waking lives; made me accepted as an "insider" who was willing to work alongside them, no matter how much drudgery it entailed; led me to understand the problems they faced at work both by experiencing it firsthand and because it more easily became a topic of conversation; and led to the families inviting me to events in their personal and social lives that extended beyond the workplace. Since I worked for free, and often added to the families' income by my efforts, I was also able to uphold my end in reciprocity obligations.

Ethical Issues

The Golden Rule

Ethical considerations in participant observation research are embodied in codes promulgated by the American Anthropological Association and the American Sociological Association. The golden rule is "to do no harm to the community or its members." This does not mean avoiding intervention to prevent one community member from doing harm to another, although some researchers believe they should not intervene in such incidents. It often means using pseudonyms for people and identifiable places. Sometimes, it means not publishing some of the information garnered. Covert research, although it appears to be the only means of securing information with some groups, is considered unethical by most scholars. Overt research means informing the group or community that one is doing research among them, informing them of the aims of the research, and explaining that the results of research may do them little good (which is true in most cases). Consent, sometimes written and sometimes not, is to be obtained from those who will be interviewed. The participant observer should also explain the aims of his or her study to people with whom he or she interacts in order to obtain information about the group or community. Assuring confidentiality and privacy is part of the "do no harm" rule.

Reflexivity

Reflexivity involves awareness of the impact of the researcher and the research on the community and self and comprises at least six aspects: (i) awareness of the possibility of ethnocentrism (i.e., the belief that the researcher's standards of behavior and values are superior to those of the group being studied) and the need to avoid it; (ii) awareness of one's positioning vis-à-vis the group under study, including differences in power and resources and differences (or similarities) in moral-political—ideological values; (iii) awareness of the impact the researcher has on the community in terms of changing community members' routines, interactions, behaviors, etc. (often the object of the ethnography); (iv) awareness that some of the information gleaned may reflect normative expectations rather than actual behavior—and this too gives insight into the community; (v) awareness of how any text produced might impact on the community or on its members; and (vi) awareness of how the field experience is also changing the researcher and his or her worldview, becoming a new chapter in autobiographical experience.

Reciprocity

Involvement in reciprocity relationships and networks is a means of establishing rapport, gaining friends, and consequently opening doors to more observation, participation, and information. Empathy and emotional ties (feelings of friendship) most usually develop in the course of reciprocity relationships. Reciprocity is also a way of paying back members of the group or community for their efforts on the researcher's behalf (and tolerance of his or her presence). At a minimum, reciprocity involves answering truthfully questions community members pose to the researcher in return for answering his or her questions. Many, if not most, participant observers have provided transportation; written letters; accompanied

individuals to offices, hospitals, or other institutionalized settings; extended first aid; filled in forms; and provided a variety of other services and goods. Reciprocity relations most often involve a flow of goods and services in both directions. Advocacy for the community or individuals within it is also a form of reciprocity. There is a moral imperative that at least some forms of reciprocity should be engaged in to "pay back" informants for their time and efforts on the researcher's behalf. Reciprocity is a basis for friendship in any case, within or outside of the field site(s).

Advocacy and Activism

Advocacy and activism concern the researcher's aiding the community to reach its goals or even envision new ones, such as education for its children. It may involve networking them into existing social services or governmental or nongovernmental organizations, programs, or agencies, such as orienting AIDS victims or drug addicts or abused women to existing treatment facilities. It may involve setting up new organizations or services, for example, engaging community members in building a school or a clinic. Those engaged in participant observation need not become advocates or activists for their group/community of study, although many do so and some have such plans before they enter the field. Others eschew advocacy or activism for fear of intruding on the daily routines and practices of the group whose life ways they wish to portray. Some participant observers take part in political rallies and organizational activities undertaken by the people; although possibly done merely to observe, the researcher may be asked for feedback, to hand out flyers, etc. (i.e., to become more of a participant). Opposing viewpoints on the responsibility for activism, and for taking a moral stance, have been documented in journals such as *Cultural Anthropology*. Researchers involved in reciprocity relationships may be expected to take some action on behalf of their friends or kinsmen.

Path Analysis

Christy Lleras
Pennsylvania State University, University Park, Pennsylvania, USA

Glossary

endogenous variable A variable whose variation is explained by one or more variables within the model.
exogenous variable A variable whose variation is explained by factors outside the model and which also explains other variables within the model.
path analysis A statistical method used to examine hypothesized (causal) relationships between two or more variables.
recursive model A path model where all the causal relationships flow in a single direction with no reciprocal effects or feedback loops.
specification error Error that occurs when significant causal variables are excluded from the path model.
spurious effects When part of the association between two variables is due to shared causal influences.
standardized path coefficient Coefficients that have been converted into standardized *z*-scores which allow researchers to compare the relative magnitude of the effects of different explanatory variables in the path model.

Path analysis is a statistical technique used primarily to examine the comparative strength of direct and indirect relationships among variables. A series of parameters are estimated by solving one or more structural equations in order to test the fit of the correlation matrix between two or more causal models, which are hypothesized by the researcher to fit the data.

Introduction

Path Analytic Methods

One of the primary goals of social scientific research is to understand social systems through the explication of causal relationships. However, given the complexity of social life, disentangling the interrelationships among variables is often a difficult task. Path analysis is a methodological tool that helps researchers using quantitative (correlational) data to disentangle the various (causal) processes underlying a particular outcome. The path analytic method is an extension of multiple regression analysis and estimates the magnitude and strength of effects within a hypothesized causal system. In addition, path analysis can be used to test the fit between two or more causal models, which are hypothesized by the researcher to fit the data.

Since path analysis assesses the comparative strength of different effects on an outcome, the relationships between variables in the path model are expressed in terms of correlations and represent hypotheses proposed by the researcher. Therefore, the relationships or pathways cannot be statistically tested for directionality and the models themselves cannot prove causation. However, path models do reflect theories about causation and can inform the researcher as to which hypothesized causal model best fits the pattern of correlations found within the data set. One of the advantages of using path analysis is that it forces researchers to explicitly specify how the variables relate to one another and thus encourages the development of clear and logical theories about the processes influencing a particular outcome. Path analysis is also advantageous in that it allows researchers to break apart or decompose the various factors affecting an outcome into direct effects and indirect components.

History of Path Analysis

Path analysis was originally developed by geneticist Sewall Wright in the 1920s to examine the effects of hypothesized models in phylogenetic studies. Wright's

analysis involved writing a system of equations based on the correlations among variables influencing the outcome and then solving for the unknown parameters in the model. According to Wright, the path analytic method was intended to measure "... the direct effect along each separate path in such a system and thus of finding the degree to which variation of a given effect is determined by each particular cause." Wright also acknowledged the fact that often causal relations were uncertain and cautioned that this method was not intended to deduce causal relations simply from correlation coefficients. Rather, the method utilized information provided by the statistical correlations in conjunction with qualitative information regarding the causal relationships to find the consequences of hypothesized structures.

Several decades later, path analysis was introduced into social scientific research by Blalock, Duncan, and others (Boudon and Turner). Sociologists Peter Blau and Otis Dudley Duncan were among the first to utilize path analysis extensively in their research on the processes involved in status attainment. In their book, *The American Occupational Structure*, Blau and Duncan utilized data collected from a sample of adult males and their parents to develop path models of the causal processes underlying educational and occupational outcomes.

During the 1970s, path analysis became even more popular and numerous papers were published featuring path analytic methods in sociology, as well as psychology, economics, political science, ecology, and other fields. Since the early 1980s, path analysis has evolved into a variety of causal or structural equation modeling (SEM) programs and computer packages. Unlike earlier path models, which were based on least squares regression, these new methods of causal modeling utilize the general linear model approach. The advantages of these new approaches are discussed below in "Extensions and Computer Software."

Elements of Path Models

The Path Diagram

Social scientific theories of causal relationships often specify a system of relationships in which some variables affect other variables and these in turn influence still other variables in the model. A single multiple regression model can only specify one response variable at a time. However, path analysis estimates as many regression equations as are needed to relate all the proposed theoretical relationships among the variables in the explanation at the same time.

To illustrate, consider the following hypothesis that a child's educational attainment is directly affected by family background, as well as individual academic achievement and engagement in school. In addition, academic achievement and school engagement depend on both the mother's educational level and parental income. Further, the level of student engagement in school is hypothesized to affect student achievement and, in turn, influence educational attainment.

A path diagram represents the hypothesized causal model in path analysis. To illustrate this hypothesis regarding educational attainment, the basic elements of a path diagram are depicted in the model shown in Fig. 1. The single straight arrows indicate a causal relationship, leading from the explanatory (causal) variable to the outcome variable (effect). For example, educational attainment is dependent upon mother's education, parental income, school engagement, and achievement. A child's level of school engagement is also dependent upon maternal education and parental income. Finally, student achievement is influenced by three factors: mother's education, parental income, and school engagement. The double-headed curved arrows linking maternal education and parental income indicate that the two

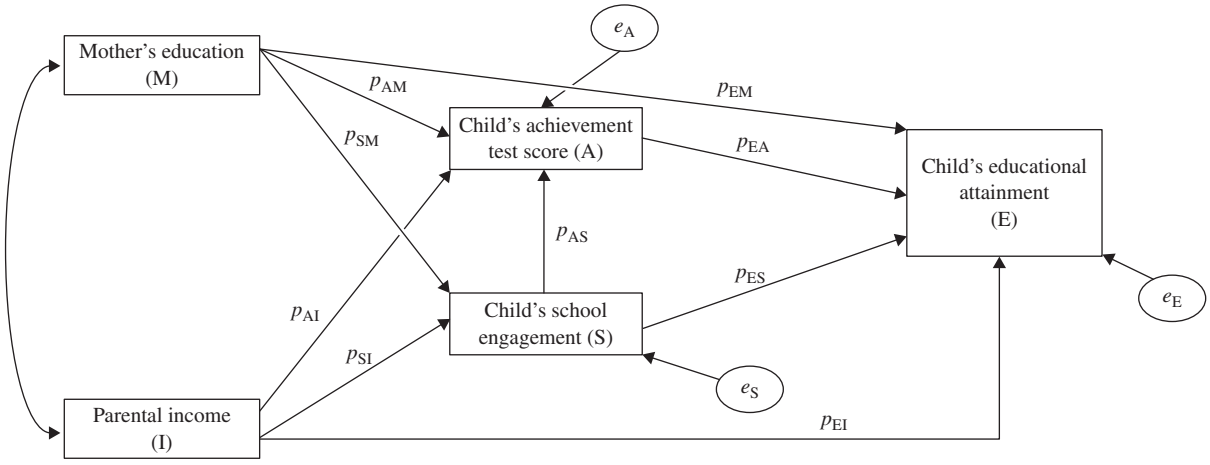

Figure 1 Path diagram for hypothesized model predicting child's educational attainment.

variables may be related, but no prediction is being made in the model as to the direction of the association.

Exogenous and Endogenous Variables

Variables often play more than one role in path models and this is reflected in the analytic language used in path analysis. Exogenous variables are variables whose cause is external to the model and whose role is to explain other variables or outcomes in the model. In Fig. 1, for example, the model does not explain the variability in maternal educational level and parental income. However, these exogenous variables are hypothesized to account for differences in child's achievement, school engagement, and educational attainment.

Endogenous variables are variables that are caused by one or more variables within the model. Endogenous variables have incoming arrows and can include outcome variables (only incoming arrows) and intervening causal variables. Endogenous variables, such as educational attainment, have only incoming arrows. School engagement and achievement are called intervening endogenous variables since they have both incoming and outgoing arrows. The hypothetical model in Fig. 1 indicates that engagement and achievement are influenced by other variables in the model (e.g., maternal education, parental income), and in turn have an effect on educational attainment.

Residual Error

Residuals or error terms (represented by e) are exogenous independent variables that are not directly measured and reflect unspecified causes of variability in the outcome or unexplained variance plus any error due to measurement. They are depicted in the diagram by arrows connecting the error terms with their respective outcome or endogenous variables. Residual error is assumed to have a normal distribution with a mean of zero and to be uncorrelated with other variables in the model. Note error terms are not always uncorrelated.

Path Coefficients

Although not required, path models often report the standardized regression coefficients (beta) or estimated path coefficients that have been converted into standardized z-scores, for each causal path depicted in the model. Standardized coefficients allow researchers to compare the relative magnitude of the effects of different explanatory variables in the path model by adjusting the standard deviations such that all the variables, despite different units of measurement, have equal standard deviations. These standardized path coefficients measure the relative strength and sign of the effect from a causal variable to an endogenous or outcome variable in the model. When more than one causal variable is present in the model, the standardized path coefficients represent partial regression coefficients that measure the effect of one variable on another, controlling for prior variables.

The subscripts for each pathway (p_{ij}) describe the causal relationship being estimated in the model. The first subscript (i) is the outcome variable and the second subscript (j) is the causal variable or variable whose influence on the outcome is under consideration. In Fig. 1, M, I, A, S, and E denote mother's education, parental income, achievement test score, school engagement, and educational attainment, respectively. The partial standardized regression coefficient depicted by the pathway p_{EA}, for example, is the estimated effect of child's achievement test score on educational attainment, controlling for family background and school engagement. The model hypothesizes that an increase in achievement test scores, holding parental income, maternal education, and engagement in school is associated with an increase in educational attainment. Similarly, the pathways p_{AM} and p_{SM} denote the standardized regression coefficients for the effect of mother's education on child's achievement and school engagement respectively, holding the antecedent variable, parental income, constant.

Structural Equations

Since the path analytic method follows the usual assumptions of ordinary least squares regression, all the relationships depicted in Fig. 1 are assumed to be linear, additive, and causal. Therefore, the model can be specified by a series of path or structural equations that describe the direct causal relationships between the variables. There are three endogenous or outcome variables in the model, so there are three sets of standardized coefficients to be estimated using ordinary least squares regression. In path models, to solve for the direct effects, each endogenous variable is regressed on all the variables with direct paths leading to it. Thus, the set of hypothesized direct causal relationships depicted in Fig. 1 correspond to the following path equations:

$$\begin{aligned}\text{Educational Attainment} &= p_{\mathrm{EM}}\mathrm{M} + p_{\mathrm{EI}}\mathrm{I} + p_{\mathrm{ES}}\mathrm{S} \\ &\quad + p_{\mathrm{EA}}\mathrm{A} + e_{\mathrm{E}} \qquad (1)\\ \text{Child's Achievement} &= p_{\mathrm{AM}}\mathrm{M} + p_{\mathrm{AI}}\mathrm{I} \\ &\quad + p_{\mathrm{AS}}\mathrm{S} + e_{\mathrm{A}} \qquad (2)\\ \text{Child's School Engagement} &= p_{\mathrm{SM}}\mathrm{M} + p_{\mathrm{SI}}\mathrm{I} + e_{\mathrm{S}} \qquad (3)\end{aligned}$$

In this model, educational attainment (Eq. 1) depends on the following partial regression coefficients: mother's education, parental income, school engagement, and achievement. Achievement (Eq. 2) is influenced by mother's education, parental income, and the level of

engagement in school. School engagement (Eq. 3) depends only upon mother's education and parental income. Each outcome or endogenous variable also has a residual path or error term (e) associated with it (i.e., e_E, e_A, e_S), which represent the variation left unexplained by the explanatory variables in the path model.

Decomposition of Path Effects

One of the unique contributions of path analysis to social scientific research is its ability to decompose the associations between several variables into causal (direct and indirect) and noncausal (e.g., spurious) components.

Direct and Indirect Causal Relationships

Causal relationships between variables may consist of direct and indirect effects. Direct causal effects are effects that go directly from one variable to another. Indirect effects occur when the relationship between two variables is mediated by one or more variables. For example, in Fig. 1, school engagement affects educational attainment directly and indirectly via its direct effect on achievement test score. Maternal education and parental income also have indirect effects on both achievement and educational attainment. Their indirect effects on achievement occur through their direct effects on school engagement. Their indirect effects on educational attainment occur through their influence on school engagement, through their influence on achievement, and through their effects on achievement and engagement, combined.

The magnitude of the indirect effects is determined by taking the product of the path coefficients along the pathway between the two causally related variables. Thus, the total indirect effect between two variables in a path model equals the sum of the products of each indirect effect. For example, child's school engagement affects educational attainment indirectly through its effect on achievement. Thus, the magnitude of the indirect effect between engagement and attainment can be estimated by multiplying the paths from school engagement to achievement and from achievement to educational attainment, $(p_{EA} \times p_{AS})$.

Calculating the total indirect effect between mother's education and child's educational attainment is a bit more complicated but follows the same logic. Maternal education affects educational attainment indirectly through child's achievement and the magnitude of the indirect effect is $(p_{EA} \times p_{AM})$. Maternal education also indirectly influences educational attainment via child's school engagement and the magnitude of the effect is $(p_{ES} \times p_{SM})$. In addition, mother's education influences child's educational attainment both through its effect on school engagement and on achievement. The magnitude of this indirect effect is $(p_{EA} \times p_{AS} \times p_{SM})$. Thus, the total indirect effect of mother's educational attainment on child's educational attainment is the sum of all of these indirect effects, $(p_{EA} \times p_{AM}) + (p_{ES} \times p_{SM}) + (p_{EA} \times p_{AS} \times p_{SM})$. Since mother's education is also correlated with parental income, all of these indirect effects also occur via this correlation.

Noncausal Relationships

In addition to decomposing relationships between variables into direct and indirect effects, path models also break down effects into noncausal components. Noncausal relationships may be spurious or due to unanalyzed prior associations. Spurious noncausal effects occur when the relationship between two endogenous variables is being influenced by a third variable. In other words, part of the association between two variables is due to shared causal influences. In the hypothesized model of educational attainment in Fig. 1, part of the relationship between child's school engagement and achievement reflects such a spurious effect. School engagement and achievement are influenced by both mother's education and by parental income. Thus, part of the association between school engagement and achievement is due to the fact that both variables are influenced by mother's education and both are also influenced by parental income.

Estimation and Testing

Estimation of Path Models

The previous example used to illustrate the elements of the path diagram and path decomposition depicts a recursive or unidirectional causal flow model. The model is recursive since all the causal linkages flow in one direction and none of the variables represent both cause and effect at the same time. This causal model is the only kind of model which can properly be called path analysis. In models where the hypothesized causality flows in a single direction, the estimation can be done relatively simply by using ordinary least squares (OLS) regression or maximum likelihood estimation (MLE) to solve the equations for each endogenous or outcome variable in the model. For a discussion of nonrecursive models, refer to "Extensions and Computer Software" below.

Model Specification

Path analysis is particularly sensitive to model specification. The inclusion of irrelevant variables or the exclusion

of important causal variables changes the value of path coefficients. In addition to recursivity, it is also assumed that all causally relevant variables have been included in the model. Specification error occurs when significant causal variables are excluded from the model. When this type of error occurs the value of the path coefficients reflect the common variance shared with these omitted variables. Since the strength of direct and indirect effects on the outcome variables in the model are evaluated using the path coefficients, the decision of whether or not to include different variables in the path model is critical to the interpretation of the underlying (causal) processes. Therefore, this method is most helpful in the testing of well-specified theories about the relationships between variables and not for exploratory purposes. Additional details on the assumptions in path analysis can be found in the literature by Kline and by Maruyama.

Data Demands

Since all the pathways or relationships must be capable of being estimated using multiple regression, the path analytic method requires the use of interval level data for all the variables included in the model. However, dichotomous and ordinal variables are commonly used in path analysis. For a review of literature on this topic see Jaccard and Wan (1996). In addition, path analysis only deals with measured variables or variables that can be observed and measured directly.

Goodness of Fit

Often researchers have more than one theory regarding which variables or what paths to include in the path model. Competing theories can be evaluated by estimating separate path models and then assessing the goodness-of-fit statistics to determine which hypothesized model best fits the correlation matrix in the observed data. Alternative theories can also be combined into a single path model and the researcher can assess which pathways are more significant by comparing the relative strength of different pathways within the same path model.

There is a variety of goodness of fit statistics that can be used to assess model fit and evaluate competing path models. The different computer programs commonly used to estimate path models generate a number of fit statistics as part of their output. While there is some disagreement over which specific tests are the "best" to use, it is commonly recommended that researchers examine more than one fit statistic when evaluating model fit. For example, Kline recommends using at least the following four tests: χ^2; GFI, NFI, or CFI; NNFI; and SRMR. For a discussion of these indexes and others refer to the work by Bollen and Long and by Jaccard and Wan.

Strengths and Limitations

Strengths of Path Analysis

The questions that are the subject of social inquiry often involve multiple causal influences. In order to explain a particular outcome it is therefore necessary to examine both the direct and indirect relationships among variables within a hypothesized model. As noted previously, one of the strengths of the path analytic method is that it estimates a system of equations that specify all the possible causal linkages among a set of variables. In addition, path analysis enables researchers to break down or decompose correlations among variables into causal (i.e., direct or indirect) and noncausal (e.g., spurious) components. Thus, path analysis helps researchers disentangle the complex interrelationships among variables and identify the most significant pathways involved in predicting an outcome.

Path analysis can also play a vital role in the theoretical or hypothesis testing stage of social research. While certainly experimental designs involving the random assignment of individuals to either a treatment or control group is the best way to test for causal effects, these experiments are often impossible to conduct given the sorts of questions that are the subject of social scientific inquiry. Since path analysis requires researchers to explicitly specify how they think the variables relate to one another within the path diagram, this method forces researchers to develop detailed and logical theoretical models to explain the outcome of interest. Thus, researchers using nonexperimental, quantitative, or correlational data can test whether their hypotheses about the relationships between variables are plausible and supported by the data and represent underlying (causal) processes.

Limitations of Path Analysis

While many researchers espouse the benefits of using path analysis in quantitative social research, the technique also has its critics. Since path analysis is an extension of multiple regression, it follows all the usual assumptions of regression. However, it is often difficult to meet these assumptions in social scientific research, particularly those of reliability and recursivity or unidirectional causal flow. The path model has to assume that each variable is an exact manifestation of the theoretical concepts underlying them and reasonably free of measurement error. In addition, the causality in the hypothesized model has to flow in one direction (no feedback loops or bidirectional causality); otherwise the model cannot be solved with ordinary least squares regression techniques. As will be discussed in the last section, however, methods have developed out of path analysis that can deal with these limitations of the least squares approach.

Finally, path analysis is a statistical tool used to evaluate whether the correlations between variables in a given data set reflect the causal hypotheses specified in the model. Since the models are based on correlations, path analysis cannot demonstrate causality or the direction of causal effects. However, as stated previously the path analytic method can indicate which of the path models best fits the pattern of correlations found in the data.

Extensions and Computer Software

Structural Equation Modeling

The limitations of the least squares method in path analysis discussed above led to the development of the general linear modeling (GLM) approach. This approach has evolved over the past 20 years into a variety of structural equation modeling (SEM) programs and computer packages. The main advantages of this approach is that it provides better measures of the theoretical constructs underlying variables and can estimate not only traditional recursive path models, but also nonrecursive models, models with measurement error, and models with unobserved variables (for further discussion see the literature from Maruyama.

The path analytic method underlies the structural equation modeling (SEM) approach, however SEM provides a more powerful alternative to path analysis and other regression techniques (e.g., multiple regression, time series). SEM allows more flexible assumptions including explicitly modeling correlated error terms, interactions, nonlinearities, and data level. In addition, while path analysis deals only with measured variables, SEM can model latent variables that cannot be directly observed in the data but rather are inferred from measured variables (i.e., factor analysis). The use of multiple indicators of a construct helps to reduce measurement error and increase data reliability.

Computer Software

Currently, path analysis can easily be conducted with any one of the following SEM computer programs: LISREL (e.g., Jöreskog and Sörbom), AMOS (e.g., Arbuckle), or EQS (e.g., Bentler). Once the model and data are entered into the program, the regression equations in the path model(s) are estimated simultaneously. The output includes the unstandardized and standardized regression or path coefficients, as well as a variety of goodness-of-fit statistics, which can be used to compare the fit of different hypothesized models against the correlation matrices, observed in the data.

LISREL is commonly used in sociology and throughout the social sciences and utilizes a programming language called SIMPLIS. AMOS is a more recent program that allows researchers to utilize either a user-friendly graphical interface to draw path diagrams or a programming language called BASIC, to estimate path models. An advantage of AMOS is that it produces high quality path diagrams and reads SPSS system files. Both LISREL and AMOS are put out by SPSS. Another program called EQS uses a graphical interface and runs the model based on the diagram drawn by the researcher using a drawing tool called *Diagrammer*. For a discussion of these and other SEM programs see the literature from Kano or Kline.

Glossary

biserial correlation Pearson devised this technique in 1909 to measure a linear relationship between one continuous variable and one dichotomous variable on the assumption that the underlying dichotomous variable is continuous and normally distributed.

chi-square goodness-of-fit test This test seeks to determine whether the observed distribution (constructed from observational data) conforms to the theoretical distribution with a "correction" of $n-1$ as termed by Pearson (or "degrees of freedom" later used by R. A. Fisher). Pearson considered first cases in which the theoretical probability is known a *priori*, where

$$\chi^2 = S\frac{(m' - m_s - \mu)^2}{m_s},$$

where m' is the observed (or empirical) frequencies in a distribution, m_s is the theoretical (or expected) distribution known *a priori*, μ is the population mean, and S is summation. A more contemporary formula for the chi-square goodness-of-fit test is $\chi^2 = \Sigma(O-E)^2/E$, where O is the observed values, E is the expected values, and Σ is summation.

chi-square test of independence Established by Pearson in 1904 to measure the differences between observed cell frequencies and expected cell frequencies. The chi-square statistic, as renamed by R. A. Fisher in 1923, is one of the most commonly used statistical tests to measure the association between two discrete (usually nominal) variables for manifold contingency tables. Pearson found the value of χ^2 as

$$\chi^2 = S\frac{(n_{uv} - v_{uv})^2}{v_{uv}},$$

where n_{uv} is the theoretical (expected) frequencies in cells, v_{uv} is the observed (empirical) frequencies in cells, and S is summation.

chi-square tests The statistical framework of Pearson's chi-square is a tripartite system because it not only incorporates a probability distribution and a goodness-of-fit test that he devised in 1900 but also includes a statistical technique for the analysis of contingency tables, which he introduced in 1904.

coefficient of variation Created by Pearson in 1896 as a standardized method for measuring the percentage of variation in the mean, where the standard deviation is treated as the total variation of the mean. Thus, C of $V = \bar{X}/\mathrm{SD} \times 100$.

method of moments Derived from Clapeyron's theorem of the three moments in mechanics, Pearson found that the covariance (Σxy) corresponded to the product moment of dynamics and the standard deviation (σ) corresponded to the moment of inertia. Pearson adopted the method of moments in 1892 for curve fitting of symmetrical and asymmetrical distributions by defining the following statistical parameters: central tendency (the mean), variability (the square of the standard deviation or the "variance"), skewness, and kurtosis.

multiple correlation Underpinned by matrix algebra, which was created by Cambridge mathematicians in the mid-19th century and which Pearson introduced into statistical theory to calculate the multiple correlation coefficient r in 1896, it measures the linear relationship between one dependent continuous variable and a set of independent continuous variables.

Pearson product–moment correlation coefficient A technique used to measure a linear relationship between two continuous variables whose values range from -1 to $+1$. Pearson's formula of the product–moment correlation coefficient is

$$r = \frac{\sum xy}{(S_X)(S_Y)} = \frac{\text{covariance}}{(\text{standard deviation of } x)(\text{standard deviation of } y)}.$$

phi coefficient This method was designed for so-called point distributions, which implied that two variables have two

points that are represented by some qualitative attribute for a 2 × 2 contingency table. This measures the relationship between two dichotomous variables that do not assume an underlying normal distribution. After finding the standard deviation, Pearson calculated the correlation between errors of the mean for two sets of variables. This led to his phi coefficient, the values of which range from −1 to +1:

$$r_{hk} = \frac{ad - bc}{\sqrt{(b+d)(a+c)(c+d)(a+b)}}.$$

regression A statistical system used for the linear prediction of two continuous variables. Pearson introduced the terms *dependent variable* and *independent variable* in 1896; this was an essential distinction to make for regression because the independent variable is the predictor and the dependent variable is the criterion. Pearson then showed that $Y' = a + bX$ was the equation for the regression (or predicted) line, and that the regression coefficients could be determined by finding the covariance of the variables x and y and dividing that by the variance of x. The regression coefficient is thus

$$b = \frac{\sum xy}{S^2 x} = \frac{\text{covariance}}{\text{variance of } x}$$

where X is the independent variable. The constant $a = \bar{Y} - b\bar{X}$.

standard deviation A technique for measuring variation at all points on a distribution and involves taking the square root of the deviational values squared and dividing by the total number in the sample. Pearson defined the standard deviation in 1893 as the error of the mean square, where $S = \sqrt{(\sum x^2/N)}$.

standard error of estimate Following Pearson's work on regression and correlation, he provided the standard deviation of correlation and also introduced the standard error of estimate in 1896 as the standard deviation of the regression coefficient:

$$\sigma\sqrt{(1-r)^2}.$$

tetrachoric correlation This measures the association between two continuous but dichotomous variables that are normally distributed and linearly related. Pearson devised this technique in 1900 when he began to analyze variables that could not be simply classified as continuous. Pearson derived the value of the tetrachoric correlation r from the value of the correlation parameter ρ of the bivariate normal distribution with frequencies from each of the four quadrants of the x, y plane by lines parallel to the coordinate axes. This division agreed exactly with four cell frequencies of the fourfold table in terms of arbitrary and precise dichotomous division of two discrete variables. The values of the tetrachoric correlation ranged from −1 to +1 and could be found by

$$r = \sin 2\pi \frac{(ad - bc)}{N^2} = \cos \pi \frac{b}{a+b}.$$

Pearson did not explain why he used the trigonometric functions of sine and cosine. In more contemporary terms, the tetrachoric correlation may be expressed as

$$r_{\text{tet}} = \frac{\cos 180^\circ}{1 + \sqrt{(BC/AD)}}.$$

Karl Pearson, Cambridge-trained English mathematician, philosopher, and statistician, was born in London in March 1857 and died at Coldharbour, Under Dorking, Surrey, in April 1936. Pearson's prodigious and innovative publications combined with a vast reservoir of energy and determination enabled him to create the discipline of mathematical statistics. He also established many institutional changes at University College London, including the creation of a department of structural (now civil) engineering, a department of astronomy with two observatories, and his department of applied statistics.

Introduction

Karl Pearson was one of the principal architects of the modern theory of mathematical statistics, or what he also termed biometrics. He was a polymath whose interests ranged from astronomy, mechanics, meteorology, and physics to the biological sciences in particular (including anthropology, eugenics, evolutionary biology, heredity, and medicine). He was also interested in the study of German folklore and literature, the history of the Reformation, and German humanists (especially Martin Luther). In addition to these activities, he also contributed hymns to the "Socialist Song Book." Pearson's writings were voluminous: He published more than 650 papers in his lifetime, of which 400 are statistical. Over a period of 28 years, he founded and edited six journals and was a cofounder (along with W. F. R. Weldon and Francis Galton) of the journal *Biometrika*. The main set of Pearson's collected papers, which consist of 235 boxes containing family papers, scientific manuscripts, and 16,000 letters, have been reposited at University College London (UCL).

Due mainly to his interests in evolutionary biology, Pearson created, almost single-handedly, the modern theory of statistics in his Biometric School at University College London from 1892 to 1903, which was practiced in the Drapers' Biometric Laboratory from 1903 to 1933. These developments were underpinned by Charles Darwin's ideas of biological variation and "statistical" populations of species, and they arose from the impetus of the statistical and experimental work of his colleague and closest friend, the Darwinian zoologist W. F. R. Weldon (1860–1906). This work led to his development of goodness-of-fit tests for asymmetrical

curves in 1892 and culminated in his chi-square goodness-of-fit test in 1900. Additional developments emerged from Francis Galton's (1822–1911) law of ancestral heredity. Pearson later devised a separate methodology for problems of eugenics, based on family pedigrees and actuarial death rates, in the Galton Eugenics Laboratory from 1907 to 1933.

In his creation of the emerging discipline of mathematical statistics, Pearson introduced a new vernacular for statistics, including such terms as standard deviation, mode, homoscedasticity, heteroscedasticity, kurtosis, and the product–moment correlation coefficient. Like a number of scientists at the end of the 19th century, Pearson was interested in the developing etymology in various disciplines, especially biology. Although he attempted to coin a number of biological words, the only word that survived him is "siblings," which he used "to cover a group of brothers and sisters regardless of sex."

Family and Education

The second son of William Pearson and Fanny Smith, Carl Pearson was born in London on March 27, 1857. The University of Heidelberg changed the spelling of his name in 1879 when he was enrolled as "Karl Pearson," and 5 years later he adopted this variant of his name and eventually became known as "KP." His mother came from a family of seamen and mariners and his father was a barrister and QC. The Pearsons were of Yorkshire descent because most of their ancestors came from the North Riding. They were a family of dissenters and of Quaker stock. By the time he was in his 20s, Pearson had rejected Christianity and had become a Freethinker, which involved the "rejection of all myths as explanation and the frank acceptance of all ascertained truths to the relation of the finite to the infinite." Although he did not regard himself as an atheist, "he vigorously denied the possibility of a god ... because the idea of one and all of them by contradicting some law of thought involves an absurdity." To Pearson, "religion was the relation of the finite to the infinite." Politically, he was a socialist whose outlook was similar to the Fabians, but he never joined the Fabian Society (despite requests from Sidney and Beatrice Webb). Socialism was a form of morality for Pearson; the moral was social and the immoral was antisocial in conduct.

There were a number of solicitors in the Pearson family, including William's brother Robert and Robert's son Hugh, as well as William's eldest child, Arthur, all of whom read law at the Inner Temple. William was a very hardworking and taciturn man who was never home before 7 PM; he continued to work until about midnight and was usually up at 4 AM reviewing his briefs. To both of his sons, William emphasized the importance of hard work quite regularly and especially once they were at Cambridge. Only during the holidays did the children spend any time with their father. In a letter to Karl, his elder brother Arthur described the experience of being home with their father as "simply purgatory ... the governor never spoke a word." In this desolate atmosphere, with her husband working incessantly and never talking to anyone when he was home, Fanny was deeply unhappy in her marriage. Thus, she transferred her love to her two sons, and she was deeply affectionate to Karl who was, without doubt, her favorite child.

For a short time in 1866, both boys received tuition at home from a Mr William Penn, who had started a school near Harrow. Both children were very unhappy being away from home, and their mother was disconsolate in their absence. As a child, Karl was rather frail, delicate, often ill, and prone to depression. There were a number of occasions when he received tuition at home because he was too unwell to go to school. After the Pearsons moved to 40 Mecklenburgh Square, in Holborn, in June 1866 (where they stayed until 1875), Karl and Arthur began attending University College London School.

When they went to Cambridge, at least one of the Pearson boys was expected to read mathematics. The Cambridge Mathematics Tripos was, at that time, the most prestigious degree in any British university. Although his father urged him to read mathematics, Arthur settled on classics. Thus, when Karl was 15 years old, his father was looking for a good Cambridge Wrangler to prepare him for the Mathematics Tripos. Less than a year later, Karl went to Hitchin, near Cambridge, where he stayed from January 28 to July 1, 1874, receiving tuition from the Reverend Louis Hensley. He was very unhappy at Hitchin and was ready to leave by the summer of 1874 so that he could be coached in mathematics in preparation for Cambridge. A couple weeks later, he decided to go to Merton Hall in Cambridge for tuition under John Edward Rendall Harris, John P. Taylor, and Edward John Routh. He stayed at Merton Hall from mid-July 1874 to April 15, 1875.

By the spring of 1875, Pearson was ready to take the entrance examinations at various colleges at Cambridge. His first choice was Trinity College, where he failed the entrance exam; his second choice was King's College, from which he received an Open Fellowship on April 15, 1875. Pearson found that the highly competitive and demanding system leading up to the Mathematical Tripos was the tonic he needed. Although he had been a rather frail, delicate, and sickly child with a nervous disposition, he came to life in this environment and his health improved. In addition to the highly competitive and intellectually demanding system, students of the Mathematics Tripos were expected to take regular exercise as a means of preserving a robust

constitution and regulating the working day. Pearson carefully balanced hard mathematical study against such physical activities as walking, skating, ice hockey, and lawn tennis.

As a diversion from studying mathematics, Pearson read works from such Romantics as Goethe and Shelley in his second year. He also read Rousseau and Dante, and he wrote a couple of articles on Spinoza for the *Cambridge Review*. Pearson's time at King's College left its legacy through his revolt over the compulsory divinity examination. Near the beginning of his third year in 1877, he decided that he no longer wished to be compelled to attend church services. Pearson also refused to retake one of his Divinity papers because it would have interfered with studying for the Maths Tripos. The events that transpired led eventually to King's College abolishing the whole system of compulsory Divinity examinations in March 1878.

Pearson spent the rest of 1878 in preparation for the Mathematics Tripos examination, which he took in January 1879. He graduated with honors, being the Third Wrangler; subsequently, he received a fellowship from King's College, which he held for 7 years. (He was made an honorary fellow of King's in 1903.) Pearson also took the Smith's Prize examination, although he did not become a Prizeman. However, Isaac Todhunter, who had been one of Pearson's examiners for the Smith's Prize, thought that Pearson had provided a better solution to one of Barŕe De Saint-Venant's problems of elasticity than Saint-Venant had. Todhunter subsequently incorporated Pearson's solutions into his manuscript on the "Theory of Elasticity and Strength of Materials." Soon after Todhunter's death in November 1879, the Syndics of Cambridge University Press asked Pearson to finish Todhunter's manuscript. During the early 1880s, Pearson began to devote more of his time to problems of elasticity, which became his specialty in mathematical physics.

A couple of weeks after Pearson had taken his degree, he began to work in Professor James Stuart's engineering workshop and read philosophy during the Lent Term in preparation for his trip to Germany. After making arrangements with Kuno Fischer, Pearson left for Heidelberg in April 1879. His time in Germany was a period of self-discovery philosophically and professionally. The romanticist and idealist discovered positivism: Pearson thus adopted and coalesced two different philosophical traditions to fulfill two different needs. Around this time, he began to write the *New Werther*, a literary work on idealism and materialism, written in the form of letters to his fiancée from a young man wandering in Germany. For Pearson, the book was about "conflict between the ideal and the real, spirit and matter." The book was published in 1880 under the pseudonym of Loki (a mischievious Norse god).

Germany and University College London

In Heidelberg, Pearson read Berkeley, Fichte, Locke, Kant, and Spinoza and was beginning to find that his "faith in reason has been so shattered by the merely negative results to him which he found in these great philosophers that he despaired his little reason leading to anything." He subsequently abandoned philosophy because "it made him miserable and would have led to him to short-cut his career." In November, he went to Berlin to study physics under Quincke and Helmholtz and metaphysics under Kuno Fischer, and he considered becoming a mathematical physicist but decided not to pursue this since he "was not a born genius." Since "philosophy did not lead to the truth" and as he would not find success in physics, he was "determined to go to the Bar": He stayed in Berlin and attended lectures on Roman international law and philosophy by Bruns and Mommsen, and he hoped to pass the Roman Law Exam in March. A year later, he took up rooms at the Inner Temple and read law at Lincoln's Inn. He was called to the Bar at the end of 1881 and practiced the law for a very short time only. Pearson's one extant case involved setting up a partnership deed between two turnip-top sellers in Covent Garden Market; the case took him 3 days to complete, which he thought was "agony" and by then he decided he "hated the law." Still searching for some direction when he returned to London, Pearson lectured on socialism, Marx, and Lassalle at the workingmen's clubs and on Martin Luther at Hampstead from 1880 to 1881.

Three months later, however, he discovered that he was tired of the law and did not want to pursue this because it depressed him; he decided instead to "devote his time to the religious producing of German literature before 1300." Later that year, his work on "The Trinity, A Nineteenth Century Passion-Play, The Son; or Victory of Love" was published. From 1882 to 1884, he lectured on German society from the medieval period up to the 16th century. He became so competent in German that by the late spring of 1884, he was offered a post in German at Cambridge. In his pursuit of German history, Pearson consulted his friend, the Cambridge University librarian Henry Bradshaw, who taught him the meaning of thoroughness and patience in research. With Bradshaw's help, in 1887 Pearson finished *Die Fronica: Ein Beitrag zur Geschichte des Christusbildes im Mittelalter* (which involved a collection of the so-called Veronica portraits of Christ).

Despite his accomplishments with German literature, however, he "longed to be working with symbols rather than words." He then began to write papers on the theory of elastic solids and fluids as well as some mathematical

physics papers on optics and ether squirts. He deputized mathematics at King's College, London, and for Professor Rowe at UCL in 1883. Having no luck in finding a job, he thought of taking up a secretaryship in a hospital, becoming a school master, possibly emigrating to North America, or even returning to law. Between 1879 and 1884, he applied for more than six mathematical posts and he received the Goldsmid Chair of "Mechanism and Applied Mathematics" at UCL in June 1884. Thomas Archer Hirst and Alexander Kennedy had recommended him to the post.

During Pearson's first 6 years at UCL, he taught mathematical physics, hydrodynamics, magnetism, electricity, and his specialty, elasticity, to engineering students. Nearly all of his teaching on dynamics, general mechanics, and statics was based on geometrical methods. He finished editing the incomplete manuscript of William Kingdon Clifford's *The Common Sense of the Exact Sciences* in 1885, and a year later he finished Todhunter's *History of the Theory of Elasticity*.

The Gresham Lectures on Geometry and Curve Fitting

Pearson was a founding member of the Men's and Women's Club established in 1885 "for the free and unreserved discussion of all matters in any way connected with the mutual position and relation of men and women." Among the various members was Marie Sharpe, whom he married in June 1890: They had three children—Sigrid, Helga, and Egon. Six months after his marriage, he took up another teaching post in the Gresham Chair of Geometry in London, which he held for 3 years concurrently with his post at UCL. As Gresham Professor, he was responsible for giving 12 lectures a year, delivered on 4 consecutive days from Tuesdays to Fridays, during the Michaelmas, Easter, and Hilary terms. The lectures, which were free to the public, began at 6 PM and lasted for 1 hour. Between February 1891 and November 1893, Pearson delivered 38 lectures. His first 8 lectures formed the basis of his book, *Grammar of Science*, which was published in several languages, and it was in his last 12 lectures where he provided the framework to the modern theory of mathematical statistics.

Pearson's earliest teaching of statistics can thus be found in his lecture of November 18, 1891, when he discussed graphical statistics and the mathematical theory of probability with a particular interest in actuarial methods. Two days later, he introduced the histogram—a term he coined to designate a "time-diagram" to be used for historical purposes. He introduced the standard deviation in his Gresham lecture of January 31, 1893. Pearson's early Gresham lectures on statistics were influenced by the work of Francis Ysidro Edgeworth, Stanley Jevons, and John Venn. Until November 1893, these lectures covered fairly conventional statistical and probability methods. Although the material in these lectures was not original in content, Pearson's approach in teaching was highly innovative. In one of his lectures, he scattered 10,000 pennies over the lecture room floor and asked his students to count the number of heads or tails: "The result was very nearly half heads and half tails, thus proving the law of average and probability." After a lecture on experimental deductions that involved the use of 16,718 throws of the ball at the Monte Carlo Roulette Table, teetotums, and 2138 tickets from lotteries, one of his students remarked that the lecture was like "an opera without a last act." It is, perhaps, not surprising that the number of students increased 5- to 10-fold in the first couple of years; by 1893, nearly 300 students were attending his lectures.

Pearson's last 12 Gresham lectures signified a turning point in his career owing, in particular, to his relationship with Weldon, who was the first biologist Pearson met who was interested in using a statistical approach for problems of Darwinian evolution. Their emphasis on Darwinian population of species not only implied the necessity of systematically measuring variation but also prompted the reconceptualization of statistical populations. Moreover, it was this mathematization of Darwin that led to a paradigmatic shift for Pearson from the Aristotelian essentialism underpinning the earlier use and development of social and vital statistics. Weldon's questions not only provided the impetus for Pearson's seminal statistical work but also led eventually to the creation of the Biometric School at UCL.

In Pearson's first published statistical paper of October 26, 1893, he introduced the method of moments as a means of curve fitting asymmetrical distributions. One of his aims in developing the method of moments was to provide a general method for determining the values of the parameters of a frequency distribution (i.e., central tendency, variation, skewness, and kurtosis). In 1895, Pearson developed a general formula to use for subsets of various types of frequency curves and defined the following curves: type I (asymmetric beta density curve), type II (symmetric beta curve), type III (gamma curve), type IV (family of asymmetric curves), and type V (normal curve). In his first supplement to his family of curves in 1901, he defined types VI and VII (type VII is now known as "Student's" distribution), and he defined types VIII and IX in his second supplement in 1916. Many of his curves were J-shaped, U-shaped, and skewed. Pearson derived all of his curves from a differential equation whose parameters were found from the moments of the distribution. As Churchill Eisenhart remarked in 1974, "Pearson's family of curves did much to dispel the almost religious acceptance of the normal distribution as the mathematical model of variation of biological, physical, and social phenomena."

Although the method of moments is not widely used by biostatisticians today, it remains a very powerful tool in econometrics.

The Biometric School

Although Pearson's success in attracting such large audiences in his Gresham lectures may have played a role in encouraging him to further develop his work in biometry, he resigned from the Gresham Lectureship due to his doctor's recommendation. Following the success of his Gresham lectures, Pearson began to teach statistics to students at UCL in October 1894. Not only did Galton's work on his law of ancestral heredity enable Pearson to devise the mathematical properties of the product–moment correlation coefficient (which measures the relationship between two continuous variables) and simple regression (used for the linear prediction between two continuous variables) but also Galton's ideas led to Pearson's introduction of multiple correlation and part correlation coefficients, multiple regression and the standard error of estimate (for regression), and the coefficient of variation. By then, Galton had determined graphically the idea of correlation and regression for the normal distribution only. Because Galton's procedure for measuring correlation involved measuring the slope of the regression line (which was a measure of regression instead), Pearson kept Galton's "r" to symbolize correlation. Pearson later used the letter b (from the equation for a straight line) to symbolize regression. After Weldon had seen a copy of Pearson's 1896 paper on correlation, he suggested to Pearson that he should extend the range for correlation from 0 to +1 (as used by Galton) so that it would include all values from −1 to +1.

Pearson achieved a mathematical resolution of multiple correlation and multiple regression, adumbrated in Galton's law of ancestral heredity in 1885, in his seminal paper *Regression, Heredity, and Panmixia* in 1896, when he introduced matrix algebra into statistical theory. (Arthur Cayley, who taught at Cambridge when Pearson was a student, created matrix algebra by his discovery of the theory of invariants during the mid-19th century.) Pearson's theory of multiple regression became important to his work on Mendel in 1904 when he advocated a synthesis of Mendelism and biometry. In the same paper, Pearson also introduced the following statistical methods: eta (η) as a measure for a curvilinear relationship, the standard error of estimate, multiple regression, and multiple and part correlation. He also devised the coefficient of variation as a measure of the ratio of a standard deviation to the corresponding mean expressed as a percentage.

By the end of the 19th century, he began to consider the relationship between two discrete variables, and from 1896 to 1911 Pearson devised more than 18 methods of correlation. In 1900, he devised the tetrachoric correlation and the phi coefficient for dichotomous variables. The tetrachoric correlation requires that both X and Y represent continuous, normally distributed, and linearly related variables, whereas the phi coefficient was designed for so-called point distributions, which implies that the two classes have two point values or merely represent some qualitative attribute. Nine years later, he devised the biserial correlation, where one variable is continuous and the other is discontinuous. With his son Egon, he devised the polychoric correlation in 1922 (which is very similar to canonical correlation today). Although not all of Pearson's correlational methods have survived him, a number of these methods are still the principal tools used by psychometricians for test construction. Following the publication of his first three statistical papers in *Philosophical Transactions of the Royal Society,* Pearson was elected a fellow of the Royal Society in 1896. He was awarded the Darwin Medal from the Royal Society in 1898.

Pearson's Chi-Square Tests

At the turn of the century, Pearson reached a fundamental breakthrough in his development of a modern theory of statistics when he found the exact chi-square distribution from the family of gamma distributions and devised the chi-square (χ^2, P) goodness-of-fit test. The test was constructed to compare observed frequencies in an empirical distribution with expected frequencies in a theoretical distribution to determine "whether a reasonable graduation had been achieved" (i.e., one with an acceptable probability). This landmark achievement was the outcome of the previous 8 years of curve fitting for asymmetrical distributions and, in particular, of Pearson's attempts to find an empirical measure of a goodness-of-fit test for asymmetrical curves.

Four years later, he extended this to the analysis of manifold contingency tables and introduced the "mean square contingency coefficient," which he also termed the chi-square test of independence (which R. A. Fisher termed the chi-square statistic in 1923). Although Pearson used $n - 1$ for his degrees of freedom for the chi-square goodness-of-fit test, Fisher claimed in 1924 that Pearson also used the same degrees of freedom for his chi-square test of independence. However, in 1913 Pearson introduced what he termed a "correction" (rather than degrees of freedom) for his chi-square test of independence of 1904. Thus, he wrote, if $x =$ number of rows and $\lambda =$ number of columns, then on average the correction for the number of cells is $(x - 1)(\lambda - 1)/N$. [As may be seen, Fisher's degrees of freedom for the chi-square statistic as $(r - 1)(c - 1)$ is very similar to that used by Pearson in 1913.]

Pearson's conception of contingency led at once to the generalization of the notion of the association of two attributes developed by his former student, G. Udny Yule. Individuals could now be classed into more than two alternate groups or into many groups with exclusive attributes. The contingency coefficient and the chi-square test of independence could then be used to determine the extent to which two such systems were contingent or noncontingent. This was accomplished by using a generalized theory of association along with the mathematical theory of independent probability.

Pearson's Four Laboratories

In the 20th century, Pearson established and ran four laboratories. He set up the Drapers' Biometric Laboratory in 1903 following a grant from the Worshipful Drapers' Company (which funded Pearson annually for work in this laboratory until his retirement in 1933). The methodology incorporated in the Drapers' Biometric Laboratory was twofold: The first was mathematical, and included the use of Pearson's statistical methods, matrix algebra, and analytical solid geometry. The second involved the use of such instruments as integrators, analyzers, curve-potters, the cranial coordinatograph, silhouettes, and cameras. The problems investigated by the biometricians included natural selection, Mendelian genetics and Galton's law of ancestral inheritance, craniometry, physical anthropology, and theoretical aspects of mathematical statistics. By 1915, Pearson had established the first-degree course in mathematical statistics in Britain.

Although Pearson did not accept the generality of Mendelism, he did not reject it completely as is commonly believed. When William Bateson published his fiercely polemical attack on Weldon in 1902, Bateson saw Mendelism as a tool for discontinuous variation only. As a biometrician, most of the variables that Pearson and coworkers analyzed were continuous and only occasionally did they examine discontinuous variables. Although Pearson and Weldon used Galton's law of ancestral inheritance for continuous variables, they used Mendelism for discontinuous variables. Indeed, Pearson argued that his chi-square test of independence was the most appropriate statistical tool for the analysis of Mendel's discrete data for dominant and recessive alleles (such as color of eyes, where brown is dominant and blue is recessive). Even today, Pearson's chi-square test is used for analyzing Mendelian data.

A year after Pearson established the Biometric Laboratory, the Worshipful Drapers' Company gave him a grant so that he could establish an Astronomical Laboratory equipped with a transit circle and a 4-in. equatorial refractor. Hence, he also referred to his two observatories as the Transit House and the Equatorial House. Pearson was interested in determining the correlations of stellar rotations and the variability in stellar parallax. One of his larger projects involved taking 132 photographs of the eclipse of the sun on June 28, 1908. He joined the Royal Astronomical Society in 1904 and resigned in 1917 following a row he had with Lord Rayleigh and H. C. Plummer on matters relating to differences in methods when calculating these variables. Pearson was also instrumental in setting up a degree course in astronomy in 1914 at UCL.

In the autumn of 1907 when Francis Galton was 85 years old, he asked Pearson if he could take "control of the Eugenics Office as a branch of the Biometric Laboratory." Pearson had, by then, been doing the work of at least three different people: He was editing the four journals he had thus far founded, writing papers, giving lectures, and managing three laboratories aided largely by various teaching assistants, an assistant professor, human computers, calculators, and computators in addition to numerous voluntary workers and visiting scholars. Given Pearson's ongoing professional commitments, he was very reluctant to take up the directorship of another laboratory. Pearson wrote a letter to Galton saying he did not think that his biometric methods were amenable for the quantitative treatment of eugenics problems.

He explained to Galton that many of the biometric problems that were undertaken in the Biometric Laboratory took up to 5 or 6 years and required the manpower from two or three generations of students plus an additional 2 years to reduce the data before they could be analyzed statistically. His methods were clearly not suitable for the quick and easy solutions that Galton favored. Galton admitted that he "had been under the false idea that the Eugenics Laboratory would have aided the Biometric Laboratory rather than hindered it." Nevertheless, Pearson felt a great deal of affection for Galton, which had increased since Weldon's death in 1906; moreover, given the frailty of Galton at his advanced age, it is clear that Pearson would not have refused to help Galton—at least not in Galton's lifetime.

As a personal favor to Galton, Pearson agreed, albeit reluctantly, to take control of the Eugenics Record Office on February 1, 1907, and renamed it the Eugenics Laboratory when he became its director. After he had been director for 1 year, he was ready to step down whenever Galton felt another man could achieve more in the particular direction desired by Galton. Pearson's overriding professional objective was unequivocally linked to the promulgation and further development of his statistical ideas and theory, which he did not think had as much application to eugenics as they did to biology and astronomy. Because no replacement was found, Pearson stayed on as director. Nonetheless, he had long been aware of the limitations of his biometric methods for problems in

the Eugenics Laboratory, and since his methods were of limited use in the Eugenics Laboratory, his only option was to devise a new methodology for problems being investigated in this laboratory. This methodology was underpinned by the use of actuarial death rates and by a very highly specialized use of family pedigrees assembled in an attempt to discover the inheritance of various diseases (which included alcoholism, cancer, diabetes, epilepsy, paralysis, and pulmonary tuberculosis).

To a large extent, Pearson stood outside many of the debates on the implementation of various social policies for eugenics, and he never endorsed sterilization or any other dysgenic state policies. The projects he initiated in the Eugenics Laboratory were long-term quantitative studies dealing with such issues as alcoholism, insanity, and tuberculosis. He received assistance from the coworkers who worked in the laboratory and from the medical community, which acquired as much family data as possible for his family pedigrees for calculating actuarial death rates. The eminent biologist, J. B. S. Haldane, regarded Pearson's family pedigrees, most of which were published in his 21-volume "The Treasury of Human Inheritance," as his most valuable contribution to biology.

Although Pearson never developed his own theory of inheritance, he considered different theories of heredity, including blending, "exclusive" and mosaic inheritance, Galton's law of ancestral inheritance, homotyposis, and Mendelian genetics; thus, he did not reject Mendelism. Pearson's view of the world was shaped by the Cambridge Mathematics Tripos, which emphasized using applied mathematics as a pedagogical tool for obtaining the truth. To this end, he was not interested in a physiological mechanism of heredity; instead, he attempted to make sense of various hereditarian models by placing them in a mathematical context.

Family Pedigrees and the Medical Community

Pearson's family pedigrees served as the vehicle through which he could communicate statistical ideas to the medical community by stressing the importance of using quantitative methods for medical research. This tool enabled doctors to move away from concentrating on individual pathological cases or "types" and to see, instead, a wide range of pathological variation of the disease (or condition) of the doctors' specialty. Major Greenwood, who was the first medically qualified person to take an interest in Pearson's statistics in 1902, became Reader in Medical Statistics at the University of London in 1922 (the first such position to be held at a university in Britain). Pearson's and Greenwood's statistical work was further promulgated by their student Austin Bradford Hill, who had the greatest impact on the successful adoption of mathematical statistics in the medical community. In 1924, Pearson set up the Anthropometric Laboratory, which was made possible by a gift from one of Pearson's students, Ethel Eldeteron. The laboratory was open to the public and used to collect and display statistics related to problems of heredity.

In the spring of 1909, Galton was discussing the future of the Eugenics Laboratory with Pearson. Although Galton thought that Pearson would have been "the most suitable man for the first Galton Professor," Pearson let Galton know that he was "wholly unwilling to give up superintendence of the Biometric Laboratory [he] had founded and confine [his] work to Eugenics Research." A month later, Galton added a codicil to his will stating that he desired that the first professor of the post should be offered to Pearson on such condition that Pearson could continue to run his Biometric Laboratory. Six months after Galton's death in January 1911, Pearson first learned about Galton's codicil to his will. He then relinquished the Goldsmid Chair of Applied Mathematics after 27 years of tenure to take up the Galton Chair. The Drapers' Biometric and the Galton Eugenics laboratories, which continued to receive separate funding, then became incorporated into the Department of Applied Statistics. The essential aim in combining both laboratories was to enable Pearson to give up his undergraduate teaching of applied mathematics and to devote himself "solely to what had been for many years the main element of [his] research: the advancement of the modern theory of statistics."

Statistical Charts and Gunnery Computations

Pearson proceeded to raise funding for a new building for his Department of Applied Statistics. Adequate funding had been raised by 1914, and contracts for the fittings had been made. In the early summer of 1914, the new laboratory was complete and preparations were under way for the occupation and fitting up of the public museum and the Anthropometric Laboratory. It was hoped that the building would be occupied by October 1915. These developments and further biometric work were shattered by the onset of World War I. The new laboratory building was taken over by the government to be used as a military hospital. Pearson and coworkers took on special war duties. They produced statistical charts for the Board of Trade's Labour Department as well as for its census production. Pearson was also involved with elaborate calculations of anti-aircraft guns and bomb trajectories both through air and water. By June 1919, Pearson was in possession of his building and plans were under way

for the opening in October 1920. It was not until December 4, 1922, that the work had been completed and the building was occupied.

His wife, Marie Sharpe, died in 1928, and in 1929 he married Margaret Victoria Child, a coworker in the Biometric Laboratory. Pearson was made emeritus professor in 1933 and was given a room in the zoology department at UCL that he used as the office of *Biometrika.* From his retirement until his death in 1936, he published 34 articles and notes and continued to edit *Biometrika.* Pearson was offered an OBE in 1920 and a knighthood in 1933, but he refused both honors. He also declined the Royal Statistical Society Guy Medal in its centenary year in 1934. Pearson believed that "all medals and honors should be given to young men, they encourage them when they begin to doubt whether their work was of value." Pearson accepted the honorary DSc from the University of London in 1934 because if he had refused, he "would have hurt the executive of the university where he had worked" for nearly half a century.

Pearson's statistical achievement not only provided continuity from the mathematical and statistical work that preceded him (including that of Francis Ysidro Edgeworth, Francis Galton, Adolphe Quetelet, and John Venn) or that of contemporaries (such as W. F. R. Weldon and George Udny Yule) but also his work engendered the modern theory of mathematical statistics in the 20th century, which in turn provided the foundation for such statisticians as R. A. Fisher, who went on to make further advancements for a modern theory of statistics.

Glossary

balanced scorecard A scorecard consists of the vital defined measures that executive teams use to manage their responsibilities in business and not-for-profit organizations. A balanced scorecard is one that contains not only an appropriate mix of both financial and non-financial measures, but also a balance of internal and external plus input and output measures. The term has been popularized since 1992 by the writings and activities of R. Kaplan and D. Norton of the Harvard Business School.

business excellence model A nine-faceted framework, consisting of five "enablers" and four "results," launched in 1992 by the European Foundation for Quality Management (EFQM) as an assessment and self-assessment framework for the European Quality Award (similar to the U.S. Malcolm Baldrige Award), sometimes adapted by organizations as a performance measurement framework.

Malcolm Baldrige Award A popular U.S. annual quality award, established in 1987, named after an American secretary of commerce who was a strong supporter of the award's aims but who, unfortunately, was killed in an accident shortly before its launch. The assessment criteria for the award address seven categories of performance excellence.

shareholder value The sum of a listed corporation's change in market capitalization (number of shares in issue multiplied by its quoted share price) plus its dividend distributions over a given period.

stakeholders All the parties who have a particular interest in, and legitimate requirements of, an organization's performance—typically, investors, customers, employees, suppliers, regulators, and the communities in which it operates.

Three fundamental premises underpin the concept of the performance prism. First, it is no longer acceptable (or even feasible) for organizations to focus solely on the needs of one or two of their stakeholders—typically shareholders and customers—if they wish to survive and prosper over the long term. Second, an organization's strategies, processes, and capabilities have to be aligned and integrated with one another if the organization is to be best positioned to deliver real value to all of its stakeholders. Third, organizations and their stakeholders have to recognize that their relationships are reciprocal—stakeholders have to contribute to organizations as well as receive something from them. These three fundamental premises underpin the holistic performance measurement and management framework—the performance prism—that this article describes.

Introduction

The performance prism is a second-generation performance management framework that consists of five interrelated perspectives on performance that pose specific vital questions:

1. *Stakeholder satisfaction*: Who are our key stakeholders and what do they want and need?
2. *Stakeholder contribution*: What do we want and need from our stakeholders on a reciprocal basis?
3. *Strategies*: What strategies do we need to put in place to satisfy the wants and needs of our stakeholders while satisfying our own requirements as well?
4. *Processes*: What processes do we need to put in place to enable us to execute our strategies?

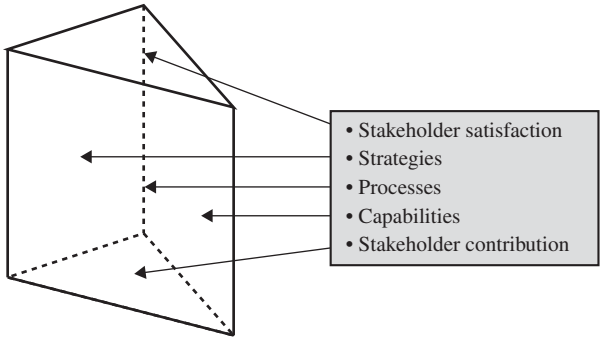

Figure 1

5. *Capabilities*: What capabilities do we need to put in place to allow us to operate our processes?

Together, these five perspectives provide a comprehensive and integrated framework for thinking about organizational performance in today's operating environment (see Fig. 1).

The performance prism also seeks to address the shortcomings of the first-generation measurement frameworks and methodologies, such as the balanced scorecard, the work on shareholder value, and the various self-assessment frameworks, such as the Malcolm Baldrige Award criteria and the business excellence model of the European Foundation for Quality Management (EFQM).

The Nature of the Measurement Problem

Why is this new performance measurement framework needed? After all, everyone knows that "you can't manage what you don't measure." And given that people have been managing organizations for years, then surely by now they must have perfected their measurement systems.

Sadly, as in so many walks of life, theory does not reflect practice. The number of organizations with weak performance measures and measurement systems in place is immense. Examples abound of organizations that have introduced performance measures that quite simply drive entirely the wrong behaviors. There must be a better way.

There has been a revolution in performance measurement and management during the last few years. Various frameworks and methodologies—such as the balanced scorecard, shareholder value added, activity-based costing, cost of quality, and competitive benchmarking—have each generated vast interest, activity, and consulting revenues, but not always success. Yet therein lies a paradox. It might reasonably be asked: how can multiple, and seemingly inconsistent, business performance frameworks and measurement methodologies exist? Each claims to be unique and comprehensive, yet each offers a different perspective on performance.

Kaplan and Norton's balanced scorecard, with its four perspectives, focuses on financials (shareholders), customers, internal processes, plus innovation and learning. In doing so, it downplays the importance of other stakeholders, such as employees, suppliers, regulators, and communities. The business excellence model combines results, which are readily measurable, with enablers, some of which are not. Shareholder value frameworks incorporate the cost of capital into the equation, but ignore everything (and everyone) else. Both the activity-based costing and the cost of quality frameworks, on the other hand, focus on the identification and control of cost drivers (non-value-adding activities and failures/non-conformances, respectively), which are themselves often embedded in the business processes. But this highly process-focused view ignores any other perspectives on performance, such as the opinions of investors, customers, and employees. Conversely, benchmarking tends to involve taking a largely external perspective, often comparing performance with that of competitors or sometimes other "best practitioners" of business processes or capabilities. However, this kind of activity is frequently pursued as a one-off exercise toward generating ideas for—or gaining commitment to—short-term improvement initiatives, rather than the design of a formalized ongoing performance measurement system.

How can this be? How can multiple, seemingly conflicting, measurement frameworks and methodologies exist? The answer is simple: they can exist because they all add value. They all provide unique perspectives on performance. They all furnish managers with a different set of lenses through which they can assess the performance of their organizations. The key is to recognize that, despite the claims of some of the proponents of these various approaches, there is no one best way to address the measurement and management of business performance. The reason for this is that business performance is itself a multifaceted concept, the complexity of which the existing frameworks only partially address. Essentially, they provide valuable point solutions.

A Better Solution to the Measurement Problem

Our solution is the three-dimensional framework that we call the performance prism. This framework has been deliberately designed to be highly flexible so that it can provide either a broad or a narrow focus. If only a partial

aspect of performance management is required, such as a single stakeholder focus or a particular business process agenda, then the performance prism can be applied to designing a measurement system and appropriate measures (and their attendant metrics) that address that context. Conversely, if a broad corporate or business unit performance management improvement initiative is required, the performance prism is equally capable of supporting that, too. How does it help to achieve these aims?

The performance prism has five perspectives. The top and bottom perspectives are stakeholder satisfaction and stakeholder contribution. The three side perspectives are the organization's strategies, processes, and capabilities for addressing those sets of wants and needs. Figure 2 illustrates these five basic perspectives of performance measurement and management.

Why does the framework look like this and why does it consist of these constituent components? It is clear that those organizations aspiring to be successful in the long term within today's business environment need to have an exceptionally clear picture of who their key stakeholders are and what they want or need. But having a clear picture is not enough. In order to satisfy their own wants and needs, organizations have to access contributions from their stakeholders—usually capital and credit from investors, loyalty and profit from customers, ideas and skills from employees, materials and services from suppliers, and so on. They also need to have defined what strategies they will pursue to ensure that value is delivered to their stakeholders. In order to implement these strategies, they have to understand what processes the enterprise requires and must operate both effectively and efficiently. Processes, in themselves, can only be executed if the organization has the right capabilities in place—the right combination of people skill sets, best practices, leading technologies, and physical infrastructure.

In essence, then, the performance prism provides a comprehensive yet easily comprehensible framework that can be used to articulate a given business's operating model. Its components are described in the following sections.

Stakeholder Satisfaction

Where should the measurement design process begin? One of the great myths (or fallacies) of measurement design is that performance measures should be derived from strategy. Listen to any conference speaker on the subject. Read any management text written about it. Nine times out of ten the statement "Derive your measures from your strategy" will be made. This is such a conceptually appealing notion that nobody stops to question it. Yet to derive measures from strategy is to misunderstand fundamentally the purpose of measurement and the role of strategy. Performance measures are designed to help people track whether they are moving in the intended direction. They help managers establish whether they are going to reach the destination they set out to reach. Strategy, however, is not about destination. Instead, it is about the route that is chosen—*how* to reach the desired destination.

At one level, this is a semantic argument. Indeed, the original work on strategy, carried out in the 1970s by Andrews, Ansoff, and Mintzberg, asserted that a strategy should explain both the goals of the organization and a plan of action to achieve these goals. Today,

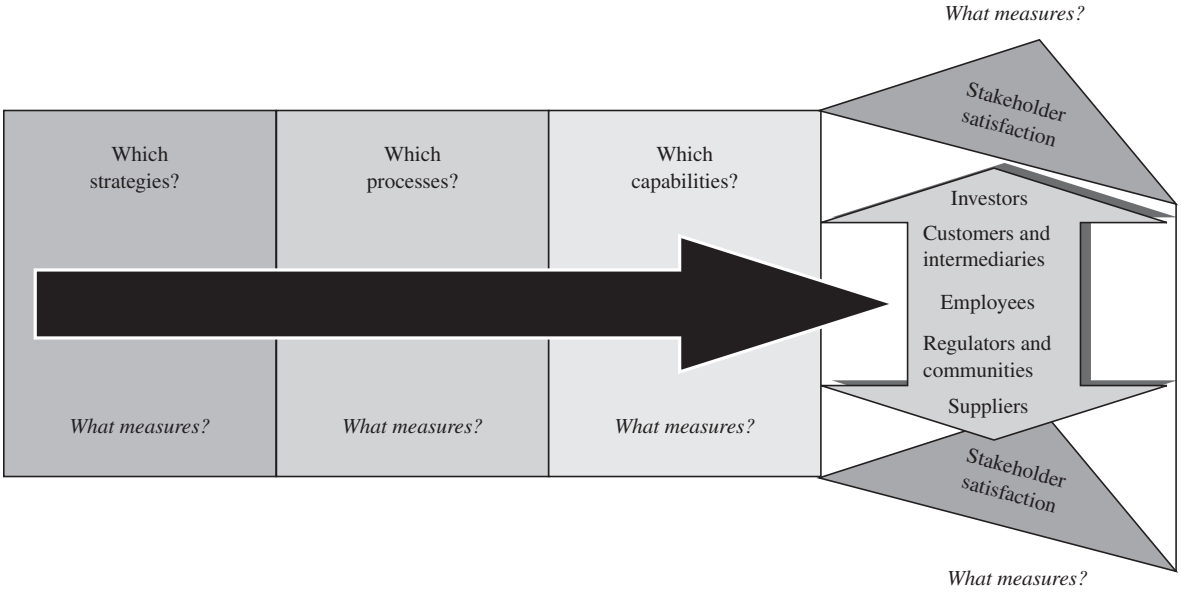

Figure 2

however, the vast majority of organizations have strategies that are dominated by lists of improvement activities and management initiatives, e.g., grow market share, extend the product range, and seek new distribution channels. While these are undoubtedly of value, they are not the end-goal. These initiatives and activities are pursued in the belief that, when implemented, they will enable the organization to deliver better value to its multiple stakeholders, all of whom will have varying importance to the organization.

An organization's key stakeholders are likely to be a combination of a number of the following:

- Investors (principally shareholders, but other capital providers too)
- Customers and intermediaries
- Employees and labor unions
- Suppliers and alliance partners
- Regulators, pressure groups, and communities.

Organizations can chose to give more attention to one stakeholder group over another, not because that particular stakeholder is implicitly more important than the others, but because that stakeholder has not received the attention it should have in the past. Executives must decide which stakeholders' wants and needs their strategies must satisfy.

So, the starting point for deciding what to measure should not be "What is the organization's strategy?" but instead, "Who are the organization's stakeholders and what do they want and need?" Hence, the first perspective on performance embedded in the performance prism is that of stakeholder satisfaction.

Stakeholder Contribution

The second perspective on performance is a subtle but critical twist on the first. Take, for example, customers as stakeholders. In the early 1980s, organizations began to measure customer satisfaction by tracking the number of customer complaints they received. When research evidence started to show that only about 10% of dissatisfied customers complained, organizations turned to more sophisticated measures, such as customer satisfaction. In the late 1980s and early 1990s, people began to question whether customer satisfaction was enough. Research data gathered by Xerox showed that customers who were "very satisfied" were five times more likely to repeat their purchase in the next 18 months than those who were just "satisfied." This and similar observations resulted in the development of the concept known as customer loyalty. The aim of this concept was to track whether customers (1) returned to buy more from the same organization, and (2) recommended the organization to others.

More recently, research data from a variety of industries has demonstrated that many customers are not profitable for organizations. For example, it has been suggested that in retail banking, 20% of customers generate 130% of profits. Other data illustrate that increased levels of customer satisfaction can result in reduced levels of organizational profitability because of the high costs of squeezing out the final few percentage points of customer satisfaction. Perhaps; but most of the evidence suggests that very few substantial companies are anywhere near running into that dilemma. Nevertheless, the reaction has been increasing interest in the notion of customer profitability. Sometimes the customer profitability data produces surprises for the organization, indicating that a group of customers thought to be quite profitable are in fact loss-makers and that other customer groups are far more profitable than generally believed by the organization's executives. Performance data allow assumptions to be challenged.

The important point, and where a subtle twist comes into play, is that customers do not necessarily want to be loyal or profitable. Customers want great products and services at a reasonable cost. They want satisfaction from the organizations they choose to use. It is the organizations themselves that want loyal and profitable customers. So it is with employee satisfaction and supplier performance. For the most part, organizations want loyal employees as well as loyal customers, and they want their workforce to do their jobs with high productivity levels. Many organizations grade their employees based on their contribution, and this grading often has a very direct bearing on their remuneration (an employee want and need, of course).

For years, managers have struggled to measure the performance of suppliers. Do they deliver on time? Do they send the right quantity of goods? And, especially, is their quality good? But these are all dimensions of performance that the organization requires of its suppliers. They encapsulate the suppliers' contribution to the organization. Supplier satisfaction is a completely different concept. If a manager wanted to assess supplier satisfaction, then he or she would have to ask the following questions: Do we pay on time? Do we provide adequate notice when our requirements change? Do we offer suppliers forward schedule visibility? Do our pricing structures allow our suppliers sufficient cash flows for future investment and, therefore, ongoing productivity improvement? Could we be making better use of our vendors' core capabilities and outsource more to them? Again, supplier satisfaction is different to supplier contribution.

The key message here is that for every stakeholder there is a *quid pro quo*: what the organization wants and needs from them as well as what the stakeholder wants and needs from the organization; the right-hand side of Fig. 2 illustrates this. We have found from experience that gaining a clear understanding of the dynamic tension that exists between what stakeholders

want and need from the organization and what the organization wants and needs from its stakeholders can be an extremely valuable learning exercise for the vast majority of organizations.

Strategies

The key question underlying this perspective is: What strategies should the organization adopt to ensure that the wants and needs of its stakeholders are satisfied (while ensuring that its own requirements are satisfied as well)? In this context, the role of measurement is fourfold. First, measures are required so that managers can track whether the strategies they have chosen are actually being implemented. Second, measures can be used to communicate these strategies within the organization. Third, measures can be applied to encourage and provide incentives for implementation of strategy. Fourth, once available, the measurement data can be analyzed and used to challenge whether the strategies are working as planned (and, if not, why not).

Strategies can be applied at different levels within an organization. Typically, corporate strategies will deal with questions such as: What businesses do we want to be in? And how shall we be successful building them? Business unit strategies will usually consider the following: What markets do we want to be in? And how shall we be successful serving them? Brands, products, and services strategies address problems such as: What brands, products and services shall we offer to these markets? And how shall we be successful offering them? Finally, operating strategies tend to ask: What processes and capabilities must we develop in order to serve these markets and provide these products and services effectively and efficiently? And how shall we successfully implement and achieve them?

The adages "you get what you measure" and "you get what you inspect, not what you expect" contain an important message. People in organizations respond to measures. Horror stories abound of how individuals and teams appear to be performing well, yet are actually damaging the business. For example, when the length of time it takes call center staff to deal with customer calls is monitored, it is not uncommon to find them cutting people off mid-call—just so the data suggest that they have handled the call within their 60 second target. Malevolently or not, employees tend to adopt "gaming tactics" in order to achieve the target performance levels they have been given. Measures send people messages about what matters and how they should behave. When the measures are consistent with the organization's strategies, they encourage behaviors that are consistent with strategy. The right measures then offer not only a means of tracking whether strategy is being implemented, but also a means of communicating strategy and encouraging implementation.

Many of the existing measurement frameworks and methodologies appear to stop at this point. Once the strategies have been identified and the right "leading and lagging" measures established, it is assumed that everything will be fine. Yet studies suggest that some 90% of managers fail to implement and deliver their organization's strategies. Why? There are multiple reasons, but a key one is that strategies also contain inherent assumptions about the drivers of improved business performance. Clearly, if the assumptions are false, then the expected benefits will not be achieved. Without the critical data to enable these assumptions to be challenged, strategy formulation (and revision) is largely predicated on "gut feel" and management theory. Furthermore, strategies can be blown off course by external dependencies that are beyond the control of the organization. Measurement data and its analysis will never replace executive intuition, but it can be used to greatly enhance the making of judgments and decisions. A critical judgment is, of course, whether an organization's strategy and business model remain valid.

A further key reason for strategic failure is that the organization's processes are not aligned with its strategies. And even if its processes are aligned, perhaps the capabilities required to operate these processes are not. Hence, the next two perspectives on performance are the processes and capabilities perspectives. Again, measurement plays a crucial role by allowing managers to track whether the right processes and capabilities are in place, to communicate which processes and capabilities matter, and to encourage people within the organization to maintain or proactively nurture these processes and capabilities as appropriate. This may involve gaining an understanding of which particular business processes and capabilities must be competitively distinctive ("winners"), and which merely need to be improved or maintained at industry standard levels ("qualifiers")—clearly, these are vital strategic considerations.

Processes

Business processes received a good deal of attention in the 1990s with the advent of business process re-engineering. Business processes run horizontally across an enterprise's functional organization until they reach the ultimate recipient of the product or service offered—the customer. Michael Hammer, the re-engineering guru, advocates measuring processes from the customer's point of view—the customer wants it fast, right, cheap, and easy (to do business with). But is it really as simple as that? There are often many stages in a process. If the final output is slow, wrong, expensive, and unfriendly, how will we know which components of the process are letting it down? What needs to be improved? In the quest for data (and accountability), it is easy to end up measuring

everything that moves but learning little about what is important. That is one reason why processes need owners: to decide what measures are important, which metrics will apply, and how frequently they shall be measured and by whom, so that judgments can be made upon analysis of the data and actions taken.

Typically, organizations consider their business processes in four separate categories:

1. Develop products and services
2. Generate demand
3. Fulfill demand
4. Plan and manage the enterprise.

Within these categories, there are various sub-processes, which tend to be more functional in nature.

Processes are what make the organization work (or not, as the case may be). They are the blueprints for what work is done where and when, and how it will be executed. The aspects or features it will be critical to measure can normally be categorized as follows:

1. Quality (consistency, reliability, conformance, durability, accuracy, dependability)
2. Quantity (volume, throughput, completeness)
3. Time (speed, delivery, availability, promptness, timeliness, schedule)
4. Ease of use (flexibility, convenience, accessibility, clarity, support)
5. Money (cost, price, value).

These five categories will help to quantify the measurement criteria for the process issues that we identify as critical to success, i.e., How good? How many? How quickly? How easily? How expensive?

We should note, however, that not all critical processes are performed continuously or even regularly. Contingency processes such as disaster recovery, product recall, or various types of system failure (e.g., power outage, labor strike) will be executed rarely, if ever, but nevertheless need to be prepared for rapid deployment at any time, with formal procedures established. The key measurement issue here will normally be the level of readiness for action.

Additionally, when measuring processes, we need to consider the component parts of the individual process itself. All processes have four common characteristics: inputs, actions, outputs, and outcomes. Starting with the process outcomes and outputs first, we need to identify measures of the effectiveness of the process:

- Does the process deliver or produce what it is supposed to do [output]?
- How well does the process output perform for the recipient [outcome]?

Next, we need to consider the actions and inputs of the process by seeking measures of the efficiency of the process, for example:

- How long does it take to execute the process?
- How frequently does the process have to be executed?
- How much volume is processed (versus capacity)?
- What does it cost to perform the process?
- What are the levels of variability in—and into—the process?
- What is the level of wastage in the process?
- How flexible (e.g., multipurpose) is the process?
- How simple/complex (e.g., transactional/knowledge-based) is the process?
- How ready for deployment is a (e.g., rarely required but essential) process?

One further feature of process measurement is its ability to be measured at either a macro or a micro level. As mentioned previously, process owners may indeed want to see the big picture, but they will also need to be able to pinpoint exactly where quality, cycle time, and bottleneck problems are occurring.

Capabilities

Even the most brilliantly designed process needs people with certain skills, policies, and procedures about the way things are done, a physical infrastructure for it to happen, and, more than likely, some technology to enable or enhance it. Capabilities are bundles of people, practices, technologies, and infrastructure. Indeed, capabilities can be defined as the combination of an organization's people, practices, technology, and infrastructure that collectively represents that organization's ability to create value for its stakeholders through a distinct part of its operations.

Measurement of a capability usually focuses on those critical component elements that make it distinctive and also allow it to remain distinctive in the future. But that does not necessarily mean that those capabilities that only need to be as good as those of competitors do not need to be measured. How would an organization know that it is not beginning to fall behind in these areas if it does not measure them? Either way, competitive benchmarks will likely be needed in order to understand the size of the gap. Competitors will also be seeking ways to create value for a very similar set of stakeholders. The goalposts seldom remain static for very long.

Lest there be any confusion about what we mean here by capabilities, consider a common business process, such as the order-to-cash fulfillment process in an electronic products business. The customer places an order, the company makes and delivers it, and then gets paid for it. It is a single process with multiple components and implies the presence of at least six different capabilities.

These capabilities are the following:

1. Customer order handling capability
2. Planning and scheduling capability
3. Procurement capability
4. Manufacturing capability
5. Distribution capability
6. Credit management capability.

Each of these capabilities requires different skill sets, practices, technologies (although some IT systems will likely be multifunctional and integrated), and physical infrastructures, such as offices, factories, and warehouses.

Linking Strategies, Processes, and Capabilities

The performance prism thus helps to identify the critical components of strategies, processes, and capabilities that need to be addressed, from a performance measurement and management point of view, in order to satisfy the wants and needs of the various stakeholders and the organization. Obviously, organizations can and should choose which elements of these three perspectives or facets of the performance prism framework they should focus their performance management attentions on at any given time in their evolution. The performance prism is a tool flexible enough to allow that selection process to be adapted in the initiatives and focus that organizations elect to pursue. Figure 3 summarizes the application of these three perspectives.

An essential element is that these three facets or perspectives of the performance prism must be linked to each other in order to understand how they fit together toward satisfying the stakeholders' and the organization's wants and needs. Bob Kaplan and David Norton talk extensively about strategy maps in their latest book on the balanced scorecard, *The Strategy-Focused Organization*. But one of the advantages of the performance prism framework is that it makes explicit what elements should be covered in a strategy map. In traditional, balanced scorecard terms, a strategy map simply covers the four perspectives on the balanced scorecard—shareholders, customers, internal processes, and innovation and learning. But, in our view, this is too narrow. Success maps, as we prefer to call them, should cover all five facets of the performance prism, using the five vital questions as prompts.

An alternative method, or perhaps most appropriately as a means of validating the outputs from the success mapping process, is to apply what we call a failure mode map (or risk map). Failure mapping helps to check whether all the critical aspects of performance measurement have been properly addressed. In essence, this technique takes the reverse approach of a success map by identifying particular scenarios that describe the opposite of success—failure. By examining each key potential failure mode, a check can be made on the strategies, processes, and capabilities that relate to this risk and whether the measures identified are sufficient to enable mitigation of the risk's occurrence or its malevolence. To be warned should be to be prepared.

Kaplan and Norton promote the application of strategy maps, but they do not go far enough since they fail to break them down into their vital components—the potential for success and the potential for failure. Organizations have many opportunities but they also face several threats; their measurement systems must be able to capture both so that executives can manage the business with a clear view of both scenarios.

Applying the Performance Prism to Measures Design

To summarize then, we have identified five distinct but logically interlinked perspectives on performance

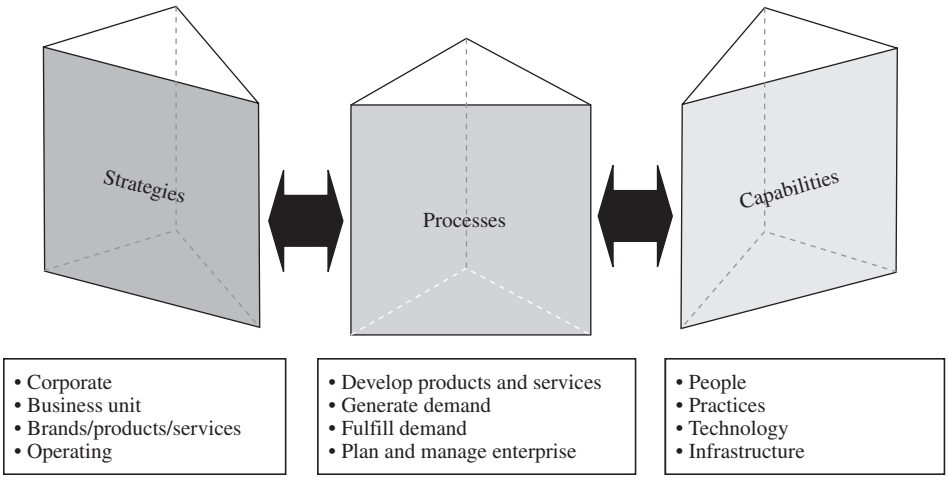

Figure 3

together with five vital questions to apply that will aid measurement design:

1. *Stakeholder satisfaction*: Who are the key stakeholders and what do they want and need?
2. *Stakeholder contribution*: What contributions do we require from our key stakeholders?
3. *Strategies*: What strategies do we have to put in place to satisfy these two sets of wants and needs?
4. *Processes*: What critical processes do we require if we are to execute these strategies?
5. *Capabilities*: What capabilities do we need to operate and enhance these processes?

As we have seen, these five perspectives on performance can be represented in the form of a prism. A prism refracts light. It illustrates the hidden complexity of something as apparently simple as white light. So it is with the performance prism. It illustrates the true complexity of performance measurement and management. Single dimensional, traditional frameworks pick up elements of this complexity. While each of them offers a unique perspective on performance, it is essential to recognize that this is all that they offer—a one-dimensional perspective on performance. Performance, however, is not one-dimensional. To understand it in its entirety, it is essential to view it from the multiple and interlinked perspectives offered by the performance prism (see Fig. 4).

The performance prism is not a cure-all tool. It will not solve all of the problems of performance measurement, and it needs to be used intelligently to optimize its potential. However, we believe that it does provide a robust and comprehensive framework through which the real problems and practical challenges of managing organizational performance can be viewed and addresses. This belief is born out of our experiences of successfully applying the performance prism within a wide variety of organizations.

Phenomenology

Shadd Maruna
University of Cambridge, Cambridge, United Kingdom

Michelle Butler
University of Cambridge, Cambridge, United Kingdom

Glossary

bracketing (or **Epoché**) Setting aside one's prior conceptions and experiences regarding how the world operates in order to be as open and receptive as possible to others' view of the world.

emergent themes Themes that arise out of the subjective accounts that bring to light certain concerns and motivations which may not be directly referred to by the person but which have an influence on the person.

interpretative phenomenological analysis A form of analysis concerned with how participants make sense of their social and personal worlds by examining the meanings that particular events, experiences and states hold for the participants.

intersubjectivity Mutual understanding or the overlap of agreement between different individuals' subjective experiences.

life world (or **Lebenswelt**) Each individual's subjective construction and understanding of the world around them, a personal narrative created with the help of building blocks and methods offered to him by others.

phenomenological reduction When one's life world is reduced by bracketing to that of a world of pure phenomena, the researcher's own viewpoint is suspended, and an effort is made to experience the world anew.

understanding (or **Verstehen**) The grasping of the subjectively intended meanings and symbolizing activities of others through empathy and deep listening.

Generally speaking, phenomenology is the study of lived experience and the subjective perceptions of human actors. Phenomenology seeks to understand how humans experience, make sense of and create meaning out of their existence. In a more specialized sense, phenomenology is also the name of a philosophical movement associated with the German philosopher Edmund Husserl (1859–1938) and the numerous social theorists influenced by him. This philosophical method concentrates on the careful analysis of conscious experience, without making assumptions about explanation, metaphysics, or other traditional philosophical issues. In the social sciences, phenomenological research involves detailed descriptions of consciousness and inner experiences from a first-person perspective. In other words, the "world" of concern to phenomenology is the "life world" or world as experienced and made meaningful in consciousness. In what follows, we will provide a closer look at the What, Who, When, Where, How, and Why of phenomenology, and conclude with an example of phenomenology in practice.

What Is Phenomenology?

Considerable definitional confusion surrounds the subject of phenomenology and this is not always aided by the primary sources of the phenomenological perspective. Phenomenological theorist Maurice Merleau-Ponty, for instance, answered the question of "What is phenomenology?" by arguing, "We shall find in ourselves, and nowhere else, the unity and true meaning of phenomenology."

Indeed, the term "phenomenology" is sometimes avoided, even by researchers engaged in phenomenological research. The word is not easy to pronounce quickly and can sometimes seem a pretentious way to describe "walking in another person's shoes." Moreover, some of

the theoretical work on phenomenology is found to be impenetrable for non-philosophers (and indeed some philosophers). Most importantly, though the term phenomenology seems to be avoided because it can mean so many different things in different contexts. The word phenomenology, after all, can refer to a philosophy, a paradigm, a method, or even an intellectual movement.

Yet, phenomenology can also simply denote an understanding of subjective experience or the study of human consciousness. The word phenomenon is rooted in the Greek term *phaenesthai*, to show itself, to flare up, to appear, and in its most basic form, phenomenology is simply about illuminating the perspectives of others. As such, one need not prescribe to the philosophical tenets of phenomenology as outlined by Edmund Hussrl or be a trained "phenomenologist" to be interested in the phenomenology of individuals in some situation. That is, one can speak legitimately about the "phenomenology of working class experience" (from Charlesworth) or the "phenomenology of criminal behavior" (from Katz) without being a philosopher or accepting the theory of mind posited by Husserl. Phenomenology in this sense simply refers to the description and understanding of lived, human experience through observable forms of immediate cognitive experience and reflective analysis.

In some ways, it is easiest to define phenomenology by first describing what it is not. Often the term phenomenology is used to indicate a contrast to traditional social science methodology, and indeed, phenomenology first emerged as a critique of paradigmatic approaches to ways of knowing in philosophy. Phenomenologists are opposed to both grand, over-arching social theories based on speculation as well as to the abstracted empiricism associated with some forms of positivist research (see also Mills). Moreover, whereas the positivist approach to social science is to seek the causes and explanations of social phenomena apart from the subjective states of the individual actors, phenomenologists are committed to understanding social phenomena from the actor's own perspective, and they prioritize description over explanation.

Indeed, one of the chief accomplishments of phenomenological research is to restore subjectivity from the derogatory status assigned to it in traditional positivist social science (e.g., the critique that something is "merely subjective"). Phenomenological theory insists that the subjective matters. It is not simply "measurement error" or idiosyncratic noise too variable or inaccessible to be studied. The most important "reality" to phenomenologists is the reality that people perceive and construct (their "life world" or "Lebenswelt") not some objective world. Phenomenology views human behavior, what people say and do, as a product of these definitions of reality. The ultimate (and probably unattainable) goal of interpretative phenomenological analysis is to experience the reality of another's consciousness through the achievement of "verstehen" or understanding. Particular attention is paid to the everyday lived experience of individuals, and subjects are typically treated as a whole and not reduced to variables.

Despite its attention to lived experience, however, phenomenological enquiry is not limited to understanding microsociological phenomena. Alfred Schutz, for instance, who is probably most responsible for introducing phenomenological philosophy to the social sciences, paid considerable attention to the role of historical, structural, and cultural factors in shaping consciousness. Likewise, although phenomenological psychologists tend to focus on individual persons as the creators of meanings in their lives, there is a universal recognition that these meanings are socially and culturally bounded.

History of Phenomenology: Who, When, and Where

The philosophy of phenomenology is over a century old, emerging in the mid-1890s in Germany and quickly spreading to Russia, Spain, and Japan prior to the First World War. As a method of social inquiry, phenomenology is most closely associated with the German philosopher Edmund Husserl (1859–1938), who wrestled with Kantian issues of epistemology (the philosophy of knowledge) in books like *The Idea of Phenomenology*. Other key proponents of phenomenology in philosophy include Merleau-Ponty, Martin Heidigger, and Jean-Paul Sartre.

This work was later popularized to the social sciences by Husserl's disciple Alfred Schutz (1899–1959) with his book *Phenomenology of the Social World*, first published in 1932, but then reprinted in 1967. It was with this latter edition, released at the height of an experimental and critical era in social science research, that phenomenology gained the most widespread acceptance among social science researchers. Unlike Husserl, Schutz focused on understanding the common sense reality of the everyday world, in particular the concept of "intersubjectivity" or the taken-for-granted assumptions and understandings that bind individuals together in a given culture or subculture. Although he was primarily a theorist rather than a sociological researcher, Schutz wrote two important, sociological treatments that apply a phenomenological perspective to sociological issues. For instance, written soon after he emigrated to the United States himself, his essay "The Stranger" focuses on the ways outsiders interpret and make sense out of a particular culture and attempt to orient themselves within it.

Yet, an interest in phenomenological questions is most certainly not limited to self-proclaimed philosophical phenomenologists. Phenomenology is closely tied to, if not wholly synonymous with, numerous other

approaches to social sciences including interpretivist sociology, symbolic interactionism, ethnomethodology, conversation analysis, social constructionism, existentialism, and humanistic-existential psychology. Practitioners from all of these perspectives share an interest in the subjective understandings of individual actors. Indeed, according to one of the founders of the movement, this interest in the construction of personal meanings was central to the "cognitive revolution" that swept throughout the social sciences during the latter part of the 20th Century.

How to "Do Phenomenology"

There is no single, "correct" method of conducting phenomenological research. Indeed, inherent in the philosophy itself is the suggestion that there should be no rule books or step-by-step guides for "doing" phenomenology. Still, in general, learning about another person's subjective reality tends to involve deep and empathetic listening to another, taking seriously his or her understandings of reality. As such, there is an emphasis on utilizing qualitative data collection techniques, such as ethnography and open-ended interviewing, that allow the researcher to remain close to the phenomena themselves and to convey in thick detail how it feels to live through some experience of reality. In this sense, phenomenological research tends to stress validity over reliability. However, empirical phenomenology sometimes employs independent raters to check intersubjectivity, sometimes utilizing a prior coding mechanism in the systematic content analysis of interview transcripts.

Crucially, the phenomenological researcher is urged to listen to others' accounts in their own terms, as free as possible of any of the researchers' own preconceptions and interferences. The maxim of philosophical phenomenology is "To the Things Themselves" (see Moustakas) and phenomenological understanding involves first "encountering" the perspective of others as if starting from a blank slate. This process of setting aside one's prior conceptions and experiences is called "bracketing" (or "epoché"). The aim is to achieve phenomenological reduction whereby the world is experienced anew. In this way, phenomenology is said to "begin in silence."

Finally, the analytic process in phenomenological work tends to be inductive, with patterns developing from deep immersion in the data. Subjects are usually sampled for theoretic reasons. Small groups of individuals who share common experiences (e.g., people who have experienced extended heroin use) will be interviewed to better understand the subjective experience (e.g., "phenomenology of heroin use"). Phenomenological analysis focuses on concrete descriptions of experiences and aims to reveal structures that are common to the group. At the same time, some of the identified patterns might be "emergent" or implicit themes that are inferred from what is said by subjects rather than that which is directly identified.

Why Phenomenology?

There are numerous reasons why introspective descriptions of individuals' conscious, inner worlds might be interesting and important to social scientists. Most pragmatically, understanding how individuals perceive the social world may help social scientists better explain and predict their behavior. Fundamental to the phenomenological approach is the symbolic interactionist truism, "If [people] define situations as real, they are real in their consequences." In the original passage containing this famous phrase, Thomas and Thomas are attempting to account for the unusual behavior of a convict at Dannemora prison who had murdered several persons because they "had the unfortunate habit" of talking to themselves on the street. They write, "From the movement on their lips he imagined that they were calling him vile names, and he behaved as if this were true." Even beyond such extreme cases, phenomenologists argue that "each individual extracts a subjective psychological meaning from the objective surroundings and that subjective environment shapes both personality and subsequent interaction" (see Caspi and Moffitt).

Phenomenology's usefulness in enhancing the predictive powers of causal explanation is not its only strength, however. Phenomenological theorists suggest that reaching verstehen (or phenomenological understanding) is "the key to understanding what is unique about the human sciences" (see Schwandt). Victor Frankl, for instance, argues that the human being's search for meaning is "a primary force in his life and not a "secondary rationalisation" of instinctual drives." Arguing against the determinism of positivist social science, phenomenologists like Frankl argue that human beings are ultimately self-determining. "Man does not simply exist but always decides what his existence will be, what he will become in the next moment." As such, from this perspective, a social science that does not include some account of this process of meaning construction and self-determination in human existence can hardly be considered a human science at all.

On the other hand, there are numerous reasons why phenomenological research is avoided by social scientists. Critics contend that phenomenological work cannot be empirically verified and is therefore antiscientific. Additionally, the practical relevance of largely descriptive phenomenological enquiry for the applied world of policy formulation is not always clear, compared, for instance, to correlational and variable-oriented research.

Phenomenology in Action: The Seductions of Crime

A recent example of the potential contribution of phenomenological research to the social sciences is Jack Katz's critically acclaimed *Seductions of Crime*. Prior to Katz's work, the study of crime had been overwhelmingly preoccupied with the background characteristics of individuals who commit crimes. Criminological research tends to ask whether some combination of variables (neighborhood of origin, IQ, personality traits, and so forth) can predict who will or will not become involved in crime. Such research, and criminological theory in general, tends to portray offenders as unfortunate, passive, over-determined products of their circumstances. As Katz and others point out, this image seems a long way from the excitement, danger and, sometimes, sheer joy of the experience of offending itself. Moreover, Katz argues:

> *The statistical and correlational findings of positivist criminology provide the following irritations to inquiry: (1) whatever the validity of the hereditary, psychological, and social-ecological conditions of crime, many of those in the supposedly causal categories do not commit the crime at issue, (2) many who do commit the crime do not fit the causal categories, and (3) what is most provocative, many who do fit the background categories and later commit the predicted crime go for long stretches without committing the crimes to which theory directs them. Why are people who were not determined to commit a crime one moment determined to do so the next?*

Katz argues for a shift from the social and psychological background factors in the criminal equation to a focus on the phenomenological foreground of crime, the seductive qualities of crime or the aspects that make crime a compelling, sensual, even morally transcendant pursuit. Utilizing analytic induction, Katz seeks to construct phenomenological understandings of a variety of criminal acts from shoplifting, to vandalism, to cold-blooded murder, in each case asking, "What are people trying to do when they commit a crime?" He suggests that this shift from background to foreground factors will explain more variation in criminality than background correlations allow.

Just as importantly though, Katz's work, unlike the majority of criminological research, provides an intimate and at times disturbing insight into the emotional and cognitive experience of crime. Getting "inside the minds" of serial killers, rapists and other offenders is a favorite pursuit of pop psychologists, novelists and scriptwriters, of course, and the public seems to hunger for the understanding such works provide. Yet, for the most part these sensationalized accounts are not based on even the barest research evidence. *Seductions of Crime*, on the other hand, is the product of a systematic analysis of what amounts to a mountain of research evidence. Katz draws on a wide array of published and unpublished ethnographic data, autobiographies, and collections of first-person accounts in constructing each of his phenomenological accounts.

Far from the last word on the phenomenology of any of these criminal pursuits, Katz's work has opened the door for a new type of criminology, focused not on prediction, but on understanding. The result is a much deeper understanding of the criminal as a person, rather than crime as a product of multiple variables interacting. Katz does not offer this portrait as a critique of criminological research on the background factors associated with crime, but rather as an essential complement to this literature. Phenomenology, in this case and others, seeks to put the "human" in the human sciences.

Phrase Completion Scales

David R. Hodge
University of Pennsylvania, Philadelphia, Pennsylvania, USA

David F. Gillespie
Washington University, St. Louis, Missouri, USA

Glossary

coarse data Coarse data has units of information that cannot be specified as equal. Ordinal-level data, for example, are more coarse than interval-level data because the units of information that comprise ordinal data cannot be assumed equal, whereas the units of information that comprise interval-level data are assumed equal.
confounding Confounding occurs when it is impossible to separate the effects of two or more variables from each other. In measurement, this happens when two or more dimensions are present in a single question.
construct An idea that identifies a phenomenon that is not directly observable, such as attitudes.
Likert items Represent a questionnaire format developed by Rensis Likert that is widely used to measure attitudes. Likert items have an introductory stem consisting of a positively or negatively stated proposition followed by a graduated response key composed of adverbs (e.g., "strongly") and verbs (e.g., "agree").
superimposition A dimension implied by the response key that differs from, and consequently is imposed over, the dimension implied by the question's introductory stem.
unidimensional Concepts that have only one source of variation. More concretely, a measure of a single attribute of a construct.
univocal stimulus A concise, unambiguous question or statement that conveys a single meaning.

Phrase completion scales are concise, unidimensional measures designed to tap ordinal-level data in a manner that approximates interval-level data. The phrase completion method of constructing scales was developed as an alternative to Likert scales. Although the Likert method is widely used, a number of disadvantages are associated with this approach to measuring sentiments. After introducing the phrase completion method and the assumptions underlying its development, the disadvantages associated with the Likert method are discussed. The delineation of these disadvantages—namely multidimensionality, multivocal stimuli and unsubstantive responses, and coarse data—highlights the comparative advantages provided by the phrase completion method. The article concludes with a brief summarization of the limitations and strengths of the phrase completion method.

Introduction

The phrase completion method was developed to improve the measurement of personality, social, and psychological sentiments. Specifically, the phrase completion method represents an attempt to either meet or more precisely approximate the assumptions underlying measurement and statistical methodologies. Three assumptions in particular animated the development of the phrase completions. The first two—unidimensionality and univocal stimulus—are basic to all measurement. The third—the assumption of normally distributed interval- or ratio-level data—is unique to parametric statistics.

Unidimensionality

Unidimensionality is an underlying assumption shared across all levels of measurement. The individual items that comprise measurement scales are commonly classified as nominal, ordinal, interval, or ratio. Nominal data

refers to discrete, categorical units of information that are not ordered in any hierarchical format (e.g., race, gender, and ethnicity). Ordinal-, interval-, and ratio-level data all rank units of information in a hierarchical arrangement. Unit *C* is greater in magnitude than unit *B*, which in turn is greater in magnitude than unit *A*. The distinguishing characteristic between ordinal and interval data concerns the magnitude or the distance between the units of information. With interval data, the units of information are identical; the distances between *A*, *B*, and *C* are the same. With ordinal data, the units of information are typically unequal; there is no guide as to the distance between *A*, *B*, and *C*. In other words, ordinal-level data consists of ordered categories of varying magnitude, whereas interval data consists of a series of equally spaced units.

All four levels of measurement, however, should be characterized by unidimensionality. In other words, each individual item in a scale should grade a population only on a single, given quality. Units *A*, *B*, and *C*, must reflect information about a distinct, discrete entity.

This is a particularly significant assumption since the existence of multidimensionality in an item raises the issue of confounded dimensions. If an item taps more than one dimension, it is not a valid measure. If an item purports to assess the level of dimension *X* but in actuality assesses some level of dimension *X* and some level of dimension *Y*, then it is impossible to distinguish the effects of *X* from the effects of *Y*. Consequently, it is impossible to establish a relationship between constructs since the researcher cannot ascertain the extent to which each item is measured.

It is important to note that even among what are commonly referred to as multidimensional measures, each theorized dimension or domain must exhibit unidimensionality. Multidimensional measures designed to assess the dimensions *A*, *B*, and *C* of a particular construct must not assess additional dimensions nor overlap with each other. In other words, the items designed to assess the level of dimension *A* must not concurrently assess the level of an additional dimension *D* nor be confounded with the items designed to assess *B* and *C*. Each individual item must be unidimensional.

Univocal Stimulus

Measurement is based on the premise that a univocal or single stimulus in the form of a set of questions can tap a given construct. A critical assumption is that all individuals understand the stimulus in the same way so that different responses are due to real differences in the amount of the construct among individuals. In short, the stimulus must be univocal rather than multivocal. If individuals encounter multiple stimuli, the internal logic of measurement is compromised since any apparent difference may be due to the different stimuli rather than a reflection of real differences in the construct of interest.

Questions must be clear and concise if they are to produce substantively meaningful results. If a question is vague and ambiguous, understandings of the question can vary. Because individuals receive multiple stimuli, different respondents can answer the same question differently due to varying interpretations. Similarly, if items are too complex, respondents that are apathetic, hurried, tired, from different cultures, or who have lower levels of education may understand stimuli differently. In such cases, variation in the construct of interest may be due to the complexity of the questions.

It is important to note that, at least to some extent, multivocalilty is a problem that can never be completely eliminated. Each individual receives a slightly different stimulus from any given question due to differences in age, class, gender, spiritual orientation, etc. Given these realities, the intent should be to produce items that come as close as possible to approximating univocal stimulus. To achieve substantively meaningful results, it is important to construct concise, unambiguous questions that reduce cognitive complexity.

Normally Distributed Interval- or Ratio-Level Data

Concise unidimensional items are fundamental to all statistical procedures. The most widely used procedures, however, are parametric statistics, such as regression, analysis of variance, or *t* tests. Additional assumptions are associated with the use of these statistics.

Specifically, parametric statistics are based on the assumption that interval- or ratio-level data with a normal distribution are used. In other words, parametric statistics require the use of data that are at least interval level. Due to the subjective nature of human attitudes, it is difficult to obtain interval-level data on sentiments. Consequently, in practice, ordinal-level data are commonly used with parametric statistics. This practice is based on the widespread recognition that many parametric statistics are robust and can withstand some violation in the underlying assumptions. Nevertheless, the violation of assumptions can result in errors, such as the failure to detect significant effects (e.g., type II errors).

The phrase completion method was developed as a concise, unidimensional approach that provides a closer approximation of interval-level data. Although from a technical standpoint the phrase completion method produces ordinal measures, it is important to note that variation exists in ordinal measurement. This variation can be understood as a continuum. At one end of the continuum, the data are very coarse. The difference between the units of information varies substantially. At the other end

of the continuum, the data are quite fine. The difference between the units of information varies minimally. At the latter end of the continuum, the units of information approximate the equal spacing that characterizes interval-level data. It is this type of relatively fine, ordered data that phrase completions were designed to capture.

Construction of Phrase Completions

Phrase completions consist of a phrase followed by an 11-point response key. The phrase introduces part of a concept. Designating a reply on the response key completes the concept initiated by the phrase.

The response key represents the underlying continuum of the construct that the completed phrase is designed to tap. In theory, most constructs exist along a continuum, ranging from the absence of the construct in question to some theorized maximum amount of the construct in question. This continuum is operationalized and specified in the 11-point response key. Specifically, verbal anchors are typically placed on the ends of the response key. The number 0 is used to signify the absence of the construct and 10 is used to signify the maximum amount of the construct.

Presented with the underlying continuum of the construct in question, the respondent selects a choice along the continuum that completes the phrase. This approach produces a concise, unidimensional measure. By delineating the underlying continuum of the construct in question, respondents can select the point along the continuum that best reflects their views. Validity is enhanced since the theoretical continuum is presented to the respondent in the measure. Similarly, the delineation of the continuum helps to ensure that the measure is unidimensional.

When numbers are presented in response keys, respondents tend to use them to guide their thinking. The presence of integers helps respondents view the range of available options. By delineating the theoretical continuum as a series of integers, which are by nature equally spaced, respondents may be more inclined to view their sentiments in terms of a continuous variable. The integers work in concert with the anchor phrases to directly imply the degree of the attribute: Zero equals the absence of the construct, 10 the maximum, and the intervening numbers signify increasing amounts of the construct. As discussed later, this type of formatting engenders data that approximate interval-level data.

Table I provides an example of the phrase completion method. Standard orienting material is provided along with three questions that tap various aspects of spirituality. As can be seen, the underlying theoretical continuum has been specified in the response keys. For example, with the first question the responses range from the absence of the attribute—never aware of God's presence—to a maximum of the attribute—continually aware of God's presence—in a unidimensional manner. The reader is informed in the orientation that the ends of the continuum depict extremes and the middle values represent the more frequently occurring amounts of the variable in question. In some cases, it may be helpful to use a third anchor phrase in the center of the response key to accent the fact that middle values represent moderate response options.

The response key is reversed for every second question to encourage thoughtful responses and to reduce any response set bias that may exist. The scores of the questions that comprise the scale are summed to create

Table I Illustrating the Phrase Completion Method

The following questions use a sentence completion format to measure various attributes. An incomplete sentence fragment is provided, followed directly below by two phrases that are linked to a scale ranging from 0 to 10. The phrases, which complete the sentence fragment, anchor each end of the scale. The 0 to 10 range provides you with a continuum on which to reply, with 0 corresponding to absence or zero amount of the attribute and 10 corresponding to the maximum amount of the attribute. In other words, the end points represent extreme values, whereas 5 corresponds to a medium, or moderate amount of the attribute. Please circle the *number* along the continuum that seems to best reflect your intial feeling.

1. I am aware of the presence of God or the Divine

never									**continually**
0	1	2	3	4	5	6	7	8	9	**10**

2. I spend periods of time in private spiritual thought and meditation

every day, without fail									**never**
10	9	8	7	6	5	4	3	2	1	**0**

3. In terms of the questions I have about life, my spirituality answers

no questions									**absolutely all my questions**
0	1	2	3	4	5	6	7	8	9	**10**

a total score for the attribute in question. This basic approach is used with all phrase competitions.

As previously implied, phrase completions were developed in response to the disadvantages associated with traditional ordinal measures, most notably Likert scales. Consequently, the advantages of phrase completions are particularly evident when they are compared with the Likert method. As a precursor to this comparison, an overview of the Likert approach is provided.

Overview of Likert Scales

Likert or Likert-type scales are perhaps the most popular method for measuring attitudes. They were originally introduced by Rensis Likert as an alternative to the more time-intensive and judgment-based Thurstone approach to attitude scaling. Indeed, their ease of construction, intuitive appeal, adaptability, and usually good reliability have been key factors in fostering their widespread use.

In contemporary usage, the Likert method consists of a declarative stem followed by a response key. The stem clearly expresses a positive or negative opinion (e.g., "Quite often I have been aware of the presence of God or the Divine"). Typically, individuals are asked to indicate their level of disagreement or agreement regarding the stated opinion on a 5-point response key ranging from "strongly disagree" to "disagree," "neither disagree or agree," "agree," and "strongly agree."

Agreement with a positively stated proposition is considered to indicate the presence of the underlying construct. The responses are equated with integers (e.g., strongly disagree = 1 and strongly agree = 5), and negatively worded items are reverse scored. The items are summed, creating an index, which is hypothesized to indicate the degree to which the respondent exhibits the trait in question.

Although the agree/disagree format is perhaps the most common form of Likert scale, other types of response keys are also frequently employed. For instance, Likert originally used a "strongly disapprove/strongly approve" continuum. However, the basic approach—a positively or negatively stated proposition followed by a graduated response key composed of adverbs and verbs—is commonly viewed as the distinguishing hallmark of Likert scales.

Although Likert scales are widely used, a number of little known disadvantages are associated with their use, perhaps most prominently multidimensionality, multivocal stimuli and unsubstantive responses, and coarse data. The various facets of these disadvantages are delineated next along with some of the approaches that have been proposed to address the difficulties. Also highlighted is the manner in which phrase completions circumvent these disadvantages.

Multidimensionality

Perhaps the most prominent disadvantage associated with Likert scales is multidimensionality. The multidimensionality associated with superimposition and the confounding of the direction and intensity dimensions exist in all Likert scales. However, an additional set of difficulties is evident in odd-numbered scales, such as the widely used 5-point scales that employ a midpoint. All three areas are discussed next, and an exposition of the advantages of the phrase completion method follows the discussion of the second and third areas.

Superimposition

As noted previously, Likert stems express opinions. In effect, the stem asks respondents to think along a given dimension. For example, a stem in a spirituality survey that states, "Quite often I have been aware of the presence of God" asks individuals to conceptualize along a dimension that might be called awareness of God's presence.

In place of a response key that taps into the dimension suggested by the stem, the Likert response key superimposes an alternative dimension (e.g., agree/disagree) over the dimension suggested by the stem. Respondents must indicate their response on this alternative dimension that is imposed over the original dimension suggested by the stem. To follow up on the previous example, no opportunity exists to directly indicate the extent to which one experiences the awareness of God's presence. Multidimensionality exists because the response key superimposes a dimension that differs from the dimension suggested by the stem.

The existence of multidimensionality raises a number of concerns. Most prominently, the assumption of unidimensionality in measurement is violated. In essence, the measurement process is contaminated by the existence of multiple dimensions. However, in addition to superimposing a different dimension on the stem, Likert response keys also confound two distinct dimensions in the response key.

Confounding Direction and Intensity

Attitudes can be expressed in different ways. For example, two different attitudinal dimensions are direction or content and intensity or strength. Direction pertains to having either a positive or a negative view toward an entity, whereas intensity refers to the degree of conviction with which the view is held. The distinction between the two dimensions can be seen in the fact that a person may disagree with a certain proposition with a great deal of conviction or only mildly.

In addition to superimposing a dimension on the stem, Likert scales confound the direction and intensity dimensions. The response key on Likert items incorporates both direction (agree or disagree) and intensity (strongly or not strongly). Consequently, by virtue of their design, Likert scales ask respondents to think across three dimensions: the dimension suggested by the stem, direction, and intensity.

To address the problem of confounding direction and intensity, researchers have attempted to separate the two dimensions by using a two-question format. Individuals are first asked whether they agree or disagree with a given proposition, and then a separate follow-up question is used to assess the level of intensity. This procedure has produced mixed results, at least in part because the response key continues to superimpose a different dimension on the stem. Some researchers report little improvement, suggesting that confounding remains a problem because the use of a sequential format continues to confound the two dimensions. However, even in instances in which the findings have been more positive, the two-question approach has limitations. The number of questions is doubled, for example, resulting in larger expenditures of resources for both researchers and potential respondents. Finally, it should be noted that the multidimensionality associated with superimposition remains an issue.

Phrase completions circumvent these disadvantages. As can be seen in Table I, the multidimensionality associated with superimposition is avoided by the phrase completion method. To follow up on the previous example, as is evident with item 1 in Table I, respondents are asked to conceptualize along a single dimension—awareness of God's presence. Accordingly, the confounding of direction and intensity is eliminated by asking individuals to think along a single dimension. Similarly, the process of operationalizing the underlying continuum in the response key helps to provide substantively meaningful options while simultaneously upholding the assumption of unidimensionality in measurement items.

The Confounded Midpoint

The confounding of direction and intensity is also a relevant issue with the use of the midpoint. Likert scales commonly employ the use of an option, such as "undecided" or "neither disagree or agree," that is placed in the center of the response key. When numbers are assigned and the items are summed, midpoint responses are accorded a value of 3 on a 5-point scale.

The use of a midpoint is not universal, however, due in part to confusion over exactly what is being signified by its selection. Based on the value that a midpoint response receives during the summation process, it is designed to represent a neutral reply. In other words, it denotes a midpoint along the intensity or strength dimension, halfway between 1 and 5.

Many respondents, however, understand the midpoint in terms of the direction or content dimension. In other words, it represents an alternative to expressing agreement or disagreement. For individuals unable to decide whether they agree or disagree with the declarative stem, the midpoint functions as a means to express an option such as "don't know," "no opinion," or "haven't thought about it."

When the midpoint is used as part of the direction dimension, it should be given no score and removed from the summation process. However, since it is impossible to determine which dimension respondents are basing their response on, due to the confounding of direction and intensity in the midpoint, it is impossible to remove their scores. Thus, in many instances, individuals are being assigned a value that indicates that they have a medium amount of the trait being assessed when in realty they exhibit no amount of the trait.

In recognition of this problem, it has been suggested that a separate, distinct, "no opinion" response be added to filter out the appropriate respondents. This approach, however, has produced mix results. If a discrete "no opinion" response option is offered, a number of respondents who are unsure about the degree of their intensity appear to select the "no opinion" response as a means of avoiding the mental work associated with making a decision. In lieu of such an option, respondents expend the required mental effort to ascertain the exact point along the intensity continuum that best reflects their views. Consequently, a number of researchers believe that the costs of incorporating a "no opinion" response outweigh the benefits, unless there is reason to believe that a large number of respondents will be completely unfamiliar with the topic under investigation, in which case a "no opinion" filter is advisable.

In contrast, the phrase completion method circumvents the confounding of direction and intensity that occurs with the use of a midpoint. As illustrated in Table I, phrase completions employ no midpoint. Consequently, no confusion exits in the respondent's mind concerning which dimension the midpoint reflects. A clear zero option is presented that represents the absence of the trait in question. In addition, researchers still have the option of incorporating a "not applicable" option when they believe it is warranted. Consequently, the measurement error that results from inappropriately attributing values to respondents is minimized.

Multivocal Stimuli and Unsubstantive Responses

As noted previously, questions should be clear and concise with the goal being the production of substantively meaningful results. At least to some extent, Likert scales

fail to meet these criteria. Specifically, Likert scales are associated with increased cognitive complexity and the production of results of questionable validity, particularly when negative wording is used. The next two sections address the former concern, and the following section addresses the latter issue. Then, an illustration of how the phrase completion method addresses the disadvantages associated with negative phrasing is presented.

The Complexity Innate in Multidimensionality

The multidimensionality inherent in Likert items increases the level of cognitive complexity for respondents. Individuals are asked to simultaneously conceptualize along three dimensions. Individuals have to keep in mind the stated opinion while simultaneously evaluating whether they agree or disagree with the proposition and the strength with which they hold their views. The added cognitive load that occurs when respondents are asked to think across three dimensions can result in measurement error.

Negatively Worded Stems and Added Confusion

An added level of cognitive complexity is related to the use of negatively worded stems (e.g., stems that incorporate the word "not" and similar variations). Likert scales commonly incorporate the use of negatively worded items, sometimes referred to as item reversals or simply reversals, to guard against response set or acquiescent bias—the tendency to agree with a set of positively worded items. These items are interspersed with positively stated propositions and then reverse scored before summing all the items to achieve a total score.

The use of negatively worded stems, however, increases the level of cognitive complexity. Consider, for example, the following Likert item intended to assess the level of respondents' spirituality: "I never spend periods of time in private spiritual thought and meditation." Respondents must disagree with this statement to record scores indicating an elevated level of spirituality. Thus, in addition to having to think across three dimensions, individuals have the added cognitive load of having to conceptually synthesize a double negative (never spend time) and disagree in order to be coded as exhibiting spirituality.

In short, many individuals have difficulty expressing agreement with a given construct by disagreeing with a negatively worded item. The effects on validity and reliability may be most pronounced among children, the elderly, immigrants from different cultures, people with low levels of education, and situations in which respondents exhibit a low level of engagement with the questions.

Validity Issues Associated with Negative Stems

As noted previously, acquiescent bias provides the rational for using negatively worded stems that are interspersed with positively worded stems. If the number of negative and positive stems is identical, individuals who indiscriminately agree with every item end up, at least in theory, in the middle of the scale, with an average value of 3 on a scale of 1–5.

It is debatable, however, if individuals who respond in such a manner warrant a score in the middle of the scale. If these people could be induced to respond in a more thoughtful manner, it seems probable that they would often record scores that place them in other positions on the scale. In other words, individuals would record a variety of positions. However, by virtue of their design, item reversals reduce this variety to a single score.

Various methods have been used to address the disadvantages associated with the use of negative wording. Some researchers have attempted to completely eliminate item reversals and state all stems using positive wording. For example, some researchers have attempted to develop items that tap a mirror image of the construct being studied. In theory, respondents agree with the positively stated items that reflect the construct and disagree with the positive stems that reflect the hypothesized mirror image of the construct. The items in the latter group are then reverse scored. Developing such items, however, is a difficult process and questions exist about the unidimensionality of the trait and its hypothesized mirror image.

Other researchers have recommended using all positively worded stems and reversing the response key. In other words, odd-numbered questions might have a response key ranging from strongly disagree to strongly agree, whereas even-numbered items would have the response key ranging from strongly agree to strongly disagree. Still other researchers, noting the tendency of respondents to rate positively worded statements more favorably, continue to recommend the use of positive and negatively worded stems as the most optimal method, even though this approach may result in two-factor, multidimensional outcomes.

Phrase completion scales circumvent these difficulties by eliminating the use of negative wording in both the stem and the response key. Consequently, the confusion associated with having to synthesize a double negative (e.g., never spend time and disagree) is eliminated. Following up on the spirituality item discussed previously,

item 2 in Table I illustrates how this Likert item might be stated using the phrase completion method. As can be seen, by presenting a concise, unidimensional item to individuals, the level of cognitive complexity is reduced.

Regarding the validity issues associated with negative stems discussed previously, having respondents indicate where they fall on the underlying continuum likely fosters responses of greater validity. By removing the option to agree with a positively worded statement, obviously respondents can no longer indiscriminately agree with such statements. Instead, thoughtful interaction with each item is encouraged, a dynamic that is abetted by reversing the response key for alternating questions. By directly presenting individuals with the underlying construct, researchers are, in a manner of speaking, placing their theoretical cards on the table. This encourages respondents to directly select the option that corresponds to their views, fostering more substantively meaningful responses.

Coarse Data

Although the use of Likert data with nonparametric statistics is appropriate, the use of Likert scales with parametric statistics is widely considered problematic. The coarse nature of Likert data results in a violation of the assumptions that inform the use of parametric statistics. The coarse nature of Likert data is apparent in at least three areas: significantly unequal units, limited number of units, and restricted range. The advantages offered by the phrase completion method are noted at the end of each section.

Unequal Units

By definition, ordinal-level data are composed of unequal data units. As noted previously, however, variation exists in terms of the equality of data units. Some ordinal data are very coarse with grossly unequal data units. Conversely, other ordinal data may approximate interval data with measurement units that are relatively uniform. Consequently, measurement units should be as similar as possible to collect the highest amount of information. Indeed, the concept of normality of distribution becomes meaningless when the distances between scale points are unknown.

A number of studies have been conducted to examine the difference between units with verbal labels that have some relationship with probabilities. Typically, these studies present individuals with a series of verbal labels and ask them to assign a numerical value ranging from 0 to 100 that best reflects the magnitude of the label. Since the studies use labels that have some type of link with probabilities, they represent a more favorable scenario than exists with the widely used disagree/agree format.

Table II presents a series of these studies collected by Krosnick and Fabrigar that examined the numerical values attributed to a continuum ranging from excellent to very poor. These studies were conducted over the course of approximately 20 years, spanning a time period from 1968 to 1991. As can be seen, the actual numerical values assigned vary across studies in most cases, a fact that emphasizes the imprecise nature of such labels. Furthermore, with the possible exception of study 4, the difference between verbal labels varies considerably. In no study are all the differences between units equivalent. In a number of instances, the difference between the smallest unit and the largest differs by a factor of two and ranges as high as a factor of eight. In study 3, for example, the difference between "good" and "poor" was eight times larger than the difference between "poor" and "very poor." Similarly, the difference between "very good" and "good" was four times larger than the difference between "very poor" and "poor."

Likert scales may yield coarser data than are obtained with labels that are regularly associated with probabilities in common usage. A sentiment such as agreement may be more difficult to parse into equally spaced units due to its amorphous nature. Feelings of intensity would seem to

Table II Difference in Units for Likert-Type Labels

	Study 1		*Study 2*		*Study 3*		*Study 4*	
Verbal label	*Assigned value*	*Unit difference*	*Assigned value*	*Unit difference*	*Assigned value*	*Unit difference*	*Assigned value*	*Unit difference*
Excellent	93		91		91		99	
		15		9		11		26
Very good	78		82		80			
		11		12		22		
Good	67		70		58		76	
		24		21				25
Fair	43		49			42	48	
		22		32				25
Poor	21		17		16		23	
		9		12		5		22
Very poor	12		5		11		1	

be more difficult to quantify than labels that are regularly used in conjunction with numerical values. Many individuals, for instance, have received test scores in academic environments accompanied with labels ranging from excellent to very poor. Conversely, few forums exist in which respondents would have gained experience quantifying sentiments such as agreement.

In addition, the problems of multidimensionality and multivocal stimuli likely accent the difference between Likert units. As previously implied, individuals generally respond differently to negative and positive wording, which in turn complicates attempts at quantitative equivalence. Consequently, it is doubtful that units of agreement are equivalent to units of disagreement. Similarly, the confounding of direction and intensity dimensions suggests that a smooth continuum of intensity is nonexistent in many cases since the direction dimension may be more salient with many respondents. This is particularly the case with the midpoint response option that respondents may view as a "haven't thought about it" option instead of a true neutral option on the intensity dimension. Additionally, the added cognitive complexity associated with the use of negatively worded items suggests that such items are quantified differently than positively stated items. These factors suggest that the units in Likert response keys may vary greatly.

In contrast, phrase completions were designed so the units of measurement are quite similar. The concise, unidimensional nature of the phrase completion method skirts the problems of multidimensionality and multivocal stimuli. By using equally spaced integers for the majority of the response key, respondents are guided toward thinking about the entity of interest in the form of a series of uniform units. The impreciseness associated with verbal labels is replaced with quantitatively similar integers. This measurement approach likely provides a closer approximation of interval-level data.

Limited Number of Units

Another facet of coarseness is the number of units. Interval-level data are commonly understood to be composed of a series of equally spaced units. Scales that consist of few units do not allow respondents to make distinctions along a continuum. Furthermore, in order for a normal distribution to exist, there must be a sufficient number of units in the scale to comprise a meaningful distribution.

The five points commonly used in Likert scales represent a relatively coarse response key. In other words, relatively few units of information exist. Although a number of researchers have attempted to subdivide Likert keys into a greater number of units (e.g., strongly disagree, disagree, and slightly disagree), this approach has met with limited success.

The response options in a given key should correspond to something that exists in respondents' actual experience. For the collected data to have substantive meaning, the options must coincide to respondents' phenomenological reality. Although the agreement/disagreement sections of the Likert scale could be further divided, it is questionable to what extent respondents are able to parse their intensity of agreement about a given opinion into fine discrete categories that have substantive meaning. Indeed, one of the reasons the standard five-point key is so widely used is because many researchers believe its response options are consistent with individuals' actual experiences.

Consequently, further sectioning of the intensity dimension may actually increase measurement error because the added options have no anchor points in respondents' experience. Respondents may skip over response options that hold little meaning or use finely graded terms interchangeably. In other words, terms such as agree and slightly agree may be selected at random with no real distinction made in the respondent's mind about the two terms.

In short, Likert response keys offer only a limited number of units. Although the data are mixed, a number of studies that have explored the validity and reliability of Likert response keys suggest that either 5- or 7-point scales represent the limit of the method. Respondents can only parse their views toward a given declarative statement into so many substantively meaningful units.

Phrase completions take a different route in terms of developing a response key with more units. In place of attempting to parse sentiment about a given statement into increasingly finely ordered categories, the underlying continuum is operationalized in the response key using a 0—10 scale. The units of this continuum are likely to hold more substantive merit to respondents than units of agreement concerning a given declarative statement. The phrase completion method is likely to produce more substantively meaningful options for respondents, at least in part due to the restricted range associated with Likert items.

Restricted Range

Another manifestation of coarseness is data that only tap a portion of the available range. As noted previously, most constructs exist along a continuum from the absence of the attribute in question to some maximum amount of the attribute. Ideally, measurement items should assess the full extent of this continuum.

However, by virtue of their design, Likert scales only tap a portion of the extant continuum. Likert stems express either a clearly positive or negative opinion. Using positively stated propositions as an example, individuals are expected to agree with positively stated stems

to the degree to which their attitudes are more positive than the opinion reflected in the stems. Agreement with the expressed opinions is posited to indicate the presence of the underlying construct.

Consequently, stems are crafted to reflect a moderate opinion. For example, the stem "Spirituality is especially important to me because it answers many questions about the meaning of life" contains the word "many" to moderate the opinion. If the opinion stated in the stem is too strong (e.g., "Spirituality answers *all* my questions"), then relatively few respondents will express agreement with the proposition. Opinions must be of a moderate nature in order for sufficient numbers of respondents to feel comfortable selecting the various agreement options. In other words, the opinion must be moderate enough so that the item is able to adequately distinguish individuals across the hypothesized continuum.

The moderate nature of the opinion, however, results in the loss of sentiment at the ends of the continuum. Moderately stated stems do not distinguish individuals who hold relatively extreme attitudes. To follow up with the previous spirituality stem, for example, devout individuals for whom spirituality does answer all their questions about life would select "strongly agree" just as respondents whose spirituality answers many questions about life would select "strongly agree."

The Likert method offers no means of tapping the ends of the attitude continuum. As previously implied, using items that express a strongly stated opinion will result in scores that fail to vary sufficiently across a population. A stem that articulates a strong opinion, however, is the only way to capture relatively extreme sentiments (e.g., to distinguish those individuals for whom spirituality answers all questions). The Likert method is only able to tap a restricted range of the underlying continuum.

In contrast, the phrase completion method operationalizes the underlying continuum in the response key. As can be seen with item 3 in Table I, this approach captures extreme sentiments that traditional Likert scales fail to assess. Since the complete continuum is presented to respondents, individuals who hold views along all points of the continuum can select the option that reflects their position. The full range is assessed.

As a final point, it is important to note that summing individual Likert items into an index does not alleviate the problems discussed previously. Although the resulting product of the summation process is often treated as if it possessed interval-level properties, in actuality the final index does not represent interval-level data. Individuals do not select a value from the index. Rather, individuals respond to single items. When these individual items are summed, the limitations associated with the individual items remain. Summation cannot eliminate these limitations or transform coarse ordinal-level data into interval-level data.

The summation process can also be understood in terms of information. The units that comprise interval-level scales contain more information than do ordinal-level units. In addition to rank ordering units, interval-level data contain information about the distances between units. By discarding some of the existing information, it is possible to collapse higher levels of information into lower levels. Interval data, for example, may be reduced to ordinal data. The rank ordering can be retained while the information concerning the distance between units is discarded.

It is impossible, however, to transform ordinal-level data into interval-level data. Information that was not originally collected cannot be added at a later date. Adding together a number of units with no information about the distance between units provides no guideline concerning how the distance between any two units is to be understood. There is nothing intrinsic in the summation process that imparts information about the distance between units. Although summed Likert data may be treated as interval-level data, the resulting index retains the limitations associated with coarse ordinal data.

Since the summation process neither adds nor subtracts information, the battle to achieve a high level of information is fought and won or lost at the item level. Each question should be designed to gather as much information as possible. Consequently, phrase completions were designed to tap information in a manner that approximates interval-level data. In turn, when phrase completion items are summed, the resulting index also approximates interval data.

Limitations and Strengths of the Phrase Completion Method

The phrase completion approach to attitude scaling is characterized by at least two disadvantages: the difficulty of operationalizing the underlying theoretical continuum and cultural limitations related to scaling.

Operationalizing the Continuum

Perhaps the most prominent disadvantage of the phrase completion method is the difficulty of operationalizing the underlying theoretical continuum. As the examples in Table I suggest, in many situations the operationalization of this continuum is a relatively straightforward process. In these cases, the original Likert items were easily transformed into similar phrase completion items. However, in some cases, it may be difficult to identify verbal anchors that operationalize the ends of the continuum.

Ideally, the ends of the scale should be anchored with simple, behaviorally based labels that are readily understood among the sampling frame of interest to the researcher. Developing such anchors may be a time-consuming process or even impossible in some cases. As noted previously, in some situations it may be helpful to employ a third verbal anchor in the center of the response key to highlight the fact that middle values represent moderate response options.

In contrast, it is important to note that creating Likert scales is a relatively simple process. Although the phrase completion approach of specifying the underlying continuum offers a number of advantages, any additional time spent constructing phrase competitions functions as a disadvantage. Furthermore, as previously implied, in some cases it may be essentially impossible to operationalize the underlying continuum in a scientifically useful manner.

Cultural Limitations

Cultural limitations may exist regarding the use of graded response keys. Specifically, some cultural groups may have difficulty expressing their views on a continuum. For example, certain populations raised outside the Western ideological context may be more inclined to use affirmative or negative, yes or no expressions. Consequently, methods such as Likert or phrase completions scales that employ responses on a continuum may lack validity with such groups. Furthermore, because the phrase completion approach is predicated on an 11-point response key, among populations for whom this limitation is a salient factor, the phrase completion method is likely to be especially disadvantageous.

Review of the Strengths of the Phrase Completion Method

The primary strength of the phrase completion method is that it represents an attempt to better meet three important assumptions. Unidimensionality and univocal stimuli are fundamental assumptions of measurement. The phrase completion method represents a unidimensional measurement procedure. The multidimensionality associated with superimposition, the confounding of direction and intensity, and the use of a midpoint are eliminated with the phrase completion approach.

Similarly, phrase completion items represent relatively clear, univocal stimuli. The cognitive complexity associated with multidimensionality and negative wording is eliminated. Specifically, the phrase completion approach avoids the use of reverse coding, items reversals, and mirror image items. By operationalizing the underlying theoretical continuum, the phrase completion approach yields relatively clear, concise, unidimensional items that are designed to yield substantively meaningful results.

With widely used parametric statistics, a central assumption is the use of interval- or ratio-level data with a normal distribution. The phrase completion method approximates interval-level data by using equally spaced integers to guide respondents' thinking along a continuum that reflects the full range of the substantively meaningful response options. Similarly, the use of an 11-point response key composed of equally spaced integers is congruent with the concept of a normal distribution.

Phrase completions were designed as an alternative to the Likert method. The limitations of the phrase completion method preclude their use in some situations, and the advantages of the Likert approach ensures the continued use of Likert scales. However, in a number of situations the phrase completion method provides a superior approach to measurement.

Pilot Study

J. Rodney Turner
Groupe ESC Lille, Lille, France

Glossary

business risk Two-sided risk due to the uncertainty of estimates.
insurable risk One-sided risk due to an unplanned event (which may or may not be foreseeable).
pilot study An element of a project or program used to gather data to reduce risk or uncertainty on the project or program, especially in the definition of the product to be produced or the method of producing that product; often used to prove technical or commercial feasibility.
program A temporary organization used as an agency for managing a group of related projects to achieve a higher order strategic objective not delivered by any of the projects on their own.
project A temporary organization used as an agency to which resources are assigned to undertake a unique novel and transient endeavor, and to manage the inherent risk, to deliver beneficial objectives of change.
prototype A sample product produced by a research project to gather data about the product to be produced by a larger project or program or about the method of producing it; often prepared as a precursor to a pilot project.
risk A threat or opportunity that can adversely or favorably affect the achievement of the objectives of an investment.

A pilot study is an element of work of a larger project or program undertaken to gather data to reduce risk or uncertainty. A pilot study can be undertaken to help in the selection of the appropriate risk mitigation strategy or in the application of the chosen method. The uncertainty in a project or program will usually lie in the definition of the product to be produced or in the method of producing that product. A pilot study can be used to gather data about either or both to facilitate project choices, particularly in proving the technical or commercial feasibility of options being considered. In the process, the pilot study may also contribute to organizational learning. In the context of social measurement, a pilot study may be undertaken for all of these purposes. It is assumed that a project or program is being undertaken to gather data to make a measurement. The pilot study may be used to test the feasibility of the data-gathering method and whether it will deliver the required data (testing the process) or whether the data gathered is a true measure of the item under investigation (testing the product). In the process, it will contribute to an understanding of the measurement methodology (organizational learning). There may also be risks, such as the measurement methodology will not work or there will be an adverse reaction from the population under investigation. A pilot study can help mitigate these risk. This article describes how pilot studies can be used to aid risk mitigation, to assist in the process of project definition, and to facilitate organizational learning. It also describes how to prepare a brief for a pilot study to aid its successful definition.

Introduction

A pilot study is an element of work undertaken as part of a larger project or program of projects to reduce risk or uncertainty. The pilot study may be a subproject of a program or an area of work or work package of a larger project. By generating additional data or information, the pilot study will help to reduce uncertainty about the product to be delivered by the project or program or about the method by which the product will be delivered. The information created from the data can also contribute to organizational learning.

Pilot studies are used extensively throughout research, technology, engineering, and business (despite the dearth of literature on the subject). In the context of the "Encyclopedia of Social Measurement," we are mainly

interested in projects for research and measurement. However, I discuss generically pilot studies and then try to relate the topics under discussion to research and measurement projects and programs.

I focus on the role of pilot studies in risk management on projects and how to structure a pilot study as a project for its successful completion. I do not engage in the debate about the difference between data, information, knowledge, or wisdom. I also do not engage in the debate about the difference between risk, uncertainty, or opportunity management. Suffice it to say that pilot studies can be equally useful in helping organizations to reduce risk and uncertainty associated with projects or to be better positioned to exploit opportunity. I also do not describe how to select and structure the data-gathering methodology used in a pilot study or how to analyze the data gathered.

Definitions

A pilot study is part of a larger project or program undertaken to improve understanding of the product being delivered by the project or program or the method of delivering that product. A project is an agency for undertaking a novel piece of work within an organization, created as a temporary organization to which resources can be assigned to do that work and to manage the inherent risk associated with it. A program is a collection of several projects with a common strategic objective. A pilot study can be a package of work in a larger project or, if sufficiently large and complex, a project in its own right, part of a larger program. Projects and programs are essentially unique, novel, and transient:

- Because a project (or program) is doing novel work, an organization will never have done a project exactly like the current one (although I do accept that some projects are more familiar than others).
- Being unique, they require novel processes for their delivery, involving novel teams of people, the human resources assigned to the agency.
- They are transient, being disbanded when the objective has been achieved.

Because they are unique and novel, projects and programs entail uncertainty. There is uncertainty about the product the project will deliver and whether it will achieve the objectives set for it, and there is uncertainty about whether the process adopted will deliver the desired objectives. The management of risk is therefore an essential part of the management of projects. Strategies for mitigating risks on projects include

1. Reducing the uncertainty associated with the definition of the product to be produced or with the method by which it is to be produced.
2. Avoiding the risk by finding a different way of doing the project.
3. Abandoning the project.
4. Reducing the likelihood of the risk occurring or the impact on the project if it does occur.
5. Transferring the risk to other parties, such as contractors or insurance companies.
6. Accepting the risk.
7. Creating a contingency plan to deal with the risk if it does occurs.

Pilot studies provide data to help in the selection of the appropriate risk mitigation strategy and so that the strategy selected can be better implemented. They also produce data to reduce uncertainty in the definition of the product to be produced by the project, or the process by which it will be produced, and therefore facilitate choices about the design of the project's product or process, further reducing risk and uncertainty. In providing this information, they also contribute to the learning of the organization.

Pilot Studies for Reducing Risk

Pilot studies can be used to help choose the appropriate risk mitigation strategy or to implement the chosen strategy.

Reducing Uncertainty of Estimates

There are two types of risk on projects: business risk and insurable risk. Business risk is two-sided risk, mainly due to the uncertainty of estimates. The estimate of the outturn value of an activity is some midrange value, usually assumed to be the most likely out-turn. The activity can turn out better or worse. A project made up of many such activities will also have a spread of possible outturns.

Insurable risk is one-sided risk, due to the occurrence of an unplanned event, which will affect the project unfavorably (or favorably). As a result, the project will turn out worse (or better) than expected.

Uncertainty of estimates leads to business risk, which can impact a project in two ways. First, the spread of possible outcomes for each activity causes a spread of possible outcomes for the project. It is suggested (based on a heuristic application of probability theory) that if ε is the average error in the estimate of each activity, E is the error in the estimate of the total project, and N is the number of activities that make up the project, then

$$\frac{\varepsilon}{E} = \sqrt{N}. \tag{1}$$

One way of reducing the error in the project estimate is to break the plan into smaller activities. However, this requires greater effort. Equation (1) implies that to

reduce the error in the project estimate by half requires four times as much planning effort as has been expended so far. This relationship has been observed empirically. Furthermore, it may not be possible to subdivide some activities, or there may be no estimating data available. Thus, it may be preferable to conduct a pilot study to reduce the uncertainly of estimates either because the pilot study is cheaper than the planning effort or because there is no other source of estimating data. In the context of social measurement, the pilot study may help determine how long the research project will take, the required sample size, or the likely response rates.

Second, if the estimated outturn of each activity has a uniform distribution (the mean, median, and mode are the same), the predicted outturn of the project will also have a uniform distribution. However, in reality the expected outcome of most activities is skewed to the worse. It does not require much of a skew in the estimates before the predicted outcome for the project becomes heavily skewed. It is often the case that the raw estimate of the project (obtained by summing the most likely outturn of each activity) has a very low chance of being achieved, and the expected outcome for the project (obtained by summing the expected outcome for each activity) is somewhat larger. The difference is contingency. Sometimes, there may be no information about how skewed an activity is, and so it may be worthwhile to conduct a pilot study, undertaking trials of specific activities, with one more of the following objectives: to determine how skewed an activity is, to find ways of reducing the extent of the skew, and to determine whether the activity should be avoided if possible (i.e., the risk should be avoided). In the context of social measurement, the measurement of the item under investigation may be skewed by an unknown amount, and a pilot study can help identify that in the selection of an appropriate measurement methodology.

Avoiding Risk

Sometimes, a risk is so severe that it has to be avoided. The potential impact on the project means that the project is very likely to fail. In order to know which risks should be avoided an organization needs to know its risk tolerance. An insurable risk should be avoided if it has both a high likelihood of occurring and a high impact if it does occur, and a business risk should be avoided if the expected outturn is very much greater than the most likely outturn. Sometimes, some of these parameters will not be known, and a pilot study is one way of determining them. Therefore, a pilot study may be conducted to determine the likelihood of an insurable risk occurring, the impact if it does occur, and the spread of possible outturns of a business risk.

In the context of social measurement, insurable risk might be that the required data cannot be gathered or an adverse reaction from the population under investigation. A pilot study can test these in advance so an appropriate response can be determined.

Abandoning the Project

One way of avoiding risk is to abandon the project, and this may often be done as a result of a pilot study; indeed, it may be the most common result. This may be very common in the context of social measurement.

Reducing the Likelihood or Impact of Risk

Similarly, if the likelihood or impact of an insurable risk is known, then a pilot study can be conducted to find ways of reducing the likelihood of it occurring or reducing the impact if it does occur. This is similar to conducting a pilot study to find ways of reducing the tail in the estimates of a business risk.

Transferring Risk

Determining the likelihood or impact of a risk is necessary if the risk mitigation strategy is to transfer the risk to other parties. Risks can be transferred in two ways. First, risks with a high chance of occurring, but with a small impact if they do occur, are often transferred to a contractor to manage. The contractor will accept the risk, allow a contingency for it, and add a profit margin for managing it. In order to do this commercially, the contractor needs to know the likelihood and impact of occurrence. If these are unknown, a pilot study can be used to help determine them. In the context of social measurement, this would entail asking a research organization to gather data on behalf of the client and carry the associated risk with the sample size, for instance. The research organization may want to conduct a pilot study to understand the risk before taking it on.

Second, risks with a very low chance of occurring, but a very large impact if they do occur, are best insured. The insurance company accepts the risk on payment of a premium and spreads its exposure over a large number of such risks. Again, to determine the premium and whether or not it wants to accept the risk, the insurance company needs to know the likelihood and impact of occurrence. A pilot study may help reduce the premium or even make an insurance company willing to accept a risk in the first place in the case in which a risk is not well understood. It might be necessary for a researcher to obtain professional indemnity insurance. If the insurance

company has no data on which to base the premium, a pilot study can help provide that data.

Accepting Risk

Sometimes, the best strategy is just to accept the risk. This is usually the case for risks with a small to medium chance of occurring and a small to medium impact if they do occur. Again, an organization needs to know its risk tolerance and what it means by small to medium in both instances. For risks that are not well understood, a pilot study can help determine whether or not a risk can be accepted.

Creating a Contingency Plan

For risks with a medium to high chance of occurrence and a medium to high impact if they do occur, allowing a contingency may be the best way of dealing with them. A contingency can be of three forms:

1. Pure contingency is a plan for how to respond if the risk occurs, with no prior action to reduce the likelihood or impact of the risk. An example with regard to a research project is to gather more data if necessary.
2. Contingency with essential prior action is a plan for how to respond with action taken to reduce the impact of the risk while the response is implemented. The essential prior action usually makes the response faster. On a research project there may be a cost and delay associated with copying the research instrument. If there is a high chance that additional data will be required, and a large cost associated with delay, it may be worthwhile making the additional copies in advance.
3. Contingency with mitigating prior action is a plan to respond with action taken to reduce the likelihood of the risk occurring. In a research project, this would entail spending money to try to increase the response rate.

With essential and mitigating prior action, the likelihood and impact of the risk without the action are compared to the likelihood and impact with the action and the cost of the action. If L is the likelihood of the risk and C the cost of its occurrence without action, l is the likelihood and c the cost with the action, and K is the cost of the action, then the action is taken if

$$L \times C > l \times c + K.$$

Pilot studies can be conducted to determine the efficacy of a contingency plan, or of the proposed courses of action, or to determine the likelihood and/or impact of a risk with and without the proposed action.

Pilot Studies for Proving Product or Process

The uncertainty in a project often lies in the definition of the product to be produced or in the method or process by which it will be produced. This is particularly the case with research projects in which the research instrument may be unproven or it is not known what results it will produce. Figure 1 illustrates a typology for projects, whereby projects are judged by the uncertainty of the product and process. In type 2, 3, and 4 projects, there is uncertainty about the product to be delivered, the method of delivering that product, or both, respectively. The risk lies in the lack of definition, the fact that the end product of the project may not work, or the fact that the method of producing that product may not be feasible; thus, the organization undertakes a pilot study to reduce uncertainty before committing to full implementation. In undertaking the pilot study, the organization may produce a prototype of the final product to prove the design of the product or the method by which it will be produced. The risk mitigation strategy adopted may be any one of those described previously. Some examples are described next.

Commercial Bank

During a research project on project categorization, a major high street (commercial) bank in the United Kingdom told me that it always conducts a pilot study for any new products or change in organization being introduced into its branch network. Innovations are introduced in a three-step process:

Step 1: A pilot in six branches
Step 2: A trial in 50 branches
Step 3: Roll out to the remaining branches

Methods well defined	Goals well defined: Yes	Goals well defined: No
No	**Type 2** Development Milestone planning using known deliverables	**Type 4** Research Soft systems planning to define deliverables
Yes	**Type 1** Engineering Activity-based planning	**Type 3** Computer systems Milestone planning using life-cycle stages

Figure 1 Goals and methods matrix.

The products of these projects may be a new product to be sold in the branches, a new method of working in the branches, a new computer system, or a new way of interfacing with customers. The uncertainty here mainly lies with the products; they are type 3 projects according to the classification in Fig. 1. The pilot study is undertaken to prove the product and make changes before trial and roll out. In this case, the change project is being undertaken in a social context, and the pilot study measures the reaction of that social context to the change.

Testing a Research Project

Huemann and Winkler conducted a pilot project as part of a larger research project on benchmarking project processes. Since they adopted a social constructivist approach to their research, they were making measurements in a social context. They used the pilot to test their instrument before roll out to a larger sample. In this case, the product of the project, the desired outcome of the research, is well defined. The uncertainty lies in the method of achieving that product, the design of the questionnaire or research instrument. It is a type 2 project. The pilot study is used to reduce the uncertainty of the project process before roll out. Van Teilingen and Hundley confirm that this is good practice. Table I provides reasons for conducting such a pilot study to test a research instrument. Many of these are familiar. Table II lists procedures for improving the validity of the instrument. However, they caution that to avoid contamination, data gathered in the pilot study should not be included in the main results, and people surveyed in the pilot study should not be resurveyed because they will not give independent answers.

Table I Reasons for Conducting a Pilot of a Research Instrument[a]

Developing and testing adequacy.
Assessing feasibility.
Designing a protocol.
Establishing and testing efficacy of the sampling technique.
Assessing efficacy of recruitment processes.
Identifying logistical problems.
Estimating variability to determine optimum sample size.
Planning and estimating resources need for the main study.
Assessing the data analysis techniques.
Training researchers in research techniques.
Convincing funding bodies that the research team is competent.
Convincing funding bodies that the study is feasible and worth funding.
Convincing other stakeholders to give support.

Electrical Goods Manufacturer

An electrical goods manufacturer planned to develop a new model of coffee maker. It wanted to reduce the price of its coffee makers to gain a wider market share. To do so, it planned to make the new model out of a cheaper plastic, polypropylene rather than polycarbonate. There was a problem in that polypropylene is more difficult to cast than polycarbonate and can suffer shrinkage, causing rippling, especially in a casting as large as the water tank. To overcome this problem, the company planned to design the water tank with a ripple effect to disguise the ripples caused during casting. There was uncertainty about the feasibility of the design and the casting process. This was a type 4 project during the initial research and feasibility stage of the project. A pilot study was conducted, and prototypes were produced to test various options. As a result, when released to market the coffee maker was very successful. (This is an example of a technical use of pilot studies. The social element of this project was the market research to test the response to the proposed new design, conducted as part of the main pilot study.)

Prototype

This last case describes the production of a prototype, which can be the result of many pilot studies. There is very little literature on pilot studies, and in the 2.5 million hits in Google and Yahoo there is little agreement about what is meant by a pilot study. However, Field and Keller state that there is a difference between a prototype and a pilot study. They are mainly discussing information systems (IS) projects, but they state that a prototype precedes a pilot study. A prototype is produced in the laboratory as part of the research, feasibility, or design stage of a project, and on an IS project will operate on trial data. A pilot study is conducted during the implementation stage of a project and is a limited implementation

Table II Improving the Internal Validity of a Research Instrument in a Pilot Study[a]

Administer the pilot in the same way as the main study.
Ask subjects for feedback to identify flaws.
Record time taken to compete the instrument and decide if it is reasonable.
Discard unnecessary, difficult, or ambiguous questions.
Assess whether questions give an adequate range of responses.
Establish whether responses can be properly interpreted to give information required.
Check that all questions are answered.
Reword and resale questions as necessary.
Shorten and revise the instrument.

[a] Adapted from Van Teilingen and Hundley (2003).

using real data in a live operating environment to generate information to reduce risk during roll out. Hayes *et al*. differentiate between prototype and pilot production run in the same way, but van Teilingen and Hundley do not.

Pilot Studies for Learning in Organizations

Another purpose or side effect of pilot studies often emphasized is the learning they provide for organizations. All the purposes discussed previously have learning as a side effect:

- Learning how to mitigate risk
- Learning how to reduce uncertainty in product or process of a project
- Learning what will work or not work in the design of a new product
- Learning by testing the efficacy of a research instrument

Van Teilingen and Hundley describe the training of research staff as a possible reason for conducting a pilot study of a research instrument. However, sometimes pilot projects are more overtly established with the express purpose of generating data to aid learning or knowledge management in organizations. Ayas describes a pilot study to demonstrate the effectiveness of the learning instruments to be adopted in a development program in an aircraft manufacturing company. Project managers often manage on short time horizons and need to see quick results. The pilot study demonstrated the efficacy of the learning instruments adopted and showed that they were likely to deliver the desired results. Ayas was describing the measurement of learning in a social context.

Preparing a Brief for a Pilot Study

A pilot study is part of a larger project or a project in a larger program. Therefore, good project management practices should be applied to its management. In particular, all pilot studies should be initiated by a project brief. Here, I describe the contents of a project brief. The brief may be 12 pages for a reasonably complex pilot project, but it may be as short as 1 or 2 pages for a study conducted as a package of work for a larger project. The brief defines the pilot study and contains the following sections:

Background: The context of the pilot study is defined; what is being done; and the difficulty encountered that has created the risk that needs to be mitigated.

Purpose: The reason for undertaking the study is defined; why it is being done. The risk to be mitigated is stated more specifically as a problem to be solved.

Objectives: The outcomes of the study are stated; the desired results or deliverables that will enable the purpose to be achieved and that will be used to solve the problem.

Scope: The work to be done to achieve the objectives is described. This gives an overview of how the data are to be gathered and analyzed. Any constraints also need to be stated, along with interfaces with other elements of work in the project or program.

Plan: This shows how the work is to be done and how long it is expected to take. For a more complex project, this may be a milestone plan as described by Turner, and on a larger pilot project each milestone may be further broken down into a list of activities. On a smaller project or a package of work the plan may just be a list of activities.

Responsibility chart: The roles and responsibilities of people involved in the study are defined. The use of responsibility charts is described by Turner.

Stakeholders: This identifies the parties who have an interest in or are affected by the study and their possible (adverse) responses. Plans to deal with any adverse responses are briefly stated.

Quality requirements: Quality standards to be met by the pilot study are defined.

Cost and schedule: Rough estimates of the cost of the study and its duration are given.

Acceptance criteria: Standards to be met by the pilot study to enable full roll out are defined.

Known risks: The pilot study is undertaken to mitigate risk but may itself entail risk. Any known risks of the pilot study are identified, and mitigation strategies for them are described.

Epilogue

I was surprised when I was asked to write a chapter on pilot study. Although I am well-known in the project management research community, and pilot studies are a common element of projects, I assumed there were many people with more experience in writing about pilot studies than myself.

However, when I did research for this article, I could not find any reference to pilot studies in any of the books in my library. There was no entry in the index under "pilot study" in books that I examined from the general management literature, project management literature (even in my own books), operations management literature, change management literature, innovation management literature, or strategic management literature. I did a search in Google and Yahoo. In both cases, I got approximately 2.5 million hits. However, in both cases the first 60 or so primarily concerned people reporting the outcomes of their pilot studies; only in one instance was somebody giving advice on how to use them.

In the literature, I found three references on conducting pilots. There was an index entry for "pilot project" in Lundin and Midler to a paper by Ayas, but like the hits in Google and Yahoo, Ayas was reporting the results of her own pilot project. There is also an entry for "pilot production run" in Hayes *et al*., but they only suggest that it is something that might be done. They give no guidance on how to do it. The only index reference to "pilot study" I found was in Field and Keller, who devote one line to the difference between pilot studies and prototypes.

Pilot studies are very important in the undertaking of research projects to ensure that the correct methodology is adopted and implemented properly to achieve the required results, yet they appear to be written about nowhere. Pilot studies are like the person who was not there upon the stair or like Bishop Berkley's tree in the quad: is it still there when there is nobody in the quad to observe it?

There once was a man who said, "God
Must think it exceedingly odd
If he finds that this tree
Continues to be
When there's nobody about in the quad."

Robert Knox (1924)

So, somewhat to my surprise, this article seems to be almost the first attempt to set out the purposes and functions of pilot studies and give guidance on how to manage them. Van Teilingen and Hundley suggest that the reason pilot studies are not written about is because data produced by them have no academic validity. Academic research papers need to be based on testable, verifiable data, which are obtained from a full survey, not from the pilot study. Thus, they are very important but not written about in research journals. Therefore, like Bishop Berkley's tree, they are there even though they are not often written about.

Dear Sir, Your astonishment's odd
I am always about in the quad
And that's why the tree
Will continue to be
Since observed by yours faithfully, God

Glossary

Biderman, Albert (1922–) American sociologist trained at the University of Chicago. He was instrumental in founding the National Science Foundation (NSF) working group on social graphics, and his NSF project on graphics can be credited with instigating the work of Edward Tufte and Howard Wainer in statistical graphics.

Euler, Leonhard (1707–1783) Swiss mathematician who trained under Jean Bernoulli. He published over 800 books and papers on every aspect of pure and applied mathematics, physics, and astronomy. In 1738, when he was professor of mathematics at St. Petersburg Academy, he lost sight in one eye. In 1741 he moved to Berlin, but returned to St. Petersburg in 1766, where he soon lost sight in the other eye; however, his prodigious memory allowed him to continue his work while totally blind. For the princess of Anhalt-Dessau he wrote *Lettres à Une Princesse D'Allemagne* (1768–1772) in which he gave a clear, nontechnical outline of the principal physical theories of the time. His *Introductio in Analysin Infinitorum* (1748) and later treatises on calculus and algebra remained the standard texts for more than a century.

Funkhouser, Howard Gray (1898–1984) American mathematician and educator who was born in Winchester, Virginia. He was a 1921 graduate of Washington and Lee and received his Ph.D. from Columbia. He taught mathematics at Washington and Lee from 1924 to 1930 and spent 1931 on the mathematics faculty at Columbia. In 1932, he accepted a position on the faculty at Phillips Exeter Academy, where he remained until his retirement in 1966. His groundbreaking paper "Historical development of the graphical representation of statistical data," published in *Osiris* in 1937, joined two other papers, "Playfair and his charts" (1935) and "A note on a tenth century graph" (1936), as the jumping off point for subsequent researchers in the history of graphics.

Louis XVI (1754–1793) King of France (1774–1793), born in Versailles, France, the third son of the dauphin Louis and Maria Joseph of Saxony, and grandson of Louis XV, whom he succeeded. He was married in 1970 to Marie Antoinette, daughter of the Hapsburg Empress Maria Theresa. He made a number of unfortunate decisions (e.g., failing to support reform of financial and social structures, involvement in the American Revolution), which exacerbated the national debt. In August of 1792 the monarchy was abolished; he was then tried by the revolutionary government, and in 1793 he and his queen were guillotined in Paris.

Meikle, Andrew (1719–1811) Millwright and inventor who was born in East Lothian, Scotland. He inherited his father's mill, and to improve production invented the fantail (1750), a machine for dressing grain (1768), and the spring sail (1772). His most important invention was a drum threshing machine (patented in 1788) that could be driven by wind, water, horse, or (some years later) steam power.

Minard, Charles Joseph (1781–1870) He was first a civil engineer and then an instructor at the École Nationale des Ponts et Chaussées (ENPC). He later was an Inspector General of the Council des Ponts et Chaussées, but his lasting fame derived from his development of thematic maps in which he overlaid statistical information on a geographic background. The originality, quality and quantity of this work led some to call him "the Playfair of France." His intellectual leadership led to the publication of a series of graphic reports by the Bureau de la Statistique Graphique of France's Ministry of Public Works. The series (*l'Album de Statistique Graphique*) continued annually from 1879 until 1899 and contained important data on commerce that the Ministry was responsible for gathering.

In 1846, he developed a graphical metaphor of a river, whose width was proportional to the amount of materials being depicted (e.g., freight, immigrants), flowing from one geographic region to another. He used this almost exclusively to portray the transport of goods by water or land. This metaphor was employed to perfection in his 1869 graphic, through which, by using the substitution of soldiers for merchandise, he was able to show the catastrophic loss of life in Napoleon's ill-fated Russian campaign. The rushing river of 422,000 men that crossed into Russia when compared with the returning trickle of 10,000 "seemed to defy the pen of the historian by its brutal eloquence." This now-famous display has been called "the best graph ever produced."

Playfair, John (1748–1819) Minister, geologist, and mathematician. Born in Dundee, Scotland, he was the older brother of William Playfair. He studied at St. Andrews and became professor of mathematics (1785) and natural philosophy (1805) at Edinburgh University. In addition to influential writings on geometry, including a widely used textbook, he also investigated glaciation and the formation of river valleys. He was responsible for clarifying and amplifying the revolutionary geological theories of James Hutton, which anticipated modern scientific ideas such as evolution, natural selection, plate tectonics, and asteroid strikes.

Playfair, William (1759–1823) Scottish engineer, writer on political and economic topics, and the father of modern graphical methods.

Priestley, Joseph (1733–1804) Chemist and clergyman who was born in Fieldhead, West Yorkshire, England. He became a Presbyterian minister in Suffolk in 1755 but returned to Leeds in 1767 where he continued his scientific and philosophical studies. He is best known for his research on the chemistry of gases and for his discovery of oxygen. Some of his most productive scientific years were spent in Birmingham, where he also wrote books on education and politics. His political activities and his support of the French Revolution were controversial, making his continued presence in England more than uncomfortable, and in 1794 he emigrated to America, where he was well received.

Rennie, John (1761–1821) Born in East Linton, Scotland, he apprenticed with Andrew Meikle and later studied at Edinburgh University. He worked briefly at Boulton & Watt, and in 1791 started his own engineering company in London. He built docks at Hull, Liverpool, Greenock, Leith, Portsmouth, Chatham, and Plymouth. He is best known for his bridges, and his successes include Leeds Bridge, Southwark Bridge, Waterloo Bridge, and London Bridge, which was dismantled in 1967 and re-assembled in Arizona as a tourist attraction.

Tufte, Edward R. (1942–) American political scientist and graphics expert. He was born in California and trained at Yale and Stanford. His seven books include *The Visual Display of Quantitative Information*, *Envisioning Information,* and *Visual Explanations*, which have received unprecedented attention garnering among them more than 40 awards for content and design. They have sold, in aggregate, more than a half million copies and their author is in constant demand as an influential critic of graphical design.

Von Humboldt, Alexander (1769–1859) Naturalist and geographer who was born in Berlin and educated in Frankfurt, Berlin, Göttingen, and Freiberg. He spent 1799 through 1804 exploring South America with Aimé Bonpland (1773–1858). When he was 58, he spent three years traveling throughout central Asia. The Pacific current of the coast of South America is named for him. His principal book, *Kosmos,* tries to provide a comprehensive characterization of the universe.

Watt, James (1736–1819) Inventor. He was born in Greenock, Scotland, and in 1754, he apprenticed as an instrument maker in Glasgow, where he stayed and set up a business. As part of his trade he carried out surveys for canals and began to study the use of steam as an energy source. In 1763, he repaired a model Newcomen steam engine and found he could improve its efficiency through the use of a separate steam condenser. In 1774, he joined with Mathew Boulton in an enterprise to manufacture an improved steam engine in Birmingham. He subsequently made numerous other inventions, including the double-acting engine, parallel motion linkage, centrifugal governor for automatic speed control, and the pressure gauge. He is credited with coining the term "horse-power." The standard unit of electrical power is named for him.

A ubiquitous practice in modern science is the atheoretical plotting of data points with the goal of looking for suggestive patterns. This practice was initiated by William Playfair, an 18th century Scot, who not only invented most of the graphical forms used today but also showed in numerous publications how they could profitably be used.

Introduction

Today, with illustration at the heart of communication, we see pie, bar, and line charts everywhere—in the press, on television, on computer screens, on boardroom desks, on blackboards, whiteboards, and greenboards, in video presentations, handouts, flyers, and so forth. Aircraft control panels and nuclear power station monitors contain displays that look like bar charts in motion, and video games often keep track of players' scores in graphical form. It is difficult to determine how many graphs are created each day, but more than a decade ago, one noted commentator estimated the number at more than 5 million. However large the true number is, you can be sure it will be larger tomorrow, and the multitude of users of all these charts, graphs, and displays will grow apace. Statisticians employ graphs but so do scientists of every stripe, and unnumbered professionals in

business and commerce make use of graphs every single day. Economists, sociologists, psychologists, social workers, medical professionals, and even historians are just a few of the occupations for which graphs are the stuff of everyday life.

Graphs convey comparative information in ways that no table or description ever could. Trends, differences, and associations are effortlessly seen in the literal blink of an eye. The eye discerns immediately what the mind would take seconds or minutes to deduce from a table of numbers. This, of course, is what makes graphs so appealing—they allow the numbers to speak clearly; they release them from their mute state. Graphs and charts not only show what numbers tell, they also help scientists—numerical detectives, if you will—tease out the critical clues from their data. Graphs transcend national boundaries—a Chinese can read the same graph that a Russian draws. There is no other form of communication that more appropriately deserves the description "universal language."

Who invented these ubiquitous and versatile objects? Have they been around for millennia, rather like the wheel or fire, the work of inventors unknown? The truth is that statistical graphs were not created in some distant past; their inventor lived only two centuries ago. He was a man of such unusual talents and background that had he not introduced his charts at the end of the 18th century, during the Age of Enlightenment, we might have waited until the 20th century for statistical graphs. The inventor was not a cloistered academic, although he was deeply knowledgeable on many subjects and wrote more prolifically than many in the ivory towers. He was a man of several careers and varied experience. He dearly wanted to be rich, but none of his many schemes realized this desire. He was something of a rogue, but oddly enough this rascally aspect may have helped bring his graphical inventions to the world.

Though born and raised in Scotland, he lived most of his life in London and Paris during turbulent times. William Playfair (1759–1823) was so convinced that he had found the best way to display economic data that he spent almost 40 years of his life trying to influence others to follow his example. He made notable converts, including the doomed Louis XVI of France, but he was unsuccessful in persuading the academic establishment and thus his inventions waited almost a century before widespread adoption.

William Playfair is the principal inventor of statistical graphs. Although one may point to isolated instances of rudimentary line graphs that precede Playfair's work,

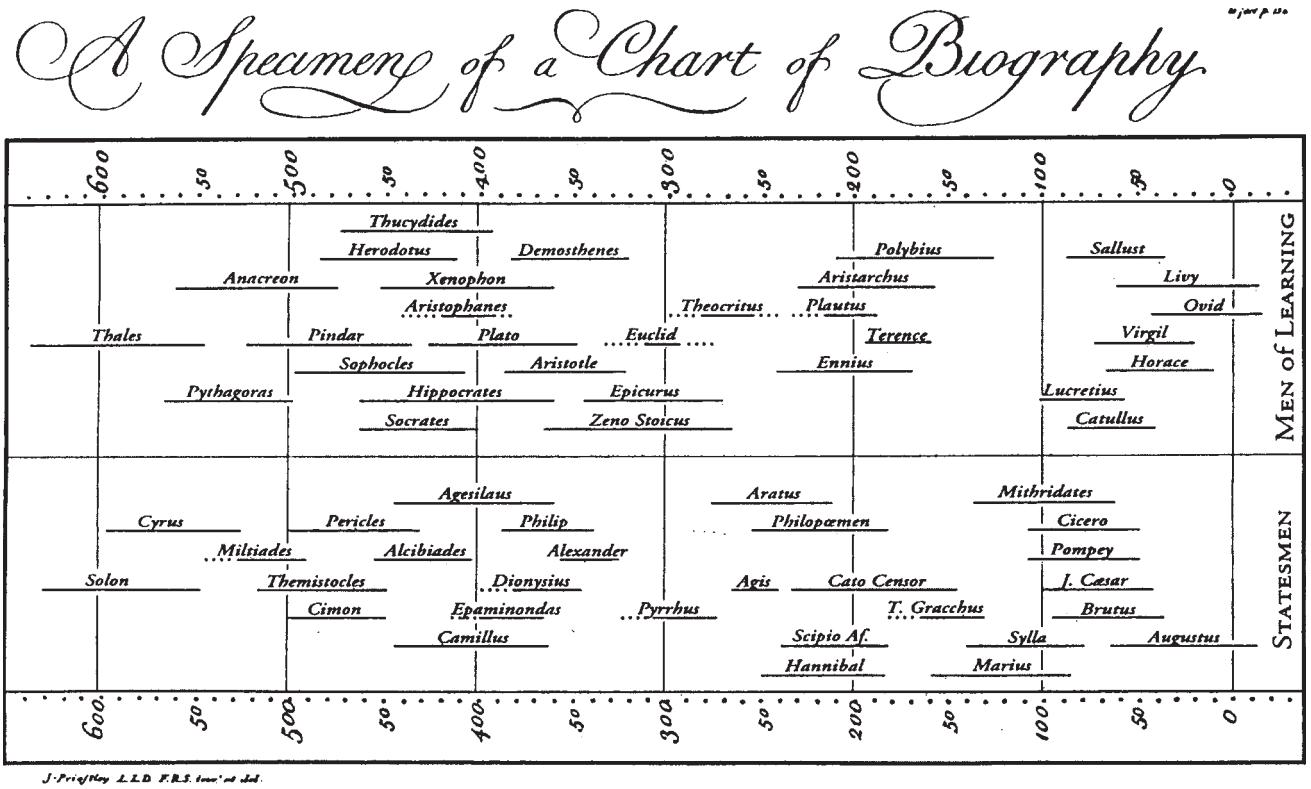

Figure 1 Life spans of 59 famous people in the six centuries before Christ. Its principal innovation is the use of the horizontal axis to depict time. It also uses dots to show the lack of precise information on the birth and/or death of the individual shown. From Priestley (1765).

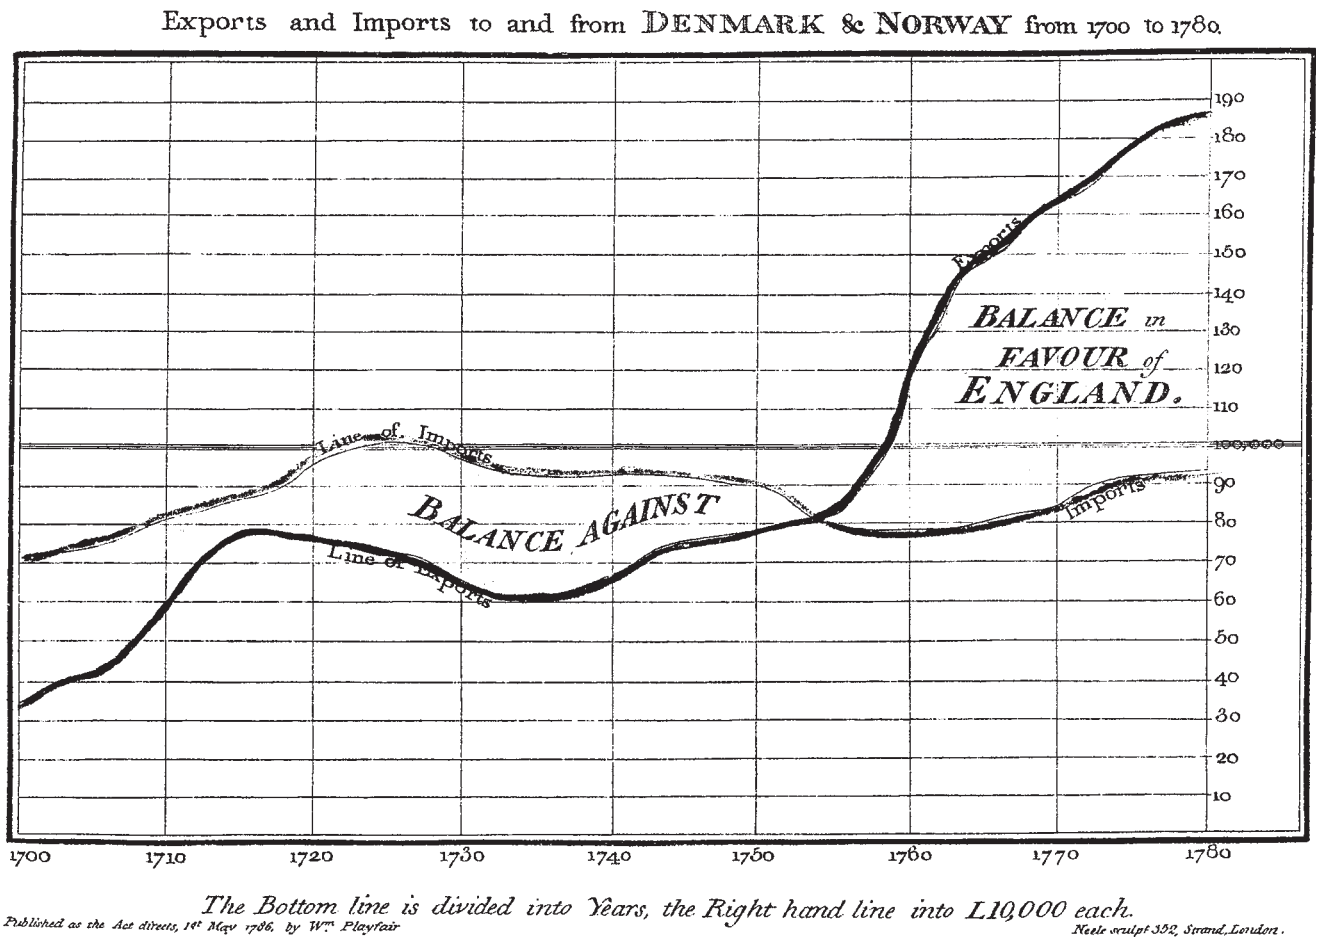

Figure 2 A typical line chart from Playfair's 1786 *Commercial and Political Atlas*, which uses one line to show imports and another for exports over the 80-year span from 1700 until 1780. The balance of trade between England and Denmark and Norway is the area between the two curves, which was shaded red (prior to 1765) when it was against England, and green thereafter when it was in England's favor.

such examples generally lack sophistication and, without exception, failed to influence others. In contrast, Playfair's graphs were elaborate and well constructed: they appeared regularly in several publications over a period of more than 30 years and they introduced a surprising variety of devices and techniques that are in use to this day. He invented three of the four basic forms; the statistical line graph, the bar chart, and the pie chart. The other important basic form—the scatter plot—did not appear until almost a century later. Playfair also invented other graphical elements that are still in use today, for example, the circle diagram and statistical Venn diagram, but these innovations were less effective and are less widely used.

William Playfair was born in 1759 in Scotland during the Enlightenment, on the cusp of the Industrial Revolution, to which he contributed as a young draftsman in the employ of Boulton & Watt. Upon his death in 1823—after a controversial and unconventional life—Playfair's obituaries were united in the conclusion that his talent had been squandered. But all published tributes missed the key achievement of his life, and a century would pass before the value of his work was fully recognized. As Funkhouser (1937) has noted, Playfair invented a universal language useful to science and commerce, and though his contemporaries had failed to grasp the significance, Playfair never doubted that he had changed the way we would look at data. Very few shared his enthusiasm for pictorial display, and it is a curiosity of history that one of those who did appreciate the inventions was the ill-fated King of France, Louis XVI. Playfair noted that, after receiving a copy of his pioneering volume *The Commercial and Political Atlas*, Louis XVI said, "[The charts] spoke all languages and were very clear and easily understood."

William Playfair was the fourth son of the Reverend James Playfair of the parish of Liff and Benvie near the city of Dundee, Scotland. His father died in 1772, leaving the eldest brother John to care for the family. John was subsequently to become one of Britain's foremost

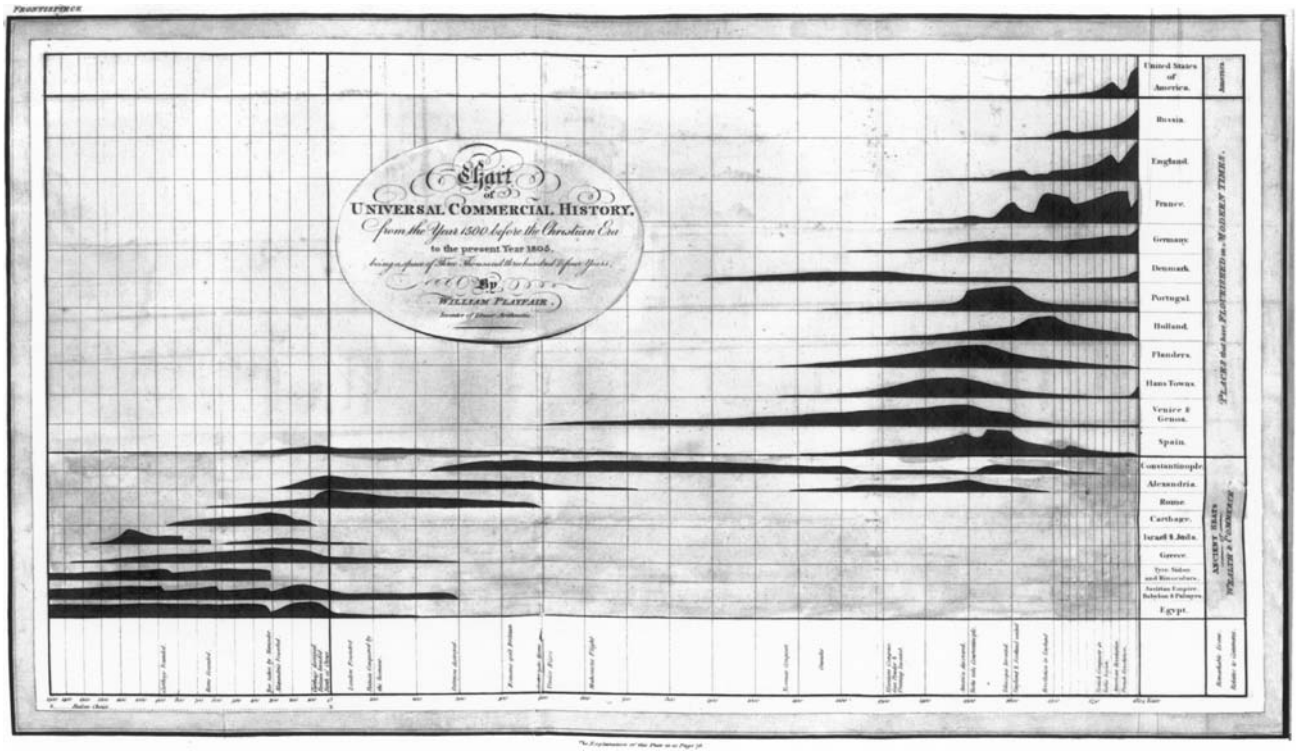

Figure 3 Playfair's only silhouette chart found as the frontispiece in *An Inquiry* (1805, 1807). This is a diagrammatic chart with no quantitative values represented. It depicts the rise and fall of 20 economies over a period of more than 3000 years. The original uses various colors in the background.

mathematicians and scientists as professor of natural philosophy, mathematics, and geology at Edinburgh University. After an apprenticeship with Andrew Meikle, the inventor of the threshing machine, William became draftsman and personal assistant to the great James Watt at the steam engine manufactory of Boulton & Watt at Birmingham in 1777. Thus, William's scientific and engineering training was at the hands of the leading figures of the Enlightenment and Industrial Revolution. On leaving Boulton & Watt in 1782, Playfair set up a silversmithing business and shop in London, but the venture failed. Seeking his fortune and hoping to apply his engineering skills to better effect in a developing French economy, Playfair moved to Paris in 1787.

It was about this time that Playfair developed most of his graphical formats and published several examples. He already had the mathematical training from his brother John, the engineering know-how from Meikle and Watt, knowledge of business and economics from men such as Boulton, and some hard practical experience of the world of affairs from his botched enterprises in London and Paris. But his charts were not readily accepted, especially in Britain, where concerns regarding accuracy were not eased by his occasional carelessness and his less than reputable personal standing. He was received more sympathetically in Germany and France, gaining approval from the geographer Alexander von Humboldt, among others. Nevertheless, there was still considerable opposition to his ideas and there was no general adoption of his methods until the second half of the 19th century, when Minard and Bertillon incorporated some of Playfair's devices in their cartographical work.

The Time-Series Line Graph

In 1786, shortly before he left for Paris, Playfair published his *Commercial and Political Atlas*, which contained 44 charts, but no maps; all of the charts, save one, were variants of the statistical time-series line graph. Playfair credits his brother for the inspiration that led to the line graph—John had made him keep daily records of temperature and chart these data in similar fashion. As Scotland's foremost mathematician of the day, John Playfair was certainly familiar with the use of Cartesian graphs to represent functions, and would also have been aware of the work of Lambert, who superimposed empirical data points on such functions. Another influence can be found, a decade beforehand, in the work of Joseph Priestley, who had conceived of representing time geometrically (see Fig. 1). The use of a grid with time on the horizontal axis was a revolutionary idea, and the

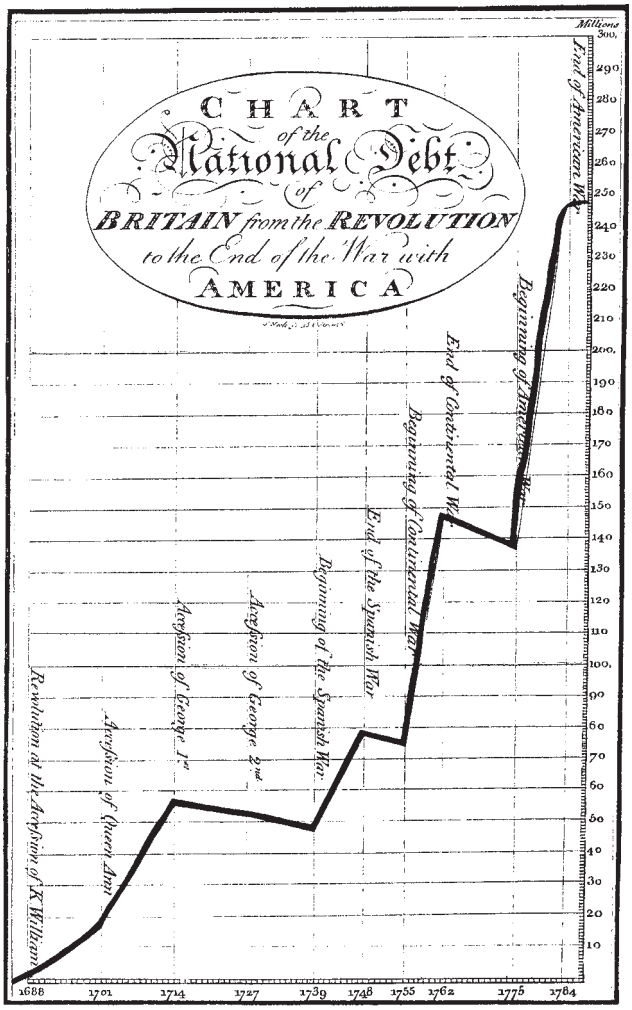

Figure 4 This remarkable "Chart of the National Debt of England" appeared as plate 20, opposite page 83 in the third edition of Playfair's *Commercial and Political Atlas* in 1801. Not only is it the first "skyrocketing government debt" chart, but it also uses the innovation of an irregularly spaced grid along the time axis to demark events of important economic consequence.

representation of the lengths of reigns of monarchs by bars of different lengths allowed immediate visual comparisons that would otherwise have required significant mental arithmetic. What is more, the relative differences in time periods and their relative position in the overall chronology could also be readily apprehended; no wonder that Priestley's device proved popular.

William Playfair was well acquainted with Priestley and his work, encountering the older man on a frequent basis in the Birmingham of the late 1770s. It was Playfair's genius to take the ideas implicit in Lambert and Priestley's charts and, with the stimulus of his brother's early instruction, to produce the first statistical time-series line graphs (see Figs. 2 and 3).

These charts introduced a large number of innovative features that remain part and parcel of the statistician's repertoire today: the use of an informative title; graduated and labeled axes; ruled gridlines, with greater line weight for major intervals; broken and solid lines, or different line colors, to distinguish time series of different kinds; hachure, solid fill, and color to indicate areas that represent accumulated amounts; the colors green and red to indicate positive and negative balances; appropriately placed labels to indicate historical events (Fig. 4); and so forth.

Playfair also introduced novelties that are still occasionally seen today: for example, in one chart, whose vertical dimension was insufficient to contain a particularly high peak in expenditures, Playfair extended the curve beyond the frame at the top and allowed it to repeat at the bottom of the graph. Although it is likely that this obvious peculiarity may have resulted from an error in planning, it turned out to be, in effect, an editorial comment. The reader is immediately drawn to the unusual nature of the sharp rise in cost—the implication is that the spike in prices is so egregious that the scope of the chart is unable to accommodate the excursion.

The Bar Chart

Playfair freely acknowledged Priestley's chronological diagrams as the source of the single bar chart that appeared in his atlas (Fig. 5). But he introduced this chart with apologies. He had insufficient data to be able to present the time-series chart that he had intended and so of necessity had to invent another form in which the horizontal axis did not represent the flow of time. He thought so little of this invention that he made no subsequent use of it, at least in its original form. He did, however, use bars in later graphs, but to display changing data over time.

The Pie Chart

Whereas both the line graph and bar chart used linear extent to represent quantity, Playfair's next inventions used area. The *Statistical Breviary* contained charts that were intended to show the areas, populations, and revenues of European states (Fig. 6). The charts also indicated which countries were maritime powers by coloring them green, while the others were stained red. The first chart of the *Breviary* shows the countries before the French Revolution of 1789, and the second chart displays the changes thereafter in 1801, the year of the Luneville peace.

Thus in two charts in a single volume, Playfair introduced three new forms of statistical graph: the circle diagram, the pie chart, and a Venn-like diagram, which is

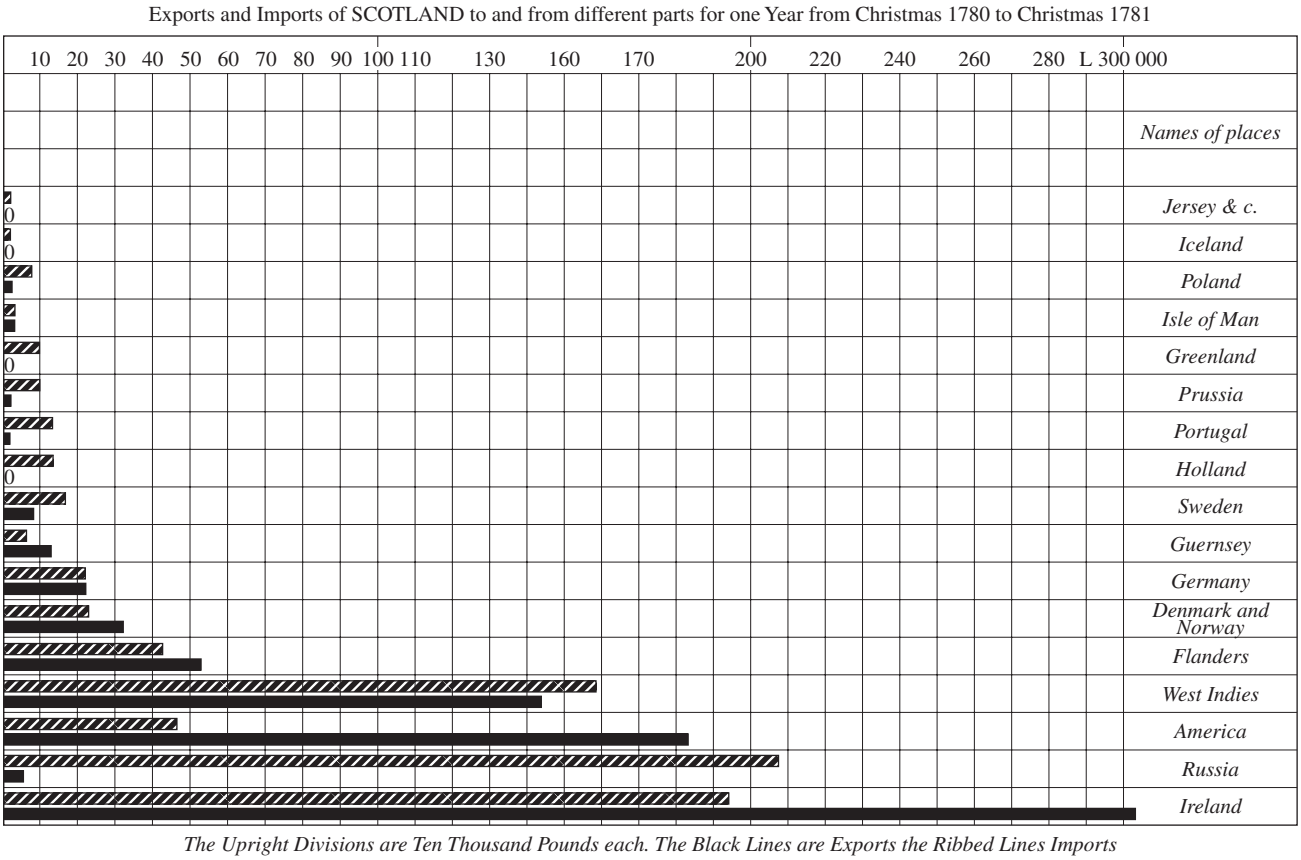

Figure 5 Imports from and exports to Scotland for 17 different places. After Playfair (1786), plate 23.

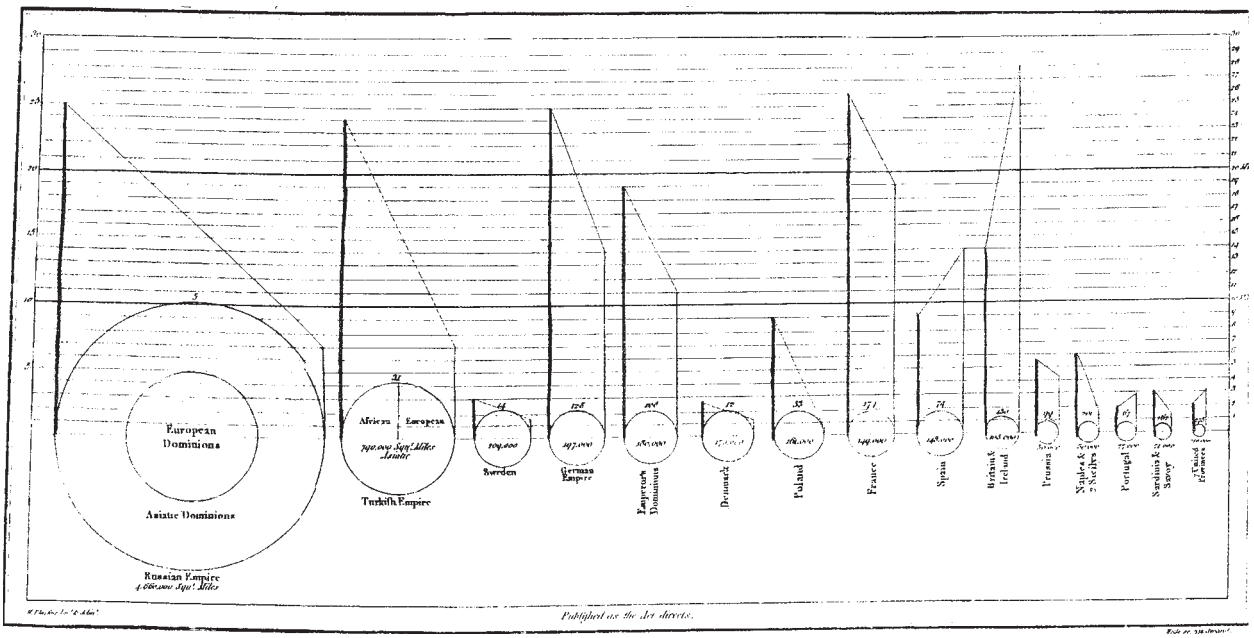

Figure 6 An innovative design from Playfair's *Statistical Breviary* (1801), which showed multivariate data using area to depict quantity for the first time. The circle represents the area of the country, the line on the left of each circle represents the size of the population, and the line at the right the tax revenues collected. The slope of the dotted line indicates the extent of the tax load. It is easy to see that the small populations of Britain and Ireland stand out as the most heavily taxed of all nations included.

used to show joint properties. As in the case of the line and bar charts that he had introduced 15 years before, his basic designs were sound and have scarcely been improved upon. The areas of circles are used to represent varying quantities, and the practice of using circles, or areas of other figures, persists to this day. In the pie chart, Playfair used angle to denote proportion, and used color and labeling to differentiate the segments that make up the whole (Fig. 7). The use of Venn-like diagrams to portray statistical quantities is less common, both today and two centuries ago, but the device is not unknown.

However, the pie chart remains a mystery—Playfair left us no indication of its inspiration. And yet it is likely that he was copying or adapting the ideas of others—his career is replete with instances of adaptation. Perhaps a clue is to be found in the intersecting and included circles. Such diagrams were used by Venn in his work on logic in 1880—but, of course, Playfair's diagrams precede Venn's. Venn (1834–1923), contrary to popular myth, was not the inventor of such logic diagrams. Euler (1707–1783) had used them for exactly the same purpose more than a century before. And before Euler, Leibniz (164–1716) devoted serious attention to the analysis of logical propositions by means of diagrams: he explored various means of representing Aristotelian syllogisms by means of geometric figures, including Venn-like diagrams as well as his own linear versions, which he considered superior. It was, however, Euler who popularized the use of circle diagrams, although he was quick to point out that the type of shape was unimportant. It is interesting to observe that the work of Euler and Leibniz was well known to John Playfair, the author of "Progress of Mathematical and Physical Science since the Revival of Letters in Europe" in the fourth edition of the *Encyclopedia Britannica*. This article has been described as the best short general history of science written during the first half of the 19th century. His concluding discourse on the genius of Leibniz and Newton was universally admired. Because of his intimate familiarity with the work of Leibniz and Euler, John Playfair could not have failed to make William aware of this work as he instructed his 12-year-old younger brother in mathematics, after the early death of their father.

After the great inventions of 1786 and 1801, Playfair introduced no further innovations of any consequence. He did, however, refine his graphs, and later publications include rather splendid examples that combined the time-series line graph, a seamless sequence of bars depicting quantities averaged over fixed time periods, and a chronological diagram in a single chart (Fig. 8).

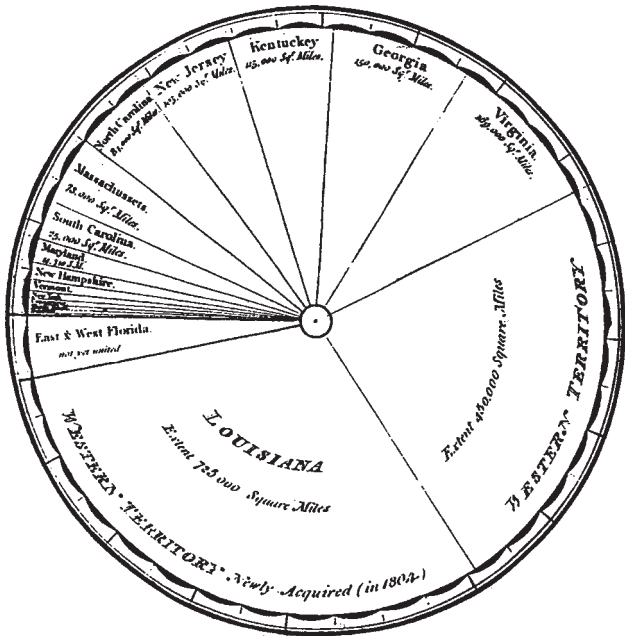

Figure 7 Playfair's pie chart using the segments of the pie to represent the relative size of each component of the United States at the beginning of the 19th century. Areas in the chart are proportional to the areas in square miles. From Donnant (1805).

Conclusion

Playfair's final two decades were not easy. He was in frequent financial difficulty, despite his involvement in a variety of schemes. These generally involved publishing, banking, and writing about economics. When he returned to London, Playfair and his partner Hartsinck opened the Security Bank, modeling its practices on schemes that he had seen in Paris during the Revolution. The London establishment, however, did not tolerate these unregulated innovations, and the venture collapsed after a conflict with the Bank of England. From the mid-1790s onward, he made his living as a writer and also as a gun carriage maker, developing the occasional new mechanical invention. He argued against the excesses of the French Revolution and commented extensively on British policy toward France. In his illustrated nine-volume *British Family Antiquity*, he catalogued the peerage and baronetage of the United Kingdom. He also edited more than one periodical, including the *Tomahawk*. After the restoration of the Bourbon monarchy, he returned to France and became editor of the periodical *Galignani's Messenger*, but his comments on a duel between a Colonel Duffay and the Comte de St. Morys were held to be libelous by the widow St. Morys and led to Playfair's prosecution. Sentenced to three months imprisonment, a fine, and damages, Playfair thought flight a better option, and he spent his remaining years in London writing. He constantly pushed the boundaries of legality and was convicted on more than one occasion.

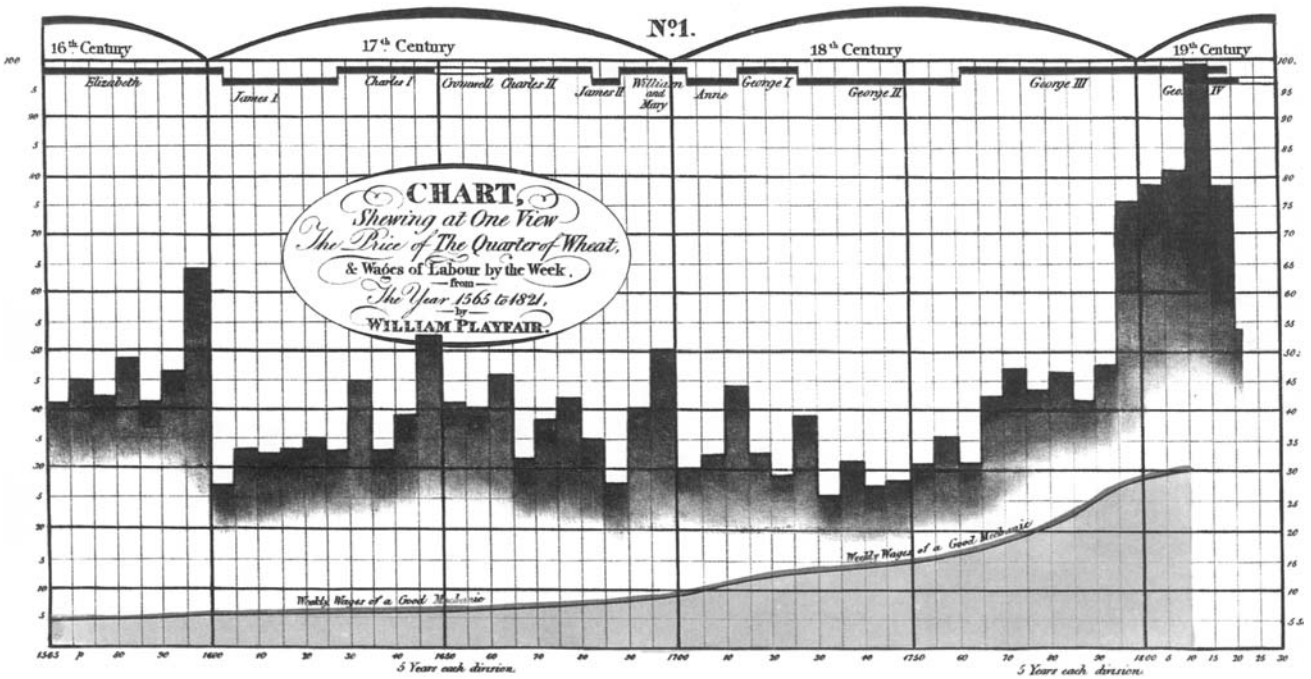

Figure 8 One of Playfair's most dramatic displays designed to show the unfair price of a quarter of wheat compared to the humble wages of a "good mechanic." In the original, the curve for the wages of the mechanic appeared in red and the area beneath was stained blue. This chart appeared in both editions of *Agricultural Distresses* (1821, 1822).

He even descended to a kind of genteel blackmail of acquaintances (for example, the famous engineer John Rennie) and more aggressively with strangers (Lord Archibald Douglas). Despite his considerable efforts, including a hopeful but brief return to France, his schemes failed to gain the fortune that he craved. He died in modest circumstances at the age of 63.

Police Records and the Uniform Crime Reports

Scott Akins
Oregon State University, Oregon, USA

Glossary

classifying The Uniform Crime Reports (UCR) requirement that local law enforcement agencies report crimes to the UCR in a manner that is consistent with the crime categories employed by the UCR.

hierarchy rule The UCR requirement that in a multiple offense situation only the most serious offense should be recorded.

National Incident-Based Reporting System (NIBRS) A program for measuring crime that uses each criminal occurrence rather than summary counts and has been argued to be better than the UCR for measuring the true volume of crime.

National Crime Victimization Survey (NCVS) A self-report survey conducted by the U.S. Bureau of the Census on behalf of the Bureau of Justice every 6 months that measures respondents' experiences with rape, robbery, assault, burglary, larceny, and motor vehicle theft.

Part I (index) offenses Eight crimes monitored by the UCR for which more extensive data are available and that are intended to give a reasonable picture of crime in the United States. Part I offenses include murder and nonnegligent manslaughter, forcible rape, robbery, aggravated assault, burglary, larceny, motor vehicle theft, and arson.

Part II offenses Crimes that are considered by the UCR to be either less serious or serious but relatively infrequent. The data available for Part II offenses are less extensive than for Part I offenses and are limited to arrest data alone.

scoring The process by which local law enforcement agencies "count" the number of offenses present in each crime category dependent on certain conditions stipulated by the UCR program.

self-report survey A research method in which people are asked to reveal information about their involvement in crime.

Uniform Crime Reports (UCR) The most widely used source of official data on crime in the United States. Maintained by the Federal Bureau of Investigation, the UCR collects and reports data on offenses reported to police and arrested offenders from local police agencies throughout the country.

Police records are those data collected as a consequence of the regular operation of the police. The most prominent source of official data on crime is the Uniform Crime Reports (UCR) and its developing National Incident-Based Reporting System. It is important to note that these data, like all data, suffer from some shortcomings. However, UCR data provide an invaluable contribution to our knowledge of crime, and the purpose of this article is to familiarize the reader with the strengths and shortcomings of the data so that they can be used with these issues in mind.

Uniform Crime Reports: Historical Perspectives

The Federal Bureau of Investigation's (FBI) Uniform Crime Reports (UCR) is the most widely used source of data on crime in the United States. Prior to the establishment of the UCR program in 1930, systematic data on crime across jurisdictions were unavailable. However, in the late 1920s, the International Association of Chiefs of Police (IACP) formed a committee to promote a national crime statistics program. In part, as noted by researchers such as Maltz, these efforts were aimed at preventing newspapers from manufacturing "crime waves" to boost paper sales and in part because estimates and comparisons of crime trends in the country were largely impossible due to differences in crime definitions, recording procedures, and recording accuracy. The IACP proposed seven types of crime that should be monitored for an understanding of crime in the United States: murder

and nonnegligent manslaughter, forcible rape, robbery, aggravated assault, burglary, larceny, and motor vehicle theft. According to the FBI, these particular crimes were selected on the basis of their seriousness, frequency of occurrence, pervasiveness in all geographic areas of the country, and likelihood of being reported to law enforcement. Referred to as Part I offenses or "index crimes," these offenses were and are the primary basis for the UCR program.

Although the UCR program has experienced few fundamental changes since its inception in 1930, some minor modifications have been made. The first significant revision of the UCR program came in 1958 when statutory rape, negligent manslaughter, and the larceny of less than $50 were all reclassified from Part I to Part II offenses. In this same year, the FBI began to make estimations of crime rates for the nation as a whole and to use a composite measure of all index crime, referred to as the Crime Index. In 1974, larcenies of less that $50 were once again included as a Part I offense, and a key revision of the UCR program came in 1979 when arson became the eighth index crime. As noted by Mosher *et al.*, the addition of arson was the result of a congressional mandate in October 1978 and occurred despite the protests of FBI officials that the accurate classification and recording of arsons would be particularly problematic. Although the passage of the Anti-Arson Act of 1982 permanently established arson as an index crime, arson figures are not included in Crime Index totals because these figures are not consistently available. The last significant modification of the UCR program (excepting the development of the National Incident-Based Reporting System, discussed later) came in 1990 when the UCR began to collect data on hate crime as a result of the Hate Crime Statistics Act.

Uniform Crime Reports: Data Collection

In addition to the information collected on Part I offenses, the UCR program also compiles data on crimes that are considered to be either less serious or serious but relatively infrequent (e.g., kidnapping). These are referred to as Part II or "nonindex" offenses. Part II offenses include white-collar crimes, such as fraud, embezzlement, and forgery/counterfeiting; public order crimes, such as drug offenses, gambling, and prostitution; and other crimes, such as simple assaults, minor theft, sex crimes excepting forcible rape and prostitution, disorderly conduct, and vagrancy. The reporting of data on Part II offenses is optional for those departments that participate in the UCR program, and the data available for these crimes are less extensive than for Part I offenses, being limited to information on arrests alone.

Although the FBI considers the participation of law enforcement agencies in the UCR program "strictly voluntary," Schneider and Wiersema note that many states have mandated that their law enforcement agencies participate in the UCR program. Despite its "voluntary" nature, the UCR program enjoys impressive participation rates. Indeed, as noted by Mosher *et al.*, a total of 16,788 state, county, and city law enforcement agencies, covering more than 272 million inhabitants, submitted crime reports to the UCR 1999. The total population covered by the UCR is an impressive 97%. However, coverage outside of urban areas drops slightly, falling to 90% in cities outside metropolitan areas and to 87% in rural areas.

The actual data collection process occurs each month as the FBI gathers crime statistics in the form of UCR tally sheets and report forms. These are obtained from local law enforcement agencies or state agencies designed to act as intermediaries between local law enforcement and the UCR program. Cross-checks of the reported data and on-site training and consultation are performed by the FBI in an attempt to maintain quality control in data collection and to ensure that the data are comparable across jurisdictions. This can prove challenging at times because an essential part of the UCR data collection process is the requirement that local law enforcement agencies report crimes to the UCR in a manner consistent with the crime categories employed by the UCR, referred to as classifying. Many local jurisdictions have definitions of crimes that differ from the definitions employed by the UCR, and classifying is apt to be particularly problematic in these instances. Following the classification of offenses, local agencies then score the offenses, or count the number of offenses in each crime category depending on certain conditions. Both the process of classifying and scoring are potential sources of error in UCR data and will be discussed in more detail later.

Sources of Ambiguity in Uniform Crime Reports Data

Despite the extensive use of UCR statistics, these data are subject to several well-known criticisms. These criticisms can be broadly grouped into those that address the reporting of crimes to the police, methodological problems with UCR coding procedures and measures, and questions of whether UCR data reflect the behavior of criminals or the behavior of police. These methodological and measurement problems have been the subject of extensive discussion and debate, and this article only touches on the many issues. Readers seeking a more in-depth examination are encouraged to see the excellent

reviews of this literature provided by Mosher *et al.* and Schneider and Wiersema.

Issues of Reporting

Because official data on crime are derived from the regular operation of the justice process, they incorporate all the issues and problems that are inherent in this process. One of these problems is underreporting. Policing is a very reactive process, with police depending heavily on regular citizens to report crimes. Indeed, unless a crime is witnessed and the witness decides to report it, the crime will typically remain unknown to the police. Because many crimes remain unnoticed by the public, and because even when crimes are witnessed many choose not to report them to the police, the majority of all crime that is committed never becomes known to the police and recorded.

This underreporting of criminal behavior in official police statistics, often referred to as "the dark figure of crime," is known to be substantial. Even among serious crimes levels of underreporting typically exceed 50%, although this varies by the type of crime and numerous other variables (discussed later). Information on the extent of underreporting became increasingly available in the late 1960s with the development of victimization surveys, which avoid some of the problems that characterize official data on crime. Indeed, the National Crime Victimization Survey (NCVS), the nation's largest and most comprehensive victimization study, was created in large part to address the shortcomings inherent in official sources of data on crime such as the UCR.

There are several reasons for underreporting. Often, people believe that the crime in question is not serious enough to merit police involvement, such as in a case of vandalism or a minor theft. Other times, people may believe that involving the police will not help them to remedy the situation in any way and will just be "one more hassle to deal with." Additionally, many crimes are never reported because of their "victimless" nature, being entered into consensually by all parties involved (e.g., drug use and sales and prostitution), and even when there is a victim in a crime many choose not to report their victimization out of a fear of retaliation (e.g., a battered wife or girlfriend) or because they distrust or fear the police. Underreporting also results because victims of crime who are engaged in criminal activity, particularly at the time of their victimization, may be especially unlikely to report an offense out of fear they will be punished (e.g., rape of a prostitute or robbery of a drug dealer). These people may choose to "just forget" the incident or to settle it themselves, which may result in more (potentially unreported) criminal activity.

Further complicating these problems is that rates of underreporting are likely to vary based on a number of factors, such as the type of crime, the demographic characteristics of the victim, the location of the crime, and the relationship between the victim and the offender. Perhaps most influential among these factors is the type of crime involved. Violent crimes are reported at higher rates than are property crimes (excepting motor vehicle theft, which is highly reported for insurance purposes), particularly for the crimes of homicide and robbery. However, although the seriousness of the crime plays an important role in reporting, many other factors are also important. Indeed, rape, an extremely serious crime, is among the most underreported of offenses. The race and gender of victims have also been found to influence reporting, with women and blacks being more likely than men and whites to report their victimization, as has region, with people in the southern states being more likely than those in other regions to report crimes. The relationship between the victim and the offender has been found to influence reporting. Indeed, Turner found that people are more likely to report crimes committed by strangers than by those they know. Levels of underreporting may also vary with time and circumstance. Indeed, evidence seems to indicate that rape, although still highly underreported, is probably less underreported now than a decade or two ago as public awareness and sensitivity about the crime and its victims have grown. Thus, it is particularly important to realize when using UCR data that not only does underreporting exist but also the levels of underreporting are not constant across offense type and many other variables.

After citizens report incidents of crime to police they may still be left unrecorded. The wide discretion granted to police enables them to decide, based on a number of factors, whether a particular offense necessitates an arrest or citation. Verbal warnings are an extremely common response by police, particularly in dealing with minor forms of crime, leaving many offenses unrecorded. This situation is complicated by the fact that an officer's decision to formally record a reported crime is influenced by a number of factors. Black's classic study on this topic concluded that variables such as the seriousness of the crime, the complainants' desire to see the matter taken further, the relationship of the offender and victim (found to be the most important factor), and the complainants' social class and behavior toward the officer all had significant effects on whether the crime was officially recorded. Police recording practices are also likely to vary by region and jurisdiction, and all these factors are likely to make comparisons across jurisdictions problematic.

Another potential source of underreporting (or misreporting) that may occur after the crimes have been reported to police deals with the alteration of data by law enforcement administrators for political or budgetary purposes. Articles such as "How to Cut City's Crime Rate: Don't Report It" reported in the *Philadelphia Inquirer* and "As Crime Falls, Pressure Rises to Alter Data" reported in the *New York Times* attest to the pressure

police administrators are under to show decreased crime rates. As Mosher *et al.* noted, methods of "cooking the data" to reduce overall crime counts may involve practices such as not reporting all crime incidents to the UCR, downgrading Part I offenses to Part II offenses so they are not included in national UCR summaries, and misusing the hierarchy rule to combine many separate incidents into a single (artificial) multiple-offense incident. Those such as Maltz have noted that although the pressure on police administrators to alter reported crimes has decreased somewhat in recent years, these temptations will likely always be present.

Reporting problems can also arise from the actions of police administrators even when they are acting in a completely even-handed manner. Changes in policy or standard police procedures may inadvertently have a major impact on the rate of crimes reported. These changes can be formal, such as providing an "emergency 911" number or mandating arrest for domestic abusers, but they can also be informal, such as a police chief telling his officers to arrest prostitutes as a result of an embarrassing newspaper report. Regardless of the cause, reported crimes may be substantially influenced because of a change in the official response to crime rather than any actual change in criminal behavior.

A final problem related to reporting in the UCR is the lack of attention given to particular types of crime. Specifically, UCR data do not address federal or political crimes, and they severely undercount organizational and occupational crime. The inadequacy of official data to address white-collar crime dates back to Edwin Sutherland's presidential address to the American Sociological Association in 1939, but only recently have any significant steps been taken to address this shortcoming. Measures of white-collar crime in the UCR are limited to fraud, forgery/counterfeiting, and embezzlement, all of which are Part II offenses with only limited information. However, the development of the National Incident-Based Reporting System (NIBRS) to enhance the UCR has addressed this problem somewhat by providing much more information on white-collar offenses. Although some reason that the UCR has paid little attention to white-collar crime because these crimes are much more difficult to detect and report on, others argue that the FBI is simply biased in favor of the upper class and thus chooses to focus on "street crimes" rather than "suite crimes" because the former are more likely to be committed by members of the underclass.

Methodological Problems with UCR Data

One of the most problematic aspects of the UCR data collection process is classifying, or taking the numerous offense titles employed by jurisdictions across the country and grouping the incidents of these categories into the appropriate standardized crime categories used by the UCR. For example, legal definitions for the crime of rape vary greatly by jurisdiction. Some laws require forced penile–vaginal penetration for a rape to occur, whereas others stipulate that other types of offensive intimate contact constitute rape. Jurisdictions may require some degree of physical "resistance" on the part of the victim for it to be considered a rape, and some may or may not allow males to be considered victims of rape. Finally, some jurisdictions may completely abandon the term of rape and classify these acts under categories such as sexual assault in the first, second, or third degree. Regardless of the legal strategy employed by the local jurisdiction, when reporting crime data to the UCR the local jurisdiction must conform to the UCR definition of the crime. This process of classification, discussed briefly earlier, can be difficult for police to accomplish and is certain to introduce some error into UCR data. However, the availability of technology and software developed for the automated reporting of UCR and NIBRS data may help to manage these problems somewhat in the future.

The process of scoring, the counting of offenses after they are classified, can also be problematic because offenses may not be counted if they meet certain conditions. When scoring, the UCR requires that for crimes against property (i.e., burglary, larceny/theft, motor vehicle theft, and arson) one offense is counted for each "distinct operation," defined as a criminal incident that is separate in time and place. In the instance of a property crime that victimizes more than one person at the same time and in the same place (e.g., the burglary of three housemates), the distinct operation criteria requires that each of the persons offended against is not counted as a separate crime.

Conversely, for crimes against persons (i.e., criminal homicide, forcible rape, robbery, and aggravated assault) each offense that has a victim is counted as one offense. For example, if a person were to murder two people in a robbery, each murder would be recorded by the UCR because there are two victims. However, although both of the homicides would be recorded, not even one robbery would be recorded. This is because scoring must also take into account the hierarchy rule, one of the most frequently discussed and debated issues with regard to counting procedures used by the UCR.

The hierarchy rule states that in a multiple-offense situation (e.g., robbery–homicide), after classifying all the Part I offenses, only the most serious offense should be scored and the rest ignored. Thus, in the previous example, each homicide is recorded but each robbery is ignored. This obviously results in a systematic underreporting of crime, but it also raises concerns about differential levels of compliance with the hierarchy

rule among reporting agencies. The only important exception to the hierarchy rule occurs for the crime of arson, which is always reported, even in multiple-offense situations. It is important that UCR data are used with these issues in mind because, as noted by Mosher *et al.*, it is likely that the index crimes are subject to considerable variability in counting and scoring across reporting agencies.

Additional methodological criticism of the UCR addresses the extent to which the crime measures used by the UCR are flawed. Criticisms have been lodged against the UCR for aggregating offenses that are conceptually dissimilar into a single category (e.g., shoplifting and purse-snatching), excluding important supplementary information about the crimes (e.g., the victim–offender relationship), and including attempted crimes along with completed crimes. Comment has also been made on the fact that the UCR uses estimates of population counts in noncensus years when calculating crime rates, which can be problematic particularly in times of rapid population growth or decline. Finally, some concern has been raised over the size of the sampling error and sampling bias that may be introduced when the UCR generates crime estimates for those areas where agencies were either unable or unwilling to provide data to the UCR.

Official Statistics: A Measurement of Criminal Behavior or Police Behavior?

As noted by Wolfgang, the last and perhaps most fundamental criticism of the UCR addresses the extent to which the data reflect the behavior of police rather than criminals. As discussed earlier, levels of reported crime in official data may be heavily influenced by discretionary decisions on the part of officers, changes in police procedure, or intentional tampering with the reported figures for political reasons. In addition to these concerns is the problem of race and social class biases in policing, which has been demonstrated by numerous studies. For example, Skolnick found that police often act in harsher or more confrontational manners when policing minority communities in part because they believed minority youth to have a greater potential for violence. Analogous work by Smith examined 60 neighborhoods of varying racial and economic composition and found that police were three times as likely to arrest a suspect in a poor and predominately minority neighborhood, regardless of the crime involved, compared to a higher class and predominately white neighborhood. Similarly, in his ethnographic study of urban communities, Anderson noted that police appear to engage in an informal policy of monitoring young black men as a means of controlling crime, and they often seem to go beyond the bounds of their duty. Finally, work by Chambliss on policing the underclass concludes that if police patrols paid half as much attention to the crimes of students at universities as they do to the crimes of young black males, the arrest and incarceration rate for young white males would be quite similar to those for young black males. In summary, bias on the part of police likely results in minorities and members of the lower class being more harshly treated by police, resulting in disproportionately high rates of citation and arrest. Furthermore, the degree to which the data are influenced by these factors is likely to vary by the type of crime (e.g., serious crimes appear to be less influenced by these factors) and other relevant variables. Therefore, it is important that the data be used with these issues in mind.

Despite the numerous problems with UCR data, they are a good source of data on crime and are extensively used by researchers. Not only are easily accessible and constantly updated they also provide excellent coverage over time. Additionally, the extensive data on homicide provided by the UCR's supplementary homicide reports are exceptionally good because nearly all homicides come to the attention of law enforcement and a large portion result in arrest. Although underreporting is an issue with UCR data, levels of underreporting are relatively stable across time for most crimes. Thus, UCR data allow us to effectively examine changes in crime patterns over time, even if the total amount of crime captured by the UCR is known to be inaccurate. In summary, it is important to note that the criticisms lodged against UCR data should not preclude the use of these data but rather warn researchers about the weaknesses present so that the data can be used with an awareness of their limitations.

The National Incident-Based Reporting System

The development of the NIBRS resulted partly in response to the criticisms levied at the UCR. The incident-based counting system employed by the NIBRS allows the collection of extensive, detail-rich data on crime that are superior to the summary data currently available through the UCR. The NIBRS collects data on each criminal incident, defined as one or more offenses committed by the same offender or group of offenders acting in concert, and arrest within 22 broader offense categories containing 46 specific crimes. Information is provided on the number of offenses that occur in each incident (avoiding the hierarchy rule), with extensive details on the offense(s) also provided. These details include whether the crime was only attempted or actually completed, whether the offender was suspected of using alcohol or drugs, whether the offender was suspected of using a computer in the commission of the crime (one

potential indicator of white-collar crime), whether the crime was motivated by bias, the location of the crime, and whether a weapon or force were used in the commission of the crime. Additionally, for each incident, data are collected on both the offender(s) and the victim(s) (regardless of whether an arrest has been made). Information on the offender(s) includes age, sex, and race. Information on the victim(s) includes the number of victims per incident (up to 999); the age, sex, race, ethnicity, and resident status of the victim(s); whether an injury was sustained by the victim(s) and, if so, what type; the relationship of the victim(s) to the offender(s); the circumstances surrounding the incident in the case of an aggravated assault or homicide; additional information on the incident circumstances in the case of a justifiable homicide; and an ID number identifying the offender(s) in the incident so that those data can be cross-referenced (although data on victims cannot be accessed through the offender records). Furthermore, for each incident, data are collected on any property that is involved (e.g., the type of property, the value, and whether it was destroyed or seized), as well as information on arrests, such as whether an arrest was made; the date of arrest; the arrest offense code; any weapon(s) the arrestee(s) possessed; and the age, sex, race, ethnicity, and resident status of each arrestee.

As noted by Chilton, the extensive volume of information collected by NIBRS is magnified by the possibility of multiple offenses, multiple victims, multiple offenders, and multiple arrests all within a single incident. Obviously, although these data are extremely impressive in terms of the volume and quality of information they can provide, they also involve further challenges in data coding and recording that will take time to implement at the local level. The FBI first began accepting NIBRS data from local agencies in 1989, and as of early 2002 it reported that there were 4192 law enforcement agencies contributing NIBRS data to the UCR program. This provided coverage for 17% of the U.S. population and accounted for 15% of the crime statistics collected by the UCR. The limited, though improving, national coverage provided by the NIBRS is indicative of the challenges faced by those attempting to implement it. For example, the tremendous complexity of the NIBRS coding process makes participation in the program by local law enforcement agencies problematic. Indeed, a widespread belief exists among law enforcement personnel that implementing the NIBRS will be very costly for local law enforcement agencies, and administrators may wonder whether it is the best use of their resources. Roberts points out that police officials often feel burdened by a complex data entry process that appears more valuable to researchers than to law enforcement agencies. Additionally, there is a widespread perception among law enforcement personnel that reported crime will increase with the adoption of NIBRS, partially due to the elimination of the hierarchy rule. Although the fact that this perception exists is of key importance for implementing the NIBRS at the local level, a study by Rantala and Edwards found little evidence to support it. Comparing NIBRS and UCR data for the same years and jurisdictions, the study found that when using NIBRS data rates of homicide remained the same; rape, robbery, and aggravate assault rates increased by approximately 1%; larceny rates increased by 3.4%; motor vehicle theft rates increased by 4.5%; and burglary rates decreased by approximately 0.5%.

In summary, although the NIBRS presents a tremendous opportunity for criminologists, the detailed nature of the data requires a meticulous and complex recording process that will take time and resources to implement. The data are tremendous in terms of their scope and address many of the problems associated with the UCR—although those dealing with data coding and entry may actually be greater, at least for the time being. It is also important to recognize that because local police agencies are vital to the collection and reporting of official crime data, it is essential that they be convinced of the value of the NIBRS for it to replace the UCR as the central source of official crime data in the years to come.

Official police data, such as the UCR and the developing NIBRS, are some of the most valuable and frequently used data on criminal behavior. Like all forms of data, they suffer from some shortcomings. The most salient of these deal with issues of underreporting; methodological problems, such as inappropriate classification and inadequate measures; and problems regarding the extent to which official police data reflect the behavior of police rather than criminals. However, research based on official police data has contributed immensely to our knowledge of crime, and these data can be extremely valuable if used with an appropriate awareness of their limitations.

Political Conflict, Measurement of

Monty G. Marshall
University of Maryland, College Park, Maryland, USA

Glossary

authority The power to direct, manage, or otherwise control political conflict.
co-optation Neutralizing conflict either by satisfying the personal interests of opposition group members or through the inclusion of opposition group goals.
demonstration A public display of group support for a political position or of group identity, strength, and cohesion.
event A single occurrence or episode of a particular type or classification of a social phenomenon.
imposition Negating conflict through the demonstration of superior force.
mobilization Organizing, preparing, and directing a social group for political action.
negotiation Neutralizing conflict through bargaining and agreement between opposing groups.
protest A principal form of communicating opposition or grievance to an established political authority group.
revolution A sociopolitical movement to overthrow an existing government and replace it with something new; alternatively, a sudden, momentous or radical transformation of the structures and values of society and governance.
riot A violent disturbance involving an assembled group; riots may result from spontaneous action or an escalatory sequence during a nonviolent demonstration; riots may also be a planned event.
separation Neutralizing conflict by constraining interaction(s) between otherwise opposing groups; separatism is often made salient by different and opposing ethnic identity groups.
war Major, open armed conflict between disciplined militant organizations representing the interests of larger opposing groups engaged in a political conflict.

The measurement of political conflict presents tremendous challenges to social scientists engaged in the quantitative analysis of political behavior. The term "political conflict" can have many different meanings depending on the context in which it is used; the appropriate measurement of political conflict depends upon meaning and context. It is crucial that any measure of political conflict phenomena include a complete and explicit delineation of its definitional parameters. In its most general sense, political conflict refers to a public demonstration of opposition, or disagreement, between two or more social groups. Social groups themselves are quite commonly organized through the impetus, or mobilization potential, of conflict. Political conflict (conflict between groups) is usually distinguished from social conflict (conflict involving individuals in a social group context) and interpersonal conflict (conflict between individuals) by reference to notions of "sovereignty," the primacy of state authority in the management of group conflict, or the inherently political nature of social group organization. Classic definitions of political conflict derive from Machiavellian principles of "state's rights" (*raison d'Etat*) and focus on the direct behavior of the sovereign state in its relations with other states (interstate conflict), direct applications of state coercion to members of constituent groups (repression), and direct challenges to state authority by constituent groups (civil conflict). Others, arguing a human rights perspective, claim that all conflicts between groups and individuals must be considered political conflict, regardless of the role of the state in defining the conflict or the presence or absence of direct actions by state authorities. From this perspective, the legitimacy of the state may be measured by the qualities of its involvement in political conflict. One can even speak of personal conflicts as political conflict as each individual struggles with internal tensions deriving from conflict between personal desires and the political nature of the need for social acceptance or approval. As political conflict involves directed group behavior in an

interactive sequence with an opposing group, it is necessarily conditioned by established authority and governance structures; that is, governing institutions are either directly or indirectly involved in all political conflict situations.

The two principal forms that political conflict may take are protest (voice) and coercion (action). The presence of political conflict impedes, or even thwarts, the direct pursuit and attainment of a group's professed goal or goals. As such, political conflict produces a contention that must be resolved before goal-oriented progress can be restored. It is generally recognized that the crucial factor in the definition of political conflict is its potential for escalation, that is, the possibility of a "resort to force" as the "final arbiter" in a conflict interaction and the attempt to negate the resistance of an opposition group (or groups) and impose a resolution of the conflict by one or more parties to the conflict without the support of the opposition. The coercive resolution of political conflict includes the implicit or explicit threat of political violence, that is, by enforcement, repression, or armed conflict. Enforcement actions are prescribed by law (rule of law); acts of repression are directed by the political interests of governing authorities (rule of force); armed conflict occurs when established authority structures are insufficient for commanding loyalty and discipline or ineffective in resolving important disputes. As armed conflict is the most dramatic and "visible" form of political conflict, the two terms are commonly equivocated simply as "conflict." This equivocation of the most common forms with the most extreme forms of social interaction tends to prejudice our understanding of the nature of political conflict and the role of force and violence in conflict behavior.

Measuring Social Phenomena

Constraints and Limitations

Conflict is at once an essential quality and principal feature of human social behavior. Louis Coser has even argued that conflict is a necessary condition to stimulate group formation and collective activity and as a *raison d'être* for social identity and group cohesion. In this formulation, some amount (or type) of conflict is seen as beneficial, or functional, in the transformation of individual to social behavior. Yet, it appears that too little conflict or too much conflict may be detrimental to the quality of social relations and the success of collective action. In a social setting, individuals politicize their interests and learn to cooperate with others (mobilize) in order to better manage social conflict and pursue common goals. As such, conflict, in its broadest sense, is a core, common, and continual feature of human relations, as is the purely individualized quality of choice of action in response to the stimulus posed by conflict. The perception of conflict is inherently subjective and the decision to act, whether alone or in concert, is necessarily complex and steeped in individualized ideas, attitudes, and preferences. However, group behavior requires more or less open communication and a convergence of ideas and attitudes among group members that makes the process of political conflict more transparent and regular, therefore, more comprehensible, predictable, and measurable.

If we accept the concepts of "free will" and "rational choice" in human behavior then we must also accept the precept that behavior is not deterministic but, rather, strategic. Individuals have a choice in how they will act and react in conflict situations and, in making choices in the pursuit of goals, behavior tends to be both rational and strategic: options are selected according to their perceived utility in attaining preferred goals. Coser goes on to identify three conflict mobilization options: participation, innovation, or rejection. Albert Hirschman provides a similar trilogy of political relations: loyalty, voice, or exit. These three main modes of social or political interaction provide the basis for distinct measures of attributes, qualities, and dynamics of conflict in the societal context. The first mode focuses on the role of conflict behavior in the creation and maintenance of the social system, the second mode focuses on system change through adaptation, innovation, or expansion, and the third focuses on separation and the potential for contention between opposing groups. While each perspective provides crucial information and the basis for unique measures of political conflict behavior in its own right, all three perspectives taken together provide a more comprehensive examination of political conflict in the social context. However, serious data limitations make such comprehensive examinations difficult, if not impossible, in many applications.

Three major limitations on the availability of political conflict data for measurement purposes are the result of administrative, technological, and statist constraints. Administrative constraints refer mainly to incomplete and imperfect record keeping. The measurement of social phenomena depends on the collection and recording of vital information; this, in turn, depends on the quality of knowledge and direction regarding what information to acquire and keep, the capacity to collect and record that information thoroughly, and the ability to maintain those records. Such extensive administrative capacity is a relatively recent and resource intensive development that has been largely monopolized by the state, especially in regard to the scope, consistency, and density of the historical record. Most historical records are highly selective and stylized accounts. Various authors, scholars, and historians have augmented shortcomings in the public record with private efforts but even these efforts have been subject to critical influence by state authorities.

Private contributions to the public record are particularly important in regard to information concerning political conflict, as will be discussed further below.

The administration of the public and historical record is heavily dependent on prevailing information and communication technologies. As our general technological capacity to collect, store, and retrieve information has expanded, so, too, has the scope and density (and accuracy and reliability) of the records available. It is really only with the expansion of the independent news media and the advent of the computer in the latter half of the 20th century (and, particularly, the personal computer in the late 1980s) that the data collection and record keeping enterprise has come of age. Even so, in most cases, the state retained a dominant and controlling grip on information resources through the end of the 20th century. The enormous costs of data administration remain daunting, if not prohibitive, for most private enterprises. Further complicating the scope and quality of the public record are the obvious security and strategic implications associated with information regarding political conflict. The interests of state security and sovereignty, particularly prior to the end of the Cold War in the early 1990s, very often led state authorities to actively suppress, or even distort, rather than effect and facilitate the collection of political conflict information. This suppression was especially acute in regard to internal conflict situations. A general recognition of the power inherent in the monopoly control and manipulation of information and the powerful role of information in the political conflict process, has contributed to greater emphasis on private, independent media; free and open communication; and expanded role of international organizations in the collection and dissemination of information in the contemporary period.

The state's preeminent role in data collection is even more apparent in the structure of the information that is available. The state, or country, is the primary focal group and unit of analysis for the vast majority of all political data and measures. The global state system strongly conditions the historical record; nearly all data is collected with the state as the measured unit. Problems for analysis arise from the fact that states themselves vary quite dramatically across many important attributes and, so, these politically "sovereign" units may not be statistically "comparable" units. Historical data focusing on other substate, or subnational, social units is extremely rare and severely restricted for most states for most years. Analysis of the internal conditions and dynamics of political conflict within states has been hampered by the lack of disaggregated information concerning variations across substate units.

The historical record is, of course, unevenly distributed. The more powerful and affluent countries are much more likely to keep and maintain detailed records on a much broader array of conditions and situations. Poorer countries may not keep even the most rudimentary records. Adequate record keeping is even less likely to occur during periods of general social turmoil and political conflict. Interestingly, Nazi Germany with its obsessive militancy, and cruelty, kept extensive and meticulous records of its crimes and those records have provided a rare insight into the intensity and totality of the war enterprise, both internal and external, for both perpetrators and targets.

In short, social phenomena are complicated situations nested within complex conditions and circumstances involving multiple, independent actors and, so, are difficult to measure directly or definitively. As such, social phenomena present serious difficulties for both measurement and analysis. The measurement, and quantitative analysis, of political conflict is a relatively recent development in the social sciences and we must keep this in mind when examining and evaluating progress in this endeavor.

General Principles of Measurement and Analysis

The inherent complexities of social phenomena present challenges for measurement and analysis. In fact, the use of the term "measurement" in regard to social phenomena is misleading and imparts a false sense of precision. "Estimation," "classification," and "coding" are the preferred terms for the most common procedures of collecting, organizing, and recording information on social phenomena. Measurement and analysis are intricately intertwined in the social sciences: measures derive, at least partially, from theory and analysis and analysis is critically conditioned by the measures available, as well as the measures actually used in the analysis. Measures are further refined as a result of advances made in analysis. In social group behavior even the most straightforward attributes are rarely, accurately known mainly because social actions involve varying degrees of spontaneity and the actions of interest cannot be isolated from surrounding or related activity. For example, the simple number of individual participants in a social action very often cannot be accurately or reliably measured because no direct procedure is employed to count and track such involvement, people move in and out of the situation over the course of time, the participatory actions of people who are not physically present may have been crucial in creating the situation, the action may attract partial or indirect involvement from bystanders or others who are stimulated by and/or react to the social action, etc.

Because of the complexities of social actions, these phenomena are usually subject to multiple levels and types of measurement. The general levels, or modes, of measurement are four: typology (classification), attributes, qualities, and dynamics. The initial step in

measurement is classification: identifying which of the myriad social phenomena constitutes a distinct type of "case" or "event" of analytic interest and can be consistently distinguished from other cases and events; that is, deciding what needs to be measured. A "case" typically references a particular social group or "actor" over a specific time frame; an "event" refers to a specific type of action. The most simple and ideal classification scheme would dichotomize, or separate, all social actions into events and nonevents with few "borderline" cases (i.e., cases that are difficult to classify). A more complex scheme would parse cases or events into multiple, related categories or typologies. The issue of borderline cases is crucial in any classification scheme; having too many such (indistinct) cases undermines the validity and utility of the scheme. The most frequent and fundamental measures, then, are the event count and event frequency, simply the number of occurrences of a particular type of event and events per unit time.

Having identified the object of analytic interest as a particular event or case, the researcher can proceed to measure and code its various parameters. The parameters of social phenomena are of three general types: attributes, qualities, and dynamics. Attributes are one-dimensional, defining properties, such as beginning and ending dates, duration, number of participants, number of fatalities, actor, target, and location. Qualities refer to general, multidimensional characteristics of social units that represent (reasonably) stable and comparable patterns of complex normative, behavioral, instrumental, or institutional factors. Each social phenomenon is in large part a unique mixture of complex traits that combine to produce a distinctive and recognizable quality. For example, personal dictatorships, oligarchies, military juntas, hereditary monarchs, and one-party states are different forms of government but share a certain quality of autocratic rule. An important facet of the complexities of social phenomena are its dynamic qualities, that is, changes over the course of the phenomena in the magnitude, intensity, scope, etc. of its several definitive attributes and qualities. For example, violent political conflict situations often fluctuate in levels of commitment among three main interactive strategies: conventional (protest and negotiation), unconventional (militancy and armed conflict), and withdrawal (noninteraction). Of particular importance in violent conflict events are escalatory and deescalatory dynamics. Each of the three general types of parametric measures: attributes, qualities, and dynamics, provide important information for the quantitative analysis of social phenomena typologies.

Earlier, it was noted that measurement and analysis are best considered an interactive and reiterative sequence in regard to the study of social phenomena, rather than separate phases of the research process. Measurement and analysis inform one another and advances in either one may lead to refinements in both aspects. Ted Robert Gurr provides a succinct procedural "map" of the circular research process in his 1972 book, *Politimetrics: An Introduction to Quantitative Macropolitics*. In that scheme, an initial "hunch or observation" stimulates the articulation of (1) a "theory" from which "testable hypotheses" may be derived. In order to test, or validate, the theory, the researcher engages in (2) "problemation," that is, identification of "the most fundamental problem requiring solution if a progressive development of theory about a subject is to occur." Having decided upon the focus of inquiry, the researcher proceeds to (3) "variable or unit specification." Specification is the essential act of measuring social phenomena; specification must be definitive, explicit, and sufficiently detailed that any researcher will understand the variable or unit in the same way. Directly related to specification is (4) "operationalization," wherein coding rules and procedures are designed whereby "reliable and valid" measures and indicators can be obtained that are in accordance with the variable or unit specification; these rules and procedures must be so precise that any independent researcher will obtain the same values when applying the coding rules to specific cases. Data collection proceeds by (5) applying the coding rules systematically over the entire "universe of analysis." Subsequent (6) analysis and (7) interpretation of results, then, further informs, and refines, the research process. The quality of measurement itself is judged according to the standards of validity (is it an adequate measure of what it purports to represent?); accuracy (is it precise enough to allow detailed or subtle distinctions among cases?); and reliability (is it comparable among cases and does it yield consistent results in successive measurements of the same case?).

In summary, the process of classification, estimation, and coding of information regarding inherently complex social phenomena such as political conflict is a theory-driven procedure that produces numerical codes and indices. This codified data is recorded and stored as "representational" numbers; representational as the relationships among the numbers used are not necessarily numeric. Social science data, unlike data in the physical sciences, cannot be precisely measured under controlled conditions. As such, they rarely approximate ratio, or even ordinal, numeric scales and, so, great care must be taken when using such "soft" and "fuzzy" data in quantitative (especially statistical) analyses. The strength of analysis and interpretation of social science data depends on the quality of the measures used and this quality is established through proper coding procedures and verified through a painstaking confidence-building process. Confidence is established and increased through extensive analysis, that is, by establishing patterns of consistency in the application of techniques, the cross-examination of multiple parallel analyses, and the substitution of alternative indicators.

Measuring Political Conflict

The state is a crucial actor in all political conflict processes, both with actors in the external (interstate) environment and actors in the internal (intrastate) environment. Historically, the state system has dominated political processes and our capabilities to measure and analyze those processes since the Peace of Westphalia in 1648. The interests of state (or national) security are critically affected by political conflicts and, so, the state, as the primary collector and recorder of social science data has been in position to actively suppress or distort information regarding political conflict behavior, especially as political conflict often poses a direct challenge to the viability of the state itself. The suppression of information in the interests of state security is most effective in regard to internal conflicts, as the sovereign state has long held a virtual monopoly over information on its internal affairs. Of course, the complex motives and incentives to suppress or distort reports concerning serious political conflict episodes affect all parties that are directly involved or have important stakes in the outcome. Disinformation has strong security and strategic value for all parties involved, often leading to wide discrepancies in key information. Great caution is required when measuring political conflict; multiple reports should be acquired whenever possible and sources should be evaluated for reliability.

Nearly all political conflicts in international affairs are channeled through and controlled by the institutions of states; thus, the concentration of power in the state system at once greatly reduces the number of potential conflict actors and imposes discipline on the course of conflict interactions through international norms and law (despite the popular fiction of an anarchic world system). Political conflict between states enjoys greater visibility than that within states as (1) the concentration of power in states greatly increases the conflict potential between states, thus, commanding greater attention, and (2) there are in all cases at least two independent actors and, therefore, two independent seats of information gathering and dissemination. In addition, conflict between states is more institutionalized and public and, so, more likely to be observed and recorded by private parties and representatives from disinterested states. Political conflict within states, in addition to being overshadowed by the security interests of the state, is largely ad hoc, undisciplined, complex, and diffuse. For all these reasons, the systematic measurement and analysis of external political conflict has progressed more rapidly than has the measurement and analysis of internal political conflict.

Quantification in studies of the most extreme (violent) forms of political conflict is a relatively recent addition to the social sciences. The systematic quantification of the problem of interstate war was greatly aided by the high profile of the institution of war in state politics, human fascination with the spectacle and horror of war, and the preeminent place of war in the historical record. The pioneering work in the quantification of classical wars is Quincy Wright's 1942 work titled *A Study of War*. In that study, Wright codified "all hostilities involving members of the family of nations [independent states] ... which were recognized as states of war in the legal sense or which involved over 50,000 troops." Wright's very narrow, statist treatment of the problem of political conflict as a legal condition of war between sovereign states fit neatly within the conventional "state security" perspective. Wright's threshold for identifying only the highest profile cases of political conflict ensured that his collection of cases would be comprehensive given the limitations on information. An alternative perspective was offered in the work of Lewis Richardson in his 1960 study titled *Statistics of Deadly Quarrels*, which purported to include all political events that involved a "quarrel" (i.e., a hostile dispute) and at least one fatality. Lewis' very low threshold for identifying cases guaranteed failure as such detailed information was not generally available at that time. However, Lewis' broad approach to the measurement of violent political conflict in many ways foreshadows the emergence of the "human security" perspective in the late 20th century.

A major point of difference between the approaches taken by Wright and Richardson concerns their conceptions of the "most fundamental problem requiring solution," that is, problematic. Both accept that the transformation of political conflict to the systematic use of violence is the core of the problem. However, Wright takes the conventional approach in assuming that distinct forms of political violence events, or events occurring at different "levels of analysis" (i.e., individual, state, and system levels), can be identified and categorized and that the within category causal relationships are fundamentally similar, whereas the causal relationships across categories are fundamentally different. The Lewis approach, on the other hand, assumes that all forms of political violence share essentially similar causal relationships and that the different forms that political violence appears to take are largely a product of the circumstances within which a particular political conflict develops. A corollary to the problematic question, regardless of the approach taken, concerns the "point or points" at which nonproblematic political conflict transforms to problematic political conflict, that is, the "process."

Interstate (External) Political Conflict

Interstate War and Militarized Disputes

Whereas Wright stood as the pioneer in the identification and measurement of war, J. David Singer emerged as its

paragon. Building on Wright's work and earlier work by Pitirim Sorokin, Singer, and his partner Melvin Small, established the Correlates of War (COW) project in the mid-1960s. The Correlates of War created a comprehensive database recording the basic attributes (inclusive dates, duration, general location, state participants, general outcome, and estimated number of "battle deaths") of each interstate war case beginning with the end of the Napoleonic wars in 1816. In a separate effort, Jack S. Levy compiled and reported basic information on war cases beginning in 1495 in his 1983 book, *War in the Great Power System*.

The standard measure of war magnitude adopted by the COW project: "battle deaths," still stands as the industry standard, however, the COW project's high threshold of 1000 annual average battle related deaths has been relaxed somewhat by subsequent researchers. The Uppsala armed conflicts data set, directed by Peter Wallensteen, provides a compilation of war events (including both interstate and civil wars) over the contemporary period beginning in 1946 that uses a 25 battle-death per annum threshold. Some argue that this threshold is too low to distinguish war events from other forms of political violence. The Uppsala war data also categorizes war episodes according to general levels of magnitude: minor (>25 battle deaths), intermediate (>100), and major (>1000). A common criticism of the strict "battle death" measure is that it does not take into account the often substantial noncombatant or civilian casualties of war, that is, the "battle-related deaths." Ruth Leger Sivard was one of the first to estimate the numbers of battle-related deaths in war events (interstate and civil) over the post-World War II period.

Complicating the issue of measuring the magnitude of war is the fact that the actual numbers of deaths in many wars, whether battle or battle-related, remain unknown; most such tabulations are only crude estimates. This is particularly true in regard to civil wars. Information that could be used to create other, more detailed, measures of war magnitude, such as injuries, damage caused, area affected, or costs, are not available, or even estimable, for most wars. Monty Marshall argues that violent political conflict is the social equivalent to "storms" that ravage the societal ecosystem with an identifiable potential that produces chaotic effects. Borrowing from meteorology, he developed a 10-point scale of the comprehensive "societal impact of war" taking into account the full spectrum of war's destructive effects on complex social systems, including general damage to human resources, population dislocations, weakening of social networks, deterioration of environmental qualities, infrastructure damage and resource diversions, diminished qualities of life, and increased nonreciprocal resource transfers.

In addition to refining Wright's original list of war cases, the COW project expanded the universe of inquiry to include a new category of war termed "extra-systemic war." Whereas interstate war occurs between two or more independent states, in an extra-systemic war an independent state "engages in a war with a political entity that is not an interstate system member;" these wars are designated as one of two types: imperial or colonial. The COW project also expanded its data collection to include all interstate military conflict events, irrespective of the occurrence of fatalities, or battles. The category of "militarized interstate disputes" includes situations of political conflict "between sovereign states below the threshold of war and include explicit threats to use force, a display of force, a mobilization of force, or the use of force short of war." It has also collected data on the conflict-related attributes of states: "national material capabilities" (power) and cultural attributes (ethnic and religious subnational groups), and attributes of the state system: system membership, formal alliances, borders and contiguity, and territorial change.

Interventions

Whereas the conceptualization of "interstate war" depends in large part on what Wright has referred to as the "legal condition of war," whether that sense of legality is explicit or implicit, the use of military force by a third party to intervene in or interfere with the course of an interstate or civil war in which it is not directly involved generally lacks this legal sense and is usually regarded an "intervention." "Military interventions" are military operations intended to alter the course or outcome of an ongoing war in favor of the interests of the intervening party; multilateral military interventions are conducted to promote common values such as the enforcement of legal principles. "Humanitarian interventions" are military operations intended to alter the course or outcome of a war in the general interests of alleviating human suffering or limiting the war's brutality and destructiveness.

There are three independent data collection efforts that focus on interventions; each of the three collections cover the contemporary period (i.e., since the end of World War II). Herbert Tillema has compiled information on contemporary cases of "foreign overt interventions," which involve any use of military force by one country outside its own borders. Tillema's concept of intervention is similar to the COW concept of "militarized interstate dispute." Frederic Pearson and Robert Baumann have collected information on cases of "international military interventions" that involve a use of military force to intervene in a civil conflict in a foreign land. Patrick Regan has compiled cases of "third party interventions" based on a much broader definition of what constitutes an intervention; his data includes cases of military, economic, and diplomatic interventions. Related to this broader definition of intervention are data collections on issues such as "arms transfers,"

"peacekeeping operations," "conflict mediation," and "foreign support."

Foreign Policy Crises

Similar to the COW project conceptualization of "militarized interstate dispute" is the concept of "foreign policy crisis" formulated by the International Crisis Behavior (ICB) project established in the mid-1970s by Michael Brecher and Jonathan Wilkenfeld. For the ICB project, a "crisis" must involve at least one state and is initiated by "a specific act, event or situational change which leads decision-makers to perceive a threat to basic values, time pressure for response and heightened probability of involvement in military hostilities." The ICB data covers the period beginning in 1918 through the present.

International Interactions

Official political interactions between the governments of countries are very formal and stylized daily "events" that are used to communicate, or "signal," various levels of conflict and cooperation. Signaling events may range from acknowledgment of subordination (e.g., surrender or acquiesce); through denials, criticisms, complaints, or protests; to more hostile demands, warnings, or threats; and even ultimatums, boycotts, seizures, and attacks. Two early compilations of "events data" are Edward Azar's Conflict and Peace Data Bank (COPDAB) and Charles McClelland's World Event Interaction Survey (WEIS). COPDAB data coverage begins in 1948 and was originally developed to study the interactive dynamics associated with the problem of "protracted social conflict;" as such, it includes both state-to-state events and interactions between states and substate groups. The WEIS data coverage begins in 1964 and focuses on official political interaction events between states as reported in the *New York Times*. Both projects attempted to develop conflict scaling techniques by which they could use events data to measure short-term changes in levels of political conflict. These global events data records have been compiled from news reports and involve tens of thousands of events per year. Events data collection has been extremely labor-intensive and costly. Recent advances in the conversion of textual news reports to electronic files has contributed to the development of machine (computer) coding techniques that may greatly reduce the costs of recording, compiling, and archiving events data.

International Terrorism

International, or transnational, terrorism refers to a very special form of violent political conflict event. The conventional conceptualization of international terrorism refers to a violent act by a member or members of a substate political group subject to one state's jurisdiction against a target associated with or under the nominal protection of another established state or suprastate zauthority. There are two data bases that have collected information on international terrorism events. The RAND–St. Andrews Chronology of International Terrorist Incidents begins its coverage in 1968. The International Terrorism: Attributes of Terrorist Events (ITERATE) data base originally compiled by Edward Mickolus also begins coverage in 1968.

Domestic (Internal or Civil) Political Conflict

The human fascination with the external subjects of war and conquest has been chronicled since the beginnings of civilization. The capacity to deter attacks and to wage and win wars (power) was even heralded as the true measure of the "good" state through much of human history. The ability to ensure domestic social order was viewed as a requisite for state power and status. The Hobbesian notion of inherent social disorder and the Machiavellian principle of state preeminence in politics combined to forestall critical examination of the modes and methods of state authority and the dynamics of internal political affairs. Greater attention to the qualities of citizens' rights, that began with John Locke's reflections on governance and gained impetus with the movement for the abolition of slavery, became imperative with the socialist and fascist convulsions that marked the 20th century.

Whereas the evolved formalities of the state system created a fairly disciplined structure based on relative power capabilities and imposed a fair degree of order and conceptual simplicity on the conflict behavior of states, the intricacies of domestic political conflict appeared especially chaotic and remained poorly understood. Modernity facilitated and energized the mass mobilization of latent constituencies that increasingly challenged the political status quo. The ground-breaking studies of "social revolutions" conducted by Crane Brinton (*The Anatomy of Revolution*) and Barrington Moore Jr. (*Social Origins of Dictatorship and Democracy*) and Franz Fanon's expose of the perversions of colonialism (*The Wretched of the Earth*) in the mid 1960s were among the first to critically examine the complex relationships between governments and the governed.

Civil War and Revolution

While the radical, Marxist ideal of social revolution piqued general interest in the dynamics of political conflict, it was the noted similarity of civil warfare to interstate warfare and the rise of "wars of independence" during the decolonization period following the end of the Second World War that first informed the systematic collection and study of domestic political conflict episodes. The COW project expanded its treatment of major wars by adding a third category, "civil war," to complement its

collection of data on interstate and extra-systemic wars over the period since 1816. In the COW project, a major civil war is defined according to four criteria: "(a) military action was involved; (b) the national government at the time was actively involved; (c) effective resistance (as measured by the ratio of fatalities of the weaker to the stronger forces) occurred on both sides; and (d) at least 1000 battle deaths resulted during the civil war." Greater attention has been drawn to the subject of civil wars as they became increasingly prevalent in the latter half of the 20th century, in contrast to the outbreak of interstate wars, which remained quite rare. Most alternative compilations of war events accept the basic COW classification scheme.

More recently, a new compilation of domestic warfare events during the period beginning in 1955 was produced for the US Government's State Failure Task Force. The list of "state failure" events includes three categories of civil violence: (1) ethnic wars, (2) revolutionary wars, and (3) genocides (ethnic mass murder) and politicides (political mass murder). Each war event is scored annually according to three measures of magnitude: number of rebel combatants, number of battle-related deaths, and size of territory directly affected by the war (genocide and politicide events are scored annually only for number of deaths). The State Failure data set is unique also because it combines information on a fourth category, "adverse regime change" events (that is, major changes toward greater autocracy), with domestic violence events and combines time-related events into complex "state failure" events.

Genocide and Human Rights Violations

An alternative perspective on civil violence, made particularly salient by the Nazi Holocaust during World War II, focuses on the state's tremendous power advantages over its own citizens. This "human rights" perspective looks at the problem of "state terror" or the systematic use of terror and violence by state authorities to subdue actual and potential opposition to its authority by individuals and substate groups. The Purdue Political Terror Scale is a five-point scale designed by Michael Stohl that provides annual scores, beginning in 1980, for the general quality of each state's treatment of its own citizens. Other researchers have compiled information on cases of political mass murder, such as Rudolph Rummel's data on cases of "democide" (mass murder by governments) and Barbara Harff's cases of genocide and politicide (incorporated in the State Failure data set mentioned above).

Governance

The crucial link between the general qualities of governance and domestic political conflict is recognized and incorporated in the Polity data series, originally designed and compiled in the early 1970s by Ted Robert Gurr. Government is charged with the primary responsibility for managing political conflict and preventing outbreaks of violent contention between political groups. The Polity scheme examines the "patterns of authority" that characterize different regime types. It combines information on the institutional qualities of executive recruitment, constraints on executive power, and the general tenor of political competition to score both the autocratic and democratic qualities of regimes, beginning in 1800.

Conflict Events

There are two broad data collection and archiving research enterprises that have been engaged in compiling information regarding daily domestic political conflict events. The Cross-National Time-Series Data Archive (formerly named the Cross-Polity Survey) was established in 1968 by Arthur S. Banks. The Banks' data is derived from the *New York Times* daily news files, begins coverage in 1815, and records annual numbers of events in nine categories of domestic conflict, including guerrilla warfare, government crises, purges, riots, revolutions, antigovernment demonstrations, coups, assassinations, and general strikes. The World Handbook of Political and Social Indicators was begun under the direction of Charles Lewis Taylor in the late 1960s; its data begins coverage in 1948. The World Handbook also uses the *New York Times* as its primary source but supplements that general news coverage with six regional news sources; it has compiled event counts on the same general types of domestic political conflict events as the Banks' data but with finer distinctions such that information on up to 38 separate event types are recorded. Both conflict events data collection efforts suffer from problems associated with human processing of large volumes of information on daily occurrences. Neither of these data projects distinguishes among subnational groups or interests actively engaged in the conflict events or levels of magnitude; they simply report raw event counts. Current plans call for updating the World Handbook using machine-coding techniques which, if proven effective, will greatly reduce the time and cost of recording events data.

Minorities and Ethnic Conflict

Perhaps the most ambitious effort to date at "unpacking" the state and recording detailed information on substate social groups and their conflict behavior has been the Minorities at Risk (MAR) project established in the late 1980s by Ted Robert Gurr. The MAR project is the first conflict data base that uses the "ethno-political group," rather than the "nation-state," as its unit of analysis; data coverage begins in 1946. The 2002 version of the MAR data set provides a comprehensive listing of 285 current and 62 historical "minorities at risk" around the world. A "minority at risk" is defined as follows: "The group collectively suffers, or benefits from, systematic discriminatory

treatment vis-à-vis other groups in a society and the group is the basis for political mobilization and collective action in defense or promotion of its self-defined interests." The general categories of information coded for each group include group identity characteristics, discrimination, group organization, collective interests (grievances), sources of transnational support, and conflict behavior (intragroup factionalism, intergroup communal conflict, protest, rebellion, and government repression).

Public Opinion

Political conflict stems from the perspectives, interests, and values of individuals and, so, gauging differences, strengths, and changes in public opinion can provide crucial information on potential and actual responses to policy issues and initiatives. Public opinion surveys have become a routine instrument for gauging public response in open societies. Comparative, cross-national surveys of public opinion are more problematic as language and cultural differences among societies complicate the survey design and interpretation of results. The first regular, multinational opinion surveys were begun under the aegis of the European Community in 1970. The Eurobarometer surveys are conducted twice annually and were expanded in 1990 to cover central and eastern Europe. Drawing upon the experience of the Eurobarometer and recognizing the need to factor in information regarding differences in cultural values, the European Values Survey was begun in 1981. Building on that experiment, Ronald Inglehart expanded coverage of the values survey to include countries representative of all major cultural regions. The World Values Survey has collected information from 65 societies around the world. More recently and in response to the increasing globalization of political issues, the Pew Research Center initiated, in 2000, the Pew Global Attitudes Project, which samples public opinion in 49 countries around the world.

State and Human Security

The "behavioral revolution" that began in earnest in the 1960s sought to apply quantitative methodologies, adapted from the physical sciences, to augment the empirical quality of the social sciences and, in particular, the measurement and study of political conflict. While a significant rift remains between the more "purist" advocates of qualitative and quantitative methods, it is clear that substantial progress has been made in the development and application of macrocomparative and statistical techniques in political science and that these procedures have transformed the field of inquiry in very fundamental ways. The evolution of social science methodologies has benefited especially from major advances in information, computation, and communication technologies, and particularly from the global processes of greater openness and democratization that have encompassed the world at the beginning of the "next" millennium. Having emerged from a strict "state-centric" political culture, the new methodologies have contributed to a shift toward greater attention to individual human rights and the articulation of a "human security" perspective that both challenges and complements the conventional "state security" perspective.

At the beginning of the 21st century, it is clear that the simplicity and discipline of the classic Westphalian "state system" is giving way to a more complex and integrated "global system." Tantamount to this change is a virtual explosion in the numbers and types of international organizations (from about 500 in the 1950s to over 16,000 today) and the volume and densities of international transactions, and with these, also, the potential for political conflict. Our ability to effectively manage political conflicts depends critically on our abilities to measure and monitor the attributes, qualities, and dynamics of those conflicts.

Glossary

event data analysis The coding and content analysis of interactions between nations (or other actors) reported by newspapers, wire services, or other sources.
JudgeIt A program for analyzing the impact on election outcomes of existing or proposed legislative districting plans.
nominate A method of analyzing legislators' ideological preferences by locating them in *n*-dimensional space based on their roll call votes.
paradox of voting (Arrow's impossibility theorem) The rule that given more than two alternatives and absent the assumption that preferences are single peaked, no method of voting will ensure that there will be majority support for any one alternative over each of the others.
prisoners' dilemma A non-zero-sum game in which each player's pursuit of rational self-interest leads to nonoptimal overall results.
Samplemiser A Web-based program for filtering out noise variance in a series of cross-sectional surveys.

Almost since political science became recognized as a separate academic discipline in the late 19th century (the American Political Science Association was not founded until 1903), its practitioners have struggled over its identity. By the 1960s, its place as a field that is at once both a social science and humanity finally had become generally accepted, although sometimes grudgingly. Today, political science as a social science draws on methods shared with the other social sciences and has developed a few of its own. Following a brief history of empirical research in the discipline, this article provides some illustrations of methods that have been used in political science to gather data (through experiments and quasi-experiments, survey research, case studies, and content analysis), to develop formal models of political behavior, and to carry out statistical analysis of data.

History

In their history of American political science to 1980, Somit and Tanenhaus dated "the first rigorous application of statistics to political data for analytic purposes" to the 1898 work of A. Lawrence Lowell. By charting election results in the United States and Great Britain, Lowell showed that "oscillations" tended for a variety of reasons to work against the party in power, thereby producing equilibrium in two-party systems.

However, it was not until the 1920s, with the emergence of the Chicago school led by Charles E. Merriam, that a systematic effort was made to create a "new science" of politics focused on the development and testing of empirical hypotheses. In an influential 1921 article, Merriam called for organized efforts at systematic data collection, more and better use of statistical techniques, and more extensive borrowing from other social science disciplines, especially sociology and social psychology.

This approach flourished for a time, but it did not really begin to reach maturity until the end of World War II. In the years that followed, what would become known as the behavioral approach to the study of politics clearly became part of the mainstream of the discipline. In 1962, 21 universities formed the Inter-University Consortium for Political Research in order to archive data and provide advanced quantitative training. (In 1975, the organization became the Inter-University Consortium for Political and Social Research. Today, it is a worldwide entity with more than 500 member institutions.) In the mid-1960s, the National Science Foundation recognized political science as a social science. With this, as Somit and Tanenhaus

observed, "the last bastion of resistance to the legitimacy of the behavioral movement had fallen."

Success produced its own backlash. For a time, a pitched battle was fought between behavioralists and traditionalists over the definition and direction of the discipline. Increasingly, however, it came to be accepted that a fully adequate study of politics would have to embrace a variety of ways of knowing. As early as 1961, Dahl argued the need for greater dialogue between behavioralists and exponents of other approaches, including political philosophy. Before the end of the decade, Easton suggested that political science was already moving into a "postbehavioral" period in which social science methods would continue to be employed but with more concern for their relevance to the pressing issues of the day. Since then, social science methods have been a major, although not an exclusive, focus of scholarship in the field.

Table I presents evidence of this. The table classifies articles from the 2001 issues of arguably the three leading journals in the discipline, the *American Political Science Review* (APSR), the *American Journal of Political Science*, and the *Journal of Politics*. Overall, quantitative analysis of empirical data is found in three-fourths of all entries. Some of these articles developed and tested formal models, but most proceeded more inductively. Similar, earlier classifications distinguish between articles with only low-level quantitative analysis (such as percentages and means) and those with more statistically complex analysis. No such distinction is made here since, with a few exceptions, all of the articles in this category of Table I employed relatively complex methods. The second category in the table includes articles containing analytical (predominantly mathematical) models and frameworks and discussions of methodological issues but no quantitative analysis of empirical data, although some did include simulated data and two involved qualitative empirical analysis. Except for these last two, critics might dismiss articles in this category as "inference without evidence." However, they were clearly intended to develop empirically testable social science hypotheses. Finally, only approximately one in seven articles are classified as humanities-oriented analysis (mostly political philosophy, with one article each in public law and literary analysis), and even a couple of these included some qualitative empirical analysis. In 2001 at least, the discipline's flagship journal, the APSR, was somewhat more hospitable to humanities-oriented research than the other two ($p < 0.01$ for the overall table).

Obviously, debates about the direction of the discipline continue. Echoing Easton, critics (such as backers of the Perestroika movement of the last few years) fault behavioral research for elevating methodological rigor over relevance to pressing social and political problems. However, critics of behavioral research are more likely now to call themselves postmodernists than traditionalists.

Experiments and Quasi-experiments

Political science is, of course, a largely nonexperimental discipline. Exceptions to this rule, however, have a long pedigree. Experiments and quasi-experiments (involving manipulation of one or more independent variable by the researcher but lacking one or more of the other elements of a true experimental design, including random assignment of subjects to groups) have been carried out in both field and laboratory environments.

Field Research

Perhaps the earliest example of the use of experimental design in political science is described in Gosnell's 1927 report of his efforts to discover methods of improving levels of voter turnout. Gosnell selected 12 census enumeration districts in Chicago intended to reflect a cross section of the city's demographics. Within each district, households were divided (although not on a truly random basis) into control and experimental groups. Before the 1924 presidential election, those in the latter group were

Table I Articles in Leading Political Science Journals, 2001[a]

	American Political Science Review (%)	*American Journal of Political Science* (%)	*Journal of Politics* (%)	*All*
Quantitative, empirical data	55	82	85	74
Analytical theory; no quantitative, empirical data	20	9	6	12
Humanities-oriented analysis	25	9	8	14
Total (%)	100	100	100	100
N	51	57	48	156

[a] Replies to other articles were counted as separate entries; review articles, book reviews, and the address of the president of the American Political Science Association were excluded. Totals may not agree due to rounding.

sent mailers urging them to register. (Chicago did not employ a system of permanent voter registration.) Those in this group who did register then received material urging them to vote.

Gosnell found that there was a substantial difference in registration rates between the two groups. Mailers urging registered voters to turn out had little additional impact since turnout among registered voters was very high even without additional stimulus. A follow-up study of the much lower turnout local elections of 1925, however, did show an increase in turnout in the experimental group. Gosnell concluded that greater efforts at civic education would "undoubtedly have an immediate and continuous effect upon the interest shown in elections."

The line of research pioneered by Gosnell has been continued, albeit sporadically, to the present. A 2000 article by Gerber and Green is clearly in the Gosnell tradition. Gerber and Green randomly assigned registered voters in New Haven, Connecticut, either to a control group or to experimental groups in which subjects received one or more stimulus: face-to-face contact, direct mail, and telephone calls. They found that face-to-face contact substantially improved voter turnout, that direct mail produced a modest increase, and that telephone calls had no impact. They concluded that declines in recent decades in personal contact with voters by parties and other organizations help explain "the ongoing mystery of why turnout has declined even as the average age and education of the population has risen."

In the sophistication of its design and methods of analysis, the Gerber and Green study is, as would be expected, worlds apart from Gosnell's work. Some things, however, change very little. A postcard sent by Gosnell included a cartoon showing the ghost of a disheveled-looking man labeled "The slacker who won't help defend his country in time of war" extending his hand and saying "Hello, brother" to a much more reputable-looking man labeled "The slacker who doesn't vote when his state needs his help." A postcard sent by Gerber and Green showed a photo of the Iwo Jima Memorial with the caption, "They fought ... so that we could have something to vote for." Although obviously different in tone, both communications employed the same underlying appeal to voting as an act of patriotism analogous to defending one's country in time of war.

Although often contrasted with experimental research as a method, survey research commonly employs experiments as a means of improving survey design. In their pioneering study of voting in the 1940 election, researchers at Columbia University divided their sample into an experimental group and three control groups in part to test for reactivity that reinterviewing respondents in a panel study might produce. Survey researchers also very commonly conduct experiments to develop and test measurements. Sniderman and Carmines, for example, randomly assigned respondents to two or more groups to assess the effect of question wording and question order on attitudes toward a series of race-related issues. They concluded that such issues are often framed in ways that inadvertently underestimate the potential for building interracial political coalitions.

Laboratory Research

Barber's 1966 study of 12 local government finance boards is an early example of laboratory research in political science. Barber invited these boards to participate in mock budget meetings conducted in a social psychology lab at Yale University. He argued that use of actual boards would provide more realistic results than those usually produced by small group experiments. Barber acknowledged that his research was not a true experiment in that he used actual rather than randomly assigned groups and in that all 12 groups were assigned the same tasks. The one variable that was manipulated was the presence or absence of the board's presiding officer, who in each case was called out of the lab midway through the session. Barber found that the absence of an active chair led to an increase in negative communications, whereas the absence of a chair with a passive style led to a decrease in conflict.

In 2002, Green and Gerber noted that "recent years have witnessed a resurgence of interest in laboratory experiments" in political science. The precision of experimental designs often makes them especially well suited for the testing of formal mathematical models. Another area that has lent itself more than most to laboratory analysis has been the examination of the impact of campaign commercials. Indeed, Iyengar has remarked that such studies "now constitute a 'dominant' methodology for political communication researchers." An example of such research was described by Ansolabehere *et al.* During the course of several actual political campaigns, subjects viewed 30-second simulated ads similar to those used in the campaigns. The visual components of the ads were held constant, and subjects were randomly assigned to groups exposed to versions of the ads that differed in the negativity of the announcer's text. The research showed that attack ads tend to have a demobilizing effect—that is, reduce the subject's intent to vote.

In general, however, experimental and quasi-experimental designs continue to represent a relatively small portion of political science research. The journal *Experimental Study of Politics* was founded in 1971 but stopped publishing on a regular basis a decade later. Green and Gerber concluded that this relative neglect is unfortunate since "well-conducted experiments are typically more persuasive arbiters of causality than comparable nonexperimental research."

Survey Research

In their 1924 groundbreaking study of the 1923 mayoral election in Chicago, "Non-Voting: Causes and Methods of Control," Merriam and Gosnell employed a variety of methods of gathering relevant information, including a survey in 1923 of more than 5000 Chicago residents. Although not employing random sampling techniques, the study was intended to be representative in terms of "sex, age, nationality, economic status, occupation, [and] length of residence." For almost the next two decades, most of the advances in the study of mass political opinion were made by the Gallup Organization and other commercial polling firms.

In 1940, scholars at Columbia University's Bureau of Applied Social Research carried out a systematic random sample of residents of Erie County, Ohio, that became the basis for "The People's Choice" by Lazarsfeld *et al.* The survey consisted of four panels, three of whose members were interviewed on two occasions and a fourth whose members were interviewed seven times during a period of 6 months. Four years later, the Bureau of Applied Social Research joined forces with the National Opinion Research Center (located at that time at the University of Denver) to conduct a nationwide survey. This survey was a two-wave panel consisting of pre- and postelection interviews.

These works are important landmarks in the use of survey research to study political attitudes and behavior. The early study with the greatest long-term impact, however, was a small ($N = 662$) national survey in 1948 conducted by the University of Michigan's Survey Research Center. This would be the first of what would become known as the American National Election Studies (NES). NES surveys have been conducted in each presidential election year since 1948 and in each midterm congressional election year starting in 1954. The cumulative file for 1948–2000 contains data from 44,715 interviews. Since 1970, the University of Michigan's Center for Political Studies has been in charge of the project. In 1978, the NES became a "national research resource" supported by the National Science Foundation (NSF). Along with two other ongoing NSF-funded efforts, the General Social Survey and the Panel Study of Income Dynamics, the NES project is a leading example of what Sapiro called "big social science."

Some sense of the impact of the NES on scholarship can be obtained by an examination of the bibliography that the NES maintains on its Web site of works using its data. The list (of books, chapters, journal articles, conference papers, internal NES reports, and a few entries in the popular media) comprises more than 3600 entries. Figure 1 (which excludes undated entries, internal NES reports, and a few duplicate entries) shows 5-year moving averages for the number of entries in the bibliography by year of publication from 1952 through 2001. It is possible that the bibliography is less complete for the earlier years. Conversely, delay in adding entries to the list no doubt accounts for what appears to be some drop-off near the end of the period. At the very least, however, the chart shows that since the 1970s, the NES has had a large and sustained impact on the conduct and dissemination of scholarship.

Survey research is hardly confined to the study of American opinion, and there are many examples of applications in other countries, including the European Commission's "big science" Eurobarometer, which has been measuring attitudes since 1974 (with forerunners

Figure 1 National Election Studies bibliography: Citations by year. Compiled from National Election Studies (2002). The NES bibliography. Available at http://www.umich.edu (accessed August 7, 2002).

of the Eurobarometer dating from 1962). Other important multinational and interdisciplinary survey efforts include the several waves of the World Values Survey and, in political science specifically, the Almond and Verba five-nation study. An important recent initiative specifically focused on the study of politics is the Comparative Study of Electoral Systems (CSES). Like the NES, the CSES is funded by the NSF. It includes both postelection surveys and aggregate data and will eventually expand to approximately 50 countries. The survey research portion of the project consists of postelection interviews including 16 questions intended to be completed in approximately 10 minutes. Because of varying election calendars, the first module of the study was designed to cover the period 1996–2000. Data are available for 19 countries for elections through 1998. A total of 32,022 cases are included in the pooled sample. A second module is planned for the 2001–2004 cycle. References to the study have begun to appear in the literature: The CSES Web site listed (as of August 7, 2002) 46 such references (from passing mentions to analyses based on the data) in its bibliography.

Case Studies

Long a staple of political science research, case studies have the advantage of examining politics holistically. Sometimes this comes at the expense of the ability to generalize findings by placing them in a rigorous theoretical context. That such is not an inherent limitation of the case study method can be seen in two very different applications of the method, one in which individual actors provide the cases for analysis and the other in which the cases consist of entire political systems.

Monroe questioned why some people act in ways that are, to varying degrees, at odds with their self-interest. Through interviews, she examined 25 individuals whose behavior fell at different points on a continuum from self-interest to altruism (the entrepreneur, the philanthropist, the hero, and the rescuer of Jews during the Holocaust). Her work explicitly challenged rational choice theories explaining behavior wholly in terms of self-interest (although sometimes defining self-interest so broadly as to make the argument tautological).

Monroe concluded that various hypotheses from sociology, economics, biology, and psychology only very imperfectly serve to distinguish the altruist, especially the hero and the rescuer, from the entrepreneur. She found that what does seem to be the distinguishing characteristic is what she called "perspective," concluding that altruists perceive their relationship to others in more universal terms than do most people, with lower boundaries between self, kin, and group identity and identification with others generally.

A very different application of the case study approach is that of Weaver and Rockman and colleagues, who sought to provide a theoretical framework for a series of case studies examining whether and how institutional differences influence the capabilities of government. Their case studies compared the American experience in a number of issue arenas with those of other industrialized democracies. Beginning with the contrast between presidential and parliamentary systems, they analyzed the ways in which this distinction, although important, interacts with various other institutional and noninstitutional factors across time and in varying policy contexts.

An important subset of the case study method is participant observation, an approach that political scientists have borrowed from anthropology. The examples used here derive from the study of the U.S. Congress.

Richard Fenno has spent his career studying Congress, is a leading practitioner of participant observation, and has written trenchantly on this method in a series of essays published in 1990. Although most studies of congressional behavior have taken place within the confines of the nation's capital, Fenno followed members back to their states and districts in order to study their relationships with their constituents. In the 1970s, he explored the "home styles" of 18 members of the House of Representatives. Later, he did the same for several members of the Senate.

For his research to be successful, it was important that Fenno develop a high level of rapport with his subjects. This might mean anything from helping to change a member's flat tire to blending in with an election campaign by pitching in with stamping envelopes, working a phone bank, or engaging in other "materially trivial" forms of participation. Fenno was aware of, and wrote perceptively about, the dangers of too much rapport. Such overidentification runs the risk of interfering with the researcher's judgment. Fenno maintained that in their research, "political scientists ... should refrain from engaging in any behavior that has the intention of affecting political outcomes." To guard against these dangers, he developed a very strict set of ethical standards as a way of maintaining appropriate boundaries between researcher and subjects, declining even to register with a political party or join any interest groups. Subsequent experience led him to modify some of his self-imposed limitations. For example, following publication of his research on Dan Quayle after the former senator had become vice president, Fenno decided to abandon his former practice of refusing to give interviews to the media.

Despite his efforts to maintain a strictly professional relationship with his subjects, Fenno found that he could not maintain complete detachment: "I could not bring myself to be indifferent to their electoral success. *I wanted them all to win.*"

As Fenno acknowledged, his research has involved much more observation than participation. This is in

marked contrast to what happens when a political scientist becomes a political actor and then writes about the experience partly from the perspective of his or her scholarly discipline. Such actors, of course, do not take the same vow of political celibacy advanced by Fenno. North Carolina Democrat David Price first came to Congress in 1987. He has since written a memoir based primarily on his experiences but drawing on the literature of his discipline, including the work of Fenno. Somewhere in between Fenno and Price on the participation–observation spectrum is the work of scholars such as Redman and also Dwyre and Farrar-Myers, who have worked on legislation as congressional staffers and then written case studies attempting to shed light in a systematic way on the legislative process.

Content Analysis

A long-standing concern among some scholars of international relations has been the development of databases, derived from public records such as newspapers or wire services, concerning events involving interactions among nations. Such scholars have hoped that by uncovering patterns of behavior in these data, they may be able to develop a sort of "early warning system" for the prevention of international conflict.

Two pioneering efforts at developing international event databases were Azar's Conflict and Peace Data Bank (COPDAB) and McClelland's World Event/Interaction Survey (WEIS). The COPDAB database includes information from various sources for the years 1948–1978. The WEIS database includes the period from 1966 to 1978 and covers events reported in the *New York Times.* Both are available from the Inter-University Consortium for Political and Social Research.

The Kansas Event Data System (KEDS) is one effort to extend (e.g., by using electronic rather than manual coding) and update COPDAB, WEIS, and other earlier work. The KEDS project Web site provides freely downloadable software and a series of regional data sets. Philip Schrodt and colleagues at KEDS have used these data to study such questions as the prediction of conflict in the Balkans, crises phases in the Middle East, and media coverage of the Intifada.

The Intranational Political Interactions project applies the events data analysis framework to conflict within nations. Downloadable data files are available for 10 countries in Africa, Latin America, and Asia.

Formal Rational Choice Models

Employing what is variously referred to as rational choice or public choice models, a number of scholars have sought to apply ideas originally developed in economics to the study of political choices. Three examples that have each led to an extended dialog within political science are described here.

The Paradox of Voting (Arrow's Impossibility Theorem)

In 1951, economist Kenneth Arrow described what he called the "well-known 'paradox of voting.'" Although he did not claim to have originated it, he is credited with the systematic formulation of what has also come to be known as Arrow's impossibility theorem. The theorem states that given more than two voting alternatives, and absent the assumption that they are "single peaked" (i.e., that an individual's first preferred choice determines his or her second choice), there is "no method of voting ... neither plurality voting nor any scheme of proportional representation, no matter how complicated" that will guarantee an unambiguous aggregate preference. For example, suppose that in 1996 three voters were asked to choose between Clinton, Perot, and Dole in that year's presidential contest. Suppose further that their preferences were ordered as follows:

Voter 1: Dole, Perot, Clinton
Voter 2: Perot, Clinton, Dole
Voter 3: Clinton, Dole, Perot

Since there are various considerations that might govern an individual's choices among these options, all three voters may have been acting quite rationally as individuals. Taken collectively, however, any one of the three options would have been rejected by a majority when pitted against only one of the alternatives. A majority would have preferred Dole to Perot, Perot to Clinton, and Clinton to Dole.

Arrow's theorem has given rise to a substantial body of literature across a number of different disciplines, including political science. Jones *et al.*, for example, employed computer simulations to show that when voters are able to order their preferences across all options, the likelihood of producing a majority decision is smaller the larger the number of voters. However, when voters are indifferent among some choices, the problem is more serious for small groups, such as committees, than with a large electorate.

The Prisoners' Dilemma

Originated in the 1920s by mathematician and physicist Von Neumann and introduced into economics in the 1940s by Von Neumann and Morgenstern, game theory has become a common approach to the study of political cooperation and conflict. One of the best known games is the prisoners' dilemma. Lalman *et al.* (1993) noted that

"the prisoners' dilemma . . . together with the voters' paradox, is by far the most widely known and celebrated example of the use of formal theory in political science."

The prisoners' dilemma is a non-zero-sum game. If two prisoners are being separately interrogated about a crime that they may have committed, their optimal strategy would be to cooperate by remaining silent. Not knowing what the other will do, however, it is individually rational for each to defect—that is, to confess in exchange for a reduced sentence.

This might suggest a rather pessimistic view of human interaction, but this need not be the case. Axelrod showed that iterative prisoners' dilemma games can lead to cooperation among players over time. He demonstrated that a strategy he called "tit for tat" ("don't be envious, don't be the first to defect, reciprocate both cooperation and defection, and don't be too clever") encourages cooperation and tends to win out against other strategies in a wide variety of contexts. Among the examples he discussed is the "live and let live" strategy adopted, under certain conditions, by soldiers on both sides during the trench warfare of World War I.

As Axelrod noted, cooperation is not always desirable (e.g., for the police who are interrogating the prisoners). Geer and Shere used this same insight to critique the common assumption of advocates of the "responsible party" approach that competition within parties (through devices such as the direct primary) weakens accountability by reducing party cohesion. They pointed out that since interparty competition is an iterative process, parties become aware of each other's strategies over time and learn to cooperate. They may reach an agreement to share patronage and other political benefits and avoid addressing voter concerns. In a more or less closed party system, such as the two-party dominant system in the United States, interparty competition by itself may not provide a mechanism for challenging such an arrangement. Intraparty competition through an open system of nominations introduces challengers who, like the prisoners in the prisoners' dilemma, have an incentive to not cooperate with the other players.

Downs's Party Competition Model

In 1929, the economist Hotelling proposed a model explaining why retailers in direct competition often choose to locate their stores in close proximity to one another. He argued that all else being equal, either of two competing companies could improve its market share by moving closer to the center of town. Near the end of his essay, he devoted a paragraph to arguing briefly that this same logic explains why in America's two-party system, "each party strives to make its platform as much like the other's as possible." Twelve years later, another economist, Smithies, suggested that if demand is elastic, a company will at some point lose more business from customers at the outskirts of town than it will gain from its competitor by moving closer to the geographic center. Although Smithies did not make the connection explicit, others have noted that nonvoting can be seen as the political equivalent of elastic demand. Some people will choose not to vote if they perceive that both parties are too distant from their preferences, and this might help explain why the Republican and Democratic parties are only somewhat similar ideologically.

In 1957, another economist, Anthony Downs, developed the political implications of these ideas systematically, considering the model under varying conditions (regarding the distribution of voters' ideological preferences, the number of parties, the entry of new parties, and the type of electoral system). His ideas have had a major influence on the way in which political scientists have thought about party competition, and his essay on this topic is a centerpiece of his book, *An Economic Theory of Democracy*, which Grofman called "one of the most influential and frequently cited works in social science of the post-World War II period."

Statistical Analysis

This section overlaps the previous ones to varying degrees. By their nature, experimental and survey research almost always require statistical analysis of the data collected. This is often true for content analysis, but sometimes such analysis is purely qualitative. As noted previously, formal models may or may not be tested against real or simulated data. Fenno notes that because of its reliance on small samples, participant observation does not lend itself well to quantitative analysis. Because of the unrepresentative as well as small size of the samples, not to mention the necessarily unscripted and unstructured nature of the observations, it is better suited to generating than to testing hypotheses. The same is true of most, although not all, case studies generally.

Overall, as shown in Table I, political research usually does involve statistical analysis of one sort or another. Contemporary political science research employs the panoply of statistical methods found in the social sciences generally, from the simplest to the most elaborate. Over time, these methods have become increasingly complex. Sometimes, however, a very basic technique can be employed with substantial elegance, as in the following examples.

The standard deviation is normally used either for simple descriptive purposes or as an intermediate step in a more elaborate calculation. Seldom is it used directly to create a variable. One exception is its use by Beck to demonstrate the decline of regionalism in American politics. Using election returns for the presidential contests

from 1896 through 1992, Beck charted the standard deviations among the states in the winning candidates' share of the popular vote, demonstrating a generally steady decline in interstate variation. A similar example is the use by Smith and Gamm of the standard deviation in roll call voting scores as a measure of lack of cohesion within political parties in Congress. Change over time in this measure was used by the authors to assess differences in the importance of party leadership.

Another example having to do with the creation of measures is the use of "feeling thermometers." A common limitation of most survey data is that although surveys are often the most direct way to measure political attitudes and behavior, the resulting measures are mathematically weak, usually only nominal or ordinal. Feeling thermometers, which have been used by the National Election Study since 1964, are usually treated as interval measures. To construct these thermometers, respondents are asked to indicate how warmly or coolly they feel about a political party, a group or category of persons, or an individual candidate or other public figure. A score of 50 indicates neutrality, with scores in the 50–100 range indicating warm or favorable feelings and lower scores reflecting cool or negative feelings. An example of the use of these thermometers in research is the work of Bolce and de Maio, who showed that negative feelings toward Christian fundamentalists have become an important predictor of feelings toward the Republican and Democratic parties, and of voting choice, even when other factors are held constant.

The treatment of feeling thermometers as interval measures has not gone unchallenged. Using data from the 1992 NES, Jacoby examined a measure created by subtracting the Clinton thermometer from the Bush thermometer. He found that intervals near the middle of the scale reflect larger differences in candidate preference than those near the extremes. Jacoby concluded that the level of measurement of these and other "pseudo-interval" measures should be tested rather than merely assumed.

More complex statistical techniques used in political science run the gamut from common forms of analysis, such as analysis of variance and correlation and regression, to more specialized tools, such as factor analysis, cluster analysis, canonical correlation, discriminant analysis, LISREL models, and Monte Carlo simulation. All of these techniques are ones that political science has borrowed from other disciplines. In addition, political scientists have developed new methods designed to address (more or less) discipline-specific problems.

NOMINATE

Students of the legislative process have long been concerned with the development of measures of roll call behavior. A common practice has been to adopt the ratings provided by interest groups such as the American Conservative Union and the (liberal) Americans for Democratic Action. These ratings consist simply of the percentage of times that legislators have voted in agreement with the group's position on "key" votes the group has selected. Other researchers have sought to develop less subjective inductively derived scales. Thurstone used factor analysis for this purpose as early as 1932, and Belknap did the same with Guttman scaling in 1958.

Poole and Rosenthal have developed a method called NOMINATE (for "NOMINAl Three-step Estimation"). This procedure is used to locate legislators in n-dimensional space based on the ideological preferences revealed by their voting patterns. The same procedures can be used to locate other actors (including interest groups and, in studies of the American Congress, the president) who take positions on roll calls. Applying NOMINATE (and more recent refinements to their original procedure) to the American Congress from 1789 through 1998, Poole and Rosenthal found that through most of America's history, most voting on roll calls can be accounted for by a single dimension closely associated with political party affiliation. This pattern was established very early and has been maintained except during periods of party breakdown (of the Federalists and, later, the Whigs). A second, much less powerful dimension accounted for intraparty divisions, most notably the north–south split within the Democratic Party during the civil rights era in the decades following World War II.

Poole and Rosenthal extended their work to the comparative study of legislative bodies. They found that across a variety of different party systems, roll call behavior in several European legislatures and in the European Parliament could be explained well in only one or two dimensions, with the most important being a Left–Right division. Generally similar results were found for the nonparty United Nations General Assembly (with the first dimension pitting NATO countries against their opponents and the second pitting north against south).

JudgeIt

In winner-take-all electoral systems (such as are used in Great Britain, France, the United States, and much of Asia and Africa) there is a complex relationship between a party's share of votes and its share of seats in legislative bodies, and an extensive body of literature has developed in efforts to unravel this relationship. First, district lines may be gerrymandered—that is, drawn to deliberately favor some parties at the expense of others. Second, there is a tendency, even in the absence of gerrymandering, for minority parties to waste votes (since only the party finishing first in a district wins representation), thus providing bonus seats to the leading party.

A specific form of this effect is the so-called "cube law," which states that in a two-party, single-member plurality system the ratio between the parties' proportion of seats will be equal to the cube of the ratio between their proportion of votes. Originally noticed at the turn of the 20th century, the cube law was first set forth formally by Kendall and Stuart. Others have since criticized the specific form of this "law" on both theoretical and empirical grounds, but there seems to be little or no dispute that some such effect usually, although not invariably, does occur.

Gelman and King developed a program called JudgeIt to sort out these effects. Among other things, JudgeIt provides estimates of the effect of "partisan bias" (favoring one party over another for a given division of votes) and "electoral responsiveness" (the effect of changes in the division of votes on the number of seats won). JudgeIt can be used to analyze an existing set of districts or to predict the impact of a proposed districting plan. It has been used both in scholarly research and in the redistricting of a number of states.

Samplemiser

Practitioners managing campaigns, journalists reporting on campaigns, and scholars doing trend analysis (on a variety of subjects) sometimes make use of series of cross-sectional surveys conducted over a period of days or longer, with each cross section often consisting of a fairly small sample. A difficulty exacerbated by these small sample sizes is that of distinguishing between noise variance and genuine change over time. Samplemiser is a program designed to filter out noise variance and "smooth" trend lines. In addition to its obvious application to day-to-day tracking polls conducted in the closing days of a campaign (in which a total sample on any given day might consist of only a couple of hundred interviews), Samplemiser is also useful in studying much larger samples, sometimes conducted over periods of years rather than days, when there is interest in studying relatively small subsets of the total.

The creators of NOMINATE and JudgeIt have made source codes for their programs freely available on the Internet. Samplemiser can be run interactively on the authors' Web site.

Political Violence

Avram Bornstein
John Jay College of Criminal Justice in the City University of New York, New York, New York, USA

Glossary

genocide Mass murder targeted to annihilate a particular group, including religious, ethnic, racial, and national groups.
militarism The ideology or practice of military domination in nonmilitary spheres of society such as the political, economic, or cultural.
post-traumatic stress disorders Persistent manifestations of anxiety caused by a traumatic event including insomnia, loss of concentration, guilt, loss of self-worth, loss of trust, hopelessness, violent outbursts, panic, and dissociative disorders.
reactive aggression Destructive behavior motivated by experiences of injury or loss, or as a reaction to a perceived threat.
structural violence Systematic deprivation resulting in chronic poverty and hunger, usually reinforced by militarized violence.
symbolic violence Attacks on human dignity and the denial of humanity including degrading representations of a group or forcing people to perform humiliating acts.
truth and reconciliation commissions Official bodies created to investigate human rights abuses of the previous regime and its opponents that aim to bring violent conflict to an end.

Politics is the struggle to maintain or transform governance over economic, bureaucratic, intellectual, cultural, or other spheres of collective activity. Violence is an action that does harm to an object. Political violence, therefore, is harmful action intended to influence or shape collective action. Political violence can target the material environment, the body, the mind, or the social order, and can include armed, structural, or symbolic forms. The motivation for choosing violence may be coordinated with clear material objectives, or it may follow complicated psychological and cultural imperatives. Acts of violence can influence victims, perpetrators, and witnesses, and it can inspire resistance or terrorize into submission. Representations of violence in writing and public ritual may work to mitigate emotional trauma and inhibit retaliation, but they can also facilitate the reproduction of violence.

Introduction

Prussian army officer and military theorist Carl von Clausewitz observed, in his famous treatise *On War* (1833), that war is merely a continuation of politics. Derived from the Greek for city or citizen, politics is a word that points to participation in governance. Political processes are those in which groups struggle and compete over a variety of goals. The essence of politics is often said to be the art of persuasion. Sociologist Max Weber, for example, wrote that charisma, tradition, and rational planning were all forms of authority that can effectively shape social action. Public ritual, literature, landscaping, architecture, education, social welfare, and the law can all shape orders of governance. Philosopher Michel Foucault emphasized the spatial, temporal, and operational organization of social institutions that discipline the body and mold self-knowledge. But when persuasion is incomplete or ineffective, coercion may become the next option. Somewhat like Clausewitz, Weber saw that the decisive means of politics is violence.

Forms

Armed Violence

Armed violence is the exertion of force meant to injure or destroy an object. Many species use their bodies to attack or defend against other bodies, but humans magnify their arms with armaments and armor. Weaponry has made

possible mass annihilations. Romans, Slavs, Crusaders, Mongols, and others wiped out entire cities over the centuries. Tens of millions died in rebellion in China in the late 19th century. Millions of indigenous Americans were murdered, and millions of Africans killed and enslaved by Europeans since the late 15th century.

In the 20th century, the increased growth of weapons manufacturing sped the pace and scope of corporeal destruction. It was the century that coined the term *genocide*: *genos* from the Greek for group and *cide* from the Latin for killing. Over 100 million people, mostly civilians, died in politically driven wars and violence including: over a million Armenians killed by Turkish assaults; 12 million Jews, Romani, leftist activists, and homosexuals killed by Nazis; over 30 million died under Stalin's rule in the Soviet Union; and over 45 million killed in China under Chaing Kai-shek and Mao Tse-tung. Millions more were slaughtered in Indonesia, Yugoslavia, Cambodia, Pakistan, the Congo, and Rwanda. Death squads tortured and murdered thousands in Guatemala, El Salvador, and Chile. Atomic bombs were dropped on two cities in Japan and a nuclear arms race ensued. The carnage continued to the end of the century. According to the United Nations, during the 1990s, about three and a half million people were killed by political violence, about 15 million lived as refugees, at least 22 million lived as internally displaced persons, and there were an estimated 300,000 child soldiers.

Although down from the 1990s, at the beginning of the 21st century weapons expenditures amounted to around $800 billion. The United States is by far the largest manufacturer and consumer of weapons, although several other countries have significant industries including Bulgaria, China, France, Germany, Israel, Romania, the Russian Federation, South Africa, and the United Kingdom. Major weapons manufactures, Lockheed–Martin, Boeing, Raytheon, General Dynamics, Northrop Grumman, and the Carlyle Group, produce missile systems, aircraft, ships, and other items costing millions or billions of dollars. The United States' military budget for 2003 was around $360 billion, and the President requested approximately $400 billion for the 2004 defense budget. By comparison, NATO, Australia, Japan, and South Korea were spending a combined total of about $225 billion, Russia about $65 billion, and China about $47 billion. This extraordinary spending is the product of what the former United States president and heroic World War II general Dwight Eisenhower called "the acquisition of unwarranted influence, whether sought or unsought, by the military–industrial complex. The potential for the disastrous rise of misplaced power exists and will persist."

Perhaps more devastating than large offensive systems are the proliferations of small weapons, like pistols, assault rifles, machine guns, grenade launchers, small mortars, and shoulder antitank and antiaircraft missiles. The United Nations estimates that there are around 500 million of such weapons in the world, between 40% and 60% of which are illicit. New nonlethal technologies, such as electro-shock stun weapons and chemical crowd-control devices, are also being marketed and sold globally. While these can reduce fatalities in some cases, they are also used to torture civilians.

There has been some movement toward arms control. Land mines, which claim 15 to 20 thousand victims in 90 countries each year, have been banned by 141 states, but China, Russia, the United States, and others refuse to sign the Land Mine Treaty. While the Strategic Offensive Reductions Treaty has led the United States and Russia to agree to make modest reductions of deployed nuclear weapons by 2012, the United States has only selectively supported the Nuclear Nonproliferation Treaty and the Comprehensive Test Ban Treaty, and may resume banned nuclear testing.

Structural Violence

Not all physical violence is directly caused by armed force. People also suffer from administrative or managerial actions that promote chronic and severe inequality. Usually reinforced by armed violence, structural violence inflicts pain slowly by systematically keeping people in poverty and material vulnerability. The concept of structural violence is at odds with economic models that frame poverty only as a product of mechanistic market forces. To identify some poverty as structural violence indicates a perpetrator and a victim, rather than a winner and loser.

In the United States, groups that are victims of recurring structural violence include indigenous Americans and African Americans. After waves of military and paramilitary violence from the 16th to the 19th centuries, in the 20th and 21st centuries indigenous Americans continue to have land, minerals, timber, fish, and other natural resources taken from their territories, while others are being poisoned by the dumping of toxic or radioactive industrial wastes. In the United States, African enslavement for plantation work formally ended in the 19th century, but segregation, enforced by Jim Crow laws and antiblack terrorists like the Ku Klux Klan, kept many African Americans in poverty as tenant sharecroppers into the 20th century. Industrial employers drew African Americans to cities, but systematic denial of rights through neglect of education, health care, employment, and other public services, combined with heavy policing and incarceration, have kept opportunity limited for many.

Across the globe, systematic disparities have grown with a handful of rich nations, including the United States, the United Kingdom, Japan, Germany, France, Canada, Italy, and Saudi Arabia, managing trade and industry through the International Monetary Fund, the World Bank, and the World Trade Organization. They have used financial and military assistance to encourage governing elite to impose

economic austerity conditions. These "structural adjustment" programs favor the deregulation of production and trade and the elimination of public welfare, making conditions attractive to investors seeking high returns. In theory, these measures assist in the economic development of "emerging" markets, but few debtor nations have eliminated their debts, many have suffered environmental and social devastation, and wealth has generally gone to small groups of local elite and international investors. At the start of the 21st century, the systematic gap globally between those with material privilege and those without sufficient resources is wider than ever before in human history. According to the UN, the richest 5% of people have incomes 114 times greater than the poorest 5%; the United States' wealthiest 25 million earn about the same as the world's poorest two billion people; in 1999, 2.8 billion people lived on less than $2 a day, 1.2 billion of whom were surviving on less than $1 a day; more than 30,000 children die each day due to curable diseases; and while extreme poverty decreased in South Asia, East Asia, and the Pacific, it rose dramatically in Africa.

Symbolic Violence

Political domination not only strikes at the material integrity of a society, it also attacks the dignity of victims. Emotional well-being and a sense of self-worth can be hurt by armed and structural violence, as well as by witnessing degrading representations of one's self or being forced to perform humiliating acts. Such symbolic violence is meant to injure or destroy the recognition of mutual personhood. The Nazi Holocaust began with acts of humiliation like forcing Jews to wear yellow stars in public, which meant to indicate that they were inferior. European colonial violence and governance were also accompanied by white supremacist images of the colonized. Africans were represented as stupid, ugly savages. So-called "Orientals," a term that refers to all "eastern" peoples from Moroccan Arabs to the Japanese, have been portrayed as sadistic, despotic, and misogynist barbarians. These forms of symbolic or representational violence define the victim as something not quite human. Dehumanization places the victim outside the community, beyond the circle of moral behavior, and allows the withdrawal of empathy. By helping ordinary people to distance themselves from the pain of those suffering, symbolic violence allows them to commit or condone horrible acts of armed and structural violence.

Actors

States

The major military and policing forces of the world, and the major wars and genocides, have been organized by modern states. Modern states vary greatly, but whether weak or strong, they often include overlapping networks of coercive and administrative agencies. Max Weber described a state as a sovereign, territorial, and compulsory organization that claims a monopoly on the legitimate use of violence to enforce its order. Enlightenment philosophers argued that such state organizations are good because they could eliminate violence among citizens, in favor of specialized agents that defend against other states and criminals. State agents are directed, but not necessarily controlled, by a particular government. In many states, militarized forces and business elites have noticeable power over official governing bodies and those whom they are to protect.

Privateers

Contrary to the idea that states monopolize legitimate violence, the business of war, in all its aspects, has flourished in the private sector, and products may be purchased by states or nonstate actors. While mercenary soldiers are often from vulnerable populations and receive minimal compensation, others are on the payroll of large private companies led by the former personnel of state-sponsored militaries. There are massive contracts for noncombat services like information technology, food, and cleaning and maintaining vehicles, buildings, and grounds. Many companies also provide lethal equipment, training, planning, protection, reconnaissance, targeting, and even combat. Among the largest are Airscan, Northrop Grumman, DynCorp, Military Professional Resources, Armor Holdings, Vinnell Corporation, Sandline International, and Executive Outcomes. Private mercenary forces have entered battles in several African countries, particularly where profitable resources like mining operations ensure their payment. They have also worked in the former Yugoslavia, Afghanistan, and with the infamous Colombian Cali cocaine cartel led by Carlos Castaño. To avoid accountability, some states use such services to create proxy militia.

Partisans

The proliferation of weapons has made it possible for many groups with antistate or antigovernment agenda to mount campaigns of violence, sometimes with the backing of other states. The victims often label their attackers terrorists, which is a pejorative term usually referring to nonstate groups who use violence to intimidate for political changes. Some of these antigovernment and antistate groups have sizable guerrilla forces and control significant territory within the state from which they operate. These would include the Fuerzas Armadas Revolucionarias de Colombia (FARC), the Zapatistas in Mexico, Tamil Tigers in Sri Lanka, the Shining Path in Peru, Hizbollah in southern Lebanon, UNITA in Angola, Kashmiri forces in India, and Mujahadeen in Afghanistan.

Largely due to the superior power of their opposition, some groups hold no significant territory and must operate in smaller units. In the United States, a militia movement organized training camps and networks implicated in the bombing of the Federal Building in Oklahoma City in 1995 that killed 168 people. Several Islamic groups have operated within and against a number of countries including Hamas in the Israeli occupied Palestinian territories, al-Gama'a al-Islamiyya in Egypt, and the Islamic Salvation Front in Algeria. According to the United States government, Al-Qaeda launched attacks in Afghanistan, Yemen, Saudi Arabia, East Africa, Indonesia, and the United States, where on September 11, 2001, close to 3000 people were killed in New York and Washington, DC. Like most other militaries, some of these groups organize financing, purchasing, training, and planning through networks that spread across several nations.

Multistate Alliances

In the 20th century, multistate organizations became directly involved in political violence, in the name of preventing continuing bloodshed. In 1948 the United Nations emerged and served as a significant global multistate organization. For its first decades, the United Nations mainly focused on the Arab–Israeli conflict, but in the 1990s its scope expanded into over a dozen countries including Cambodia, Kuwait, El Salvador, Guatemala, Haiti, East Timor, eight African nations, two former Soviet states, and much of the former Yugoslavia. In 2003, there were 14 U.N. peace keeping missions, with about 37,000 security personnel from 89 countries, and 10,000 more supporting personnel. In the 1990s, the United Nations also helped organize two ad hoc international criminal tribunals, one for the former Yugoslavia and the other for Rwanda. In 1998, an International Criminal Court, to complement national judicial systems when they are unwilling or unable to investigate or prosecute war crimes, was approved by 120 U.N. members, but China and the United States, among others, refused to participate.

Motivations

Economic

Violence can often be instrumental to obtaining desired objects. For several thousand years, the power of violence allowed victors to demand tribute from the vanquished. With trans-Atlantic colonialism European monarchs centralized their control at home and went from merely taxing peasant and mercantile subjects to sponsoring extensive monopolies on trade and even direct organization of production. The Spanish, Dutch, English, and French struggled over resources from the Americas, Africa, South Asia, and East Asia. The slave trade and the seizure of land for plantations and mines defined much of the colonial process. In the 20th century, military forces continued to be deployed around the world to secure important markets, especially for primary resource extraction in the developing world such as mines, narcotics, timber, and oil.

Psychological

Clausewitz's famous phrase, that war is a continuation of politics, is often understood incompletely. Clausewitz was comparing this proposition with its antithesis, that war is nothing but a brutish act. He explained that war is a synthesis of both brute aggression and political calculation with a great deal of chance. While rational economic interest may shape conflict, there is often too much violence to be explained merely by instrumental motivation or material want. Sometimes violence aims only to make the victim suffer. Sigmund Freud argued that such brutish aggression is innate, an instinct, like the drive for pleasure. Ethologists have described aggression as common to most animals and humans. Some sociobiologists have argued that aggression is a selected trait in the brain involving the production of neurotransmitters like noradrenalin, dopamine, and serotonin in the limbic system.

Though there are biological components of violence, humans are not always violent. Contextual factors often cause violence to manifest. Psychological theories have emphasized the role of frustration in the creation of aggression projected either toward the source of frustration or a substitute object. Erich Fromm wrote that while humans can develop the love of life, if frustrated humans develop destructive behaviors such as the desire to control others, sadism, or the desire to destroy things, necrophilia. Such a personality prefers violence to solve a problem rather than sympathetic efforts. Human destructiveness often comes from experiences of injury or loss that produce reactive aggression. From this perspective, collective forms of violence may be a reaction to a perceived threat, a "counter" violence. Revolutionaries, counter revolutionaries, terrorists, and counter terrorists, all portray their movements as the offended victims in order to motivate and justify violent retaliation. Even if such reactionary aggression can achieve no clear political goal, such violence appeals to a psychology of recognition. Despite the futility of armed resistance against overwhelming militaries and police apparatuses, those feeling overwhelming frustration may pursue suicidal revenge rather than submit to their oppressors.

Cultural

Violence takes very specific cultural forms. The choice of targets is often made according to culturally based, often

relatively local notions of affiliation or identity that combine notions like racial, ethnic, gender, or religious difference. The colonial torture and murder of indigenous Americans and Africans was often predicated on European fantasies of taming wild, heathen, and satanic races. The Nazi Holocaust took place within a context of long-standing anti-Jewish and anti-Semitic myths of Jews as a race of conspirators and despicable materialists. Not only the target, but also the act may be structured by specific cultural distinctions. The castration of African American men when lynched expressed the pervasive white supremacist stereotypes of African men as rapists. In the Hutu genocide of Tutsi in Rwanda, the cutting off of limbs and breasts was patterned by a local logic of healthy flow in the body and body politic. In the Balkans, rape became a weapon of war largely because of the powerful cultural shame involved with such violence. The target and the method show distinct cultural patterns.

There are also international patterns of identification that transcend local ideas of culture. Modern religious fundamentalism, characterized by textual literalism, moral certainty, and outstanding organizational capacity, spread across state borders in the 20th century and included Christian, Islamic, Hindu, Buddhist, Jewish, Sikh, and other expressions. Many of these groups provide education, social services, and electoral support, and they have come to influence some states and their militaries or even form independent paramilitary groups. A second more pervasive global cultural influence on violence is militarism. In addition to the central role of military groups in politics and industry, somewhat like religious fundamentalism, the military has strong symbolic significance. Those in the military are directly exposed to messages that associate manhood, honor, and violence. The general public, too, receives similar messages. The military parade has become a standard ritual of state display. Audiences across the globe watch the movies, many from Hollywood, that make military violence seem glorious and titillating. These cultural images, like ancient warrior myths, may shape widespread patterns of political violence.

Impacts

Trauma

Dead bodies, amputated limbs, torched farms, slaughtered livestock, bombed out buildings, these are the most visible traumas of war. Violence's powers to kill or maim people, and destroy natural resources and community infrastructures, are the most obvious costs to the victims of battle. But there are less visible traumas. Bruno Bettelheim's studies of Holocaust survivors revealed surprising patterns of emotional burden. Some victims experienced guilt for surviving when so many died. Others described a sense of identification with their jailers and executioners. Many psychologists have observed post-traumatic stress disorders in which the anxiety of past trauma continues to manifest in behaviors and experiences such as insomnia, depression, violent outbursts, and dissociative disorders. Such experiences can tear apart family and community and destroy images of self, trust of others, and a sense of hope.

The trajectory of trauma has several intersubjective aspects. Psychotherapists have long argued that for healing to occur, victimized people must develop a way to talk about, or even commemorate and mythologize what occurred. Through these processes the trauma comes to define part of their identity as members of a group. Public rituals, monuments, testimonial narratives, historical studies, and bodily practices are familiar forms through which people collectivize emotional trauma. Such memorial practices can transmit trauma from one individual to another, across a family, to a community or even transgenerationally, and while they may help people mourn, they may also keep feelings for retribution alive and frame future reprisal.

Domination

One consequence of violence is that fear can inhibit the organization of resistance to domination or exploitation. Public torture and execution, and some military attacks, are meant to display the overwhelming power of the state and terrify subjects into obedience. The threat of future violence can exert great control. Political actors sometimes use old, or even create new enemies that heighten popular anxiety for political advantage. As Randolph Bourne said, "War is the health of the state."

Resistance

Violence is often permitted or encouraged to secure the passivity, compliance, or elimination of particular populations; but, sometimes it can create solidarity and communities of resistance. For example, the mothers of those who disappeared at the hands of the Argentine military were united in their grief and demonstrated in the Plaza de Mayo in Buenos Aires to demand knowledge of their missing loved ones and, eventually, to call for criminal prosecution of the perpetrators. Cycles of violence between groups, Pakistanis and Indians, Tamils and Sinhalese, Palestinians and Israelis, and many others, while intended to intimidate, may only harden defiance on each side and perpetuate reprisal.

Representations

Writing

Several international organizations, like Human Rights Watch, Amnesty International, Physicians for Social

Responsibility, and many local organizations and individuals witness and record violence to work against suffering in at least three ways. Some victims need to talk about their trauma in order to render it speakable, to mourn the dead, or to reconstruct a self image. Giving voice and face to suffering can reduce the social distance between victims and those who may be sympathetic allies. Writing about violence can expose abuses of human rights and incriminate those responsible for crimes.

However, in other circumstances, writing about violence and recording suffering can further the terror it purports to explain. Talk of violence can increase terror, fear and panic. Reading about or watching repeated television images of suffering may also desensitize viewers to violence rather than create empathy. Rather than being a step toward ending suffering, when watching violence stirs panic or becomes a voyeuristic form of entertainment, it encourages more violence.

Rituals

Healing people and communities from trauma and breaking cycles of violence often requires public ceremonies to communicate the restored dignity of victims. Sometimes ritual feasting or exchange reestablishes recognition between people. Modern courts have ritualized establishing truth and extracting retribution to restore a sense of justice. A new and significant ritual to emerge in the 20th century was the truth and reconciliation commissions (TRC). TRCs are official bodies that investigate human rights abuses committed by governmental or rebel forces in order to ease the transition to a new political order by creating a renewed sense of justice and legitimacy. In South Africa, the TRC was charged with the tasks of creating a complete record of past abuses, making recommendations to prevent future abuses, restoring the dignity of victims, and granting amnesty to perpetrators who confess fully. Anglican Archbishop Despond Tutu recognized that to heal the nation, the restoration of justice and dignity must happen without retribution. Retribution would have been an obstacle to establishing truth and could have perpetuated the violence of the conflict. In addition to South Africa, in the last quarter of the 20th century, about two dozen TRCs were created across the world including Guatemala and East Timor.

D. Stephen Voss
University of Kentucky, Lexington, Kentucky, USA

Glossary

benchmark poll Large public opinion survey, typically taken at the beginning of a campaign to gauge the initial party, candidate, and policy preferences of constituents; helps shape campaign strategy by providing vital information about what kinds of messages will motivate the public.

dial groups Small groups of individuals who are given handheld electronic devices that allow them to register their ongoing feelings about a speech, debate, or political advertisement while they are being exposed to the message; may not be representative of a constituency or audience, but can provide detailed information about the types of people in the sample.

direct mail Surveys mailed (or emailed) to potential voters; recipients participate voluntarily, and so may not be representative of the electorate. A relatively inexpensive way to poll, thus commonly used by public officials to measure statewide or district-level opinions of constituents.

exit poll Survey conducted by media outlets during primary and general elections to project the outcomes before the ballots are tallied. Questionnaires ask respondents about their vote choices, as well as various demographic questions; the accuracy of the poll depends on the representativeness of both the selected precincts and the participating respondents at each precinct.

focus group A group consisting of about 7 to 10 individuals who are talked through political issues by a trained moderator. The modest size of the group does not permit a representative sample, but focus groups do provide more detailed information than can be obtained from traditional survey research. Because focus groups can indicate how individuals respond to alternate ways of phrasing the same political messages, for example, campaigns use them to plan advertisement strategies.

media ratings Surveys that provide information about television viewership in various markets, as well as demographic information about the audience. These ratings are used to determine the costs and the target audiences for television political advertisements.

push poll An unscientific poll conducted by political campaigns under the pretense of objectivity; although evidence about how constituents intend to vote in an upcoming election may be obtained, the main purpose of a push poll is to disseminate political propaganda that either benefits those conducting the poll or damages the campaign of an opponent.

recruitment survey A poll conducted by political parties very early in the campaign cycle to provide potential candidates with information about the viability of their candidacies.

straw poll Although used to refer generally to a poll with a large but unscientific sample, the main usage in politics applies to surveys conducted among the membership of a political party. Due to the sampling methods of a straw poll, results cannot be generalized to the entire population, but are useful for determining which issues, messages, or candidates can motivate the party faithful.

tracking poll A survey taken frequently during the latter stages of a campaign to monitor public reactions to various political events, such as speeches and political advertisements.

trend poll A survey taken intermittently during a campaign following the benchmark polls; results indicate changes in mood and issue and voter preferences that occur throughout the campaign process.

Public opinion polls are a common feature of democratic politics. Numerous political actors, regardless of whether they are governing or are involved in conducting elections, take advantage of the usefulness of polls to characterize citizen attitudes and policy preferences.

Introduction

Literature and history are replete with stories of despots who nonetheless worried about the sentiments of their subjects. All four gospels of the *Bible*, for example, portray Roman governor Pontius Pilate as reluctant to crucify Jesus; he does so to pacify the people he rules. Shakespeare's "Julius Caesar" opens with the tribune Marullus berating citizens for their political fickleness, then climaxes as Marc Antony's funeral oration whips his audience into a mob against those who have taken power at Caesar's expense. Western history is littered with the corpses of real rulers who failed to recognize the danger of their declining popularity. Notorious examples include English King Charles I in the 17th century, French King Louis XVI in the 18th century, and Russian Czar Nicholas II in the 20th century. Even autocrats have—to paraphrase the late political scientist V. O. Key, Jr.—found it prudent to heed public opinion.

Compared to autocrats, politicians in democratic systems may have to place more emphasis on satisfying the citizenry, because elections institutionalize mass participation. But prior to World War II, the tools available for gauging popular impulses in democracies were not much more effective than were those possessed by other regimes. Elected leaders usually relied on trusted advisors, well-connected party bosses, or savvy legislators to gather information about voter sentiment. Leaders also have paid close attention to voices in the media, treating them as indicative of regional attitudes. For example, after Teddy Roosevelt invited Booker T. Washington to dinner (the first instance of a U.S. president entertaining an African-American man at the White House), the critical response of Southern journalists convinced Roosevelt to shy away from future contact with Black leaders. In short, elected officials of the past customarily depended on limited, and usually biased, avenues of popular expression.

The birth of scientific survey methods, however, opened vast new resources for democratic leaders seeking to measure popular sentiment. Technological and intellectual developments in the aftermath of World War II, such as scientific sampling, advanced statistical analysis, and behavioralism, combined to create workable polling techniques that politicians could use to promote their own interests. They have exploited the new techniques to strategize election campaigns, to shape political platforms, to select among public policies, and to guide legal rulings. As a result, public opinion polls have contributed significantly toward increasing the responsiveness of democratic governments, and perhaps also toward increasing the ability of a nation's leaders to manipulate the citizenry.

Because the scientific aura surrounding surveys appeals to populist, pragmatic, and empiricist strains in the national culture, political actors in the United States have been especially quick to adopt polling innovations. It is no accident that the first commercial pollsters emerged in the United States or that, until recently, at least, pioneering polling techniques and electioneering strategies have typically originated in the United States. American media organizations, meanwhile, have learned that audiences appreciate seeing themselves reflected back in newsprint or in broadcasts. Opinion polls serve as the centerpiece of political journalism in the United States. The remainder of this discussion therefore focuses, out of convenience, on the use of polls in American politics.

History of the Use of Polls

The desire to survey public attitudes is as old as the American political system. Although the birth of modern polling changed the face of public opinion research, allowing unprecedented access to the pulse of the public mood, experimentation with surveying popular opinion preceded the development of sound methods for doing so. One of the earliest techniques was the use of the "straw poll," an unofficial vote, to gauge public opinion and support for various candidates for office. The practice traces back to a time before scientific polling methods, perhaps as far back as the elections of 1824. Sometimes voters attended meetings called explicitly to assess their political preferences; sometimes voters answered straw polls taken during militia or party meetings called for other purposes. Political activists also sometimes conducted straw polls by leaving "poll books" in public places for citizens to provide information about their voting preferences. All of these methods rely on unrepresentative samples; they cannot be generalized to all voters.

Another early sampling technique involved mail-in ballots. A periodical called *Literary Digest* successfully predicted the winner of every presidential election between 1916 and 1932 by tabulating millions of mail-in ballots. However, the magazine distributed ballots to an unrepresentative sample culled from automobile registration lists and telephone directories, and relied on respondents to complete the questionnaire voluntarily. Because respondents with telephones and automobiles during this depression-era election were much wealthier than the typical voter, the *Digest* incorrectly predicted an overwhelming Republican victory in 1936, rather than a Franklin Delano Roosevelt (FDR) reelection. The 1936 election, however, was the first time that scientific polls were taken by George Gallup, Elmo Roper, and Archibald Crossley. Gallup not only predicted that FDR would defeat Alf Landon, he also predicted that *Literary Digest* would get the prediction wrong because of bias in their sampling methods. That Gallup's organization could outperform *Literary Digest*, despite a sample of thousands rather than millions, underscored the importance of scientific sampling

methods. This success led to widespread development of sampling techniques around midcentury—not only in politics, but also in marketing.

Some of the innovations in survey sampling techniques resulted from generous government investment. The U.S. Department of Agriculture established a Division of Program Surveys in 1939 to study farm opinion. The division, directed by Rensis Likert, was the first governmental body to conduct public opinion research regularly. It developed numerous polling techniques that have become standard. These included using open-ended rather than yes-or-no questions, asking multiple questions on the same topic to develop a scale of opinion, and following methods of probability sampling that limited the discretion of interviewers when they obtained respondents. The federal government continued to commission surveys during World War II. In 1942, for example, the Office of War Information established a Surveys Division that conducted more than 100 studies of civilian attitudes about wartime problems. During the same period, a U.S. Army research branch studied troop morale. The wartime research programs took advantage of the specialized insights of multiple social sciences and so contributed enormously to an understanding of how opinions are formed and changed. They also helped sustain the polling profession and cultivate its expertise during a time of limited resources.

Trial-and-error experimentation contributed significantly to technical polling innovations. For example, Gallup's sampling methods came up short in the 1948 presidential election; his organization's prediction that Thomas Dewey would oust President Truman led some newspapers to print embarrassingly wrong articles headlined "Dewey Defeats Truman." Some blamed Gallup's faulty prediction on a decision to stop polling nearly 2 weeks before the general election, even though approximately 14% of respondents remained undecided at that time. Others blamed Gallup's use of quota sampling, a method that seeks samples perfectly representative of population demographics but allows individual interviewers more discretion to pick cooperative and easy-to-reach subjects. Gallup's high-profile failure led to several adjustments in survey techniques. For example, polls taken in the days before a presidential election became more common and firms increasingly opted for random samples rather than those collected under demographic quotas.

Use of Polls by Politicians/ Officeholders

Almost every U.S. president has tried to gather intelligence on public sentiments in one way or another, starting with George Washington, who reportedly rode around the countryside to gauge citizen opinion toward the federal government. But America's wartime president, Franklin Roosevelt, was the first who could exploit sound polling data, because scientific survey techniques were only just developing during his administration. For example, FDR used polls to tap public sentiment toward some New Deal programs, especially Social Security. He was also interested in popular views on World War II and the role that the United States should play in the war. Roosevelt often checked public opinion data before making key decisions relating to the war, such as whether Catholics approved of bombing Rome in 1944.

Harry Truman, FDR's successor, was much more uncertain of the validity and accuracy of polls. Like many politicians during his time, Truman did not believe that polls could represent the opinions of the public at large. Gallup's faulty prediction that Truman would lose in 1948 only encouraged such skepticism, and may have slowed the widespread adoption of public opinion polling for more than a decade. Not until the Kennedy presidency did the White House start using polls extensively. The use of polls by John F. Kennedy (JFK) began well before he won the 1960 presidential election. Kennedy commissioned Louis Harris to conduct polls during the campaign. Before the Democratic National Convention, a Harris survey showed that Kennedy's leading Democratic opponent, Hubert Humphrey, might be politically vulnerable in West Virginia and Wisconsin. Kennedy increased his attention to these states, and although he fell short in Wisconsin, he was victorious in West Virginia. He eventually won the nomination and the presidency. Once in office, Kennedy retained Harris' services so that he could gauge his own approval ratings as well as probe specific policy preferences of the citizenry.

Following JFK's assassination, Lyndon B. Johnson (LBJ) used polling data to measure public support for his domestic agenda. LBJ especially concentrated on public opinion late in his presidency, because he was extremely concerned with how the American people perceived their country's involvement in Vietnam. In 1966, Johnson's nightly reading included summarized results of a series of questions relating to public support for the war. President Richard Nixon took the use of polls to new heights. In his first year in office, Nixon commissioned more private polls than Johnson commissioned during his entire presidency. Nixon was obsessed with public opinion, particularly his own approval rating. During his reelection campaign in 1972, Nixon had his pollsters working frantically to find the best strategy to run against both contenders for the Democratic nomination, Hubert Humphrey and George McGovern.

Public opinion polls have never lost their critical importance since the Nixon administration. Following Nixon's resignation, President Ford examined strategies

for maneuvering out of the political hole left by the Watergate scandal. President Carter felt that public opinion was so important that he gave his pollster, Patrick Caddell, an office in the White House. Reagan met with his pollster, Richard Wirthlin, almost monthly to monitor public support for the administration and its policies. George H. W. Bush kept close tallies on public opinion and reportedly relied on poll results to shape his posture with respect to Iraq. President Bill Clinton employed surveys to a great extent, not only to conduct his election efforts but also to shape his policy stances, resulting in some observers calling his administration a "horserace presidency." Clinton made no secret about the role of pollsters in his White House. He commissioned regular polls about every aspect of American political life, at first from Stanley Greenburg and later from Dick Morris. Morris, in a kiss-and-tell book written after he fell from grace, denies that Clinton used polls to select his policies, but verifies that Clinton was constantly aware of the political significance of his policy decisions. Clinton's White House used polls to determine which actions were winning the most support and to shape public messages accordingly, resulting in a highly politicized and highly responsive form of governance that scholars call "the permanent campaign," because of its reliance on tactics once reserved for electioneering. During the 2000 presidential election, Texas Governor George W. Bush criticized the Clinton White House's reliance on surveys, promising that he would discontinue the "permanent campaign" and instead govern based on firmly held principles. Although this posture may have appealed to voters weary of Clinton-era scandals, it ignored the reality of contemporary political life, which is that polls are an invaluable and regular tool used by politicians because they are commonly accepted as a legitimate and accurate representation of mass opinion. Indeed, once in office Bush apparently recognized the necessity of watching public attitudes closely. His White House cut back on polling relative to Clinton's, but it still surveyed public opinion quite frequently by historical standards, and Bush confidant Karl Rove moved smoothly from campaign consultant to domestic advisor.

Although conventional wisdom states that presidents have used public opinion polling to gauge popular sentiment and cater to it, recent work challenges this claim. These scholars assert that politicians monitor public opinion to determine how to present their messages to win public support for their own policy preferences. Rather than following public opinion, politicians strategically craft their political messages to manipulate public opinion, in order to feign responsiveness.

Members of Congress usually lack the resources for extensive polling, although they can sustain some polling activity through the party organizations or through well-funded campaign organizations. Officeholders therefore supplement scientific polling methods with direct-mail (or constituent) surveys, which provide a cheap means for checking the mood of attentive constituents in their home districts. These polls are questionnaires sent to constituents' homes, often at public expense. Recipients determine whether to participate in the survey, and respondents complete the surveys outside the presence of interviewers. Direct-mail surveys are widely used because they provide information about voter preferences at a low cost to politicians at all levels of government.

Use of Polls by Campaigns

The use of public opinion polls becomes most intense during election years; they are invaluable to politicians seeking to attain or retain office. Political campaigns use an extensive battery of polling methods, each providing candidates with different sorts of information. Well-financed campaigns customarily use a series of benchmark, trend, and tracking polls during the election season. Early in the campaign cycle, candidates conduct benchmark polls to measure the initial issue preferences and likely vote choices of a large sample of individuals within their districts or states. These polls also can provide vital information about the relative name recognition of candidates and their opponents and can test different campaign messages. They may contain both open-ended and highly structured questions. Candidates for the U.S. House of Representatives often conduct these polls as early as a year before the general election, and Senate candidates may commission these polls 3 years prior to the election.

As campaigning commences following the initial benchmark poll, shorter trend polls, then tracking polls, are taken intermittently, up to the date of the general election. Trend polls gauge shifts in opinions and preferences that occur after the initial benchmark poll. Trend polls allow a campaign to gauge how well its messages are resonating with various portions of the constituency. As the election season moves into its final days, though, many campaigns move to tracking polls. Tracking polls generally use small samples and few questions, but they may occur daily, which allows a candidate to measure public opinion continuously. Tracking polls can help the campaign staff determine how respondents feel about various political advertisements, speeches, and policy positions. Given the expensive nature of conducting public opinion polling, most House candidates conduct tracking polls only during the last few weeks of the campaign.

A more problematic type of survey, appearing with increasing frequency in modern campaigns, is the push poll. Unlike objective public opinion polls, which seek to determine where respondents stand on candidates

or issues, push-poll questions intentionally provide participants with negative information about opposition candidates (or, on occasion, positive information about candidates on whose behalf they are being conducted). Motives for push polling vary. These polls are a useful way to test criticism of the opposition before investing in negative advertisements. They also tend to produce skewed survey responses, which may be important to a campaign that wants to claim publicly that it enjoys significant voter support. But probably the biggest reason why push polls are growing in popularity is that they provide a means to criticize opponents at a time when voters think they are hearing from an impartial survey organization.

Another important campaign resource is the focus group. These small-group interviews typically consist of 8–12 voters. A paid moderator leads free-flowing discussions with participants about a variety of topics important to the candidate. The role of the moderator is to steer the discussion without imposing a formal setting or skewing the answers, providing the campaign with a sense of how voters perceive the campaign. The moderator's task might be to test particular issue positions, to try out different ways of framing an issue, to evaluate how voters perceive the candidates, or to test out criticism of opponents to figure out which attacks raise the most ire. Focus groups are usually not representative of an entire constituency, given their small size. Indeed, sometimes campaigns intentionally select a skewed membership, perhaps to concentrate on swing voters or on a particular advertising demographic. Nevertheless, focus groups can provide very detailed and specific information unavailable from more scientific forms of survey research. Perhaps the most important trait of focus groups, from the point of view of political campaigns, is the rich detail they provide on voter reactions in an environment simulated to resemble the "real world" of political discussion. Dick Morris claimed that the Clinton reelection campaign often conducted focus groups to test the effectiveness of various political advertisements. They not only used focus groups to test the independent impact of their ads, they also tested which ads were the most effective responses to opposition critiques.

A new technique, used by both political campaigns and politicians, is the use of dial groups. Much like focus groups, dial groups are not representative of the entire population, but they can still provide information unavailable by other means. Participants are given "dials," which are small electronic devices with a wireless connection to a computer. Participants may be asked questions, or they may view political advertisements, speeches, or debates. These respondents turn the dial on the device, indicating their gut-level reaction to whatever they are witnessing, giving high numbers when they like what they are hearing and low numbers otherwise. Because respondents repeatedly adjust their responses over the course of the survey, dial groups offer real-time qualitative and quantitative information rather than just blanket judgments after the fact. Campaigns therefore receive detailed, instant feedback about the way audiences perceive different portions of a campaign event.

Use of Polls by Political Parties

Political parties once played a central role in campaigns, because they were the main mechanism for organizing a ticket and persuading voters to show up on election day to support that ticket. These critical mobilizing agents faded in importance over the course of the 20th century, however, and especially after World War II. Candidates increasingly constructed their own campaign organizations from funds provided by powerful political-action committees (PACs), and approached voters through high-technology advertisements rather than via door-to-door appearances by party workers.

To a certain extent, the parties restored their political importance in the 1980s by becoming brokers of cheap campaign consulting, including public opinion polling. Today, parties conduct and fund polls on behalf of the party candidates. In addition to benchmark, trend, and tracking polls, they also fund recruitment surveys. These surveys allow those considering a run for political office to examine the viability of their candidacies. Although political parties may split a poll's costs with the campaign for which it is commissioned, the parties have found ways of deflecting the financial burden away from the candidates. For example, the parties sometimes release poll results to the press, which means that the polling expenditures do not count as campaign contributions or expenditures.

In the 1990s, the parties began using polls and focus groups to shape appealing, unified political messages as a means of countering the localized nature of candidate-driven elections. Newt Gingrich, along with fellow Republican candidates during the 1994 congressional elections, used focus groups to assemble their "Contract with America" ideological package. Through various national surveys, the Republicans were able to construct a package of policies that were supported by popular majorities. The 1996 Democratic response, their "Families First" agenda, used polling data to support their initiatives in an attempt to regain some of the seats lost in the 1994 election.

Political parties use the same tools for measuring opinion as do candidates and government officials, i.e., large public opinion polls, focus groups, and direct-mail surveys. However, parties also traditionally conduct straw polls (often held among the party faithful) to determine the popularity of potential nominees for office. Political

parties and their candidates also use poll information to determine the most effective audiences for advertisements. A firm called Nielsen Media Research regularly reports on the viewership of various television programs; the report reveals not only how many people watch a certain program, but also certain demographic information about each audience. This is critical information to campaign managers who want to buy television time—that is, set up "media buys"—that will spread the campaign's message widely and target the right voters.

Use of Polls by the Media

Media organizations use several types of polls. Some of these polls serve little more than an entertainment function, whereas others genuinely assist with the news coverage of campaigns and elections. Call-in polls and Internet polls are examples of unscientific polls that have become common in recent years. The two sorts of polls are similar. Call-in polls prompt radio or television audiences to answer questions by calling a telephone number, whereas Internet polls provide the same opportunity to people who visit a Web site. Both call-in polls and Internet polls differ from legitimate public opinion surveys because respondents choose whether to participate. This lack of randomness means that the results will not be representative of the entire population. The resulting bias is likely to be especially large when these polls are taken for entertainment purposes, because individuals who participate tend to be those with the strongest opinions on an issue. Yet, despite the near uselessness of these polls as a source of political information, audiences apparently find the results interesting.

Media outlets conduct exit polls on election night, hoping to use that information to determine the winner of a particular election before the official tally arrives. The organization generates a representative sample of precincts, and then stations pollsters at each precinct during an election. To get a representative sample of those who turned out to vote, the pollsters select voters as they leave the precinct station. Usually participants receive a questionnaire to fill out and drop in a ballot box set up at the polling site. These questionnaires ask how the respondent voted in various contests, as well as a variety of demographic questions. The results of these polls allow making projections on election night. They also allow analysts later to probe how different social groups voted and to speculate on why particular candidates won or lost.

Exit polls are expensive. They take advance preparation and a large, well-trained staff. As a result, the major television networks and the Associated Press banded together in the 1990s to create a single group, Voter News Service (VNS), to conduct the exit polls. VNS has collected exit poll data since 1993, saving the partner television network and news organizations (ABC, CBS, NBC, FOX, CNN, and Associated Press) millions of dollars every election year. Although all of the sponsors receive access to the same data, they analyze the results individually. Until the 2000 election, exit polls primarily faced criticism from those who were upset with how the media used the exit data. News organizations sometimes broadcast their projections while voting was still underway, prompting critics to accuse them of swaying voter turnout. In particular, party activists worried that knowing presidential election results from eastern states might discourage voters in the western states from participating at the same rates as they otherwise would have.

By contrast, the methodology of exit polls received little scrutiny before the 2000 election debacle—when every media outlet, using exit poll data provided by VNS, originally called the state of Florida for Al Gore, then called the state for George Bush, before stating that the election was "too close to call." Flaws in the VNS procedure apparently caused the embarrassment, ranging from the method for estimating absentee ballots, to the method for selecting precincts, and on to the system for transmitting poll results to journalists. The number of actual absentee ballots cast, for example, was nearly twice the quantity predicted by VNS. The sampling method, meanwhile, apparently pumped up the number of votes for Gore. VNS initiated numerous reforms in the wake of the 2000 election. These changes will include updating VNS's computer systems, improving the statistical models used by the organization, and creating better measures of absentee ballots. However, VNS could not get the system working in time for the 2002 congressional contests, leaving the long-term fate of the enterprise in doubt.

Another media practice to receive criticism in recent years is that media outlets increasingly engage in "horserace journalism." This sort of coverage pays little attention to campaign issues, the sort of information that might aid undecided voters attempting to choose among candidates. Instead, it focuses on the likely outcome of an election, the sort of information sought by the large number of partisans who already know who they support and want to know if their horse is going to win the race. Preelection polls play a central role in this sort of coverage, because they provide the best information about who is leading a contest and why they are ahead. Critics note that projecting an election winner before the fact provides little useful social or political function, but might distort election results—for example, by preventing dark-horse candidates from attracting public support by getting their message out to voters through the news. Polls also tie up media resources that otherwise might support

investigative journalism, creating news rather than finding it. However, media polls show little sign of abating.

Conclusion

Politicians possess a much better resource for measuring public opinion than they have ever enjoyed before: the scientific public opinion poll. This powerful new tool allows modern governments to be much more responsive to voters than those in the past were. Polls have become such a common device in politics that, for some social scientists, they raise the specter of a hyperactive democracy, one that slavishly accommodates the whims of public opinion. Social critics bemoan the replacement of public leaders with public followers and worry that political discourse has become little more than an echo chamber of ill-considered popular attitudes. Nonetheless, polls have been shown to be invaluable for politicians seeking to obtain and retain public office, for political parties seeking to exercise influence over their members without the inducements of the past, and for political journalists seeking a source of news unmediated by the "spin doctors" who mastermind election campaigns. It is unlikely that a practice so useful to so many political actors will be allowed to fade in significance.

Polling Industry

Frank Newport
Editor in Chief of the Gallup Poll, Princeton, New Jersey, USA

Glossary

census The calculation of the characteristics of a population based on measuring every member of that population.
direct-to-the-media polls Polls that have not undergone scientific peer review of prior publication in journals or outlets that provide quality control and that are published or released directly in media outlets as received from the polling organization that conducted the poll.
full-service polling companies Businesses that provide complete polling services, including development of the questionnaire, drawing the sample, interviewing, data analysis, and report writing and summary. These are usually differentiated from niche firms that focus on only one aspect of the polling process.
polling A process that uses scientific principles of probability sampling to obtain a representative sample from a population and then uses measure of attitudes from this sample to estimate population values on specific variables of interest. Polling usually refers to a process in which the results from the sample are released publicly.
probability sampling The process of selecting samples from a population in such a way that every member of the population has an equal or known probability of falling into the sample.

Any discussion of polling companies must start with a precise definition of the word "polling." Polling is often used in casual conversation to describe a process by which the views of a group of people are measured and tabulated. Most people have heard the term polling used in common conversation, for example, "poll the jury." We also use the word "poll" to describe the place where we vote (i.e., "go to the polls on election day").

Introduction

In this article, the term polling is used in reference to a process that is more specific than the typical generic use of the term. The definition of polls focuses on a process that has three key parts: (i) the attempt to measure human attitudes or opinions, (ii) the effort to use sampling techniques to get those measures from a small group of people and generalize them to a large population, and (iii) the public release of the results so that everyone in the population is exposed to them.

The first of these components is straightforward. One can in theory conduct a poll of breeds of dogs represented in a community or the types of minerals represented in a geologic area. Here, discussion is confined to research involving human attitudes and opinions.

The second point in this definition is particularly important because it differentiates polling from more general processes of survey research. It is possible to measure the opinions of every member of a population under consideration. This is commonly called a census, and it is an easy process when the population of interest is small (e.g., a school or a business) and an extremely complex process when the population of interest is an entire country (the best example of which is the biennial census in the United States). However, censuses are not polls under the definition used in this article because they do not include the process of sampling and generalizing from that sample to a population.

The third point is key in terms of the discussion of companies that engage in polling. There is a very wide group of procedures that have as their object the measurement of human attitudes and that use scientific random sampling techniques to efficiently generalize to a large population. However, many of the results of these procedures are not released to the public but are instead analyzed and used only in confidential privacy

by the organization commissioning them. These come under the rubric of "market research" and are outside of the purview of this article. We are focusing here only on the process by which survey research results are released publicly after they are gathered and analyzed.

History

The widespread use of polls in the United States began in the 1930s when several men widely recognized as pioneers of the polling process began to apply the principles of random sampling to human attitudes. These men included George Gallup, Elmo Roper, and Archibald Crossley. Later, two other pioneers in this field, Louis Harris and Daniel Yankolovich, joined this roster of prominent pollsters. Most of these pollsters founded full-service polling companies. The Gallup Organization, for example, was a very successful and profitable company focusing primarily on providing polls to newspapers from the mid-1930s to World War II. Firms carrying the names of Gallup, Roper, Harris, and Yanklovich still exist today. However, it is important to note that none of these firms focus exclusively on polling today. All conduct publicly released polls as part of a much broader set of research services.

This transformation is symptomatic of the general trends that have affected the polling industry during the past half-century. There is little question that the promise of polling and its value to society have been realized successfully—as evidenced by the ever increasing number of polls that are reported in the news media and thus are available to the citizens of the countries in which they are conducted. However, the value of the polling enterprise to provide a foundation for a commercial, for-profit business has been much less successfully realized.

A significant challenge facing the polling industry has been the search for ways in which polls can be conducted, analyzed, and reported in a manner that provides incentives for profitable, creative, and entrepreneurial companies. This challenge has not been successfully addressed. As a result, the polling industry today is not the vibrant collection of fast-moving competitors that characterize other business sectors in which there has been rapid innovation and advancement. Rather, the polling industry (at least in the United States) has evolved to the point where most polling is conducted in one of the following ways: (i) as a ancillary service provided by firms mainly focused on providing market research for business and industry; (ii) by nonprofit government and educational institutions; (iii) by niche providers that focus only on one small aspect of the polling process; and (iv) by companies attempting to use methodologically slipshod techniques involving the Internet or robotic, impersonal telephone calling to provide high-volume, low-cost polling. The economics of polling has to a large degree dictated that traditional, for-profit polling companies have a very difficult time surviving.

As noted previously, this is not to say that there is a diminished demand for polls. Most observers agree that there are more polls released into the flow of media news coverage today in the United States and throughout the world than ever before. This is particularly true, for example, before a presidential election in the United States, or when there is a major news story about which the public's opinion is germane. Part of the explanation for the increased number of polls has to do with the increased number of news outlets reporting news, particularly cable television news channels and Internet news sites. However, there also seems to be a genuine increase in the thinking of media gatekeepers (i.e., newspaper editors and television producers) that polls are a legitimate and interesting component of news coverage.

When we look at polling from a business perspective today, we find a paradox that results from the difference between this demand for polls, on the one hand, and the inability of this demand to support a vibrant commercial polling industry, on the other hand. We can examine the reasons behind this paradox by discussing in more depth at the types of organizations willing to commission and pay for polls.

One type of group or organization interested in sponsoring polls consists of nonprofit foundations and educational and government entities. These organizations sponsor and pay for polls because they believe polls are in the public interest and help fulfill the purpose for which the organization was founded. (In this sense, polling follows the same model as nonprofit public radio, sponsored by government and charitable contributions for the public good.) The Philadelphia-based Pew Foundation, for example, invests each year in sponsoring a significant polling program through the Pew Research Center. Its polls are released in their entirety, free of charge, to anybody who wants them. The Harvard School of Public Health, along with the nonprofit Kaiser Foundation, sponsors a series of polls asking Americans about their health and health-related issues. Several small colleges, most notably Quinnipiac in Connecticut and Marist College in New York, sponsor polls of their region in an effort to attract recognition and brand awareness. The University of New Hampshire conducts polls of its home state, as do a number of other state universities. Nonprofit advocacy or charitable groups will also sponsor polls that focus on their particular issue or concern.

Relatively few of these nonprofit entities pay full-service prices to outside firms to conduct the polls. Many conduct the polls themselves. Others work out

an arrangement by which the cost of the polls is shared with research organizations interested in providing them.

A second and very important group of organizations that sponsor polls consists of news and media outlets that support polling programs primarily because they believe polls add an important element to their news coverage and/or because they believe that having their name attached to polls will increase brand awareness and legitimacy. This use of polls by news and media outlets is a time-honored tradition. George Gallup, who founded the Gallup Organization, initially released his polls through a syndication service that provided poll results, analysis, and interpretation to newspapers in a ready-to-use format. Fortune Magazine was one of the original sponsors of Roper Polls. In today's news environment, almost all major news organizations sponsor polls, including CNN/USA Today (with Gallup), ABC/Washington Post, CBS/New York Times, Fox News, NBC/Wall Street Journal, the Los Angeles Times, Time Magazine, Newsweek Magazine, and the Associated Press.

However, these media polls are not numerous or frequent enough to sustain an industry of polling companies focused just on providing them to news and media outlets. Additionally, the media organizations that sponsor these types of polls have developed a series of ways of keeping the costs low (discussed later).

A third type of organization that sponsor polls consists of "normal" for-profit companies that commission polls primarily because they believe that having their name attached to the results when they are publicly released is good business and makes sense from a "branding" viewpoint. (This latter motivation can be called the "Goodyear" motivation because it reflects the same rationale used by the Goodyear Corporation in sponsoring its famous blimps.) These types of polls are often associated with the companies' areas of interest, based on the hope that either the results are favorable to their business objectives or the association of their name with topics related to their business will generate name identification and legitimacy.

Why Polling is not Profitable

There are a number of specific reasons why the demand for polls as represented by these three types of organizations has not led to the development of a large and thriving industry of polling companies. Many polls are conducted in-house by the sponsoring organizations, much as would be the case for organizations that use in-house legal or accounting services. This situation is particularly true of government and educational organizations, as well as for some news and media outlets that have ongoing polling programs. These entities have developed self-contained polling units and therefore the ability to subsume polling into their internal business structures. The New York Times/CBS polls, for example, are conducted using in-house polling operations supervised by employees of these two sponsoring media outlets. A number of colleges and universities in the United States conduct polls within institutes or academic departments, in some instances as part of an educational or learning experience. This is true for the Quinipiac Poll, the University of New Hampshire polls, and the Marist College polls. The implications of these procedures for the polling industry are quite obvious. In-house polling lessens the need for private, independent polling organizations.

Even when outside polling companies are used to conduct polls, however, there are several factors that mitigate against the development of a robust and profitable polling industry. First, conducting publicly released polls is an attractive proposition to many research companies because it helps their business to be associated with news stories potentially read and seen by hundreds or thousands of people. In other words, many research organizations are quite eager to get involved in the business of providing polls because of the valuable increase in name identification that results. The supply is higher than the demand, and this makes a business focused just on conducting polls less attractive for all but companies that can provide polls in a high-volume, low-cost way or to conduct polls as a sideline to other businesses.

A second factor results from the specific nature of the typical news poll or other polls conducted for brand identification purposes. These types of polls do not require a great deal of consulting or other value-added services from the organization conducting the poll. The sponsoring organizations may need only the bare essentials of the poll process, eliminating the demand for the less tangible "intelligence" services that are more profitable for full-service polling companies. This in turn diminishes the ability of polling companies to charge for the typical value-added consulting, analysis, and interpretation that provide high margins in research.

These factors have created a situation in which companies providing polling services today often do so as a sideline to other, more profitable businesses, much of the time as a loss-leader to generate attention and increase name awareness. On the other hand, companies interested in polling have focused on the attempt to harness the Internet and other technologies to provide polls on a high-volume, low-cost basis. Some of these companies have attempted to conduct polls entirely without human intervention using telemarketer-type calling technology coupled with recorded voices and the capability to allow respondents to answer questions via the touch-tone pad on their phone. Other companies attempt to gather large numbers of individuals who have e-mail addresses and then to persuade these individuals to follow through and complete online polls.

There is another factor that limits the potential profitability of polling companies that attempt to provide polls as their primary business. There is usually not much of a direct-to-the-bottom-line payoff to organizations or entities that sponsor polls. Much market research (i.e., survey research whose results are not released to the public but used in a proprietary fashion by the organization or entity that commissions the research) is of great value to the commissioning organization because it can be used by it to achieve a business goal. This includes research relating to brand names, product characteristics, and the positioning of political candidates. Companies and political campaigns are willing to pay high prices for the provision of this type of information in the same way that they pay for strategic consulting and positioning studies because these organizations can ultimately find a relationship between the recommendations developed as a result of the research and revenues and profits. This unique value provided by marketing research gives companies an incentive to seek out and pay for the best possible research services, including research that is of the highest quality and that involves higher level consulting and expertise.

There is a key differentiating factor that prevents polling companies from justifying these same high costs. Poll results by definition are released to everyone and therefore have no unique or proprietary value to the commissioning entity. The commissioning organization cannot gain a unique advantage or a significant business edge based on poll results that are essentially available to anyone who wants them, including competitors, regardless of who pays for them. This lack of a direct connection between polls and an organization's bottom line puts even more pressure on an organization interested in commissioning polls to control costs and obtain polling services at the lowest possible price. This in turn compresses the return on investment for polling companies and restricts the viability of polling as a stand-alone business.

There are business benefits other than revenues and profits that accrue to organizations that sponsor polls. Many of these benefits are based on the value of legitimacy and name identification that comes from being associated with polls, the use of polls as a component of news coverage, or polls as part of an educational or governmental function. However, the fact that poll results are by definition shared with everyone severely limits the number of business organizations willing to pay for polls on a systematic or continuing basis and, more important, limits the amount of money organizations are willing to pay for polls. Thus, the situation today is one in which there is a considerable demand for and interest in polls but a limited willingness or capability on the part of those who have this interest in paying for them.

In summary, several major factors that affect polling as an industry today have been reviewed. First, the fact that many organizations conduct polling in-house restricts the need for outside polling companies. Second, organizations commissioning polls do so as either a public service or as a means of building name awareness and burnishing the company's image, neither of which has the direct-to-the-bottom-line value of proprietary market research. This creates a situation in which organizations often have more limited budgets for polling and seek out lower cost polling providers. Third, conducting publicly released polls has intrinsic value to many research companies, which means that there are usually more research companies interested in providing polls than there is demand. All of this results in a situation in which the business of polling is not one that has, to date, developed into an industry with strong revenues and high profitability. This has kept the number of companies interested in doing nothing but providing polling services at a quite low number.

Differentiation of Polling Services

As has been the case in many industries over the years, one of the major changes in the field of polling has been the differentiation of the polling process into discrete phases, each of which can be executed by specialized companies focused just on one aspect of the process. These companies operate profitably in a particular niche by providing their service to a wide variety of research and business clients. The fact that firms can provide these component services allows those interested in conducting polls to in essence "assemble" a poll by obtaining each part of the poll from a different vendor. A random sample of the adult population can be purchased from a sampling company, field interviewing services can be commissioned from a high-volume company that does nothing but telephone interviewing, and basic analysis of the polling data can be obtained from a company that does nothing but such data tabulations. Each of these niche players provides these services to market research clients as well as polling clients and sustains a profitable business in that manner. The ability of organizations interested in commissioning a poll to contract with these individual vendors provides a further disincentive for companies to enter the polling arena as pure, full-service polling providers.

Thus, there are a number of forces at work that limit the ability of companies to sustain a full-time business doing nothing but providing poll services. Although there are more publicly released polls today than at any other point in the polling industry's relatively brief history, the total number of polls is still small enough to limit the number of businesses needed to provide them. Some organizations that sponsor polls end up doing the polling work in-house, further limiting the need for outside polling companies. There are name identification and

branding benefits that accrue from conducting publicly released polls that create a situation in which companies compete to provide polls at very low margin rates. Most organizations that sponsor polls do not need the value-added consulting services that are often the most profitable components of the survey research process. The polling industry today has many niche companies that can provide specific elements of the poll process, thus allowing sponsoring organizations to organize a poll by contracting separately for each of its components.

All these factors have opened the polling industry to low-cost providers that attempt to compete by using the Internet or other high-technology techniques to obviate the cost of live human interviewers. Additionally, many of the companies that conduct polls are full-service market research companies whose main business is providing more lucrative and remunerative services in addition to polling—primarily market research services for business and industry. These companies often provide polling services as an adjunct to these businesses, sometimes as a way of obtaining brand identification. A market research company can become widely known as a result of providing a highly visible publicly released poll, helping the company establish legitimacy in the eyes of potential commercial clients.

In summary, the nature of the polling business today has created a situation in which there are few for-profit polling companies that do nothing but provide polling services. The landscape of companies involved in polling consists of the following: (i) nonprofit educational and government entities that conduct polling in-house; (ii) news and media organizations that conduct polling in-house; (iii) full-service research companies that conduct polling as a low-margin side business; (iv) companies that provide specific components of the polling process, such as samples, field interviewing, or data processing; and (v) companies focused on provided commodity such as polling services using the Internet and other high-technology methodologies.

The Business of Polling and Quality Concerns

The structure and dynamics of the way in which the polling industry is configured today have repercussions on the overall level of consistency and quality of the polling that is released to the public. In general, the "stepchild" nature of polling results in a situation that leads, in some cases, to less than optimal quality.

As reviewed in the previous section, there are few full-service firms that provide polls as the major function of their business. This means that the polling industry misses out on specific benefits provided by larger firms concentrating just on polling. Full-service polling companies that conduct polls from beginning to end provide the positive benefit of quality control and a coherent monitoring of how the pieces of the polling puzzle fit together. In some ways, this is similar to the process of building a new house. A homeowner can contract separately with an architect, cement foundation specialists, carpenters, electricians, plumbers, roofers, and so on, but the odds that the results will be a well-built house are lower than if an experienced contractor is in charge of the entire process and supervises it from beginning to end. The fact that there are few full-service companies that provide polling services has led to a general diminishment in the standards of control of polling that would exist if full-service companies were more involved in the process. This is particularly true in the case of polls that are purchased from low-cost providers or assembled from the contributions of a series of different companies. This is little different from the situation that develops in any industry in which there are intense pressures to provide products or services in the cheapest manner possible.

There is another aspect of the way in which the polling industry is set up today that gives rise to concerns about poll data quality. This has little to do with the cost structure of the polling industry but, rather, is a result of the way in which poll results are released to the public. The vast majority of polls to which the public is exposed in print or broadcast are not screened, reviewed, or published in refereed journals before they are used by the news media. For the most part, this is a result of the fact that a good deal of polling is conducted primarily for immediate release to a lay audience through print and electronic media means, without moving through any sort of the more traditional scientific process.

This direct-to-the-media nature of the polling business includes survey research that is funded and conducted by media organizations (such as the CNN/USA Today/Gallup poll and the New York Times/CBS poll) and polling that is conducted by others with the primary intention of gaining release through the media (rather than via scholarly publication). The purpose of these polls—that is, polling for direct dissemination to a lay audience—may include understanding and accumulation of theoretical knowledge, but the parallel, latent, or, in some instances, overt motivation often becomes one of generating and sustaining reader and viewer interest. The major purpose of scientific polling intended primarily for a scientific audience, in contrast, is the accumulation of knowledge.

The nature of direct-to-the-public polling means that it is often released within days or even hours of its completion. There is no peer review and journalists have little opportunity to review the research before it moves into the news stream. Journalists have a higher probability of being guilty of inaccurate or incomplete reporting when they summarize polling that is handed to them

by nonscientists intent on getting it published, when they summarize polling that they commission themselves, and/or when they report polling that is conducted without having gone through a scientific or scholarly screening process.

It could be argued that direct-to-the-media polls actually simplify matters because the needs of the media are directly taken into account when the polling is done. In other words, with the encumbrances of the need for scientific reporting not an issue, the execution and reporting of polls in "media-ready" form can be done much more quickly and in a fashion that is more targeted to reporters' needs.

However, this simplification comes at a cost. In the drive to meet media requirements and to gain access to media channels, pollsters may run the risk of creating more superficial, selective, or incomplete research and reporting than they might otherwise.

Scientists too have desires for public recognition of their work, and competition in science often results in rushed research and can distort truth. Scientists also can conduct bad, sloppy, or poorly designed research and have problems when their conclusions are not dramatic or easily summarized. However, a scientific orientation at a minimum encourages a desirable motivation for the research: adding to the accumulation of knowledge. The criteria for media use are different. Media polls are focused more on adaptability to the media's format and the interest value of the research report to the print or broadcast audience. The need to get results to the public quickly and easily can supersede the need to present results that are accurate and complete. The probability of less than optimal reporting of polling results can increase significantly in these situations in which research is conducted without the limiting context provided by scientific context and motivation. The balance, in short, gets out of whack.

Of course, direct-to-the-media polling does not always avoid or ignore scientific procedures. A good deal of this type of polling is built on a foundation of science and the scholarly approach to the accumulation of data. Many of the researchers who work for the media and report polling data directly to the public are highly trained and experienced polling professionals. The issue, however, is that there are no universal requirements or standards of quality in these situations, and thus what the public receives in these direct-to-the-media polls can suffer.

Summary

There are few "pure" polling companies left in existence today, at least in the United States. The structure of the polling industry as it has evolved during the past 70 years makes it extremely difficult for companies to focus just on conducting polls and at the same time maintain a profitable business. As a result, a good deal of polling is done as a sideline to other business and/or is commissioned by organizations searching only for the cheapest, bare-bones way to conduct the research. Some polling is assembled by purchasing the various components of the polling process from niche providers. The nature of the polling industry has also opened the door to a variety of low-cost, high-volume providers that conduct polls using the Internet or computer-based telephone-calling equipment. Most polling is conducted and reported through the news media without the peer-review process that is associated with other scientific work, sometimes within hours or days of being completed.

These facts, coupled with the increased demand for polling today, have resulted in a situation in which the quality and validity of poll results released to the public are often of a lower level than would be desired.

Glossary

completely automated telephone surveying (CATS) A polling technique in which an automated voice interviews participants and a computer directly processes the answers, by interpreting responses punched into a touch-tone telephone, for example.

computer-assisted telephone interviewing (CATI) A polling technique that prevents human error in the sampling and interviewing because phone numbers identified by the sampling frame are directly computer dialed and interviewers are walked through the questions in the survey. CATI systems also add flexibility by randomly assigning questions to a subset of respondents or by randomly ordering possible responses to a question.

dial groups Small groups of individuals who are given handheld electronic devices that allow them to register their ongoing feelings about a speech, debate, or political advertisement while they are being exposed to the message; may not be representative of a constituency or audience, but can provide detailed information about the types of people in the sample.

Literary Digest An influential periodical that successfully predicted presidential election outcomes from 1916 through 1932, using a survey that sampled millions of telephone users and car owners; collapsed after a terribly wrong prediction for the 1936 election caused by the class bias in its sampling frame.

Nielsen ratings Statistics generated by Nielsen Media Research that report the overall size of the audience for broadcast programs. Not only do these ratings help determine advertising costs for television programs, the company's data on media audiences also allow both commercial and political advertisers to target their messages efficiently.

polling alliance A cooperative effort among disparate news organizations to conduct polls; allows control over survey methods yet keeps costs down compared to individually organized polling efforts. Generally unites news organizations from different media formats (for example, newspapers with either magazines or television networks).

quota sampling Selecting poll respondents systematically to ensure that a sample matches the demographic characteristics of the larger population.

sampling bias Polling data slant that results from using improper or unscientific methods to select the people whose opinions will be sampled. Not to be confused with "sampling error," which is not a form of bias but instead results naturally when using small numbers of people to estimate the opinions of a larger group.

straw poll Although used to refer generally to a poll with a large but unscientific sample, the main usage in politics applies to surveys conducted among the membership of a political party. Due to the sampling methods of a straw poll, results cannot be generalized to the entire population, but are useful for determining which issues, messages, or candidates can motivate the party faithful.

Public opinion polls are a complex and costly enterprise. Although they have become ubiquitous in contemporary society, polls did not always dominate social discourse in the way they do now. Rather, early polling companies got off to a rocky start, including embarrassing failures when they tried to predict presidential election winners in 1936 and 1948. However, survey practices have been institutionalized in the form of professional polling organizations. Most of these organizations focus on marketing research, and some of the highest profile organizations

generate large quantities of political and social data. Regardless of their prime function, though, polling organizations have helped establish stable survey methods and have also been leaders in the innovation of better methods. The wealth of data produced using modern, scientific polling techniques has become an invaluable resource for both journalists and social scientists.

Market Research Organizations

Market research companies regularly studied public preferences early in the 20th century, decades before academic polling became prevalent. Such marketing organizations exist in large numbers today. They conduct surveys on behalf of clients interested in the kinds of products and advertisements that appeal to consumers. Although product development and consumption patterns sometimes interest social scientists, this is not really the focus here. Multitudes of such organizations do exist around the world, and many of these businesses consist of little more than small operations squared away in tiny shopping-mall offices, grabbing respondents from among the pedestrians passing before their storefront.

Marketing research, however, has played an important role in the development of polling, beyond its function of probing consumption patterns. The early marketing firms that survived by helping clients increase sales held a significant stake in getting the answers right. The profit motive encouraged marketers to develop sophisticated and successful polling techniques. Eventually, their methods trickled down to other forms of social research, often because individual pollsters carried their expertise from the commercial world to academia, to research institutes, or to specialized polling firms. George Gallup, who would later become perhaps the most widely recognized pollster, got his start performing market research for the *St. Louis Post-Dispatch*, conducting interviews with subscribers to inquire about the columns they liked to read.

Before Gallup began conducting survey research on public issues, political polling consisted almost entirely of election forecasting conducted by marketers. Marketing organizations used political polls as a form of publicity. They would project election results as a high-profile way of showing off their techniques. For example, market research analyst Archibald Crossley established Crossley Incorporated in 1926. This organization, though predominantly involved in commercial survey research for private corporations, nonetheless regularly issued election projections. Crossley's ability to predict the correct outcomes, at times more accurately than Gallup or Elmo Roper, demonstrated that market-research firms could conduct political polls validly. The effects of Crossley's work are still seen today, in that many political actors and organizations still use marketing firms for much of their consulting needs.

Early Techniques for Measuring Public Opinion

Before the birth of the modern poll, public opinion research was labor intensive, time consuming, costly, and often inaccurate. The most common techniques for measuring public opinion were various types of "straw" polls. The purpose of these polls was to determine how citizens would vote in upcoming elections. The polls (votes) were taken in various gatherings, from meetings called specifically to gauge voter intentions to meetings of militia or political parties. To get a sense of the overall public opinion in any election, those interested this information would need to conduct straw polls regularly, during a variety of different public meetings. The effort required a great deal of time and manpower. Due to the extreme time requirements and labor constraints, straw polls seldom produced meaningful results; their samples were not representative of the electorate and the methodology for conducting this research was inconsistent.

Literary Digest, an influential periodical, developed the most famous political poll of the early 20th century. The magazine's methods initially seemed very accurate, primarily because it collected a massive sample that dwarfed the numbers found in straw polls. *Literary Digest* sent out tens of millions of questionnaires to people all over the United States. The surveys were mailed to people whose names appeared on automobile and telephone registration lists. As long as political behavior did not correlate strongly with access to cars or telephones, the method worked. Indeed, using these techniques, the *Literary Digest* poll correctly predicted the winner of every presidential election from 1916 to 1932. The New Deal political realignment after 1932 changed party politics, however. By 1936, Republicans were notably more likely than Democrats to own luxuries such as telephones or cars, so the magazine's days as a preeminent election prognosticator were numbered.

Rise of the Representative Sample

Survey specialists had criticized the *Literary Digest* poll before 1936. Informed social scientists and market research analysts recognized the methodological problems with the sampling methods used in the poll. Among these critics were George Gallup, Elmo Roper, and Archibald Crossley, all of whom instigated scientific opinion polls in 1936 to demonstrate the flaws of the famous *Literary Digest* effort. Gallup in particular strongly believed that

the use of sophisticated, scientific polling techniques would lead to a more-accurate portrayal of electoral preferences. During his time at the University of Iowa, Gallup conducted careful research on the attributes that helped department store sales representatives achieve success. His doctoral dissertation looked at the reading habits of newspaper subscribers, using a sample of approximately 1000 consumers. In this dissertation, the approach followed, eventually known as the "Gallup method," was in essence the same set of techniques that Gallup would employ when he began political polling.

In 1935, Gallup and Harry Anderson founded the American Institute of Public Opinion (AIPO) with the purpose of accurately determining public opinion by the use of representative sampling. Gallup incorporated the technique of quota sampling, common to market researchers, into his methods for political polling. Gallup and Anderson selected participants proportionally based on demographic information about the population. Each interviewer would receive particular quotas when identifying respondents: a certain balance of men and women, a certain balance of employed and unemployed, etc. This technique ensured demographic representativeness, but it did not ensure accurate social measurement, in part because it allowed interviewers wide discretion in identifying the respondents who appeared in the sample. Nevertheless, the 1936 election showed both the capability of these methods—even when used to collect modest samples—and the inadequacy of large but unrepresentative samples. *The Literary Digest* returned with its massive polling apparatus that year, using the same automobile and telephone registration lists that it had used in previous elections. The poll predicted that Republican candidate Alfred Landon would defeat Democratic candidate Franklin D. Roosevelt (FDR) by almost 20% of the vote. Of course, FDR went on to win more than 60% of the popular vote, which translated into 523 Electoral College votes. His victory dealt an immediate deathblow to the *Literary Digest* poll.

Scientific opinion polls proved more accurate in 1936, despite their much smaller samples. Gallup not only forecast FDR's victory over Landon, for example, he predicted that *The Literary Digest* would incorrectly predict the outcome. Gallup knew that *The Literary Digest* would make the wrong prediction due to sampling bias. The Gallup group found that higher income voters were more likely to support Landon, whereas lower income voters favored Roosevelt. The names on the automobile registration and telephone owner lists were those of wealthier and more conservative people than represented the population as a whole. This meant that the magazine's sample would not be representative even though it included over 2 million respondents. Although Gallup correctly forecasted the winner of the election, his prediction still missed the vote totals by approximately 7%. Some have attributed this error to the imperfections of the quota sampling techniques employed by Gallup at the time, requiring the sample of respondents to mirror the demographic distribution of the entire population. This method led to selection biases on the part of those conducting the surveys.

Gallup and Roper became famous for their ability to create polls that were representative of the population. Gallup also became an important voice in the debate over public opinion polls. In a 1940 book, *The Pulse of Democracy*, Gallup and Saul Rae asserted that the desire to measure public opinion on political issues was motivated by a drive to improve American democracy. In particular, they argued that representative samples would empower politicians, making them "better able to represent" than they had previously. Polls would replace "the kind of distorted picture sent to them by telegram enthusiasts and overzealous pressure groups who claim to speak for all the people, but actually speak for themselves." Public opinion research was promoted as vital to the health of a democratic political system, reforming a political system dominated by special interests by providing a stronger voice for "the people." Political polling would send public officials information directly from the voters so that the data would not have to be mediated through interest groups. Elected officials hearing the results of these polls would know that catering to special interests could cost them their political careers. However, just as the election of 1936 gave Gallup and his methods instant credibility, the close election of 1948 constituted a major setback to public perceptions of polling companies. Gallup and other pollsters, using the same quota sampling methods they had used in previous elections, predicted that Republican Thomas Dewey would defeat incumbent President Harry Truman. Though Gallup's predictions for 1948 actually were more accurate than the 1936 poll predictions in terms of each candidate's percentage of the vote, he forecast the wrong winner. The public image of polling companies fell as a result of this embarrassment. Gallup, Louis Harris, and Burns Roper would continue to conduct polls after 1948, hoping to regain public faith in their research methods, but their image did not recover for several years.

Modern Polling Organizations: Faith in Public Opinion Rebounds

During the 1950s and 1960s, Louis Harris conducted private polls for over 240 political campaigns. Harris served as a pollster for President John F. Kennedy, conducting numerous surveys for the administration about policy preferences and presidential approval ratings. The widespread use of polls by high-profile and

successful clients helped gain enough media attention to restore some of the public confidence in the industry. It became clear that pollsters could accurately gauge public opinion using scientific polling methods; some observers therefore consider the 1950s and early 1960s the modern era of political polling.

The polling companies that were founded by Gallup, Roper, and Harris began a period of enormous growth. These pollsters became common staples in political campaigns and in the daily routines of elected officials. Their survey agencies sold increasing numbers of reports to governmental actors, private corporations, and media organizations. They stepped up their polling on the hot political issues of the day, as well as on the public approval of the president. They also continued their tradition of accurate election forecasting. The overall enterprises are now massive indeed. Today, for example, the Gallup Organization conducts countless surveys every week, serving both the market research and political polling segments of the industry. Gallup gauges public opinion on various issues of the day, from controversial Supreme Court cases, to public sentiments on international wars and crises, to how Americans feel about the job performance of the president.

Eventually, numerous rivals joined Gallup, Harris, and Roper in the industry; prestigious examples include the Chilton Research Associates, the Princeton Survey Research Associates, the Pew Research Center, Yankelovich Partners Inc., and Rasmussen Research Group (now called Portrait of America). These companies generally receive less attention than the big three receive, but they play an equally important role in social measurement because their lower profile allows flexibility in techniques or question wording. For example, Rasmussen has experimented with ideological measurement that is more complex than the simple liberal/conservative scales customarily used in political polls. Such innovative poll results can receive significant news coverage.

In addition to the independent polling organizations, there are also numerous archives of public opinion data. These archives have made public opinion data widely available and are important sources for scholars and researchers alike. Among the largest and most frequented archives are the Roper Center for Public Opinion Research (located at the University of Connecticut), the Interuniversity Consortium for Political and Social Research (located at the University of Michigan), and the Odum Institute for Research in Social Science and the Louis Harris Archive (both located at the University of North Carolina at Chapel Hill). These smaller level polling companies also play a critical social role because they produce or develop services that otherwise would be unavailable to politicians and private industry. For example, government bodies such as the U.S. Department of Education hire lower level polling companies to conduct accurate surveys on behalf of the public. Other companies sell software and equipment that allow politicians, political parties, and campaigns to conduct "dial groups." This polling method allows political actors to gauge responses and opinions toward different aspects of speeches, debates, or advertisements while the event is still going on. In coming years, presidents may choose to use this technology to monitor responses of voters to portions of the State of the Union address, or candidates for political office may use dial groups to see what parts of a political speech or political debate particularly resonated with their audiences.

Not all of the competitors to Gallup, Roper, and Harris developed as for-profit polling companies. Government agencies, nonprofit organizations, and public-interest media outlets also started conducting important social research using opinion polls. For example, groups of news organizations and media outlets have teamed up to form major polling alliances. Some of the more well-known polling alliances are between television networks, newspapers or newsmagazines, and pollsters: ABC/*Washington Post*, CBS/*New York Times*, NBC/*Wall Street Journal*, *Time*/CNN, *USA Today*/CNN/Gallup, and Gallup/*Newsweek*. These alliances provide journalists greater direct input on the sampling methods used in polls, as well as allowing them relatively quick access to the data, but still allow individual organizations to share costs with others. Cheaper polls permit the news organizations to conduct large surveys more frequently. Their efforts have greatly expanded the overall body of social statistics available to analysts.

Large polling organizations are associated with academic institutions. Among these types of organizations are the National Opinion Research Center (NORC), associated with the University of Chicago, and the Survey Research Center (SRC), associated with the University of Michigan. NORC's clients include governmental departments and agencies, nonprofit organizations, and private corporations. *U.S. News and World Reports* commissions NORC to conduct some of the polls necessary for their various national rankings, such as their ranking of "America's Best Hospitals." The Survey Research Center has been conducting social science research for over 50 years and has been commissioned to conduct countless studies of public attitudes, beliefs, and values, including some of the seminal works on voting behavior.

Organizations do not necessarily need to gauge public opinion to be considered a polling company. The Nielsen Media Research organization provides valuable information about television audiences and viewers based on research conducted in every major television market in the United States. A "box" attached to a television set records each program that a household watches, as well as any changing of channels that occurs. The box also monitors which individuals in a household are viewing each program by allowing them to "log in" on a special remote

control. The resulting data, detailing which kinds of people are watching which television programs, allow both private companies and political actors to target specific audiences with advertisements. For example, corporations may wish to aim their ads at consumers who are most likely to purchase a given product, so they will select programs with a large audience among the target group. Political campaigns similarly target their ads at particular constituencies, such as swing voters or particular voting blocs likely to respond to a political message. The "Nielsen ratings," which report the overall size of each program's viewership, influence how much stations charge to air either corporate or campaign advertising.

Conclusion: The Future of Polling Organizations

A vast majority of polling resources are spent on consumer research. In fact, approximately 95% of all polling is conducted on market research. Nevertheless, the most widely publicized polls are still those conducted about political issues and figures. Polling information is almost seamlessly infused into daily news coverage and the national discourse on heated issues.

As technology has improved over time, the methods employed by pollsters and polling companies have changed. Early mail-in surveys gave way to face-to-face polling, which has yielded to telephone surveys. Within the modern era of random-digit-dialing (RDD) techniques, telephone polls dominate among the polling organizations. The methods have improved with time. Current polling companies have access to enormous telephone databases and statistical packages that allow those conducting the surveys to generate a random sample for the entire country (or any segment of the entire population), and analysis of the resulting data is easily done. Some polling companies use a new wave of computer techniques in collecting their telephone surveys. Computer-assisted telephone interviewing (CATI) and completely automated telephone surveying (CATS), relatively new innovations in telephone polling, facilitate the process of collecting public opinion data. With CATI, telephone numbers are generated randomly and are dialed by a computer that also displays the questionnaire on a computer screen for the interviewer. Questions may be randomly assigned to some respondents but not to others, and answers may appear in a random order so that respondents are not systematically influenced by where any one answer appears in a list. The CATI system then allows an interviewer to enter responses directly into a database, reducing the risk of human error during the data manipulation stage. With CATS, respondents interact with an automated voice that administers the entire survey. Neither technique is used universally, but both have become more common. In the coming years, technological advances will continue to shape the way that pollsters gauge public opinion on political issues and consumer interests.

Though polling methods have evolved as technology has improved, the pursuits to obtain a representative sample and an accurate reflection of the population have remained the same. Some popular polling methods, however, may not be so scientific. Internet polls are inexpensive and convenient to conduct, but respondents decide whether to participate (or, for that matter, whether to use the Internet). This selection process increases the risk of biased data; responses gathered in such a fashion cannot be generalized to the entire population. However, some scholars believe that the next technological innovation in the polling industry will be the advent of representative sampling methods for Internet surveys. For example, George Terhanian, the director of Internet Research at Harris Block, argues that Web-based polling eventually will be able to predict election results accurately. One company has already found ways to overcome some of the problems associated with Internet-based polling. Knowledge Networks is a market research company conducts surveys by using the Internet. Knowledge Networks has provided Internet access to a random sample of Americans who agree to participate in surveys. This Internet polling has been used in traditional market research as well as in public opinion polling. Knowledge Networks was commissioned to conduct polling during George W. Bush's 2003 State of the Union address, as well as polling to predict the outcome of the Gray Davis/Arnold Schwarzennegger 2003 California recall election. This kind of polling avoids the pitfalls typically associated with Internet polls and may represent a new direction in future polling endeavors.

Population vs. Sample

John A. Grummel
West Virginia State University, Institute, West Virginia, USA

Glossary

accessible population The population that is actually accessible to the researcher. It may not be possible for a researcher to draw a sample from everyone (or everything) in the theoretical population because there may not be a complete listing of all the cases. The list of the population from which a sample is actually drawn is the accessible population. The accessible population does not have to be different from the theoretical population.

population The entire group of individuals, places, or other objects such as voters, organizations, political parties, and cities that conform to a set of specifications that a researcher wishes to study. Populations can be distinguished between the accessible population and the theoretical population.

population parameter A value, usually a numerical value that describes a population. Examples of population parameters include the mean, range, and standard deviation.

sample A set of individuals, geographical areas, or other objects selected from a population intended to represent the population in the study.

sampling error The discrepancy, or amount of error that exists between a sample statistic and the corresponding population parameter. If a sample is the same as a population there is no sampling error. The larger the sample the more closely the sample reflects the population of interest and as such the smaller the amount of error. Smaller samples are less like to mirror the larger population and the sampling error will be larger.

sampling frame The population from which the sample is actually drawn is known as the sampling frame. The sampling frame is a list of all known cases in a population. For example, the sampling frame for all residents in Los Angeles could be the Los Angeles phone book.

sample statistic A value, usually numerical, that describes characteristics of a sample such as the mean and standard deviation.

theoretical population The population about which one wants to make generalizations. The theoretical population includes all cases of the population of interest. The theoretical population may differ from the accessible population because all the possible cases might not be known or accessible to the researcher.

Determining whether to study a population or to study a sample from a particular population is usually not a difficult decision due to practical concerns such as costs in time and money. If it is impractical to study a population, there are certain problems that should be taken into account when studying a sample. The following are descriptions of populations and samples and their use in the social sciences. Also included is a discussion of why samples are studied more often than populations, as well as a general description of sampling, and concerns researchers should take into account when studying samples of larger populations.

One of the main points of research is to make inferences about events, people, nations, organizations, etc., in the population. By analyzing the results from a sample, for example, researchers hope to make general statements about the population, whatever the population under consideration. It would not be research, for example, if you tested three particular motorcycles to see which gets better gas mileage—unless you hoped to say something about the gas mileage of those models of motorcycles in general. In other words, a researcher might do an experiment on the effect of a particular method of teaching sociology using 50 students as participants in the experiment.

The purpose of the experiment would not be to find out how those particular 50 students respond to the experimental condition but rather to discover something about what works best in general when teaching sociology. The strategy and underlying logic of inference in almost all social and behavioral science research is to study a sample

that is believed to be representative of the general population (or of some particular population of interest). The sample is what is studied, and the population is an unknown that researchers draw conclusions about on the basis of the sample.

Definition of Terms

Broadly understood, a *population* is the entire group of individuals, objects, or cases, such as states, school districts, and parties) that a researcher wishes to study. By entire group, it is literally meant every single case. More specifically, a population is defined by Chein as the "aggregate of all cases that conform to some set of specifications." For example, by the specifications "pupils" and "attending public high school in the United States," the population would be defined as all pupils attending public high school in the United States. It is the population about which researchers wish to generalize. A researcher might desire to investigate the attitudes of public high school pupils concerning the quality of their educational environment.

One can distinguish between two types of populations: *theoretical* and *accessible*. The population that one desires to make generalizations about is known as the theoretical population. The theoretical population may also be referred to as the target or study population. Given the above example, all pupils attending public high schools in the United States would be the theoretical population. The accessible population is the population that is in fact accessible to the researcher. The accessible and theoretical populations are not always the same. Using the above theoretical population example of all pupils attending public high school in the United States there might not be, for whatever reason (i.e., reporting problems), a complete listing of all the pupils attending public high school in the United states. The available list would be the accessible population.

The size of any given population being considered depends on how the investigator defines the theoretical population. If the population is defined as all pupils attending public high schools in the United States this would be a large population, whereas defining the population as all pupils attending high school in a sparsely populated county would be a much smaller population. Examples of other large populations could include studying all the women on the planet, all the registered Republicans in the United States, or just married men in major cities, such as St. Louis, Chicago, New York, or Los Angeles. One might desire to be more specific, limiting the size of the population. For example, only married men who are registered voters in the United States (a smaller population) or conservative heads of state (an even smaller population) might be investigated. Furthermore, the specific nature of the population of interest depends on the research question and phenomenon being studied. For example, if the researcher decided to study only female pupils and their attitudes toward their educational experience, the population would be defined as all female pupils attending public high schools in the United States. These examples indicate that populations can vary in size from extremely large to very small.

It is quite important that the researcher identify the theoretical population that is being studied. If the theoretical population is not adequately defined or identified, any discussion of the misidentified population might be inaccurate. As noted earlier, populations are the aggregation of all cases conforming to set of specifications or specified elements. For example, specifications could refer to "people" but it could also refer to things such as businesses, interest groups, community organizations, minority businesses, corporations, political parties, parts produced in a factory, or anything else an investigator desires to study. Specifications could also refer to people or things in a particular geographic location, such as Canada or New York.

Once the accessible population is clearly defined, the researcher lists the members of the accessible population. For example, if the researcher is studying voting behavior, the members of the accessible population might be eligible voters within a particular geographic area as listed with the voter registrar's office. The accessible population becomes the sampling frame, the population from which the sample is drawn. All the elements—sets of specifications—that are part of the population of interest to the research question should be part of the sampling frame. The specifications could refer to individuals but it could also refer to objects or organizations such as businesses, interest groups, community organizations, minority businesses, corporations, political parties, parts produced in a factory, or anything else an investigator desires to study. If the elements are not included, any data collected for the sample might not be representative of the population being considered.

It is important to note that sampling is not always necessary, for example, if all the units in the population are identical. In some cases, for example, for smaller theoretical populations, it may even be possible to conduct a census as the United States does every 10 years. For a discussion of the debate regarding sampling and the census see Fienberg, Anderson and Fienberg, and; Brunell, as well as the additional readings listed in Further Reading. In social science research, however, this is not normally the case because of the immense cost and time that is often involved.

Since it is often impractical to study populations given limits of such things as time and money, typically researchers study samples of individuals in order to make inferences about populations. A sample differs

from a population in that a sample is a set of individuals (or things) selected from a population that is intended to represent the theoretical population being studied. It is important to note that a sample is the group of people or things that are selected to be in the study, not the group of people or things that are actually in the study. For example, all the individuals chosen to be in a study, for one reason or another, might not be able to participate. Researchers should always identify the sample in terms of the accessible population from which it was selected. Ideally, the sample is selected from a population using a strictly random procedure. A description of the random sampling procedure and issues of sampling are addressed below.

Like populations, samples can vary greatly in size. A sample might consist of 50 Mexican women who participate in a particular experiment, whereas the population might be intended to be all Mexican women. In an opinion survey, for example, 1000 individuals might be selected from the voting-age population through random digit dialing and asked for whom they plan to vote. The opinions of these 1000 people are the sample. Depending on the resources, such as money and time, the researcher could use a larger sample—for example, 2000 people. As illustrated below, researchers desire to study the largest sample possible because the larger the sample size the less error associated with the generalizations made concerning the population of interest. A researcher then hopes to apply the findings from the sample of 1000—that is, generalizes—to the larger population.

Statistical Terminology for Populations and Samples

Before discussing why samples are studied rather than populations, it is necessary to distinguish whether the data collected by a researcher is from a population or a sample. Any characteristic of a population is called a population parameter. The mean (arithmetic average of a distribution of scores), range (the difference between the highest and lowest score in a distribution), and standard deviation (reflects how well the mean of a variable represents the central tendency of a population or sample) of a population are examples of what are called population parameters. A population parameter usually is unknown and can only be estimated from what you know about a sample from that population.

A parameter may be obtained from a single measurement, or it may be derived from a set of measurements from the population. A characteristic of a sample is called a sample statistic. Like a population parameter, a sample statistic may be obtained from a single measurement, or it may be derived from a set of measurements from the sample. For example, the average of the scores (the mean) for a sample is a statistic. Another type of sample statistic would be the range of scores for the sample and standard deviation.

Table I Symbolic Representation of Several Population Parameters and Sample Statistics

	Population	*Sample*
Mean	μ	X
Standard deviation	σ	S
Variance	σ^2	s^2

As displayed in Table I, statisticians frequently use different symbols for a population parameter and a sample statistic. By using different symbols one can readily distinguish whether a characteristic, such as an average, is describing a population or a sample.

Why Study Samples Instead of Populations?

The decision whether to collect data for a population or from a sample is usually made on practical grounds. If conclusions are to be drawn about a population, the results would be most accurate if one could study the entire population, rather than a subgroup—a sample—from that population. However, in most research situations this is simply not practical or feasible. Studying an entire population is often too expensive and time consuming. Furthermore, some studies do not lend themselves to sampling, such as case studies. More importantly, one of the main points of research is to be able to make generalizations or predictions about events beyond our reach.

Sampling Concerns

There are a number of problems associated with using samples. Before proceeding with the problems, however, it is important to discuss the idea of random sampling. The objective of random sampling is to select a particular number of units from the sampling frame such that each case has an equal chance of being selected. Examples of procedures to achieve this objective include the use of a table of random numbers, a computer random-number generator, flipping a coin, or a mechanical device to select the sample. One problem with using samples, as discussed below, is that a sample provides only limited information about the population. There is always some degree of error associated with the information acquired from samples. Although samples are often representative of their populations, sometimes they are not. A sample is not

expected to give a perfectly accurate picture of the whole population.

A sample statistic (for example the mean) obtained from a sample generally will not be identical to the corresponding population parameter (population mean). There usually is some discrepancy between a sample statistic and the corresponding population parameter. This discrepancy is called *sampling error*. Sampling error, or margin of error, is the discrepancy, or amount of error that exists between a sample statistic and the corresponding population parameter. It gives the researcher some idea of the precision of the statistical estimates. There are two factors that reduce sampling error: sample size and variability. In other words, the less variability in the population or the larger the sample size, the lower the amount of error or discrepancy between the sample statistics and the actual population parameters.

It is essential that any sample is as representative as possible. A representative sample is a sample that looks like the population from which it was selected in all respects that are potentially relevant to the study. The distribution of characteristics among the elements of the representative sample is the same as the distribution of those elements among the total population. In an unrepresentative sample, some characteristics are over- or underrepresented. The researcher needs to be certain whether the sample is representative of the population being studied. If not, the study may not be externally valid. External validity refers to the degree a researcher, based on a sample, can make generalizations about the population of interest as well as other cases and at different times.

There are other problems associated with using samples. For example, to estimate unknown population parameters accurately from known sample statistics, three major problems must be dealt with effectively: the definition of the population, the sample design, and the size of the sample. The importance of defining the population was discussed above. To reiterate, if the population is poorly defined, errors in sampling can occur. If a researcher does not take care to properly define the population, the sampling frame will be inaccurate, and consequently the sample might be unrepresentative of the population the researcher actually desires to study. Thus, the accuracy of a sample depends on the sampling frame, and if the sampling frame is incomplete or inappropriate, sample bias will occur. In such cases, the sample will be unrepresentative of the population and inaccurate conclusions about the population may be drawn. Potential problems in sampling frames include incomplete frames, cluster of elements, and blank foreign elements. The problem of incomplete frames occurs when sampling units (a single member of a sampling population) included in the population are missing from the sampling frame. A detailed example is provided below. The problem of cluster of elements occurs when sampling units are listed in clusters rather than individually. For example, the sample frame of a particular study might include census blocks, whereas the study focuses on individuals and heads of household. A possible solution to such a problem would be to take a sample of blocks and then to list all the individual households in the selected blocks. The problem of blank foreign elements occurs when sampling units of the sampling frame are not part of the target population. The problem of blank foreign elements is illustrated by the following example. The population is defined as eligible voters but the sampling frame contains individuals who are too young or ineligible to vote.

An example of a well-known error in sampling frames, in this case incomplete frames that led to an extremely erroneous conclusion was the 1936 *Literary Digest* election poll. In 1936, Franklin Delano Roosevelt was running against Republican candidate Alfred Landon. In the poll, the largest in history (2.4 million individuals), *Literary Digest* predicted a victory for Landon by 57% to 43%. Despite this prediction, Roosevelt won by 62% to 38%. Despite the large sample size, the error was the largest ever made by a polling organization. The reason for the error was in the sampling frame. Questionnaires were mailed to 10 million people based on lists compiled from such things as telephone directories and club memberships. In 1936, few people had telephones and even fewer belonged to clubs. The sampling frame was incomplete and systematically excluded the poor and as such the sampling frame did not accurately reflect the voting population.

The second problem concerns sample designs and arises in connection with securing a representative sample. As noted above, an essential requirement of any sample is that it be as representative as possible of the population from which it was drawn. In sampling theory, a distinction is made between probability and nonprobability sampling. For a more in-depth discussion of these topics, see Carroll, Galloway, Glasgow, Handwerker, Harter, and Wright (this volume).

Probability sampling is one that can specify for each sampling unit of the population the probability that it will be included in the sample. In nonprobability sampling there is no way of specifying the probability of each unit's inclusion in the sample and includes such designs as convenience sampling, purposive sampling, "snowball" sampling, and quota samples. Although accurate estimates can only be made with probability samples, social scientists do employ nonprobability samples. Examples of research using nonprobability samples include the use of college students in psychological and public opinion studies by professors because of the convenience.

Probability sample involves some form of random sampling and, in most cases, is the ideal method of picking

a sample to study. Random selection, or random sampling, is a process for obtaining a sample from a population that requires that every individual in the population have the same chance of being selected for the sample. A sample obtained by random selection is called a random sample. Examples of random sampling include stratified random sampling, systemic random sampling, cluster random sampling, and multistage random sampling.

It is important not to confuse truly random selection from what might be called haphazard selection, such as just choosing whoever is available or happens to be first on the list—convenience sampling. It is quite easy to accidentally pick a group of people to study that is really quite different from the population as a whole. Unfortunately, it is often impossible to study a truly random sample. There are a number of possible problems. One problem is that there is usually not a complete list of the full population (although telephone directories come close). A second possible problem is that not everyone a researcher approaches agrees to participate in the study (telephone surveys, for example, are often biased against the wealthy and educated, who are away from home more and use answering machines to screen calls). Another potential problem is the cost and difficulty of tracking down people who live in remote areas to participate in the study. For these and other reasons as well, social and behavioral scientists often use various approximations to truly random samples.

The third problem concerns sample size. (For an in-depth discussion on sample size see Suchindram, this volume.) As noted above, there is usually some discrepancy between a sample statistic and the corresponding population parameter and that this discrepancy is known as sampling error. The following example is intended to illustrate how sample size may reduce or increase the amount of error, which has an impact on the level of confidence a researcher has in the conclusions he or she makes regarding a particular population. The equation for sampling error is

$$s = \sqrt{\frac{P \times Q}{n}}$$

The symbols P and Q equal the population parameters for the binomial, n equals the number of cases in the sample, and s is the standard error. To illustrate, assume that 70% of a college student body is in favor of ending affirmative action and 30% disapprove. Also, assume that the researcher is working with a sample of 100 students with 60% of the sample in favor (P) and 40% of the sample against (Q) ending affirmative action. Before proceeding, it is important to understand that the standard error is a valuable piece of information concerning how tightly estimates will be distributed around the actual population estimates (in this case support for ending affirmative action). According to probability theory, certain proportions of the sample respondents will fall within 66% of the mean, which are equal to plus or minus one standard error, from the true population mean. Furthermore, probability theory dictates that 95% of a sample will fall within plus or minus two standard errors of the true population mean and 99% will fall within plus or minus three standard errors of the actual population mean. When these numbers are entered into the equation, the standard error is 0.05, or about 5%. Based on the above discussion, with a sample of one hundred, if the researcher wants a 95% confidence level (plus or minus two standard error) the estimates will be plus or minus 10% of the actual value. If the sample size is increased to 200, the standard error is .035 or 3.5%, and the sample estimates will fall within plus or minus 7% of the true value. If the sample size is increased even more, say 500 the amount of error is even lower: 0.2, or 2%, indicating that the estimates are within plus or minus 4% of the actual population parameter. This example demonstrates that the greater the sample size, the lower the amount error and the greater the confidence a researcher will have in the conclusions he or she can make based on a given sample.

Conclusion

If possible, it is always better to study the entire population, but this is often simply impractical due to excessive cost, both in terms of time and money. It is for this reason that samples are often studied, and as outlined above, researchers need to take into consideration a number of potential problems when studying a sample from a given population. When researchers take into account the possible problems that can occur when studying samples, they can be almost as confident of their findings as if they had studied the entire population.

Prevalence and Incidence

Stephen W. Marshall
University of North Carolina at Chapel Hill, Chapel Hill, North Carolina, USA

Glossary

case fatality rate The proportion of outcome-positive individuals that die.
closed population A population in which there is no migration or loss to follow-up.
competing risk (competing causes of death) The risk of death from causes other than the outcome of interest.
current case A person who is outcome-positive.
follow-up Monitoring a population (or subset of a population) to determine incidence.
incidence The occurrence of new outcome-positive cases in a population, quantified either in units of person-time at risk (incidence rate) or people at risk (incidence proportion).
incidence proportion (cumulative incidence) The proportion of the population that becomes outcome-positive over a defined period of time.
incidence rate (incidence density) The number of new cases divided by person-time at risk.
new case A person who has just become outcome-positive.
observation period (monitoring period) The period of time over which a population (or subset of a population) is followed to determine incidence.
outcome The disease or other ill-health condition of interest.
person-time at risk The sum of individual at-risk periods in a group of individuals.
prevalence The proportion of a population that is outcome-positive at a specific point in time.
prevalence pool The subset of a population that is outcome-positive at a specific point in time.
steady state When the flow of subjects into the population is exactly equal to the flow of subjects out of the population, and determinants of prevalence and incidence are static.

Prevalence and incidence are fundamental concepts that underlie the measurement of health outcomes in human populations. These concepts, although simple, are frequently misunderstood, even to the point where the terms prevalence and incidence are sometimes used interchangeably. Formally, prevalence is the proportion of a population that is outcome-positive (has the outcome of interest) at a specific point in time. Simply put, prevalence is the proportion of current cases in a population; a "current case" is a person who is outcome-positive at that point in time. Prevalence quantifies the status of the population with respect to the outcome of interest at a given point in time. It does not, however, express anything about how frequently new cases occur in the population. Incidence, on the other hand, measures the occurrence of new outcome-positive cases in the population. Two measures of incidence are of interest: incidence rate (or incidence density) is the number of new cases per unit of person-time at risk, whereas the incidence proportion (cumulative incidence) refers to the proportion of the population that becomes outcome-positive over a defined time interval. Prevalence and incidence proportion are proportions, but incidence rate is measured in units of inverse time.

Overview of Main Concepts

Introduction to Prevalence

Prevalence of disease quantifies the disease status of a population at a given point in time. Prevalence measurement addresses the question concerning what proportion of the population currently has the outcome of interest. People who are currently outcome-positive are often referred to as the pool of prevalent cases, or the prevalence pool. In Fig. 1, the pool of prevalent cases within a population at a given point in time is represented by

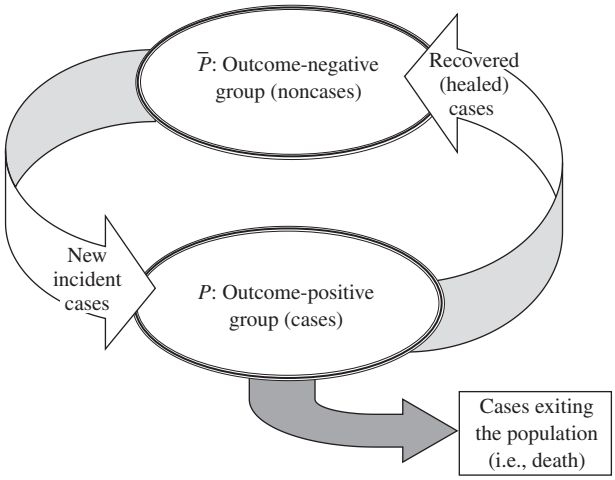

Figure 1 Relationship between prevalence and incidence in a closed population, $N = P + \bar{P}$. The group of people who are outcome-positive (lower circle) are prevalent cases. This "prevalence pool" is fed by incident (new) cases (left arrow). Cases exit the prevalence pool when they recover (right arrow) or die (lower arrow).

the lower circle (outcome-positive group, or cases). This is the prevalence pool. The upper circle represents the remainder of the population, cases that are outcome-negative at the same point in time. The two circles are a mutually exhaustive and exclusive partition of the population. The total population, N, equals $P + \bar{P}$. To quantify prevalence, it is necessary to sample from the whole population, and determine what proportion is outcome-positive. In essence, this amounts to determining the relative size of the two circles in Fig. 1. As people recover from illness, they return to the outcome-negative pool, at which time they are presumably again eligible to develop the outcome condition (e.g., reinfection); however, for some outcomes, reinfection is unlikely or impossible. People who do not recover die and exit the population.

Introduction to Incidence

Incidence quantifies the occurrence of new outcome-positive cases, i.e., how rapidly new cases are added to the prevalence pool. Measurement of the incidence of health outcomes in a population is an important aspect of documenting the burden due to various diseases and other sources of ill health. To measure incidence requires first identifying a group of outcome-negative people, and then prospectively following them over time to identify how many of them develop the outcome. In Fig. 1, incidence is the rate at which people flow along the left-hand arrow from the outcome-negative pool (top circle) to the prevalence pool (bottom circle). Whereas prevalence is measured at a single point in time, measurement of incidence involves prospectively following people over time to quantify the rate of conversion from the outcome-negative state to the outcome-positive state.

Can Prevalence Be Low When Incidence Is High (and Vice Versa)?

The answer is yes. The relationship between prevalence and incidence involves the duration of the outcome condition (the disease). If the disease duration is short, say, due to an extremely lethal virus, the prevalence pool will remain small, even if the incidence is high. If the disease is due to a virus such as Epstein–Barr virus, which causes infections from which people apparently never recover, but which is rarely directly lethal, then the prevalence pool can be large, even if the incidence is quite low.

Initial versus Recurrent Events

Recurrent events occur whenever an individual experiences multiple distinct episodes of the same outcome. For some conditions and/or individuals, the fact that they were outcome-positive once makes them unable to return to their original state, e.g., reinfection following the primary infection is very rare for some diseases. One approach to the problem of reinfections is to focus on determining only the incidence and/or prevalence of initial infections (i.e., first infections). Thus, episodes of reinfection would be excluded. In practice, it may be difficult or impossible to eliminate reinfection cases.

Measurement Concepts

Measurement of prevalence and incidence should utilize two types of statistical estimator: a point estimate (e.g., 35%, or 25 per 100,000 person-years) and an interval estimate, or confidence interval (e.g., 33–37%, or 22–28 per 100,000 person-years). Use of the 95% confidence interval (95% CI) is traditional. The purpose of the interval estimator is to quantify the precision of the point estimate, and it is a function of the sample size and the variability of the outcome in the population. In general, it is considered desirable to have a point estimator that is unbiased in expectation and an interval estimator with optimal coverage. Ratio, or difference, effect-measures can be computed by dividing, or subtracting, prevalence or incidence measures for subgroups within the population and, under certain conditions, these effect-measures permit inference concerning causal effects.

What Is Prevalence?

Definition of Prevalence

Prevalence is the proportion of the population that is outcome-positive at a given point in time. It measures

the current overall outcome-positive status of the population, whereas incidence reflects the pace of arrival of new cases. Prevalence is determined by the size of the population and the number of outcome-positive cases. Prevalence is sometimes referred as the prevalence rate, but prevalence is actually a proportion. It can never be less than zero or greater than one. It is often expressed as a percentage, e.g., "68% of the population tested positive for Epstein–Barr virus." Sometimes, the count of the number of prevalent cases is defined to be the prevalence (rather than the proportion).

Measurement of Prevalence

A common method of measuring prevalence is to conduct a one-time cross-sectional survey. Such a survey might simply involve a self-administered or interview-administered questionnaire, or a clinical test for the outcome. In some settings, it is practical to survey the whole population (to conduct a census). In most situations, however, some form of sampling is required for logistical reasons. A rich class of statistical designs for such surveys is available. Designs include simple random sampling, systematic sampling, stratified sampling, and cluster sampling. The common features of all these designs is complete (or nearly complete) enumeration of the population of interest, followed by a probabilistic sampling so that each member of the population has a known and defined probability of selection into the sample. These defined probabilities of selection can be used to make inferences about the whole population, based on the sample. In the simplest situation, a simple random sample in which all members of the population have equal probability of selection, the population prevalence is directly estimated by the sample prevalence P, defined as

$$P = \frac{y}{n}, \tag{1}$$

where y is the number of outcome-positive cases in the sample and n is the sample size. The standard error (SE) of the sample prevalence in a simple random sample is estimated by

$$\mathrm{SE}[P] = \sqrt{\frac{P(1-P)}{n}}, \tag{2}$$

and a 95% confidence interval can be estimated as

$$P \pm 1.96 \cdot SE[P]. \tag{3}$$

Prevalence Example

Joel M. Clingenpeel and S. W. Marshall, physicians concerned about head injuries, sought to quantify the prevalence of helmet rentals in U.S. ski areas. The study population (the sample frame) was enumerated on the basis of a listing of all U.S. ski areas. Hypothesizing strong regional variations in prevalence, a stratified sample was drawn to ensure that adequate numbers of ski areas would be sampled in each geographic region. In analysis, each respondent ski area was weighted by the inverse probability of selection, accounting for the stratification. The overall prevalence of helmet rentals at U.S. ski resorts in 2003 was 50.5% (95% CI: 48.2 : 52.7).

What Is Incidence?

Definition and Measurement of Incidence

Incidence quantifies the occurrence of new outcome-positive cases in the population. Whereas prevalence defines the proportion of the population that comprises current cases, incidence quantifies how quickly new cases arise. To measure incidence requires defining a subset of the population that is outcome-negative, and then prospectively monitoring this subgroup to determine how many of them become outcome-positive. This monitoring is commonly referred as to "follow-up." Incidence is defined by the length of time of monitoring, the number of people being monitored, and the number of new cases.

Two measures of incidence are of interest: incidence rate (the number of new cases per unit of person-time at risk) and incidence proportion (the proportion of the population that becomes outcome-positive over a defined time interval). These two measures both use the number of new cases divided by some measure of the population at risk. They differ, however, in how the population at risk is defined. Incidence rate is quantified in units of person-time at risk, whereas incidence proportion is quantified in terms of people at risk. Incidence rate is interpreted as an instantaneous measure, whereas the interpretation of incidence proportion is closer to an intuitive sense of individual risk.

Incidence Rate (Incidence Density)

The incidence rate is the number of new cases divided by person-time at risk. This epidemiologic concept of person-time at risk is a key element in computing incidence rate and it requires some explanation. Person-time at risk accounts for the fact that the length of follow-up may vary from one person to another. For example, once a subject has become outcome-positive, they are removed from the outcome-negative pool and do not contribute person-time at risk to the denominator of the rate calculation while they are outcome-positive. Once a person has recovered from the outcome and has returned to an outcome-negative state, they return to the pool of subjects eligible to sustain the outcome and can again contribute person-time at risk to the denominator of incidence rate

(this assumes, however, that the incidence for those who have a positive history of the outcome is identical to that for those who have no history, which is not true for certain infections). People who do not sustain the event of interest during the monitoring period contribute the full length of monitoring period to the person-time computation (in the language of lifetables and survival analysis, these individuals are referred to as "censored"). There are other reasons why people might cease to contribute person-time at risk during the monitoring period. Sometimes subjects are lost to follow-up for logistical reasons, or they may emigrate from the population. In addition, it is usually impossible to begin follow-up for all members of the outcome-negative pool at exactly the same moment. Finally, people may die during the monitoring period due to an outcome other than the outcome being studied (i.e., due to a competing cause of death). All of these complexities can be readily accommodated through the use of the concept of person-time at risk. The essence of person-time at risk is that each person has an individual amount of time during which they are at risk of becoming outcome-positive. The sum of these individual at-risk periods is the overall person-time at risk. Formally, incidence rate (IR) is estimated as

$$\mathrm{IR} = \frac{a}{\sum_i n_i}, \tag{4}$$

where the subscript i indexes the individual subjects, n_i is the amount of time that each individual was at risk of the outcome, and a is the count of new outcome-positive episodes during the observation period. The incidence rate is also sometimes referred to as the incidence density or the force of mortality (or morbidity, for nonfatal events). Because a is a count, the assumption is that it follows a Poisson distribution, and therefore its variance will equal its mean. Assuming that the person-time at risk is a fixed constant (i.e., does not have a probability distribution), then the standard error of the incidence rate can be estimated as

$$\mathrm{SE}[\mathrm{IR}] = \frac{\sqrt{a}}{\sum_i n_i}, \tag{5}$$

and a 95% confidence interval can be defined as

$$\mathrm{IR} \pm 1.96 \cdot \mathrm{SE}[\mathrm{IR}]. \tag{6}$$

The assumption that person-time at risk is a fixed constant might seem restrictive, but relaxing this assumption appears to have minimal effect in practice. However, Eqs. (5) and (6) invoke certain assumptions regarding study size. For small samples, it is preferable to use exact techniques to estimate the confidence interval. Exact techniques involve computing large numbers of permutations based on the observed data. StatXact is one of several software packages that implement the numerical algorithms required for exact computations.

Equation (5) also assumes that all outcome episodes are independent. If the outcome is transmitted (as in an infection), alternative techniques may need to be employed. If there are multiple outcome episodes per person during the observation period, the variance estimator should be statistically adjusted for this dependence using methods for clustered or correlated data. If the focus is only on the incidence of first episodes, then a is the count of new outcome-positive individuals during the observation period, and Eq. (5) is valid. Because incidence rate is the count of new cases divided by units of person-time at risk, it follows that the units of the incidence are inverse time. For convenience, epidemiologic incidence rates are usually defined in terms of person-years and are multiplied by 100,000 when reporting the rate (e.g., "the rate of cardiovascular mortality was 35 per 100,000 person-years"). However, this is strictly convention, and in theory, any time unit or multiplier can used, provided that they are clearly specified. In fact, the actual numeric portion of incidence rate is meaningless unless the units and multiplier (if any) are clearly specified. Incidence rate is an instantaneous measure, analogous to the concept of speed as defined in physics. Note that speed also has units of inverse time.

As was noted previously, prevalence is a proportion and thus can never be less than zero or greater than one; it will soon become apparent that the same is true of incidence proportion. The incidence rate can also never be less than zero; however, unlike prevalence and incidence proportion, incidence rate has no upper bound, and can range up to infinity. This is consistent with the interpretation of incidence rate as an instantaneous measure. In fact, any incidence rate can be made to exceed one by simply rescaling the time unit. An incidence rate of 500 per 100,000 person-years, for example, is equivalent to 5 per 10 person-centuries and 5 per person-millennia.

The term "annual incidence rate" is in common use, but this term should be avoided. Use of this term masks the fact that incidence rate is an instantaneous measure. The confusion arises from that the fact that an incidence rate can often be readily computed by taking the annual number of new cases in a defined population and dividing this number by the size of the population at risk in the middle of the year. The resulting estimator is the average incidence rate (in units of person-years) for the year being studied. The size of the population at midyear has been multiplied by one to denote an average of 1-year of follow-up per individual. Though this procedure is numerically correct and a very reasonable method for estimating the average incidence rate, the mechanics of this computation have given rise to the unfortunate misperception that the resulting estimate is an "annual incidence rate," and as a result this rate is sometimes reported as being per

100,000 persons, instead of per 100,000 person-years. In fact, this estimator is the average incidence rate for the 1-year period under study, and its units are person-years, not persons. Although the distinction is subtle, this error confuses the correct interpretation of incidence rate.

Because the units of incidence rate are inverse time, the interpretation of the reciprocal of the all-cause mortality rate has a surprising interpretation, under certain conditions, as the average life expectancy of the population. These conditions include that the number of people exiting the population due to death or emigration is identical to the number of people entering the population due to birth or immigration. In practice, this condition is unusual.

Incidence Rate Example 1

David Savitz and Dana Loomis retrospectively constructed a cohort of workers employed in the electric industry to examine exposure to electromagnetic radiation and the incidence of leukemia and brain cancer. The cohort consisted of 138,905 workers who were employed in the industry between January 1, 1950 and December 31, 1988. Workers entered the cohort when they were hired into the industry and exited the cohort when they died. The total number of deaths from all-cause mortality was 20,733, of which 164 deaths were due to leukemia. The 138,905 workers accumulated 2,656,436 person-years of follow-up during the 38-year study period. The mortality rate from leukemia in these workers was therefore 6.2 per 100,000 person-years (95% CI: 5.2, 7.1).

Incidence Rate Example 2

The National Highway Traffic Safety Administration has estimated that the number of deaths from motor vehicle crashes in the United States in 2001 was 42,116. The total resident population of the United States in 2001 was 284,796,887. Thus, the incidence of motor vehicle fatality for 2001 was 14.8 per 100,000 person-years. Another way to express this incidence rate is as deaths per miles driven. During 2001, U.S. residents traveled 2781 billion miles in motor vehicles, with a fatality rate of 1.5 per 100 million vehicle miles traveled.

Incidence Proportion (Cumulative Incidence)

In addition to incidence rate, a widely used alternative measure of incidence is incidence proportion. The incidence proportion (also frequently referred to as cumulative incidence) is the proportion of the population that becomes outcome-positive over a defined time interval. As with incidence rate, the estimation of this measure uses data on the length of time for which the group was monitored, the number of people being monitored, and the number of new cases. The incidence proportion (IP) is estimated as

$$\mathrm{IP} = \frac{a}{m}, \tag{7}$$

where m is the size of the group being monitored at the beginning of the observation period and a is the number of individuals who become outcome-positive during the observation period. The standard error of incidence proportion is estimated as

$$\mathrm{SE}[\mathrm{IP}] = \sqrt{\frac{\mathrm{IP}(1-\mathrm{IP})}{m}}, \tag{8}$$

and a 95% confidence interval can be estimated as

$$\mathrm{IP} \pm 1.96 \cdot \mathrm{SE}[\mathrm{IP}]. \tag{9}$$

Again, exact techniques, such as those implemented in StatXact, should be used when a is small. Because incidence proportion is a proportion, it is bounded by 0 and 1, and has no units.

Two important considerations arise for incidence proportion. First, the length of the observation period must always be specified when reporting incidence proportion. This measure has no valid interpretation unless the observation period is given. Second, this measure does not take account of the attrition in the population due to causes of illness and death other than the outcome being studied. Unlike incidence rate, the denominator of incidence proportion is not adjusted for those who exit the population risk due to emigration or death from other causes (outcomes other than the outcome being studied, also referred to as competing causes). Nevertheless, the measure is important because it has strong intuitive appeal. The proportion of the population that will fall ill over a defined time period is closely related to the concept of risk that is central to demography and epidemiology. Incidence proportion can be thought of as average risk, subject to the absence of competing risks.

One frequent use of incidence proportion is to quantify the so-called case fatality rate, which is the proportion of outcome-positive individuals who die. Note that the case fatality rate is a proportion, not a rate. In terms of recurrent episodes of the outcome per individual, typically only the initial episodes are used in computing incidence proportion. That is, the incidence proportion would be the proportion of individuals with one or more episodes of the outcome during the observation period.

Incidence Proportion Example

The Centers for Disease Control (CDC) conducted an investigation of an outbreak of staphylococcal food poisoning at a private party in Florida in 1997. The CDC interviewed 98 people who attended the party; of these, 18 developed symptoms of food poisoning within 8 hours

after eating food at the party. The 8-hour incidence proportion of food poisoning for this group was therefore 19% (95% CI: 12, 27).

Relationship between Incidence Rate and Incidence Proportion

Intuitively, it would be expected that incidence rate multiplied by the observation period would equal incidence proportion. That is, if the average incidence rate is 1 per 1000 person-years, and the population is observed for 10 years, incidence proportion will be $10 \times 0.001 = 0.01$, or 1 per 100. In fact, this is an approximation that is true only under certain circumstances. The true relationship between incidence rate and incidence proportion is more complex. More formally, the intuitive expectation is

$$\mathrm{IP}_t = \mathrm{IR}_t \Delta t, \tag{10}$$

where Δt is the observation period and IR_t is the average incidence rate over this period. This equation is true when Δt is short, so that the size of the outcome-negative pool (the number of noncases) declines only slightly over the observation period. In addition, Eq. (10) assumes that the population is closed (no immigration or emigration) and there are no competing risks (outcomes other than the outcome being studied that remove individuals from the pool of noncases).

More generally, incidence rate may vary over the observation period, yielding

$$\mathrm{IP}_t = \sum_i \mathrm{IR}_i \Delta t_i, \tag{11}$$

where $\Delta t = \sum_i \Delta t_i$. Accounting for the fact that individuals leave the pool of prevalent noncases when they become incident cases requires using the methods of survival analysis. Specifically, application of the Kaplan–Meier survival estimator yields this relationship:

$$\mathrm{IP}_t = 1 - e^{\sum_i \mathrm{IR}_i \Delta t_i}. \tag{12}$$

As before, Eq. (12) assumes that the Δt_i values are short such that the number of noncases declines only slightly within each subinterval, that the population is closed (no immigration or emigration), and that there are no competing risks. Equation (12), commonly referred to as the exponential formula, describes the true relationship between incidence proportion and incidence rate (in a closed population without competing risks). However, Eq. (10) provides an excellent approximation when Δt is short, so that the number of noncases declines only slightly over the observation period. If Δt is not a short period, then Eq. (12) should be used in place of Eq. (10).

Relationship between Prevalence and Incidence

Now assume that the population is in a condition in which the flow of incident cases into the prevalence pool is exactly equal to the flow of cases out of the prevalence pool. This is the steady-state condition. The number of new cases entering the prevalence pool along the left arrow of Fig. 1 is perfectly balanced by removal of cases from the prevalence pool through death (bottom arrow) or recovery (right arrow), so that overall size of the prevalence pool is static over time. If the prevalence is <0.1, and there is no migration into, or out of, the population, then the relationship between the prevalence (P) and incidence rate can be approximated by the simple formula

$$P = \mathrm{IR} \cdot \bar{D}, \tag{13}$$

where $\bar{D}$ is the mean duration of the disease, i.e., the average time to death or recovery. This formula can be extended to apply to age-specific prevalence. If prevalence is ≥ 0.1, the relationship is only slightly more complex:

$$\frac{P}{(N-P)} = \mathrm{IR} \cdot \bar{D}, \tag{14}$$

where N is the size of the total population. The quantity $P/(N-P)$ is referred to as the prevalence odds. Note that the inflow into the prevalence pool is given by $\mathrm{IR}(N-P)\Delta t$ and the outflow is $P\Delta t/\bar{D}$. If these are equal (i.e., the steady-state condition), then the resulting equation can be solved to obtain Eq. (14).

Special Situations

Birth Outcomes

Suppose it is desired to ascertain some measure of the number of children born with a specific congenital complication, such as cleft palate. A question arises as to whether prevalence or incidence should be measured. On one hand, the goal could be to quantify the incidence of cleft palate births in the overall population, but this is clearly influenced by many factors, including fertility and fecundity. To remove the influence of these factors, it is usually considered desirable to determine the proportion of all live births with cleft palate. Note that this measure is technically the prevalence, not the incidence, of cleft palate in the population of live births (note that it is a proportion, not a rate). Thus, even though the cleft palate births are incident events in the overall population, within the population of live births, they are prevalent.

Chronic Outcomes

A number of chronic conditions, such as arthritis, depression, or musculoskeletal pain, have ill-defined onset times. This means it is difficult to determine their incidence. The standard approach in this situation is often to develop some measure of the prevalence of the outcome. For example, in a large community survey of osteoarthritis, it would be desirable to ask about current symptoms and diagnoses of this largely irreversible condition. Determining the incidence could be problematic because sufferers may be in an advanced stage before obtaining a diagnosis.

Glossary

arboreal A tendency of inhabiting trees.
cathemeral A pattern in which waking activities occur at various times of both day and night.
folivore An animal that primarily relies on a diet of leaves.
frugivore An animal that primarily relies on a fruit diet.
polyandry A polygamous system in which a female mates with more than one male within the same general timeframe.
polygamy A mating strategy in which one sex mates with more than one individual of the other sex.
polygyny A polygamous system in which a male mates with more than one female within the same general timeframe.

Nonhuman primates inhabit much of Africa, Asia, South America, Central America, and some associated islands. Most nonhuman primates live in tropical, arboreal habitats but also some quite varied nontropical habitats. Within these varied environments, primates may walk quadrupedally (on the ground or on tree limbs), bipedally, or may move by swinging below or leaping among tree branches and trunks. Primates are active diurnally, nocturnally, or both, and thus occupy different temporal as well as spatial niches. Social systems range widely, from one adult to multi-male/multi-female groups. Studies on primate ecology and behavior have shifted in focus regarding causal mechanisms that influence the type of social systems used by primates. The nature and distribution of food resources and predation pressure are prime influences; these factors may have a cascade of influences on primate behavior, including mating strategies.

Introduction

Primate Origins

The Order Primates evolved in the Cretaceous period around 81.5 million years ago from an ancestral stock of mammals, possibly with insectivore-like characteristics and most likely nocturnal in activity pattern. Several scenarios have been advanced to account for the origin of primates (see Cartmill and Sussman for a more thorough discussion and for original references therein). The arboreal theory held that the first primates evolved from a tree-dwelling stock of insectivorous, nocturnal mammals. In such an arboreal environment, it was suggested that vision and tactile senses would have been relied on more heavily while olfaction would have become less important since these animals hunted insects in the dark and made their way along complex tree limbs. Over time, the orbits shifted from a lateral position (typical of many nonprimate mammals) to a more frontal position. This "orbital convergence" would have produced stereoscopic vision, important for a mammal subsisting in an arboreal setting. In this scenario, a division of labor between fore and hind limbs was seen as a product of arboreality. The hind limbs became most important in locomotion, while the fore limbs acquired added specializations for manipulating and grasping tree limbs and insect prey (e.g., the appearance of nails instead of claws). The arboreal theory eventually came under criticism since this suite of traits (enhanced vision and tactile senses, reduced olfaction, nails instead of claws) is not typical of arboreal mammals in general. It was argued that, had a switch to an arboreal lifestyle in the last primate ancestor been the driving force in the evolution of primates and their unique suite of

traits, then these traits should be apparent in most other arboreal nonprimate mammals. In fact, no other arboreal mammals display stereoscopic vision or nails.

An alternate theory suggests stereoscopic vision and grasping hands/feet were initially an adaptation to a very specific niche within the arboreal habitat. This hypothesis considers grasping hands and feet as a common feature of terminal branch feeders. This, combined with stereoscopic vision that primates have in common with mammals such as the carnivores, has led to the visual predation hypothesis. This view holds that the earliest primates inhabited the smaller branches of trees and shrubs, feeding on insects and fruit found in this habitat. This refinement explains the development of vision and grasping hands and feet with the simultaneous reduction of the nasal region (assumed to correlate with reduced olfaction) by focusing on the necessity for greater dexterity and accurate depth-perception in vision while foraging at the less supportive terminal branches.

Most recently, Sussman has suggested the earliest primates were omnivorous, consuming fruits and associated items (e.g., insects) in terminal branches. Sussman points out that the advent of primates corresponds to the radiation of angiosperms (flowering plants), which would have presented a variety of potential new food resources such as flowers, exudates, and fruits. Here, stereoscopic vision would have been important, but for discrimination between potential foods under the new lower light conditions in the canopies of forests at night. These animals would have been feeding on new resources that were relatively small and would have benefited from an increased visual acuity which would have also improved hand–eye coordination.

Whichever theory best reflects the origin of the order, the fossil evidence for the earliest known primates begins about 55–60 million years ago (late Paleocene/early Eocene). Fossil records indicate that the early primate inhabited woodlands and savannas in the Northern Hemisphere, zones that were uniformly warm throughout the year with little seasonality in temperature or rainfall. However, fossil evidence of primates in tropical or subtropical regions (the primary modern habitat) may simply be underrepresented as preservation and the number of archeological investigations in these geographic regions have not been ideal. It also should be emphasized that the common ancestor of primates likely predates the earliest fossil finds; some molecular evidence has indicated a much earlier date of origin in the Cretaceous, at about 81.5 million years ago.

Most extant nonhuman primates are found in southern Mexico, Central and South America, Africa, Asia, and associated islands (Table I). There are two extant taxonomic groups of primates (Table I), arranged into the Suborders Strepsirrhini (lemurs and lorises) and Haplorhini (tarsiers, monkeys, apes, and humans). The ensuing discussion focuses on nonhuman primates, except as specifically noted.

Habitats, Activity Patterns, and Locomotion

Extant nonhuman primates are widely distributed, being found in all continents except Antarctica and Australia. While most nonhuman primates live in tropical, arboreal habitats, present day habitats also reflect millions of years of dispersal to nontropical regions and nonarboreal substrates. In particular, African primates inhabit savannas, mountains, and limited desert regions, as well as tropical forests (ranging from higher elevations to swamps and flood forests). It may be generalized that the majority of primates spend most of their time in arboreal habitats (Table II). Some may spend nearly equal amounts of time on the ground (semiterrestrial; e.g., *Lemur catta*, Fig. 1A). Relatively fewer primates spend most of their day on the ground (e.g., Fig. 1D; although such primates may sleep and seek shelter in trees). It is noteworthy that most of these primates live in large groups (see below for adaptive reasons) and most are Old World haplorhines (Table II).

Within the variety of arboreal habitats, nonhuman primates use several locomotor strategies (Table II; Fig. 1). In arboreal quadrupedalism (Fig. 1C), fore- and hindlimbs are used relatively similarly to maintain a close contact with branches (although limbs are used differently for feeding). In leaping, primates more rapidly cover distances by using hindlimbs to propel themselves between discontinuous supports. This category simplifies locomotion to a great extent, and one example of this is leaping behavior coupled with a vertical posture when landing (vertical clinging and leaping), which occurs in tarsiers (Fig. 1B), sportive lemurs, sifakas, indris, wooly lemurs, and some lesser bushbabies. Finally, orangutans (Fig. 1E: genus *Pongo*), spider monkeys (genus *Ateles*), gibbons (genus *Hylobates*), and chimpanzees (genus *Pan*) all use a suspensory form of locomotion, which generally involves a more upright posture than seen in arboreal quadrupedalism. Gibbons and spider monkeys use a specialized suspensory behavior termed brachiation, in which the body is propelled via arm-swinging with hands alternating to grasp support branches. In terrestrial habitats, primates move either on all fours (Fig. 1D: terrestrial quadrupedalism, seen in some Old World haplorhines) or, more rarely, upright on two limbs (bipedalism, only used habitually by *Homo sapiens*, and occasionally in some other primates). Specialized forms of terrestrial quadrupedalism are used by chimpanzees and gorillas ("knuckle-walking") and orangutans ("fist-walking"), although suspensory locomotion is arguably as important for great apes (at least at some stages of ontogeny).

Table I Classification and Distribution of Living Primates

Taxonomic group[a] *(common names)*	*Distribution*
Suborder Strepsirrhini	
Infraorder Chiromyiformes	
Family Daubentonidae	Madagascar
Genus *Daubentonia* (aye-aye)	
Infraorder Lemuriformes	
Superfamily Lemuroidea	
Family Indriidae (wooly lemurs, sifakas, indris)	Madagascar
Genera: *Indri, Propithecus, Avahi*	
Family Megalapididae (sportive lemurs)	Madagascar
Genus *Lepilemur*	
Family Lemuridae (lemurs and bamboo lemurs)	Madagascar
Genera: *Lemur*, *Eulemur*, *Varecia*, *Hapalemur*	
Superfamily Cheirogaleoidea	
Family Cheriogaleidae (dwarf and mouse lemurs)	Madagascar
Genera: *Allocebus*, *Cheirogaleus*, *Microcebus*, *Mirza*, *Phaner*	
Infraorder Lorisiformes	
Family Galagonidae (bushbabies)	Africa
Genera: *Eoticus*, *Galago*, *Galagoides*, *Otolemur*	
Family Loridae (lorises, pottos)	Asia (India, SE Asia)
Genera: *Arctocebus*, *Loris*, *Nycticebus*, *Perodicticus*, *Pseudopotto*	
Suborder Haplorhini	
Infraorder Tarsiiformes	
Family Tarsiidae (tarsiers)	Asia (islands of SE Asia)
Genus *Tarsius*	
Infraorder Platyrrhini	
Superfamily Ceboidea	
Family Cebidae	S. America, Central America
Subfamily Callitrichinae (marmosets and tamarins)	
Genera: *Callimico*, *Callithrix*, *Cebuella*, *Leontopithecus*, *Saguinus*	
Subfamily Cebinae (capuchins, squirrel monkeys)	
Genera: *Cebus*, *Saimiri*	
Subfamily Aotinae (owl monkeys)	
Genus: *Aotus*	
Family Atelidae	S. America, Central
Subfamily Atelinae (howler monkeys, spider monkeys, wooly monkeys)	America, Mexico
Genera: *Alouatta*, *Ateles*, *Brachyteles*, *Lagothrix*	
Subfamily Pitheciinae (sakis, uacaris)	
Genera: *Cacajao*, *Chiroptes*, *Pithecia*	
Subfamily Callicebinae (titi monkeys)	
Genus: *Callicebus*	
Infraorder Catarrhini	
Superfamily Cercopithecoidea	
Family Cercopithecidae	Africa, Asia
Subfamily Cercopithecinae (macaques, baboons, mandrills, geunons, patas monkeys, swamp monkeys, vervets)	
Genera: *Allenopithecus*, *Cercocebus*, *Cercopithecus*, *Chlorocebus*, *Erythrocebus*, *Lophocebus*, *Macaca*, *Mandrillus*, *Miopithecus*, *Papio*, *Theropithecus*

Subfamily Colobinae (colobus monkeys, langurs, proboscis monkeys, snub-nosed monkeys)	
Genera: *Colobus*, *Kasi*, *Nasalis*, *Piliocolobus*, *Presbytis*, *Procolobus*, *Pygathrix*, *Rhinopithecus*, *Semnopithecus*, *Simias*, *Trachypithecus*	
Superfamily Hominoidea	
Family Hylobatidae (gibbons and siamangs)	SE Asia and associated islands
Genus: *Hylobates*	
Family Pongidae (orangutans)	SE Asian islands
Genus: *Pongo*	
Family Hominidae (bonobos, chimpanzees, gorillas, humans)	Africa (humans: worldwide)
Genera: *Gorilla, Pan, Homo*	

[a] The taxonomic groupings followed here reflect suborders used by Groves and other researchers. Taxa within Strepsirrhini also are grouped according to Groves. All other taxonomic divisions follow Fleagle. It should be noted that many authors believe platyrrhines and catarrhines comprise a clade, Anthropoidea.

Table II Habitat and Locomotory Patterns of Living Primates

Taxonomic group (common names)	*Habitat*	*Locomotion*
Suborder Strepsirrhini		
Family Daubentonidae	A	AQ
Family Indriidae	A	L (B on ground)
Family Lepilemuridae	A	L
Family Cheirogaleidae	A	AQ (also L for mouse lemurs)
Family Lemuridae	A, S-T	TQ, AQ, L
Family Galagidae	A	AQ, L
Family Lorisidae	A	AQ
Suborder Haplorhini		
Family Tarsiidae	A	L
Family Cebidae		
Subfamily Callitrichinae	A	AQ, L
Subfamily Cebinae	A	AQ, L
Subfamily Aotinae	A	AQ, L
Subfamily Atelinae	A, occasionally T	AQ, S
Subfamily Pitheciinae	A, occasionally T	AQ, L
Subfamily Callicebinae	A	AQ, L
Family Cercopithecidae		
Subfamily Cercopithecinae	A, T, or S-T	AQ, TQ or both (some guenons are also capable leapers; Patas monkeys are most highly terrestrial)
Subfamily Colobinae	A, or S-T	AQ, L (Hanuman langurs use more TQ than any colobine)
Family Hylobatidae	A	S (B on ground)
Family Pongidae	A, T or S-T	S, TQ (fist-walking)
Family Hominidae	A, T, or S-T	S, TQ (knuckle-walking), B (habitually, only in humans)

Note: Habitats: A, arboreal; T, terrestrial; S-T, semi-terrestrial. Locomotion: AQ, arboreal quadrupedalism; TQ, terrestrial quadrupedalism; L, leaping; S, suspensory (including brachiation); B, bipedalism. This table is based on locomotory behavior described for each taxa in the work of Fleagle.

Primates have varied patterns of temporal activity. Activity patterns influence access to resources (e.g., access to prey that may be available for restricted parts of the day). Primates may be active primarily during the day (diurnal), night (nocturnal), or at various times of both day and night (cathemeral). The most diverse primates in regard to activity patterns (or cycles) are the Malagasy strepsirrhines (Table III). Most of these animals are strictly nocturnal (e.g., the cheirogaleids) or cathemeral (most true lemurs). Ring-tailed lemurs are diurnal and bamboo lemurs, though active at various times, are active mostly at dawn and dusk (crepuscular). Whereas most strepsirrhines are nocturnal, only one primate is nocturnal among anthropoids

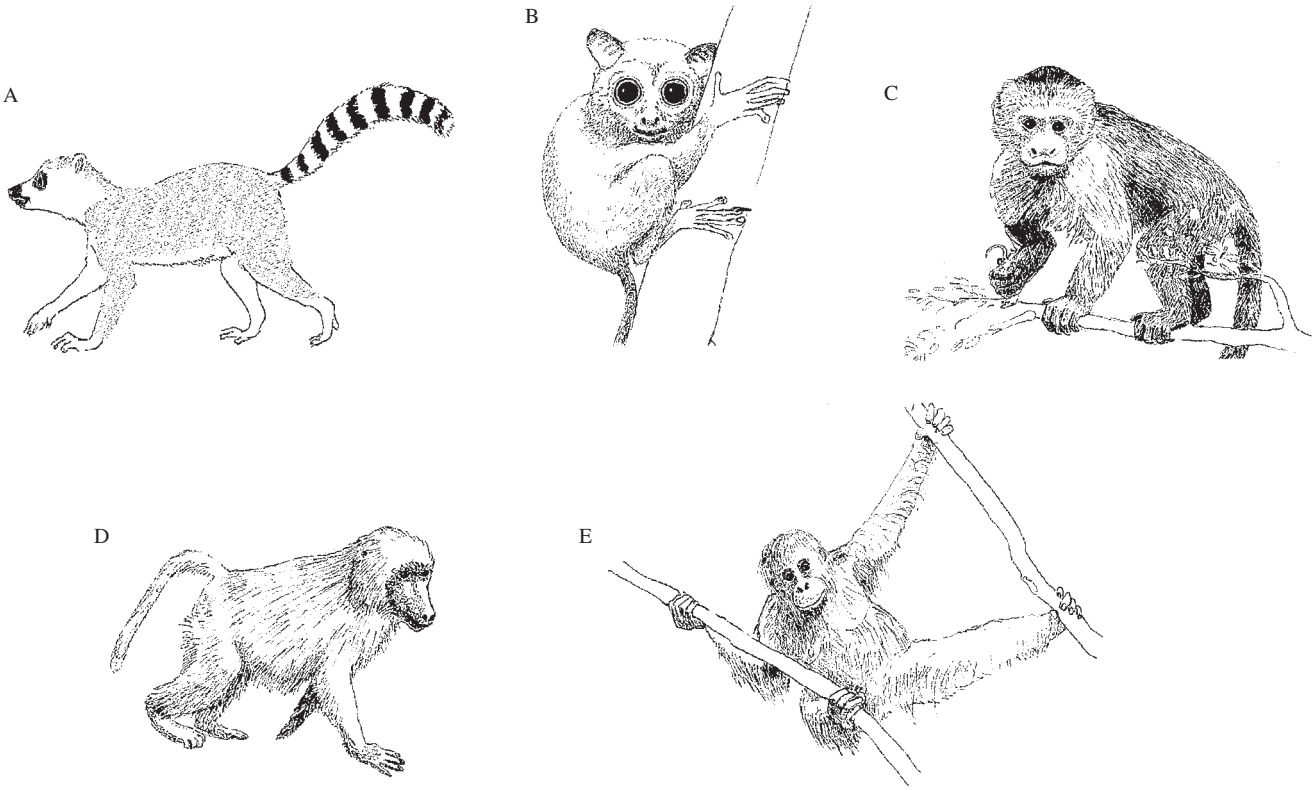

Figure 1 Examples of primates and their different locomotor behaviors. The ring-tailed lemur, *Lemur catta* (A) is semi-terrestrial, whereas most strepsirrhines primarily rely on arboreal quadrupedalism. The tarsier (B) (*Tarsius syrichta* is shown) and some strepsirrhines use leaping to move about tree limbs and adopt a vertical posture after landing. All New World monkeys, such as *Cebus capuchinus* (C), are primarily arboreal quadrupeds. Some Old World monkeys, such as baboons (D) (*Papio hamadryas* is shown), are mostly terrestrial quadrupeds. The great apes utilize a variety of locomotor patterns, including suspensory (the (E) orangutan, *Pongo abellii* is shown). All drawings copyright 2003, T. D. Smith.

(monkeys, apes, and humans), the New World owl monkey (genus *Aotus*). Particular social and ecological implications of these activity patterns are discussed below.

The varying habitats of Asia, Central and South America, and Africa house primates with numerous locomotor patterns. Dispersal beyond forested habitats necessitated adaptations for terrestrial life. Terrestrial locomotion may be employed by any primate for at least short periods of time (e.g., arboreal primates may transiently feed on the ground). However, numerous Old World monkeys and apes (e.g., macaques, baboons, chimpanzees) and one strepsirrhine primate (ring-tailed lemur) spend the majority of their days (all are diurnal) on the ground. Whereas arboreal primates may use arm-swinging or vertical clinging/leaping as the most specialized modes, the most prevalent pattern is arboreal quadrupedalism (Table I). Nocturnal arboreal quadrupeds have small group sizes, sometimes solitary, and this may well describe ancestral primates.

Primate Groups

Social Systems (Table III)

Traditionally, primates have been described according to mating systems (monogamy, polygyny, etc.), but recent authors group primates according to social systems or social groups. The reason for this altered trajectory is an understanding that reproductive behavior is not the sole factor dictating group composition in primates (a more thorough discussion is found in the work of Sussman). Although we use the term "social system" herein, it corresponds conceptually with the "social groups" identified by Sussman. Sussman's definition of

Table III Ecological and Behavioral Aspects of Living Primates (excluding humans)

Genus	*Diet*	*Activity*	*Group size*	*Social system(s)*
Daubentonia	A, Fr, S, N	N	1–2	One adult

Note: This table is primarily based on information from Rowe with updates based on Sussman. *Homo sapiens* are excluded above, since they are more variable in all categories than other primates. Diet: A, animal matter or prey; B, bark; Ex, exudates; Fl, flowers; Fr, fruit; L, leaves; N, nectar; S, seeds; *, appears to constitute the largest percentage part of the diet among all components (note that some primates may vary the major dietary component based on seasonal availability, e.g., *Saguinus* spp.); Activity: C, cathemeral; Cr, crepuscular; D, diurnal; N, nocturnal.

[1] Preferred by *E. mongoz*.

[2] In *Galago*, some species appear to primarily feed on animal matter (*G. senegalensis*) while others feed primarily on fruit (*G. alleni*).

[3] *Otolemur crassicaudatus* feeds primarily on exudate, and *O. garnettii* relies equally on fruit and animal matter.

[4] *C. flaviceps, C. jacchus,* and *C. penicillata* consume more exudates than other *Callithrix* spp.

[5] Some species may not consume significant quantities of animal resources.

[6] *C. satanas* has been reported to utilize seeds as primary food.

[7] Seeds are another major dietary element and are the primary food for at least one species.

[8] It is likely that a dominant pair may bond within multi-male/multi-female groups.

a social group is helpful at the outset: ". . . individuals who interact socially more frequently among themselves than with other individuals; group members exhibit different behavior toward nongroup members and occupy the same home range." Below, we provide categories of social systems used by Falk.

1. Multi-male/multi-female (a.k.a., multi-male group). This system includes more than one breeding adult of each sex and offspring and varies greatly in size. In these groups, either males or females may mate with multiple partners (some authors use the term polygamy to describe this practice, rather than its more general definition in the glossary above). Although this appears to refer to overall promiscuity, in most groups there are hierarchical male or female subunits that may limit/enhance opportunities for individuals of either sex. Furthermore, even in multi-male/multi-female groups, it may be the case that one individual male mates with multiple females (polygyny) or one female mates with multiple males of a subgroup (polyandry). Polygynous subgroups occur in some baboons and langurs. Multi-male/multi-female systems are more prevalent in haplorhines than strepsirrhines (Table III) and appear to occur in the context of relatively abundant resources, a variable degree of predation pressure, and diurnal activity patterns (see below for further discussion).

2. One male/multi-female group (a.k.a., one-male group). This system includes one dominant, breeding adult male that mates with multiple females in the group, reflecting a polygynous mating system. In these species, such as the gorilla, juvenile males stay with the natal group until they are of reproductive age. They then typically migrate out of the group to locate new groups where they may have access to females.

Certain complexities should be noted. For instance, one male/multi-female subunits may exist *within* larger multi-male/multi-female groups (e.g., some baboons). In addition, all male groups may occur in species that primarily form one male/multi-female social systems. Such groups may be temporary alliances that create opportunities to oust a male that currently holds tenure in a one male/multi-female group (see Strier for further discussion and references therein to the work of Hrdy). These are not indicated in Table III, but they are seen in proboscis monkeys and langurs, for example. Infanticidal attacks by competing males may occur in one male/multi-female groups (e.g., in gorillas, at least some langurs), a strategy that quickly makes new reproductive opportunities available.

3. One female/multi-male (a.k.a., cooperative polyandrous) group. This system includes one breeding adult female that mates with two or more adult males in the group (polyandry), along with offspring of various ages. This is a stable family group, that is, males do not leave the group and mate with other females. This typifies numerous callitrichines. Interestingly, these primates are quite comfortably monogamous in captive settings, and it was not until field data were available that group composition became clearer.

The number of males per group in primate social systems appears to depend on multiple factors, some of which are discussed further below. In the case of callitrichines, males may tolerate one another because paternity may be uncertain and twinning and relatively high infant body mass make care-giving highly taxing. In other words, the reproductive benefits gained by receiving help with infant care outweigh costs associated with uncertain paternity.

4. All male group. In some primates, males may form sex-exclusive, temporary associations that may cooperate in gaining access to resources and/or females. Many langurs have stable one-male, multi-female systems that must be maintained against such groups (see above). More long-term alliances occur in other primates such as chimpanzees and bonobos, and these alliances appear to increase access to resources for group members.

5. One male/one female (a.k.a, pair bonds). This system consists of small family groups, with one breeding adult female, one breeding adult male (i.e., monogamous pair), and their offspring. This system is common in some callitrichines, and in gibbons, siamangs, and bamboo lemurs. The circumstances and benefits of this social system are discussed more below. It should be noted that there are instances of pair bonded animals within multi-male/multi-female groups (e.g., lion tamarins).

6. One adult (a.k.a., solitary but social). This system is found in most nocturnal primates and orangutans. Adult males mate with more than one adult female but do not participate in the care of offspring. The solitary behavior is mostly foraging. Whereas adult males avoid one another, males associate with multiple females. Adult nesting groups exist in some species, although most nesting groups consist of adult females and their subadult offspring. This system is present in most nocturnal strepsirrhines (Table III).

Influences on Primate Social Systems

The distribution of resources influences foraging strategies for female primates, who have high energetic costs associated with their own metabolic needs, especially during pregnancy and lactation (see below for more discussion). The way in which female primates are distributed (and perhaps dispersed) hinges on the availability and distribution of resources (food, habitat). Male reproductive options, in turn, are limited by the resulting spatial distribution of females.

The approach to obtaining resources and/or maximizing reproductive fitness, may be further delineated as female and male social strategies. It seems such strategies

are most frequently about access to resources first, and then about reproduction. If all of the above factors allow, primates appear more likely to form groups than not. In such contexts, male strategies for acquiring resources may become extremely intense, involving more direct and frequent confrontations with other males or other groups. For males, the ability to monopolize access to females dramatically maximizes their reproductive fitness (provided they are effective in doing this). When reproductive prospects are low (for migrating males or all male groups), another seemingly extreme male strategy is infanticide. This is quite common among one male/multi-female or multi-male/multi-female groups, and has a potentially high payoff since the mother could be fertilized again by a new male much sooner than otherwise possible. Also in such groups, female primates may employ more frequent polyandrous matings with invading males as a counter strategy. By keeping paternity uncertain, polyandrous matings can have a high payoff in either protecting infants from infanticidal males or, in the case of callitrichines, recruiting added parental care (e.g., many callitrichines).

In large primate groups, male or female alliances and hierarchies represent a major important social strategy. Female alliances are another important influence on the likelihood of infant survival in multi-male/multi-female groups. Male–female relationships may even dictate duration of male tenure in one-male, multi-female groups. The dynamics of these relationships have a major role in access to food or reproductive opportunities for each sex, as discussed in much more detail by Strier.

Communication

Communication between primates may be grouped under broad categories of visual, acoustic, and chemical forms. Primate groups use all forms of communication, with varying emphases. The term "solitary," used in some contexts to describe primates of the one adult social system, may be misleading. The one-adult social system is actually characterized by numerous interactions if one considers the different nature of communication used by such primates (mostly nocturnal strepsirrhines—Table III). In the nocturnal activity pattern, chemical (either scent and/or pheromonal) cues may be much more effective long range signals than the acoustic signals preferred by diurnal primates. These signals may carry valuable information ranging from territory boundaries to reproductive status, i.e., information that might be more readily acquired by other special senses in diurnal activity. Broadly speaking, nocturnal primates rely more heavily on chemical signals than diurnal primates (e.g., see the work of Hrdy and Whitten regarding reproductive signals), although diurnal primates certainly use olfactory signals. Among primates, by far the best evidence for a functional "accessory olfactory" sense, via the vomeronasal organ, exists for strepsirrhines. In at least some strepsirrhine primates, the vomeronasal organ likely is sensitive to pheromones conveying reproductive information, whereas the precise function of this organ is more uncertain in platyrrhines, and probably negligible in catarrhines that possess it.

Diurnal primates in general tend to have relatively greater emphasis on visual/acoustic signals than nocturnal species. Communication in callitrichine primates is highly interesting in that the use of scent marks is extremely frequent compared to most other haplorhines. It is likely that scent may convey complex information that even may allow individual identification of primates. Chemical communication may be of a more subtle nature in other instances, where pheromones appear to play a role. Pheromones are substances released by one individual that may have a neuroendocrine effect on another individual (in other words, these signals may alter the physiology of a conspecific). One notable putative pheromonal effect in callitrichines is reproductive suppression of one female by the dominant female in a group. Interestingly, this behavior appears to not be pheromonally influenced in certain callitrichines (lion tamarins), which instead intimidate subordinate females (for further discussion, see Dixson).

Communication within multi-male/multi-female groups is highly complex. For instance, females in this system have the most obvious behavioral (e.g., presentation of hind-quarters) or anatomical (reddening of genitalia) cues of proceptivity among primates. Interesting exceptions exist regarding anatomical cues, notably in callitrichines that may have large group sizes, but have polyandrous subgroups. Multi-male/multi-female groups may use a highly complex repertoire of vocalizations to communicate about food resources and predators over large distances. Facial displays can be very elaborate in members of these groups, communicating information among different animals in hierarchies, for example.

Ecological and Behavioral Influences on Primate Social Systems

Temporal, spatial, and geographic availability of resources and predators have critical influences on the geographical distribution of primates. These same factors may be strong selective influences on the activity cycles of a species which, in turn, can limit the prevalent type(s) of communication. This cascade of influences has a profound importance to social systems of primates, as described below. More subtle determinants of group dynamics are not considered below, such as conflicting female and male strategies regarding reproduction and

meeting metabolic needs (readers are referred to Strier for further discussion).

Diet and Feeding Behavior

Perhaps the greatest driving force in the life of any primate is the need to obtain enough calories on a daily basis in order to survive. Arguably, securing enough food of a high enough quality is the most important waking activity. Of course, different primates consume different foods depending upon their size, teeth, gastrointestinal tract, etc. As a general rule of thumb, smaller primates tend to consume high-quality protein-rich foods that are relatively easy to digest while larger primates tend to consume lower quality foods that take a longer time to digest (see Table III). For example, some species of the diminutive tarsiers consume only large insects and small vertebrates such as snakes and birds while the massive gorilla consumes mostly tough mature leaves. This dietary phenomenon is closely associated with basal metabolic rate (BMR). Relatively small primates, such as the tarsier, have relatively high BMRs and require a high amount of energy for routine daily physiologic functions. In order to support these functions, small primates require a diet of easily digestible calorie-rich foods that do not need a great deal of mechanical effort and time to collect them. Such a diet would typically be represented by other small animals (large insects, reptiles, etc.) and perhaps supplemented by fruits and/or exudates. This is the case seen in many small primates such as the tarsiers, bushbabies, and marmosets. Large primates, such as orangutans and gorillas, have relatively low BMRs and are not under such intense pressure to consume high-quality easily digestible diets. Such large-bodied primates tend to be folivorous and consume lower quality but highly available foods including tough mature leaves, roots, and wood with supplementation from fruits. In addition to orangutans and gorillas, other large primates such as gibbons and baboons pursue this dietary niche. Mature leaves represent a low-quality diet that is difficult to digest but one that is generally available in large predictable quantities and varies little in seasonal availability (imagine the amount of insects a gorilla would need to consume on a daily basis in order to gain enough calories!). Large primates with a low BMR can tolerate the increased time necessary to digest such a poor-quality diet while smaller primates with a high BMR must consume food that can be relatively quickly broken down.

With this dietary quality/quantity information, we can now examine how dietary needs have a role (perhaps the largest role) in shaping primate social systems. The three major food categories for primates are fauna (including large insects and small vertebrates), fruits, and leaves. Other sources such as roots, exudates, and flowers are not considered to be major sources of calories but, for some primates such as the needle-clawed bushbaby (*Eoticus* spp.) and the mongoose lemur (*Eulemur mongoz*), are the major source of calories (see Table III for their occurrences across genera). Distribution of these resources occurs spatially (in clumps or more evenly spread out) and temporally (seasonal occurrences or regular availability). In foraging spatially for a particular food, primates must consider the potential quality of that food as well as what it will cost them to obtain enough of that food in order to meet their caloric needs. For example, is the tree which bears the desired fruit found in clumps with others (requiring little travel effort and time to harvest the fruit) or does it occur in only isolated locales (requiring long travel distances and potentially greater exposure to predators)? Does the desired insect swarm in a particular location or are they found only singly here and there on tree branches?

Most foods occur in clumps, whether they are small clumps or much larger ones. By and large, it is the size of the clump that determines how large a primate group can feed there at the same time. A food clump that is relatively large, such as a savanna of grasses or leaves from trees in a rainforest, can support a large number of individuals feeding there at the same time. Primate folivores thus tend to occur in large groups or troops, such as the hamadryas baboons of the east African savannas (up to 750 individuals per troop, Table III) and the rhesus macaques of the southeastern Asian forests (up to 200 individuals per troop, Table III). A large number of individuals feeding at a clump will indeed compete with one another for the food but there are potential benefits that outweigh such a cost. More individuals in one area can defend the clump of food against other species or other conspecifics from different troops as well as provide increased predator detection. Increased predator detection may provide increased survival chances for one's offspring, siblings, and extended kin, individuals who have a high likelihood of having the same genes. Thus, most primate folivores occur in large groups or troops (see Table III). Notable exceptions include the most massive primates, gorillas. These animals are indeed folivores but occur in much smaller group sizes, around 20 individuals. Whereas their food resources are relatively abundant and found in clumps, such a large primate is not subject to predator pressure (humans excluded). This relaxation of predator pressure may influence the relatively small group size in these folivores.

Frugivorous primates do indeed most commonly occur in groups but group size is typically far smaller than in folivores. Fruits tend to grow on trees and are present in clumps but they are relatively less abundant than the leaves that grow on trees and are often more seasonal in availability. In addition, because the fruit is less clumped than leaves or grasses, a frugivorous primate often requires high travel time and distance in order to

obtain enough calories. In addition to spatial clumping of fruits, frugivorous primates must deal with the temporal clumping of fruits. Many ecological zones, such as rainforests, produce fruits in a highly seasonal pattern. In these circumstances, frugivorous primates feed almost exclusively on fruits when in season but supplement their diets with such resources as nectar and exudates during the off season. Such a drastic divergence in temporal availability of fruits along with their spatial clumping patterns may not, then, support the large number of individuals in a group that are seen in folivores. Indeed, many frugivorous primates such as the lion tamarins, spider monkeys and mangabeys occur in groups from about 15 to 60 individuals.

Faunal resources such as large insects and small vertebrates tend to be spread out more randomly and at greater geographic intervals than leaves and fruits. Thus, a faunivorous dietary niche usually cannot support a large number of individuals feeding on them at one time. For example, large insects and snakes tend to occur singly or in small groups, not in densely concentrated clumps. These small irregular patches of food could not support more than one or a few individuals feeding at a time together. Faunivorous primates, such as tarsiers, tend to occur singly or in small groups of up to three individuals.

Territoriality is in part a direct consequence of how dense each food patch is. If a food is densely concentrated in a patch it may be easily defensible in a primate's home range. However, the availability and quality of food plays a part in determining the worth of defending it. Evenly spaced, abundant, low-quality foods such as grasses would probably not be worth defending but clumped, higher quality foods such as fruits or large insects may be worth the potential costs of defending.

In addition to spatial distribution, food availability can vary temporally. Seasonal variation in sunlight, rainfall, and temperature affect plant productivity and faunal availability. Primates typically occur in ecological zones that have a distinct rainy season, such as tropical forests. During the rainy season there is great availability of high-quality foods such as fruits and young leaves. Consequently, primates tend to feed exclusively on these abundant foods during the rainy season. While these foods are abundant, individuals tend to focus on these foods exclusively and form smaller feeding parties, splitting up the larger group or troop. During the dry season, high-quality foods tend to become more scarce and most primates are forced to diversify their diets to include less desirable, low-quality foods such as mature leaves and roots. At these times individuals tend to reaggregate into the larger group or troop.

In primate species that group into large numbers, such as the hamadryas baboon and the rhesus macaque, there are, consequently, large numbers of females concentrated in a relatively small area. Female primates will be found where the food is. There is, then, the potential for one or a few males to control access to all of the reproductive females. While females go where the food is, males go where the females are. A male who is strong enough, showy enough, fast enough, or has enough allies of these characteristics can control other males' access to females of reproductive age. Thus, polygyny (one male having more than one female mate) tends to be seen in primate species that group in large numbers. Primates such as baboons, macaques, guenons, langurs, and others that feed on abundant low-quality foods (such as leaves and grasses) live in the most extreme polygamous multimale/multi-female groups (Table III). In these groups, one or a few males guard and mate with a large number of females or "harems." It is only these strong, showy, dominant males that usually mate with the females. Other males tend to migrate out of the natal group into new groups while females tend to stay with their natal group for life.

Frugivorous primates are also polygamous multi-male/multi-female groups but tend to be less extreme than the folivorous primates. In these species one male may control access to female, but there are typically fewer females controlled by the male. In such groups, females may have more access to reproductive opportunities with other males.

Primate species that feed on higher quality foods that tend to be relatively rare and spread out are usually solitary or occur only in small groups that consist of a mother and her young offspring. These species, such as the nocturnal lemurs and bushbabies, tend to be promiscuous, although at least some tarsiers occur in monogamous pairs (Table III).

In those species that consume foods that are relatively high quality and are regularly available with little travel time between clumps, such as exudates, some fruits, and bamboo, monogamy may be seen (Table III). If resources are predictable and relatively abundant, females may not gain an advantage by grouping together. In addition, concentrated clumps of high-quality food may favor the development of territoriality in these species, such as gibbons, siamangs, and the pygmy marmoset. While the male of these species gives up a potentially high reproductive rate by bonding with only one female, he does gain a higher paternal certainty and offspring survival rate, since he provides a great amount of parental care.

Predation Pressure

Virtually all primate species are subjected to predator pressure and some are themselves predators. Predators such as hawks, eagles, and other primates (excluding humans) can have a profound influence on social systems. Primates that exist in regions where predators are present in considerable numbers and who are small enough to be prey tend to group in relatively large numbers. Species

taken as prey, such as the red colobus monkey and guenons, tend not to occur in groups as enormous as the larger-bodied grass/leaf eaters (the baboons and macaques), but they do aggregate into fairly large groups (up to 35 individuals).

In addition to intraspecific associations, many small- to medium-sized primates subject to predator pressure associate with other primate species under similar pressure during feeding and sleeping bouts. While such an association during feeding may decrease foraging efficiency and total calorie intake, it may provide increased predator detection and, ultimately, increase survival. For example, red colobus and Diana monkeys inhabit tropical forests of western Africa and both feed on leaves in similar geographic areas. However, these species often forage together when one of their main predators, the chimpanzee, is near. When these species forage together they change the composition of their diets but gain the potential benefit of increased predator detection.

Larger bodied primates typically have low predation pressure. These species tend to be more stable in their associations with other primate species. However, some of these primates, especially male chimpanzees and baboons, are themselves predators. Chimpanzee males are significant and regular predators of red colobus monkeys in western Africa. Male chimps regularly form "hunting parties" that prey upon several primate species. The parties typically consume the meat themselves without sharing it with females or other males.

Activity Patterns

Predation pressure is one causal mechanism of nocturnality in primates, and also may influence body size (nocturnal primates are generally smaller) and group size (see Table II). Predator avoidance is not the sole cause of nocturnality or small group size in mammals. As illustrated by some solitary, nocturnal predators of primates, access to resources is another important influence. Although not generally considered a direct influence on social systems, activity patterns themselves impose important limitations on social interactions. For example, nocturnal mammals in general rely more heavily on nonvisual (e.g., auditory, olfactory) and/or longer lasting (e.g., scent-marking) modes of communication compared to diurnal mammals. Nocturnality itself reinforces small group size in primates by diminishing the impact of close range modes of communication.

Conclusion: Influences on Primate Social Systems

Primate social systems vary widely, from one adult to multi-male/multi-female groups. Recent studies on primate ecology and behavior focused on the nature and distribution of food resources and predation pressure as prime influences on primate social systems, influencing group size and structure. More subtle dynamics of primate interactions may also be attributed to such factors, such as the often conflicting female and male strategies regarding reproduction and meeting metabolic needs. Thus these ecological factors may have a cascade of direct and indirect effects, influencing activity patterns (nocturnality, diurnality, etc.) and even types of interactions among group members.

Florida State University, Tallahassee, Florida, USA

Glossary

additive model A model in which the effect of each independent variable on the dependent variable is the same regardless of the value of the other independent variables.
binary variable A variable that has only two possible values (typically labeled zero and one).
instantaneous effect The slope of a probability curve for an independent variable.
latent variable An unobserved variable presumed to measure an observed variable.
linear model A model in which the effect of each independent variable on the dependent variable is the same regardless of the value of that independent variable.
logit of a binary dependent variable The log of the odds that a binary dependent variable equals one (rather than zero).
odds of an event The probability that the event will occur relative to the probability that it will not.
probability curve A graph of the relationship between an independent variable and the predicted probability that a binary dependent variable equals one (rather than zero) when the remaining independent variables are held constant at specified values.

Probit and logit are techniques for estimating the effects of a set of independent variables on a binary (or dichotomous) dependent variable. When ordinary least squares is used to estimate a binary dependent variable model, the model is often called a linear probability model (LPM). Probit and logit avoid several statistical problems with LPMs and generally yield results that make more sense.

Introduction

Probit and Logit: An Alternative to Regression When the Dependent Variable Is Binary

Multiple regression is the most widely used technique in the social sciences for measuring the impacts of independent (or explanatory) variables on a dependent variable. Regression—more technically, ordinary least squares (OLS) regression—generally assumes that the dependent variable is continuous. Yet many of the dependent variables social scientists wish to study are not continuous. Indeed, many have only two possible values (an event did, or did not, occur), and are termed binary (or dichotomous) variables: for example, whether a nation is at war, a candidate wins an election, an organization adopts some innovative practice, or an adult is married. Other statistical methods are more appropriate when the dependent variable is binary, and probit and logit are the most common.

A Review of Regression

Consider a regression model with a continuous dependent variable Y and two independent variables assumed to influence Y: X, which is continuous, and D, which is dichotomous (scored either zero or one):

$$Y = \alpha + \beta X + \delta D + \varepsilon. \quad (1)$$

The equation expresses the value Y for any observation as a function of its values for X, D, and an error (or disturbance) term, ε. ε represents those variables influencing Y (in addition to X and D) that have not been measured and included in the model. α, β, and δ are termed parameters and are constants; the latter

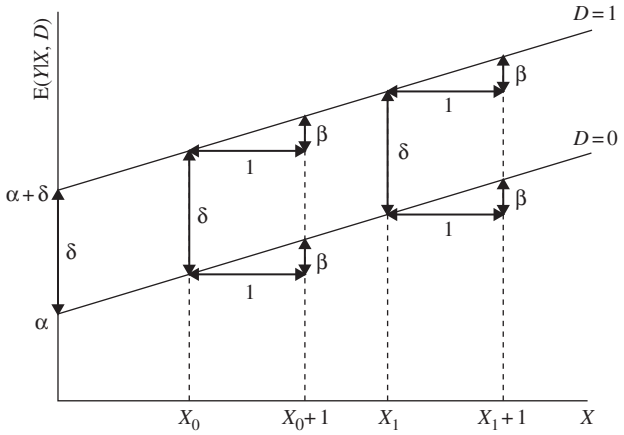

Figure 1 The population regression function (PRF) [Eq. (3)] for a linear additive regression model (LARM) [Eq. (1)].

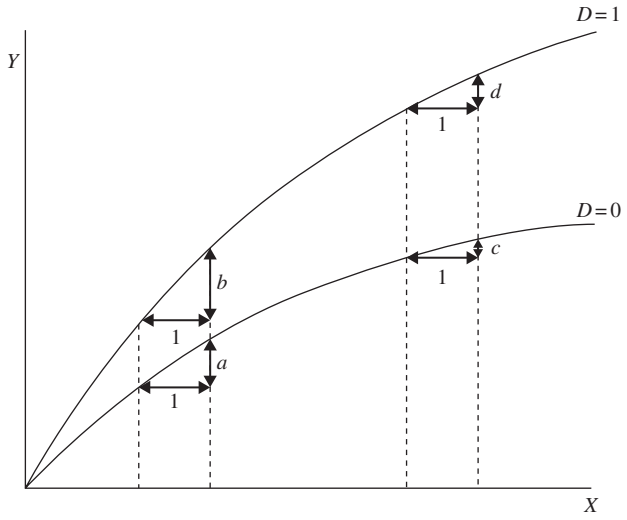

Figure 2 A nonlinear, non-additive model.

two—the parameters for the independent variables—are called partial slope coefficients.

It is generally assumed that the error term in Eq. (1) has a conditional mean (or expected value) of zero. If so, the regression model of Eq. (1) implies a population regression function (PRF) of the form

$$\mathrm{E}(Y \mid X, D) = \alpha + \beta X + \delta D. \qquad (2)$$

The left side of Eq. (2) is a conditional mean and is read "the expected value of Y, given X and D." The PRF writes the expected (or mean) value of Y (given specific values for X and D) as a function of the values of X and D. Notice that the error term ε is not in the PRF; while this variable influences the value of Y for a particular observation, if ε has a mean of zero for any fixed values of X and D, then the mean of Y for a case is fully determined by X and D, and is not influenced by the value of ε. The PRF is graphed in Fig. 1 in a format showing the relationship between X and the expected value of Y for both values of D (0 and 1).

In this model, the slope coefficient β characterizes the impact of X on Y: it tells the change in the expected value of Y resulting from an increase of one in X when the other independent variable, D, is held constant. For example, Fig. 1 shows that when D is held constant at one (see the higher line), and the value of X rises by one from x_0 to $x_0 + 1$, the expected value of Y grows by β (capital letters indicate variables, and lower case letters indicate specific values that a variable assumes). Similarly, δ reflects the impact of D, as it indicates how much Y can be expected to change if D is increased from zero to one while X remains fixed. In the graph, δ is the vertical distance between the lines reflecting cases for which D equals 0 and D equals 1.

Linearity and Additivity

Equation (1) can be called the linear additive regression model (LARM). A model is termed linear if it assumes that the effect of each independent variable on the dependent variable is the same regardless of the value of that independent variable. The linearity of the equation is evident from the fact that both curves in Fig. 1 take the form of a straight line: the expected response of Y to an increase of one in X is the same whether we begin at x_0, at x_1, or at any other value of X. A model is called additive if the effect of each independent variable on the dependent variable is the same regardless of the value of the other independent variables in the model. The additivity of Eq. (1) is reflected in the two lines in Fig. 1 being parallel: X has the same effect on Y whether D is zero or one, and D has the same impact on Y at any fixed value of X.

But consider Fig. 2. This graph reflects a model that is neither linear nor additive. The model is non-additive because at any fixed value of X, the effect of X on Y is different when $D = 0$ than when $D = 1$: at any value of X, Y responds more to a unit change in X when $D = 1$ than when $D = 0$. (For example, in Fig. 2, $b > a$ and $d > c$.) The model is nonlinear because at either value of D, the impact of X on Y depends on the value of X: this impact declines gradually as X gets larger. (For example, $c < a$ and $d < b$.) Thus, Fig. 2 presents a nonlinear, non-additive model, in which the effect of each of the independent variables depends on the value of both.

The Linear Probability Model: Using OLS Regression with a Binary Dependent Variable

When one ignores the typical assumption made in OLS regression that the dependent variable is continuous, and employs it with a binary dependent variable, the model is frequently labeled the linear probability model (LPM).

Consider the PRF for an LPM with a single continuous independent variable, X, and a dependent variable, Y, with two possible values, zero and one.

$$E(Y \mid X) = \alpha + \beta X. \tag{3}$$

This equation is graphed in Fig. 3 along with the X and Y values for some hypothetical observations. The fact that the dependent variable can be only zero or one means that all observations in the graph fall on one of two horizontal lines ($Y = 0$ or $Y = 1$).

The Meaning of Slope Coefficients in a Linear Probability Model

To understand the nature of the slope coefficient β in the LPM of Eq. (3), consider the conditional mean on the left side. Since Y can assume only the two values zero and one, the expected value of Y given the value of X is equal to 1 multiplied by "the probability that Y equals 1 given the value of X" plus 0 multiplied by "the probability that Y equals 0 given the value of X." Symbolically,

$$\mathrm{E}(Y \mid X) = (1)[\mathrm{P}(Y = 1 \mid X)] + (0)[\mathrm{P}(Y = 0 \mid X)]. \tag{4}$$

Of course, one multiplied by any value is that value, and zero multiplied by any number remains zero; so Eq. (4) simplifies to

$$\mathrm{E}(Y \mid X) = [P(Y = 1 \mid X)]. \tag{5}$$

Given this equality, $\mathrm{P}(Y = 1 \mid X)$ can be substituted for $\mathrm{E}(Y \mid X)$ in Eq. (3), obtaining

$$\mathrm{P}(Y = 1 \mid X) = \alpha + \beta X. \tag{6}$$

This revised form of the PRF for the LPM—with the probability that Y equals 1 as the dependent variable—implies that the slope coefficient β indicates the change in the probability that Y equals 1 resulting from an increase of one in X.

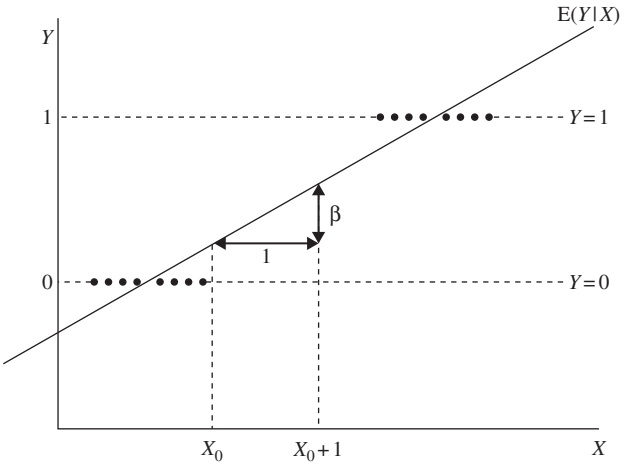

Figure 3 The population regression function (PRF) [Eq. (3)] for a linear probability model (LPM).

In the more general LPM with multiple independent variables (say k of them—$X_1, X_2, \ldots, X_k$), the PRF takes the form

$$\begin{aligned}\mathrm{E}(Y \mid X_1, X_2, X_3, \ldots, X_k) &= \mathrm{P}(Y = 1 \mid X_1, X_2, X_3, \ldots, X_k) \\ &= \alpha + \beta_1 X_1 + \beta_2 X_2 + \beta_3 X_3 \\ &\quad + \cdots + \beta_k X_k.\end{aligned}$$

If (bold italicized) $\mathbf{X}$ is used as a shorthand for all the independent variables, this equation simplifies to

$$\begin{aligned}\mathrm{E}(Y \mid \mathbf{X}) = \mathrm{P}(Y = 1 \mid \mathbf{X}) &= \alpha + \beta_1 X_1 + \beta_2 X_2 + \beta_3 X_3 \\ &\quad + \cdots + \beta_k X_k.\end{aligned} \tag{7}$$

The slope coefficient, β_i, for independent variable X_i (where i can be 1, 2, 3, . . . , k) can be interpreted as the change in the probability that Y equals 1 resulting from a unit increase in X_i when the remaining independent variables are held constant.

An Illustration of the Linear Probability Model: Class Performance

Data collected by Spector and Mazzeo (1980) on the performance of students taking a course in macroeconomics can be used to illustrate the LPM. The dependent variable, denoted GRADE, is a student's class performance, measured dichotomously. For convenience, the two outcomes will be called "success" (GRADE = 1) and "failure" (GRADE = 0). There are three independent variables in the LPM: (1) the student's entering grade point average, denoted GPA, and ranging from 2.06 to 4.00 in the sample, (2) an exam score indicating the student's knowledge at the beginning of the course, denoted BEGIN, and ranging from 17 to 29 in the sample, and (3) a dichotomous variable distinguishing two teaching methods, an experimental approach called PSI and the traditional method. The last variable is labeled METHOD:PSI and is scored 1 for PSI and 0 for the traditional approach.

Using OLS regression with Spector and Mazzeo's data yields the coefficient estimates in column 1 of Table I. The slope coefficient for GPA is 0.46, indicating that when a student's pre-course knowledge and teaching method are held constant, an increase of one in a student's entering grade point average—a little over half the range from 2.06 to 4.00—is estimated to produce an increase of 0.46 in the probability that the student will succeed in the class. In particular, the estimated probability of success for a student with GPA of 2.5, a BEGIN value of 21.94 (the mean value in the sample), and who is taught by the PSI method (i.e., METHOD:PSI = 1) is 0.27 [calculated as $-1.4980 + 0.4639(2.5) + 0.0105(21.94) + 0.3786(1)$].

Table I Coefficient Estimates for Binary Dependent Variable Class Performance Models

Independent variable	*(1) OLS coefficient estimate*	*(2) Probit coefficient estimate*	*(3) Logit coefficient estimate*	*(4) Instantaneous effect (with all variables at their mean)*[a]
GPA	0.4639[b]	1.6258[b]	2.8261[b]	0.5333
(s.e.)	(0.1620)	(0.6939)	(1.2629)	
Z	2.864	2.343	2.238	
BEGIN	0.0105	0.0517	0.0952	0.0167
(s.e.)	(0.0195)	(0.0839)	(0.1416)	
Z	0.538	0.616	0.672	
METHOD:PSI	0.3786[b]	1.4263[b]	2.3787[b]	0.4679
(s.e.)	(0.1392)	(0.5950)	(1.0646)	
Z	2.720	2.397	2.234	
Intercept	−1.4980	−7.4523	−13.0214	
Likelihood ratio statistic[c]		15.55	15.40	

[a] Based on probit estimates in column 2.
[b] Different from zero at 0.05 level of significance (1-tail test).
[c] Distributed as chi-square with 3 degrees of freedom.

In contrast, the predicted chance of success for a student with GPA one unit higher, at 3.5, but the same values for GPA and BEGIN is 0.73: 0.46 higher. The slope coefficient for METHOD:PSI is 0.38. This means that the predicted probability of success of a student taught by the experimental PSI method is 0.38 greater than the chance of success of a student trained using the traditional method but having the same GPA and BEGIN values.

Weaknesses of the Linear Probability Model

Non-normally Distributed Error Term

An assumption that the error term, ε, is normally distributed, in combination with other assumptions of OLS regression, can be used to justify various techniques of statistical inference (e.g., hypothesis testing). However, the assumption that the error term is normally distributed cannot hold for an LPM: given any fixed values for the independent variables, ε can assume only two values, and a dichotomous variable is not normally distributed.

Heteroscedasticity

OLS regression assumes that the error term, ε, is homoscedastic, i.e., that the variance of ε is constant. In an LPM, because the dependent variable is constrained to two possible values, this assumption is violated; the variance of the error term is larger for some values of the independent variables than others, a condition called heteroscedasticity. Goldberger (1964) demonstrated that this problem can be overcome by using a weighted least squares (WLS) procedure for estimation instead of OLS. But even when heteroscedasticity is avoided by this means, other more serious problems remain.

Predicted Probabilities with Nonsensical Values

We have seen that the dependent variable in the PRF for an LPM can be interpreted as the probability that Y equals 1 [i.e., $P(Y = 1 \mid \mathbf{X})$], and thus should be no less than zero and no greater than one. Unfortunately, there is nothing that constrains predicted values that Y equals 1—based on either OLS or WLS estimation of an LPM—to the range between zero and one. For example, the OLS estimates of the class performance model in column 1 of Table I imply that the predicted probability of success for a student taught by the traditional method (i.e., METHOD: PSI = 0) with GPA at 2.5 and a BEGIN value of 21.94 (the mean in the sample) is $-0.11[= -1.4980 + 0.4639(2.5) + 0.0105(21.94) + 0.3786(0)]$. This prediction is nonsensical, and illustrates a significant flaw in the LPM.

Linearity and Additivity Cannot Hold

Just like the LARM, the LPM is both linear and additive. But the linearity and additivity of the LPM are at odds with the fact the dependent variable in the PRF for an LPM can be viewed as the probability that Y equals 1 [i.e., $P(Y = 1 \mid \mathbf{X})$]. Consider any one of the independent variables in an LPM: say X_i. The linearity of the model implies that a unit increase in X_i results in the same change—β_i—in the probability that Y equals 1, regardless of the value of X_i. However, if every unit increase in X_i leads to a change of β_i, no matter the size of β_i, eventually

X_i will become large enough to push the probability that Y equals 1 out of its acceptable range (between 0 and 1). Beyond the mathematical imperative, the linearity and additivity of the LPM often makes no sense substantively. Returning to the class performance model, assume that at certain values of the independent variables (BEGIN, GPA, and METHOD:PSI), the probability that a student will succeed is 0.50. It is certainly conceivable that for students with these independent variable values an increase in GPA (or any of the other independent variables) could lead to a substantial increase in the probability of success. In contrast, assume that at different values of the independent variables, the probability of success is 0.99. Given this very high chance of success at the outset, no increase in GPA (or any other variable) could appreciably increase the probability of success. Thus, a nonlinear, non-additive model—allowing the effects of independent variables on the probability of success to differ depending on the values of the independent variables—would be superior.

Other Binary Dependent Variable Models: Probit and Logit

Probit and logit assume that the effects of independent variables on the probability that Y equals 1 are nonlinear and non-additive. In particular, these models assume that the effects of independent variables decline in magnitude as $P(Y=1\,|\,\mathbf{X})$ approaches either zero or one. For most applications involving binary dependent variables (BDVs), this assumption will be quite sensible. Figure 4 presents a graph of the probit model with a single independent variable. The graph of the logit model is very similar. Indeed, the shapes of the curves are so close that probit and logit can be viewed as functional equivalents in applied research settings. With both probit and logit, the gradual flattening of the S-shaped curve as X gets either small or large makes clear that as X becomes large or small, the effect of X on $P(Y=1\,|\,X)$ diminishes in strength.

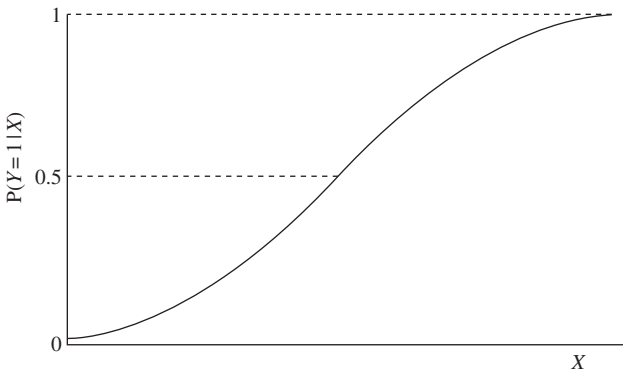

Figure 4 The probit model with a single independent variable, X.

A Latent Variable Model: One Derivation of Probit and Logit

Assume a continuous dependent variable, Y^c, that cannot be observed directly. But a binary indicator, Y, of Y^c is observable. In particular,

$$Y = 1 \quad \text{if} \quad Y^c \geq T^*$$

and

$$Y = 0 \quad \text{if} \quad Y^c < T^*,$$

where T^* is some threshold value for Y^c. In effect, T^* is a cut-point that divides values of Y^c into two groups: lower than T^*, and greater than or equal to T^*. Y^c is referred to as a latent variable (or unobserved indicator) for Y.

Assume that a set of independent variables have linear and additive effects on Y^c:

$$Y^c = \alpha + \beta_1 X_1 + \beta_2 X_2 + \beta_3 X_3 + \cdots + \beta_k X_k + \varepsilon. \quad (8)$$

Although Eq. (8) takes the form of a LARM, it cannot be estimated using OLS regression because Y^c is not observable. But the model can be estimated using maximum likelihood (ML) estimation, as long as some arbitrary assumptions about the value of T^* (typically that it equals zero) and the distribution of the error term, ε, are made. Specifically, both probit and logit assume that $E(\varepsilon\,|\,\mathbf{X}) = 0$. In probit, it is assumed, in addition, that ε is normally distributed (for all possible values of the independent variables) with a constant variance of one. In logit, it is assumed that ε has a logistic distribution (for all values of the Xs) with a constant variance of $\pi^2/3$.

An Alternative Derivation of Probit and Logit: Transforming $P(Y=1\,|\,\mathbf{X})$ to an Unbounded Variable

One can derive probit and logit without introducing the notion of a continuous latent variable. We start with the PRF for the LPM:

$$E(Y\,|\,\mathbf{X}) = P(Y=1\,|\,\mathbf{X}) = \alpha + \beta_1 X_1 + \beta_2 X_2 + \beta_3 X_3 + \cdots + \beta_k X_k. \quad (9)$$

It was previously shown that a problem with this model is that $E(Y\,|\,\mathbf{X})$ is the probability that Y equals 1, yet the linearity and additivity of the model ensures that $E(Y\,|\,\mathbf{X})$ is not constrained to be in the range between zero and one, the only possible values for a probability. The solution

is to use a mathematical function to transform (1) $P(Y=1\,|\,\mathbf{X})$ from the range between zero and one to the range between negative infinity and positive infinity so that it is consistent with the range of $\alpha+\beta_1X_1+\beta_2X_2+\beta_3X_3+\ldots+\beta_kX_k$, or (2) the unbounded value, $\alpha+\beta_1X_1+\beta_2X_2+\beta_3X_3+\cdots+\beta_kX_k$, to the range between zero and one so that it is consistent with the range of $P(Y=1\,|\,\mathbf{X})$. There are countless mathematical functions that accomplish this transformation.

With logit, $P(Y=1\,|\,\mathbf{X})$ is transformed first into the odds that Y equals 1 (i.e., the probability that Y equals 1 relative to the probability that Y does not equal 1):

$$\text{the odds that } Y=1 \text{ given } \mathbf{X} = \frac{P(Y=1\,|\,\mathbf{X})}{1-P(Y=1\,|\,\mathbf{X})} = \frac{P(Y=1\,|\,\mathbf{X})}{P(Y=0\,|\,\mathbf{X})}.$$

The odds (being the ratio of two non-negative values) cannot be negative, but as $P(Y=1\,|\,\mathbf{X})$ approaches one, the ratio approaches infinity, so the constraint to values less than one has been eliminated. Taking the logarithm of the odds removes the constraint to values greater than zero, arriving at a value that can range from negative infinity to positive infinity. The logit model assumes that the log of the odds that Y equals 1—also called the logit of Y— is a linear and additive function of the Xs:

$$\ln\left[\frac{P(Y=1\,|\,\mathbf{X})}{1-P(Y=1\,|\,\mathbf{X})}\right] = \alpha+\beta_1X_1+\beta_2X_2+\beta_3X_3+\cdots+\beta_kX_k. \quad (10)$$

With probit, $\alpha+\beta_1X_1+\beta_2X_2+\beta_3X_3+\ldots+\beta_kX_k$ is transformed to the range between zero and one using the cumulative distribution function (CDF) for the standard normal distribution.

Assessing the Impacts of Independent Variables

What Probit and Logit Coefficients Tell Us Directly

Since both probit and logit can be derived by assuming that independent variables have linear and additive effects on an unbounded latent variable, Y^c [see Eq. (8)], the probit or logit coefficient for independent variable X_i can be interpreted as the expected change in the latent variable associated with a unit increase in X_i when all remaining independent variables are held constant. Just as in the case of regression, a positive value for β_i indicates that when other independent variables are held constant, an increase in X_i tends to lead to an increase in the latent variable, whereas a negative coefficient means that an increase in X_i tends to prompt a decrease in Y^c. For example, the probit and logit ML coefficient estimates for GPA are positive (see columns 2 and 3 of Table I). This means that when BEGIN and METHOD:PSI are held constant, increases in a student's GPA tend to produce increases in the latent variable that the observed dichotomous variable, GRADE, measures—presumably a continuous measure of course performance. The positive coefficient estimates for METHOD:PSI imply that a student exposed to the experimental method (METHOD:PSI = 1) is expected to outperform one trained through traditional means (METHOD:PSI = 0) yet having the same values for BEGIN and GPA. Additionally, the standard errors of the coefficient estimates for METHOD:PSI and GPA suggest that these two variables have effects on class performance that are statistically significant.

Thus, probit and logit coefficients tell us the direction (positive or negative) of estimated effects of independent variables, and whether these effects are statistically significant. However, since the measurement scale for the latent variable is unknown, probit and logit coefficient estimates offer little directly interpretable information about the strength of the effects of independent variables. Fortunately, probit and logit coefficients can be used to calculate other statistics that can be very valuable for assessing the magnitudes of impacts.

Analyzing Changes in Predicted Probabilities that Y Equals 1

The best way to clarify the magnitude of the impact of an independent variable on a dependent variable is to estimate how much the dependent variable shifts when the independent variable is changed by a specified amount while the remaining independent variables are held constant. Armed with either probit or logit coefficient estimates for a model, one can predict the probability that Y equals 1 for any set of values for the independent variables. (Using software called CLARIFY, recently developed by Gary King and associates, one can also easily compute a confidence interval for this predicted value.) Such predicted probabilities permit a characterization of the magnitude of the impact of any independent variable, X_i, on $P(Y=1\,|\,\mathbf{X})$ through the calculation of the change in the predicted probability that Y equals 1 that results when X_i is increased from one value to another while the other independent variables are fixed at specified values. With probit and logit, since the effects of the independent variables on $P(Y=1\,|\,\mathbf{X})$ vary depending on the values of all independent variables, characterizations of the impact of a variable must specify the values at which the other independent variables are fixed. Most often, researchers report impacts when other independent variables are held at central values (i.e., their mean or their mode), but sometimes other values of theoretical interest are analyzed.

When assessing the strength of the impact of X_i, a variety of types of changes in X_i may be considered. For

a variable with a readily interpretable measurement scale, a change representing an easily described small increment is appropriate: for example, $1000 in annual income, 1 year of age, or 10 points on an IQ test. Studies have also reported the response of the predicted value of $P(Y = 1 \mid \mathbf{X})$ to a change based on specified locations within an independent variable's distribution: for instance, a change in the variable (1) from the lowest value in the sample to the highest, or (2) from one or two standard deviations below the mean to a comparable amount above the mean. With a binary independent variable, the choice of increment to analyze is simple, since the only possible change in the value of a binary variable is from one value to the other.

The need to select a single specific increment in X_i can be avoided by constructing a probability curve: a graph showing the relationship between X_i and the predicted value of $P(Y = 1 \mid \mathbf{X})$ over the range of X_i values in the sample, when the other independent variables are fixed at specified values. Such a graph can also include vertical "bars" around predicted $P(Y = 1 \mid \mathbf{X})$ values that depict confidence intervals for the predicted values. Figure 5 presents two probability curves reflecting the impact of a student's grade point average on class success, constructed using the probit estimates. (Because the graph is designed to show more than probability curves, bars indicating confidence intervals are excluded in the interest of visual clarity.) Both probability curves show the relationship between GPA and the predicted probability of class success assuming that knowledge at the beginning of the course (BEGIN) is held constant at its mean value in the sample (21.94). The upper curve shows the relationship for students taught by the experimental method (METHOD:PSI = 1); the other shows the relationship for students taught using the traditional approach (METHOD:PSI = 0). It can be seen, for example, that the predicted probability of success for a student with GPA equal to 2.5, with a BEGIN value at the mean, and who is taught by the traditional method is about 0.03. (Compare this to the nonsensical prediction produced by the LPM discussed earlier.)

Both curves have a substantial positive slope over a wide range of values of GPA, indicating that, overall, the effect of GPA on the probability of class success is strong among both groups of students. But for students with low GPAs and taught traditionally, even when they have a BEGIN value at the mean, the effect of GPA is quite weak. An increase in GPA from its lowest value in the sample (2.06) to the 25th percentile (2.80) leads to an increase in the predicted probability of success from 0.017 to 0.060, for a probability difference of only 0.043. Also note that, overall, the effect of GPA on the probability of success is stronger among students taught by the experimental approach than among students taught by traditional means. We can see this by calculating the predicted response of the probability of success to an increase in GPA from the lowest value in the sample (2.06) to the highest (4.00) among students taught by traditional methods to the same response in the PSI group. In the PSI group, the probability of success increases by 0.79 (from 0.11 to 0.90) as GPA increases from 2.06 to 4.00; in the traditional group, the same increase in GPA prompts an increase of 0.54 in the probability of success (from 0.02 to 0.56). The "difference in increases," 0.25 ($= 0.79 - 0.54$), is substantial. But because the sample

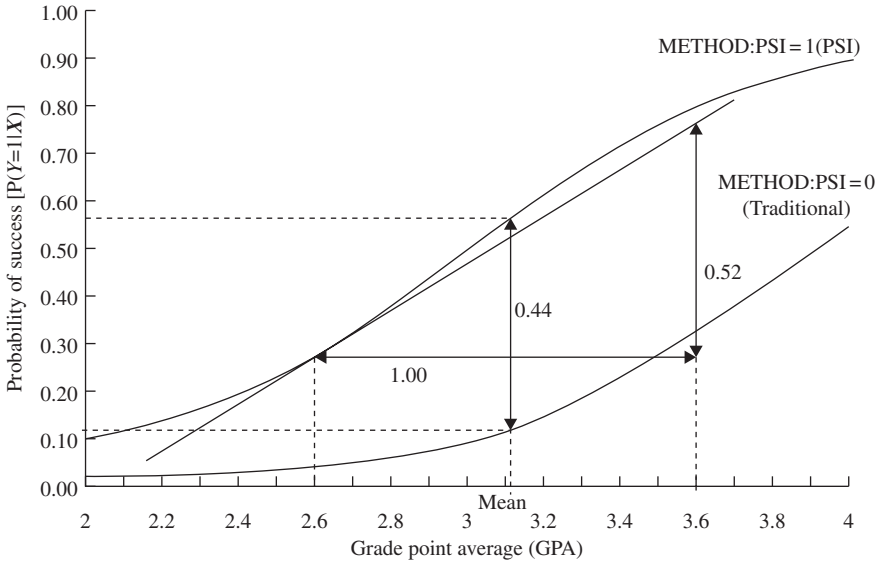

Figure 5 Probability curves for the class success model (based on the probit results in column 2 of Table 1). Note that this graph assumes that BEGIN is fixed at 21.94, its mean in the sample.

is very small ($n = 32$), the 95% confidence interval for the probability difference is quite wide: from just above 0.00 to 0.57.

We can also analyze predicted probabilities to assess the nature of the effect of method of instruction on student success. The impact of method of instruction is indicated in Fig. 5 by the vertical distance between the probability curves. When both GPA and BEGIN are set at their mean (for GPA, 3.117), students exposed to the traditional teaching method have a predicted probability of success of 0.12, but PSI-taught students are predicted to have a 0.56 chance of success, for a probability difference of 0.44 ($= 0.56 - 0.12$). Again, the 95% confidence interval for this probability difference is wide: from 0.09 to 0.74. At lower levels of GPA, the effect of teaching method is weaker, but the 95% confidence interval for the probability difference stays above zero over the entire range of GPA values in the sample.

Calculating Instantaneous Effects

Given a probability curve showing the estimated relationship between an independent variable (say X_i) and $P(Y = 1 \mid \mathbf{X})$ when the remaining independent variables are held constant, one could determine the slope of the curve at any value of X_i, x_i. (The slope of the curve at $X_i = x_i$ is defined as the slope of the line tangent to the curve at this point.) For example, Fig. 5 shows the tangent to the upper curve when GPA = 2.6, and indicates that the slope at this value is 0.52. Just as a partial slope coefficient in a LARM can be interpreted as a measure of the magnitude of the effect of an independent variable, so too can the slope of a probability curve. Indeed, the slope of a probability curve for an independent variable is often described as a measure of the instantaneous or marginal effect of the variable. (Note that the instantaneous effect of X_i is the derivative of $P(Y = 1 \mid \mathbf{X})$ with respect to X_i.)

For a LARM, a partial slope coefficient can be used to determine the expected response of the dependent variable to a change of any amount in the independent variable. If the partial slope coefficient for an independent variable, X_i, is β_i, then a k unit increase in X_i results in a change of $k\beta_i$ in the expected value of Y, no matter the value of k. In contrast, because the probability curve is not straight, the slope of a probability curve at a particular value of GPA does not give sufficient information to calculate the response of $P(Y = 1 \mid \mathbf{X})$ to any discrete change in GPA. In fact, because in probit and logit the effects of variables on $P(Y = 1 \mid \mathbf{X})$ are nonlinear and non-additive, the instantaneous effect of an independent variable depends on the value of that variable and all other independent variables. When BEGIN is at its mean and METHOD:PSI = 1, GPA has the greatest instantaneous impact (0.65) when GPA takes the value 3.01; this is the value of GPA at which the probability curve has its steepest rate of ascent.

Probably the most common practice when reporting the instantaneous effect of a variable is to calculate it assuming all independent variables are held at central values. Column 4 of Table I reports the instantaneous effects of independent variables in the class performance model (based on the probit results) when all independent variables are held at their mean. Instantaneous effect estimates are most meaningful when all independent variables are continuous, since "holding all independent variables at their mean" nicely reflects a hypothetical case with typical values. However, if one of the independent variables is dichotomous (like the method of instruction in the class performance model), holding the variable at its mean yields a value that does not exist in the sample, making it difficult to glean substantive meaning from an instantaneous effect estimate.

Calculating Changes in the Odds (with Logit)

Another approach to interpreting the effects of variables in a BDV model is estimating the change in the odds that Y equals 1 associated with a given increase in an independent variable. (Recall that the odds that Y equals 1 is the ratio of the probability that Y equals 1 to the probability that Y does not equal 1.) This method is applicable when logit is used, but not probit. Assume that the logit coefficient estimate for an independent variable, X_i, is β_i. One hundred multiplied by $[\exp(\beta_i) - 1]$ yields the percentage change in the odds that Y equals 1 resulting from a unit increase in X_i when the remaining independent variables are held constant. Equivalently, it can be said that a unit increase in X_i changes the odds that Y equals 1 by a multiplicative factor of $\exp(\beta_i)$. This factor is independent of both the starting value for X_i and the values at which the other independent variables are fixed, and thus $\exp(\beta_i)$ is a single value that can summarize the effect of X_i. This is an advantage of $\exp(\beta_i)$ over characterizations of independent variable impacts based on predicted probabilities—which are specific to particular values for the independent variables.

Consider the logit coefficient estimate for METHOD: PSI in our exam success model: 2.38. The antilog of 2.38, exp(2.38), is 10.80. This means that a shift from a student being taught traditionally to being taught by the PSI method increases her predicted odds of success by a factor of 10.80. [If her odds of success when being taught traditionally were 1.5, her odds would be (1.5) (10.8) = 16.2 under PSI.] Subtracting 1 from 10.80 yields 9.80, which when multiplied by 100 becomes 980. Thus, we can also say that the change in method of instruction increases the odds of success by 980%. [1.5 increased by 980% = 1.5 + (9.8) (1.5) = 16.2.] If for some independent variable $\beta_i < 0$, this implies that an increase in X_i decreases the odds that Y equals 1. For example, if $\beta_i = -0.50$,

then $\exp(\beta_i) = 0.61$, and $0.61 - 1.00 = -0.39$. This means that when X increases by one, the odds that Y equals 1 decreases by 39%; equivalently, the odds that Y equals 1 changes by a multiplicative factor of 0.61.

Statistical Inference and Goodness of Fit

Many of the possibilities for statistical inference with probit and logit mirror the options available in regression. Software for estimating probit and logit models generally reports standard errors for individual coefficient estimates. The standard errors can be used, just as with a regression model, to determine for each independent variable whether the estimated effect of the variable is statistically significant. The running example has shown that the effects of both GPA and method of instruction on class performance are statistically significant (at better than the 0.05 level). One can also conduct joint hypothesis tests for a subset of coefficients (e.g., that $\beta_1 = \beta_2 = 0$), or a test of the null hypothesis that the coefficients for all independent variables are zero (which serves as a measure of the goodness of fit of the model). Both of these tests are based on a likelihood ratio statistic that approximates a chi-square distribution. In the class performance illustration, the chi-square statistic for the goodness of fit of the model is a bit over 15 (with 3 degrees of freedom) for both the probit and logit analyses, indicating significance at better than the 0.01 level.

Probit and logit do not yield the R^2 coefficient produced by regression. A number of "pseudo-R^2" coefficients that range between zero and one have been developed and can serve as goodness-of-fit measures for a probit or logit model. However, none of these statistics has achieved wide acceptance as a standard measure of fit.

Another common goodness-of-fit measure for probit and logit is the so-called percent correctly predicted (PCP). This is computed by using the coefficient estimates along with the values of independent variables for cases in the sample to predict $P(Y = 1 \mid \mathbf{X})$ for each case. Every case for which $P(Y = 1 \mid \mathbf{X})$ is estimated to be greater than 0.5 is predicted to have a Y value of 1; all cases for which $P(Y = 1 \mid \mathbf{X})$ is less than 0.5 are predicted to have $Y = 0$. Then, these predicted Y values are compared with the observed Y values for cases, and the proportion of the cases for which the two agree is calculated. The higher this value, the better the presumed fit of the model. The value of this statistic declines, however, as the distribution of the dependent variable becomes skewed. This is because the PCP cannot drop lower than the proportion of cases in the modal category (PMC) of the dependent variable. The proportional reduction in error (PRE) is a statistic that overcomes this weakness of the PCP by indicating how much a probit or logit model reduces prediction error over the model that predicts that all cases have the modal value of the dependent variable. The PRE can be calculated by

$$\text{PRE} = (\text{PCP} - \text{PMC})/(1 - \text{PMC})$$

For the class performance model, the PCP is 0.813 with either probit or logit. In the data set, the modal category of GRADE is "failure" (0), with 65.6% of the cases. Thus, $\text{PRE} = (0.813 - 0.656)/(1 - 0.656) = 0.157/0.344 = 0.456$. In effect, the naïve model assuming that all cases are in the modal category of the dependent variable is in error for 34.4% (100% − 65.6%) of the cases. Since the PCP by the probit/logit model is 15.7% (i.e., 81.3% − 65.6%) greater than the PCP by the naïve model, the probit/logit model reduces the error in prediction by 45.6% = (15.7%/34.4%).

Problem-Solving Methodologies

Ton de Jong
University of Twente, Enschede, The Netherlands

Glossary

card sorting Assessment technique for charting the structure of knowledge in the knowledge base of the problem solver. Subjects have to arrange cards with information. The content of this information depends on the goal of the assessment.
problem A perceived gap between a current situation and a desired situation that the problem solver does not immediately know how to bridge.
problem representation The mental representation of a certain state of a problem.
problem-solving process The transformation of the start state of a problem to the goal state.
thinking aloud Assessment technique in which subjects solve a problem while concurrently reporting aloud on their problem-solving process and the evolving problem representation.
transfer problems Problems different from originally learned problems that can be used to measure the range of applicability of problem-solving knowledge.

Problem solving is the process in which a person wants to reach a desired situation from a present one and does not know immediately what to do. Problems can be classified on two dimensions: the amount of domain knowledge needed to solve the problem and the ways the start state, goal state, and operators of the problem are defined. In the problem-solving process, a distinction is made between states of a problem, the processes involved in taking the problem from the start state to the goal state, and the relevant knowledge base of the problem solver. A number of assessment techniques are available for measuring the problem states, the problem-solving processes, and the knowledge base.

Problems and Problem Solving

Problem solving is a widely esteemed capability and much of our education aims to teach learners problem solving in some kind of domain. In 1945, Duncker defined a problem as a perceived gap between where a person is (the current situation) and where he or she wants to be (the goal situation) and, in addition, when the person does not know immediately how to cross the gap. According to Duncker, problem solving involves "thinking," namely devising steps that will take one from the current to the desired situation; Robertson also discussed problem solving in a 2001 book.

Problems exist in many variations and in many domains. There are physics problems, algebra word problems, design problems, etc. In the literature, there are two general classifications of problems. One is on the dimension that involves the amount of domain knowledge that is necessary to solve the problem (semantically rich vs. semantically poor problems), and the second dimension has to do with the way the start state, end state, and necessary operators in the problem are defined (well-defined vs. ill-defined problems).

Semantically rich (or knowledge-rich) problems are those that require knowledge of a specific domain to be solved. Of course, these domains can be very diverse, including medicine, biology, and physics. Semantically rich problems require their own specific operations in moving from the current problem state to the goal state. In physics problems we probably have to use physics procedures, in mathematics problems we may have to apply operations such as differential equations, and in

medical problems we use medical knowledge to link symptoms with diseases. On the other side of the spectrum are semantically poor (or knowledge-lean) problems. These problems do not require prior domain knowledge; basically, all the information needed is in the problem statement. Puzzle-type problems fall into this category; examples, discussed by Simon and Hays in 1976, are the missionaries and cannibals problem and the Tower of Hanoi. The second dimension on which problems can be characterized is the level of "definedness." Well-defined problems are those for which the start state is well described, the goal state is clear, and the necessary operators are in principle known. In contrast, ill-defined problems have a start state that is not fully defined, it is not always clear when the goal state is reached precisely, and new operators may be necessary. Examples of ill-defined problems come, for example, from design. In designing a building, there may be much negotiation at the start of the project. One may debate (and one generally does) if the final design meets the requirements (and is esthetically well done), and a creative element is involved in the design process, as described, for example, by Goel and Pirolli in 1992. Ill-defined problems (which are sometimes called wicked problems) are problems that generally require collaboration of people with different expertise, as discussed by Van Bruggen *et al.* (2003).

The Problem-Solving Process

Whatever the kind of problem or the domain involved, the problem-solving process can be described in general terms. In 1957, Polya divided problem solving into the following four stages: understanding the problem, devising a plan, carrying out the plan, and looking back. Polya's seminal work has been of great importance for our first understanding of problem solving and for the design of courses on how to learn to solve problems. Later, more detailed and cognition-oriented descriptions of the problem-solving process have been presented. Figure 1 gives an overview of the problem-solving process based on a 1996 model by de Jong and Ferguson-Hessler.

In Fig. 1, a distinction is made between states and processes. The states represent (i) the problem statement, which is the description of the problem as presented to the problem solver; (ii) the problem representation, which is the internal representation of the problem as created by the problem solver; (iii) the problem solution, which is in fact the final problem representation including the "answer" to the problem; and (iv) the knowledge base, which comprises the prior knowledge that the problem solver brings to the task. The processes presented are (i) selective perception, which is the process through which the problem statement is "filtered" and in which the selection of information to be included from the problem statement in the problem representation is made; (ii) information retrieval, which is the process of selecting relevant information from the prior knowledge of the problem solver; and (iii) the problem-solving process, which transforms the problem representation from the start state to the goal state.

Figure 1 can be used to describe the problem-solving process of all kinds of problems. Differences between problems will only emerge when the states and processes are examined in more detail. For semantically poor problems, for example, no information, apart from general reasoning strategies, has to be retrieved from memory. For wicked problems, the development of an initial problem representation will be more complex than for a semantically poor problem.

Assessment of Problem Solving

Figure 1 may also form the basis for classifying techniques on how to measure problem solving and its related components. Basically, all the processes and knowledge states from Fig. 1 can be measured.

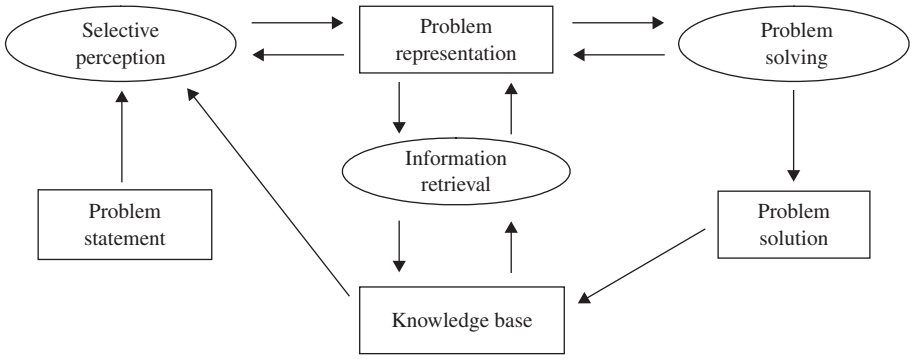

Figure 1 Schematic overview of the problem-solving process.

The problem solution is the aspect that is measured most often. In schools, students are mostly graded by the solution they give to a problem. For well-defined problems this is quite straightforward: there is only one good solution and this is straightforwardly evaluated. For ill-defined problems, solutions are less easy to assess. A rubric to judge the solution will be necessary and in some cases (e.g., architectural design) a reliable assessment will not be easily reached.

The problem representation is the evolving representation of the problem in the mind of the problem solver. Problem solvers alter the problem continuously while solving, either by adding information from the knowledge base or by applying operators that change the state of the problem. The starting state is the problem statement as given to the problem solver; the ultimate representation is the problem's solution. This solution is normally externalized, which is not necessarily the case for the intermediate states. Assessment procedures, therefore, need to include mechanisms to create access to the problem representation.

The knowledge base that the problem solver brings to the task is, of course, multifaceted. An adequate measurement of the characteristics of the knowledge base considers the knowledge base from the perspective of problem solving. In this respect, in 1996 de Jong and Ferguson-Hessler distinguished situational knowledge (knowledge of characteristic problem situations), conceptual knowledge (concepts and principles), procedural knowledge (domain-specific operations), and strategic knowledge (general approaches in the problem-solving process) and recognize that, in addition, the organization of these types of knowledge in the mind of the problem solver is especially important. Assessment methodologies for the knowledge base differ with respect to the aspect that is being measured and include techniques such as reproduction, card sorting, and concept association.

In the actual problem-solving process we can distinguish between the procedures used by the learner (procedures bring about the changes from one problem state (representation) to another) and the overall strategy used. Procedures are mostly domain specific (called strong methods). The overall strategy includes the way the problem solver finds his or her way through the problem space. These strategies or "weak" methods include approaches such as depth first, breadth first, hill climbing, and means-ends analysis. Also, overall strategies that divide the problem-solving process into distinct phases, as discussed by Polya in 1957, can be mentioned here. Measurement techniques for charting the problem-solving process include thinking aloud and cued recall.

In the information-retrieval process, the problem solver "decides" what knowledge to use from his or her knowledge base. This information can be specific concepts, procedures, etc. Together with the information that was selected from the problem statement, this information forms the basis for the problem-solving process. For this process, the situational knowledge that a problem solver brings to the task is especially important. Problem solvers can have schemata of situations that help them to add relevant information to the problem situation as presented. This is not a trivial issue since studies have shown that problem solvers often have relevant knowledge in their knowledge base that they use in solving a problem. Perfetto *et al.* in 1983 called this inert knowledge. The information-retrieval process can be measured by, for example, think-aloud techniques.

Selective perception is the process in which the problem solver decides what to use from the problem statement and, as a consequence, also what not to use. This process is strongly guided by the problems solver's situational knowledge. Selective perception can be assessed by using eye tracking techniques.

In the following sections, measurement techniques for assessing the previously mentioned aspects of problem solving are discussed. First, an analysis of an assessment technique that is most obvious and most widely used is discussed—that is, having people solve problems. Then, a number of assessment techniques that have an emphasis on measuring either processes or states are presented. The techniques discussed are empirical (and not logical) and conceptual (and not statistical) methods.

Measurement by Solving Problems

Examinations often consist of problems to be solved. As such, they measure all aspects of the knowledge base together with the actual problem-solving process. By changing the characteristics of the problems to be solved, an emphasis on different knowledge and process aspects can be achieved. A theoretical task analysis of the problems may clarify the knowledge needed to solve the problem. In the case of domain-specific problems (e.g., physics and medicine), there is, of course, an emphasis on knowledge from the specific domain. However, problems may also focus on more general skills. For example, the PISA 2003 framework includes a test for the assessment of general problem-solving skills. The test focuses on three general types of problems: decision making, system analysis, and design and troubleshooting. Analytic reasoning, quantitative reasoning, analogical reasoning, and combinatorial reasoning are required for solving these type of problems. At an intermediate level, there are problem-solving tests that focus on problem-solving abilities in specific areas (e.g., science).

A specific characteristic of problem-solving knowledge and skills is the range of applicability. In transfer test, problems are offered that differ from the problems a subject knows how to solve, and the idea is that when

a known solution procedure has general character, it will facilitate solving the transfer problems or facilitate the learning of how to solve the transfer problems. Transfer problems can take many forms, such as variations in context or problem-solving procedure.

One disadvantage of offering learners problems to solve is that normally only the problem solutions become available. Problem solvers may have achieved their result through very different routes, and, maybe even more important, problem solvers may have failed to reach the solution for many different reasons (e.g., miscalculations). One solution might be to ask problem solvers for intermediate results. Another approach could be to examine notes that problem solvers take.

A second disadvantage of placing people in a traditional problem-solving situation is that only an aggregate of performance can be measured. Snow (1989) made a strong plea for the development of instruments that measure specific aspects or qualities of knowledge and skills. The next two sections present techniques that can be used to concentrate on particular parts of the problem-solving process as distinguished in Fig. 1.

Measuring Problem-Solving Processes

Thinking Aloud

Thinking aloud (and the protocol analysis that follows it) is possibly the most widely used technique for measuring processes. The well-cited 1980 book by Ericsson and Simon marked a very strong revival of this technique after the abandoning of introspective techniques. Part of its popularity is due to the relative ease with which it can be applied. However, the analysis of the data makes the technique just as laborious as many other techniques that require more preparation time. A second advantage of this method is that it delivers qualitative data and can be applied to as few as one subject. An obvious disadvantage of thinking aloud is that it may interfere with the main task a subject has to perform and tasks may be so automated that they are not accessible for thinking aloud anymore. Also, thinking-aloud data are subject to potentially low reliability. Thinking aloud can also be used to get an impression of problem states. One can, for example, use protocol analysis for determining the students' cognitive structure of Newton's second law. In 1992, Boshuizen and Schmidt examined the encapsulation of domain terms used in protocols of experts and medical students when solving a medical diagnosis problem.

Discontinuous Thinking Aloud

In discontinuous thinking aloud, subjects are interrupted while performing a task at certain times or during specific events and asked to report on what they were doing just before being interrupted. The advantage of this method over full thinking aloud is twofold: There is no constant interference of speaking aloud with the main task and the interruptions also provide a prompt to uncover processes. As they reported in 1990, Ferguson-Hessler and de Jong used this method for charting learning processes of learners in a domain of physics. Instead of asking subjects to think aloud at certain points, they posed specific questions at several points in the problem-solving task (such as "What do you plan to do next?" and "Why would you do this?").

Stimulated Process Recall

A modification of thinking aloud is stimulated process recall. In stimulated process recall, subjects are confronted with actions that they performed while doing a task (and that were recorded in one way or another) and are asked to describe in retrospect what they did at that moment. The advantage over full thinking aloud is that the subject's main task (problem solving) is not interrupted. A clear disadvantage is that subjects may rationalize their acts and possibly will not report their factual thoughts. Stimulated recall is recommended over thinking aloud when it is expected that the main task will consume much of the subjects' cognitive resources.

Conversations

A more natural way of collecting thinking-aloud data is to record the conversation of subjects solving a task together. When the task is being done on a computer, it is common practice that subjects work together. Miyake, for example, used this method in 1986, to get a view of people's process of trying to understand the working of a sewing machine. Others have used the same technique to study mathematical problem solving.

Logfiles

When a task is performed with the use of a computer, subjects' procedures or strategies can be measured by the recording of logfiles. For example, in a 1983 study, Sweller *et al.* had subjects solve mathematics problems on a computer and inferred the strategies used from the sequence of steps employed by the subjects. The ACT-based tutors (see for example Anderson *et al.* 1992), discussed by Anderson *et al.* in 1992, are among the best known computer programs (intelligent tutoring systems) that teach problem solving and make extensive use of recording students' actions for cognitive diagnosis. A precondition for an adequate analysis here is that the domain is well structured and has a "procedural" character, as is

the case with the ACT-based tutors (that teach domains such as LISP programming and geometry proofs), because only then can a more or less exhaustive domain description be made to match the subjects' actions.

Eye Movements

Recordings of eye movements of subjects who solve problems can be used to gain information on specific parts of the problem-solving process (e.g., the selective perception). In a study in which expert and novice dentists were presented X-rays of caries problems, it was found that experts pay more attention to what they call cognitively and visually conspicuous areas.

Measuring the Knowledge Base

Reproduction

Reproduction is the main objective of most traditional tests, in which subjects are requested to reproduce information that they have previously seen and rehearsed. This type of test is very well suited for measuring knowledge of a superficial level. It normally concentrates on conceptual and procedural knowledge.

Card Sorting

We use the term card sorting as a general term for the technique in which subjects have to arrange, in some way, pieces of information ("cards") they are offered. This technique is mainly used for getting an idea of the organization of knowledge. Originally, this technique was restricted to finding the relations between concepts. One can let subjects indicate the similarity of pairs of concepts by drawing lines between them and ordering the lines, have subjects quantify the relations between concepts, or have subjects sort concepts that are printed on cards. As a modern variant of the card-sorting technique, computerized concept mapping techniques have been introduced. Here, elements of knowledge (mostly concepts) are placed on the computer screen and subjects can arrange them spatially to indicate a relation. Some of these programs include extensive algorithms for analyzing the resulting configurations.

Although most frequently used for arranging concepts, in the context of problem solving, cards have also been used with other information, such as subjects' problem situations. This approach was used by Chi *et al.* in 1981. In this well-known study, students had to sort descriptions of physics problems. Chi *et al.* found that experts sorted the problems according to domain-related features, whereas novices used surface characteristics as a basis for their sorting. From this, the authors inferred that novices and experts differ in their level of knowledge, with the experts having a deeper knowledge. In other studies, subjects had to sort problems (area-of-rectangle problems) that contained missing, sufficient, or irrelevant information into one of these three categories. In 1986, De Jong and Ferguson-Hessler offered subjects cards that contained situational, conceptual, or procedural information from the physics topic "electricity and magnetism." Subjects were instructed to sort the cards so that coherent piles would result. Comparing the sorting from the subjects to an ideal sorting according to problem schemata, it was found that good novices had an organization that was much closer to the schema-based organization than did poor novices. When the same task was performed to experts, a different type of organization emerged.

Concept Association

Word or concept association is in fact the same technique as card sorting, with the exception that subjects are offered one stimulus (frequently a concept) and they are free to name all the other concepts they can think of. This technique has been used in many studies over many years. As with the card-sorting technique, only concepts were originally used as the starting stimulus. Other types of stimuli have now also been used, such as complete problem descriptions. In their 1981 study, Chi *et al.* offered their subjects labels of categories of problems and gave their subjects 3 minutes to tell everything they could about problems involving each category label and how these might be solved. From these data, Chi *et al.* made inferences about the knowledge organization of their subjects.

Explanations

A rather open way to measure subjects' knowledge is to ask them to give a free explanation of phenomena. In a 1991 study, Andre and Ding, for example, presented subjects with diagrams of electrical circuits and asked them to tell whether the system would work and explain why or why not. Mestre *et al.*, in 1993, presented subjects with a situation in physics, the experimenter introduced a change, and the subjects had to predict the result. Then, subjects had to write down a free explanation of the phenomenon. Mestre *et al.* developed a method of analysis to measure the structured use of a key concept—in their case, the work–energy concept. In the field of medical problem solving, in a 1993 study, Schmidt and Boshuizen had subjects write down so-called "pathophysiological explanation protocols" after they had given reconstruction of clinical cases.

Reconstruction

Reconstruction techniques are frequently used for measuring or indicating the presence of schemata in the

knowledge base. Subjects are offered information (e.g., a story or a problem description) that they have to reconstruct later. The basic idea behind this technique is that what is remembered reflects the knowledge of the learner. If this knowledge is expected to comprise schemata, one might expect that information that is part of a schema is remembered better than information that is not incorporated in the schema. This latter information, for example, concerns information on details. In this technique, the experimenter takes care that the information that is offered cannot be learned by heart. To prevent learners from doing so, one can present a sequence of a number of problems and subsequently have subjects give reconstructions, or one can make the time for reading the information too short to allow for learning by heart. This technique was introduced by Jongman in 1967 in his study of memorizing chessboard positions. For a very short period of time, subjects were shown configurations of pieces on a chessboard, which they had to reproduce afterwards. In theory, the very short "exposure time" made it impossible to learn the positions by heart. The same technique in the context of problem solving was used on electronic circuits, algebra word problems, and complex devices. In 1991, de Jong and Ferguson-Hessler introduced a modification of this technique by having subjects reconstruct problem statements from physics (after a short exposure to these statements) and asking subjects in a number of cases to reconstruct a problem statement in a different modality (words or figures) from the one in which it was offered. They found that good problem solvers gave better reconstructions than poor problem solvers when they had to change modality from reading to reconstruction, but that the poor students outperformed the good students when they could stay within the same modality. They inferred that good students have a deeper understanding of problem situations. In 1992, Boshuizen and Schmidt used a reconstruction technique to assess the characteristics of conceptual knowledge of medical students. Clinical cases were presented under a controlled period of time, and subjects had to reconstruct the case later. Boshuizen and Schmidt analyzed the protocols on the type of concepts used and concluded that experts use higher level concepts than novices and intermediates. The authors varied the time of studying and found that expert's reconstructions were largely unaffected by this manipulation but that novices and intermediates produced better reconstructions when studying time was longer. They explain that this result is due to the fact that experts use so-called encapsulated knowledge while processing and reconstructing the case. Finally, in a 2002 study, Savelsbergh *et al.* let subjects construct problems on the basis of formula that could be used in a problem-solving process. In comparing novices and experts, they found that competence is related to the structure of knowledge of problem situations rather than the use of particular concepts.

Process Evaluation

Sandra Vergari
University at Albany, State University of New York, Albany, New York, USA

Glossary

applied research An investigation aimed at producing findings that can be used to address a real-world problem.
evaluation The use of social science research methods to assess the effectiveness of a policy or program.
formative evaluation An assessment conducted during program implementation, aimed at providing feedback for continuous improvement.
policy An official course of conduct linked to the achievement of one or more social objectives.
program A structured social intervention or treatment in which specific resources and activities are aimed at producing one or more outcomes.
program implementation failure The outcome when program activities assumed to be necessary for program effectiveness are not performed as planned.
program monitoring The ongoing assessment of program dynamics during implementation, to determine whether actual practice reflects the assumptions and objectives of the planning phase.
program process theory A set of interrelated statements specifying the assumptions and expectations about how a program will operate.
program theory failure The outcome when a program is implemented as planned, but does not produce the expected results.
triangulation The use of multiple methods or sources to study a phenomenon, thereby increasing confidence in the validity of the findings.

Process evaluation is aimed at discovering whether a policy or program is operating as originally planned. Process evaluators examine what is actually occurring during the implementation and delivery of a program. Process evaluation assesses the extent to which program planning assumptions were accurate and program goals are being met. Whereas impact evaluation focuses on identifying effects produced by a program, process evaluation helps to explain why such results occurred.

Evolution of Process Evaluation

History and Experts

Evaluation has historical roots in the 17th century, but evaluation as currently practiced is a relatively recent phenomenon. The emergence of evaluation as a specialty field coincided with the growth of the social sciences and with increased support for research on social policies. Health and education programs were the frequent subjects of early evaluation efforts in the 20th century. Although outcomes (or "impacts") have traditionally been the focus of many evaluation efforts, experts note that process evaluation is also critically important. In contrast to early impact evaluations, which tended to assume that a program was operating as intended or as administrators claimed, process evaluation examines practice and data to determine whether the program is indeed operating as intended or claimed.

Pioneers and experts in the evaluation field include Ralph W. Tyler in the early 20th century, and Donald T. Campbell, Lee J. Cronbach, Howard E. Freeman, Peter H. Rossi, Edward A. Suchman, and Carol H. Weiss in the second half of the 20th century. By the 1960s, evaluation research was common practice and evaluation emerged as a specialty field in the 1970s. Today, there are academic journals devoted to evaluation, such as *American Journal of Evaluation* and *Evaluation Review*, and professional organizations for evaluators, such as the American Evaluation Association. Advances in social science research methods, especially developments in survey research and in applications of computer

technologies, have contributed to the rise of evaluation as a specialty field. Whereas the nascent evaluation field was shaped largely by social science researchers, contemporary evaluation has been influenced by policymakers, program administrators, and other stakeholders such as political interest groups.

Evaluation Training

Evaluators typically receive training in the social sciences or in professional schools that provide instruction in applied social research. Beyond evaluation research methodology, evaluators need to be knowledgeable about the specific program areas, such as education, crime, or welfare, that they investigate. Evaluation projects that are technically complex, longitudinal, and costly are often completed by highly skilled evaluation staffs based in evaluation centers or research firms.

Evaluation Standards

Evaluation experts have not developed a concrete evaluation theory that prescribes precise evaluation activities for particular contexts. The disciplinary diversity of the evaluation field, disagreement among experts regarding optimal methodologies, and the scope and fluidity of the settings in which evaluation occurs have precluded the formation of such a theory. However, the field has developed evaluation standards and methodological guidelines aimed at promoting ethical, feasible, and useful evaluation. One well-known set of 30 evaluation standards has been produced by The Joint Committee on Standards for Educational Evaluation. The 1981 version of the standards was revised in 1994 to include applications to sites in addition to school settings. The American Evaluation Association has also approved its own set of five "Guiding Principles for Evaluators."

Both the broader context and site of a process evaluation may be fluid and unpredictable. As a result, evaluators operate according to a carefully designed research plan and are also flexible in tailoring their efforts to particular dynamics that arise while the evaluation is underway. Accordingly, process evaluation is frequently characterized as both an art and a science.

Process Evaluation and Its Purposes

What Is Process Evaluation?

Process evaluation involves the use of social science research methods to make judgments about the operation of a policy or program. As a form of applied research, it is aimed at helping to address real-world problems or questions. Process evaluation compares a program as implemented to the program as planned. Observations are focused on what is done during the implementation or delivery of a program and how it is done. Process evaluation identifies those involved in program implementation, those affected by the program, and problems encountered by the program's administrators and clients. Process evaluation assesses the extent to which program planning assumptions were sound and program goals are being met. One of the key purposes of process evaluation is to identify changes that need to be made in order for a program to operate as originally planned, be more effective, and/or be more efficient.

Process evaluation may take place over a period of months or years and can be narrow or broad in scale. A process evaluation might assess the operation of a particular after-school program in a single school district or state, or it might assess the implementation of a multifaceted preventative health program across a range of cities.

Purposes of Process Evaluation

It is important to note that process evaluation does not assess whether a program yields the planned outcomes for its clients. When a program model has been found to be effective elsewhere and process evaluation of a given program indicates that it is well implemented, it is still possible that certain features of the particular setting have prevented the program model from producing the desired outcomes in that setting. Conversely, impact evaluation assesses outcomes, but does not scrutinize whether features and dynamics of the program delivery process are operating as planned. Whereas impact evaluation focuses on identifying effects produced by a program, process evaluation helps to explain precisely why such results occurred. The findings of process evaluation complement those of impact evaluation.

In cases in which impact evaluation discovers the absence of predicted effects, process evaluation can determine the type of program implementation failure that has occurred. Types of implementation failure include the absence of a particular program activity or insufficient activity, use of the wrong procedure or activity, and nonstandardized program delivery that varies significantly across the target population. Process evaluation is especially helpful in cases in which the program implementation or delivery process varies across several settings. This is because process evaluation can identify differences across the settings; these can be matched up with the findings of impact evaluation in order to draw conclusions about the most effective way to deliver a given program. When a process evaluation finds that a program was implemented as planned, yet the impact evaluation indicates

Table I Questions Addressed by Process Evaluation

Primary question	*Detailed assessment*
How well is the program plan being implemented?	Are administrators implementing the program according to the program plan?
	Is the target population being served and responding as planned?
	How do program personnel perceive the operation of the program?
	How do program clients perceive the operation of the program?
	How do expert observers perceive the operation of the program?
Are the theoretical assumptions underlying the program plan accurate?	Is the program operating as indicated in the program process theory?
	Is it likely that program outcomes are connected directly to particular program components and processes, or are the outcomes likely to be due to factors separate from the program?
	Which circumstances and practices appear to promote effective delivery of the program?
How can the program be improved?	What are the barriers to efficient and effective delivery of the program?
	What changes would make the program delivery process more efficient and effective?
If the program in its current form is implemented at a different site, are the desired processes and results likely to occur?	

that anticipated outcomes were not produced, the evaluators have discovered a program theory failure.

As indicated in Table I, process evaluation is aimed at addressing a number of important questions about program delivery. The primary purposes of process evaluation can be summarized as follows. First, process evaluation is a type of formative evaluation aimed at improving the design of a new program and at facilitating continuous improvement. Second, process evaluation may be focused on monitoring the operations of established programs with the aim of gauging fidelity to the original plan, effectiveness, and efficiency. Third, process evaluation may be used to assess the validity of the theoretical assumptions at the heart of the original program plan. Fourth, process evaluation may be used to demonstrate accountability to program funders and policymakers. Finally, process evaluation is undertaken in order to discover the reasons for the results observed in an impact evaluation and to enhance overall confidence in the findings of an impact evaluation.

Methods of Process Evaluation

Planning the Process Evaluation

A sound process evaluation design identifies the key program components to be assessed during the evaluation. Such components may include program strategies, target population(s), activities and opinions of program administrators and clients, and technology and media used for program delivery and recordkeeping.

In planning the process evaluation, the evaluator figures out answers to a number of key questions:

- What types of information will be included in the study?
- How often will data be collected?
- Who will collect the information?
- How will the evaluator gain access to program administrators and clients?

The process evaluator can try to prevent barriers to researcher access during the study by clarifying the research relationships between the evaluator, program personnel, and target population prior to beginning the study. In addition, the evaluator must plan data collection measures that are feasible for use within the time frame and budget for the project. Prior to beginning the process evaluation, it is wise for the evaluator and sponsor to formulate an agreement on the type of evaluation and type of report that are reasonable to expect given the resources and time frame allotted. Evaluators also take care to consider the purposes of the process evaluation as viewed by the sponsor and other stakeholders.

Many experts suggest that data collection for process evaluation is best guided by a carefully developed causal model that specifies the key components of the program, how it is intended to function, and the relationships necessary for program effectiveness. A program process theory specifies the assumptions and expectations about how a given program will operate, including the organizational plan and the types of relationships between program personnel and the target population. Prior to undertaking the process evaluation, the evaluator may develop hypotheses

about causal relationships between key program components, intervening variables, and program outcomes. The evaluator might construct diagrams that portray the functions that the program is supposed to fulfill and the specific performance goals that have been established for the program. The process evaluator then uses performance measures to gauge the extent to which the program is performing according to the planned functions and performance goals.

Data Collection Methods

Process evaluation usually employs primarily qualitative research methods. It includes observation of both informal and formal activities and patterns during program implementation. Process evaluation data may be derived from a range of sources. Program personnel and members of the target population are key sources of information for process evaluation. Structured, formal interviews with program administrators and clients can provide valuable information about program processes. Open-ended interviews and informal conversations can also provide critically important information for the process evaluation. It is important to interview both program personnel and members of the target population to obtain their respective perspectives on how the program is actually operating. Moreover, external actors with expertise on a given program, such as journalists, community members, and university professors, might be interviewed. Interviews may be face-to-face or over the telephone. Process evaluators might also administer questionnaires to program personnel and clients. For example, the process evaluator might secure the cooperation of the program administrators to ensure that each time program personnel are in contact with a client about program delivery, the client is asked to complete a questionnaire for the process evaluation.

Other data sources for process evaluation include program records (e.g., the volume of program pamphlets distributed, the venues in which they were distributed, the number of queries received in response, and the average time frame for responding to such queries), meeting schedules, meeting minutes, e-mail communications, and formal and informal direct observations of program dynamics.

Skilled process evaluators take care to engage in triangulation, whereby research findings are based on multiple perspectives. Process evaluators seek information and perspectives from knowledgeable sources located inside and outside of the program.

Process Evaluation Challenges

Process evaluators are confronted with various technical and political challenges during the research design, implementation, and dissemination phases. First, it takes time to secure approvals for evaluation procedures and access to program administrators and the target population. Program personnel may be reluctant to participate in the process evaluation and to provide information for the study. They may resent having their activities scrutinized, and may be concerned about the process evaluation findings and implications for the continuity of their program. In its most extreme form, lack of cooperation from program administrators and clients can preclude the completion of a process evaluation. Thus, prior to beginning the process evaluation, it is useful for the evaluator to meet with program administrators and personnel in order to learn about any concerns on their part, to try to ease those concerns, and to promote cooperation between the evaluator and the research subjects.

A second concern is that program circumstances and activities may change during the course of a process evaluation, requiring potentially costly changes in the evaluation research design. It may be difficult, for example, to track program dropouts, and the rate of client attrition in a program may compromise the validity of the study. Similarly, expectations for the process evaluation may not materialize. For instance, the target population may be difficult to locate and identify and may be uncooperative. In addition, the sample of program clients to which the evaluator has access may be too small to ensure confidence in the process evaluation findings.

Third, the evaluator who plans to use program records as a data source may find biased, inaccurate, and sloppy data and recordkeeping processes. For example, a school might intentionally record some forms of student misbehavior as minor disciplinary incidents rather than as serious incidences of harassment. Operators of a community renewal program may neglect to track the precise number of community members who show up for scheduled meetings. Moreover, data collected for purposes other than evaluation may not be tailored to components of the process evaluation.

Another concern is that the diversity of process evaluation perspectives and approaches may leave the evaluator with little firm guidance on the best way to proceed. Evaluators may also face pressure to complete a process evaluation within a short time frame. The process evaluator must decide on the appropriate balance between a high-quality scientific study and one that meets the immediate pragmatic demands of the evaluation sponsor. In addition, when a process evaluation produces findings that differ from what was anticipated or preferred by stakeholders, they may publicly question the credibility of the evaluator. Finally, commissioned process evaluations are not always publicized or published by the sponsors. Evaluators who have worked diligently to produce a high-quality study may be disappointed

when their work is not disseminated to a broader audience.

Process Evaluation Benefits

Process evaluation provides valuable information to program implementers. It can make them aware of problems in the implementation process and provide details that can be used to formulate and apply corrective measures. Process evaluation provides feedback on the quality of ongoing program delivery and such information can provoke efforts to make delivery consistent with the program plan. Process evaluation provides useful feedback during the developmental stages of a program as well as for more established programs by identifying program features that are operating well and those in need of improvement. Such information facilitates continuous improvement and can be used to promote the diffusion of effective programs.

Process evaluation can identify the aspects of a program that appear most responsible for the outcomes. In other words, process evaluation can illuminate precisely how and why a desired result has transpired, thus enabling administrators to focus on the most productive program activities. Process evaluation may also offer useful critical analysis of the theoretical assumptions that are the foundation of a given program. When impact evaluation discovers the absence of impact, process evaluation can reveal whether this outcome is due to implementation problems or due to errors in the theoretical assumptions underlying the program. Similarly, process evaluation can indicate whether the observed impact is actually due to key features of the program or instead the result of other factors.

Some experts recommend that process and impact evaluations be conducted as part of a coherent single research project. In this way, the findings of the outcome evaluation are understood more accurately. The findings provided by impact evaluation are more useful and complete when accompanied by the information about program dynamics provided by process evaluation.

Psychological Testing, Overview

Miriam W. Schustack
California State University, San Marcos, California, USA

Howard S. Friedman
University of California, Riverside, California, USA

Glossary

assessment Psychological evaluation of an individual, typically based on data from testing.
forensic psychology The application of psychology to questions and issues relating to law and the legal system, including criminal justice.
measurement The psychological assessment of human subjects, and the processes and tools used.
psychometric Relevant to the quantitative measurement of some psychological characteristic.
reliability The extent to which an instrument provides consistent measurement.
validity The extent to which an instrument measures what it purports or intends to measure.

The concept of psychological testing is very broad, in terms of the goals, content, and methodologies involved. Psychological testing is important in educational settings, in vocational settings, in legal settings, in clinical settings, and in the laboratory. In each of these domains, there are multiple methods of measurement that may be appropriately employed, each of which has benefits and limitations. All psychological testing involves some potential risk, and ethical considerations are an important part of the testing situation.

The History of Psychological Testing

The history of modern psychological testing can be traced back to the late 19th century, when interest in the measurement of intelligence coincided with the development of laboratory techniques to study human sensory and motor abilities. There were earlier antecedents, though, including the Chinese system of examinations for civil servants that began over 4000 years ago and was in active use until the early 20th century. The emperors required a grueling succession of tests over several days and nights; passing the examination was required for initial appointment as a government official, and officials were also required to complete the exam successfully every three years to remain in service. Centuries later in medieval Europe, universities began to require students to undergo oral examinations to demonstrate their knowledge. Written exams became part of the process of earning a university degree several hundred years later (when paper became more commonly available in Europe). These early examples can be seen as the backdrop to the development of modern testing, but it was not until the late 1800s that the beginnings of modern approaches emerged.

James McKeen Cattell's classic 1890 paper on "Mental Tests and Measurements" is often viewed as a foundational document for the field—it introduced the term "mental test" into general usage. In the decades immediately preceding, scientists in both Europe and the United States were involved in work that contributed to the development of psychological testing. Gustav Fechner published his *Elements of Psychophysics* in 1860, bringing a mathematical perspective from measurement in the physical sciences to the measurement of human psychological functioning. Edwin G. Boring, in his landmark 1929 book, *A History of Experimental Psychology*, credits Fechner with developing "the first

methods of mental measurement." The science of psychometrics was emerging.

Sir Francis Galton, in England, was interested in many aspects of individual differences in human abilities. Galton, inspired by the evolutionary theory of his cousin Charles Darwin, set out to measure all sorts of individual differences that might be relevant to survival. On one hand, from a modern perspective, Galton's work on "hereditary genius" appears seriously flawed by his racist preconceptions and by his lack of attention to the importance of environmental variables in influencing abilities and achievement. On the other hand, Galton pioneered the use of unobtrusive measurement, helped advance the development of techniques involving objective and repeatable measurement, and invented ingenious and reliable instrumentation for measuring human abilities.

During this same period near the end of the 19th century, Alfred Binet was working in France on the problem of predicting children's scholastic achievement. He was attempting to develop an instrument to test children's intelligence, with the goal of identifying those children who were too limited in their mental abilities to benefit from instruction in a normal classroom. He also searched for bright children who were being overlooked. With the assistance of Theodore Simon, Binet developed a test that focused on higher mental functions of judgment and reasoning. Binet and Simon published the first version of their test in 1905. The revised version of that test published just a few years later (in 1908) introduced the notion of mental level. This idea was further developed by Lewis Terman of Stanford University. Terman's revision of the Binet–Simon instrument was termed the Stanford–Binet test; it is still in use today. In their revision of the test, Terman and his colleagues significantly expanded the range of individuals for whom the test could be used, in terms of both age and ability level, but the more important modification was the introduction of the concept of the "Intelligence Quotient" or IQ, which allows chronological age to be integrated with mental ability into a single index with a mean of 100.

The next major historical influence on the development of psychological testing came with the advent of World War I. Close to four million men (draftees and volunteers) were recruited into the armed forces of the United States within a very brief period, and there was a pressing need to determine how the assignment of these recruits to different types of positions within the military could be done quickly and appropriately. Robert M. Yerkes of Harvard developed two tests, called Army Alpha and Army Beta, suitable to be administered to large groups—a departure from the prior practice of labor-intensive individual tests administered and scored by expert examiners. It is not clear that these tests were optimally designed or appropriately used (especially in the case of servicemen who were immigrants or from racial minority groups), but the enormous amount of testing that was involved seems to have set the stage for the large-scale educational testing that developed in the years that followed.

For almost 20 years before the massive testing of military recruits began, the College Entrance Examination Board (CEEB) had been in existence as a centralized college-admissions testing service, but the years just following World War I saw major changes in how the CEEB developed and administered its tests. The current Educational Testing Service (ETS), which is the successor to that organization, plays a central role in the process of admission to college and to graduate and professional school. The SAT has become a universal cultural experience among high-school students who are planning to attend college in the United States. For people who have never studied psychology, the SAT may be the most familiar form of psychological test.

For the field of psychology, however, the domain of personality testing is at least as important as that of educational or intelligence testing. Over the course of the 20th century, personality testing was a very active area of research, and the development of new tests and new methods continues to be an active and important field. Personality testing, like intelligence testing, can be traced back to Galton, but the testing domains diverged substantially at the start of the 20th century. Carl Jung developed a word-association method of exploring what he termed "complexes" (groupings of emotionally charged feelings, thoughts, and ideas). Jung's technique differed in two important ways from the earlier Freudian technique of "free association" in which a patient would verbalize thoughts and images as they reached awareness: first, Jung's "association method" was systematic and controlled, including a fixed set of word prompts to which the patient would respond, and second, it was used as an approach to assessing the patient rather than as a form of therapy in itself. At around the same time that Jung was developing the word association method, another Swiss psychiatrist slightly younger than Jung was working on a related approach. While Jung was refining a test where patients revealed their inner conflicts by their responses to a carefully selected set of words, Hermann Rorschach was developing an analogous technique that provided pictures as the stimulus instead. Rorschach created and refined a set of images formed from inkblots, and developed a methodology for interpreting a person's response in identifying the images. While there are serious reservations about the reliability and validity of Rorschach's test, it provided a foundation for the development of more modern forms of projective tests. Projective tests endeavor to assess thoughts and feelings that are too difficult to put into words or are outside of consciousness.

In more recent years, psychological testing has been transformed by the development of modern computer-based methods. New methods not only enable a more extensive analysis of the results yielded by a complex test instrument, but the development of computerized adaptive testing techniques and item response theory allow for the testing to be more responsive to the characteristics of the examinee, and thus a more accurate score or profile can be obtained with a shorter instrument.

Domains and Uses of Psychological Testing

The essential goal of virtually all forms of psychological testing is to measure or assess something about an individual person. Although many common applications of psychological testing involve administering a test to a large number of people, and although the test results from large numbers of people are often aggregated for reporting, psychological testing is nevertheless focused on individuals. There are many different domains in which psychological testing is commonly used, and a wide range of uses for the test results. Reference sources such as *Tests in Print* and the *Mental Measurements Yearbook* provide listings of thousands of tests of many different types, updated at regular intervals. One straightforward way to categorize these many domains and uses and types of tests is in terms of the different goals that the testing serves.

Intelligence Testing

One major domain of psychological testing is closely connected to its historical roots—the testing of intelligence. Intelligence testing is used in qualifying children for educational programs for those of atypically high intelligence, and is also used extensively in the classification of children in need of special education because of their atypically low intelligence. Intelligence testing is also part of the battery of tests that are used to diagnose the specific disorders of children who have some developmental abnormality or learning disability. Because of the possible effects of bias in the way IQ tests are constructed, administered, and interpreted, however, the practice of using IQ tests in the placement of low-IQ children in special education is in question. Federal court decisions (in 1979 and 1986) barred school districts in the state of California from using IQ test results to place African-American children in classes for the "educable mentally retarded" or equivalent categories, based on the tests being biased against this group and thus not providing valid results for these children.

Intelligence tests are much less commonly used in adults at present—among the most common current uses are as part of a general ability and skill battery, or to qualify for membership in the MENSA society. They are also used in court-ordered tests of mental capacity (see section below on forensic and clinical testing).

Educational Testing

Everyday classroom testing, such as a spelling test, a quiz on the state capitals, a geometry chapter examination, or a test on the names of the bones in the human body can be seen as outside the realm of psychological testing. There is no well-defined boundary, though, that separates such testing from the forms of educational testing that are more obviously within the realm of psychological testing, such as aptitude tests, or tests of learning styles.

The very prominent testing programs offered through the Educational Testing Service (including the SAT, PSAT/NMSQT, GRE, AP, MCAT, LSAT, CLEP, and many others) are central to current practices for admission to college and to graduate and professional schools, and for awarding educational credit and scholarships. The educational fates of students at all levels are heavily influenced by how well they score on these standardized tests, and there has been substantial controversy over the years about how these scores should be used. Scores on these standardized tests do have some correlation with college success, but the consensus of studies of the relationship is that the scores predict freshman year grades only to a modest degree, and predict overall college success (such as cumulative GPA and graduation) to an even smaller extent. The scores are statistically valid as predictors, but not quite as good as high school grades at predicting academic success in college.

In recent years, the use of standardized tests in educational settings has become even more prominent with the advent of what is often called "high-stakes" testing. The stakes are high because scores on a standardized test of academic achievement are used to make consequential decisions both about individual students, such as whether the student will be promoted to the next grade or granted a high-school diploma, and also about schools, which may lose some funding or even be shut down based on the scores received by students. This trend is worrisome to those in education who are sensitive to the limitations of this type of testing. The American Educational Research Association, concerned about the increasing prevalence of high-stakes testing, recently developed a position statement setting forth conditions that are necessary for sound and appropriate implementation of this kind of testing, intended both to guide and to caution those involved in mandating, implementing, or using these testing programs.

Personality Testing

Another very active area of psychological testing is in personality. Hundreds of personality tests are available,

arising from a variety of theoretical orientations, and using a broad range of methods. Some tests are focused on careful measurement of a single construct or variable, while others attempt to assess the personality as a whole, including many dimensions or variables. The methodologies of these tests run the gamut as well, including virtually all the methods discussed in the methodology section below. Among the most heavily used general personality inventories is the MMPI (Minnesota Multiphasic Personality Inventory), and the NEO-PI (based on the current five-factor or "Big 5" model of personality structure). Also common is the Myers–Briggs Type Indicator, which is based on the typological personality theory of Carl Jung. The goals in the use of personality tests are quite varied as well—people who are well adjusted may simply be interested in learning more about themselves, or those who are having psychological problems may want to use the testing to find areas of weakness or dissatisfaction. Those who have problems in a relationship may find that personality testing can improve their understanding of differences or incompatibilities with their partners.

Forensic Testing

Forensic psychology is the application of psychology to questions and issues relating to law and the legal system, including criminal justice. Psychological tests are used at many points in the investigation, prosecution, and punishment of a crime. One common application of psychological testing in the legal system is in the determination of whether an accused person is psychologically fit to stand trial. In the United States, the criminal justice system requires that a defendant be able to understand the charges that he or she is facing, and requires that the defendant be able to understand that the criminal behavior being charged was wrong. In cases where the accused person suffers from severe mental illness or extreme mental retardation, he or she may be unable to meet that standard; the determination would be made through psychological testing. A less common application of psychological testing is in determining the status of a defendant who pleads not guilty by reason of insanity. It is the task of psychological examiners (working either for the defense or for the government) to report on the status of the defendant's sanity. Although the public hears quite frequently about defendants claiming "the insanity defense," it is much more common for a defendant to be unable to stand trial than to plead insanity.

Another use of psychological testing within the legal system is for the determination of custody in contested cases. This may involve testing of one or both parents to determine fitness to have custody of a child or children, and may also involve testing the child to better understand the child's needs and the child's relationship with each parent.

In civil lawsuits, psychological testing may be necessary to determine the extent of harm from the actions of a person or corporation. For example, if a lawsuit involves compensation for brain damage, psychological testing may be involved in determining the extent of the harm.

Within the legal system, psychological testing is also called upon to determine the risks posed by those who have been convicted. Tests are used to help assess the risk of recidivism (re-offending), the suitability of a convict for parole, and the level of risk posed by a sex offender who has completed a sentence. However, such tests have limited validity; that is, they are far from perfect predictors.

Some forms of psychological testing that do not meet current standards continue to be used in the legal system. The polygraph or "lie detector" test is still commonly used in criminal investigations (although its use is restricted in formal court testimony), despite decades of data documenting its serious limitations. Polygraphy works by recording blood pressure, breathing (rate and depth of each breath), and the electrical conductance of the skin (which increases in the presence of sweat) as a person responds to a series of questions. Changes in these bodily functions (which are largely under the control of the autonomic nervous system) are interpreted as reflecting the increased anxiety associated with lying. Law enforcement also continues to use a device called a voice stress analyzer (VSA) as a way of determining if people under interrogation are telling the truth. This test relies on a machine that detects the occurrence of tiny tremors in the voice that are not audible to the listener, and can measure changes in the prevalence of these subaudible tremors. Under stress, these subaudible tremors decrease. The logic (and fallacy) of both these techniques is similar—they rely on a chain with several weak links. These tests are useful only to the extent that telling a lie necessarily causes stress, and only to the extent that this stress necessarily causes physiological changes that can be detected by the machines. Some people lie but are not detected (a false negative), while some people are "detected" as liars even when they are telling the truth (a false positive).

Clinical and Psychopathology Testing

In the clinical setting, psychological testing plays an important role in diagnosis of mental illness. In addition to allowing for the planning of proper treatment, psychological testing is also an important component in determining if a patient needs to be treated on an in-patient versus out-patient basis, or even if the patient may need to be involuntarily committed to a hospital to prevent further harm to the patient or to others. Many tests have been developed that can be used to diagnose specific forms of psychopathology, using the categories of the American Psychiatric Association's Diagnostic and Statistical Manual of Mental Disorders (DSM-IV).

Testing of Attitudes, Values, and Personal Orientations

In many situations, both in everyday life and in the psychology laboratory, it would be useful to have reliable and valid measures of a person's values, attitudes, and personal orientation. Tests of attitudes can use either direct or indirect methodologies. One direct method is based on simply asking a person to evaluate how much he or she agrees with a statement expressing an attitude. For example, an item about capital punishment on an attitude measure might take the form of asking a person how strongly they agree with a certain statement about capital punishment. An alternative method is to offer a pair of statements on the topic and require the test-taker to choose the statement that more closely matches his or her opinion. In many cases, test-takers may not be willing (or able) to disclose their true attitudes if those attitudes are controversial or socially unacceptable. For example, many people would not disclose an overtly racist attitude, even if they were aware that they held such an attitude. Indirect measures can sometimes provide an alternative mechanism for measuring attitudes.

Using a similar variety of techniques, a person's values (what the person thinks is important and worthwhile) can also be determined. Personal orientation (sometimes also called world-view) is amenable to similar techniques. Notable test approaches in this domain include the Personal Orientation Inventory (POI), which focuses on Maslow's construct of self-actualization. There are also multiple commonly used measures of gender roles, and masculinity/femininity such as Sandra Bem's scale, called the Bem Sex-Role Inventory. Sexual orientation can also be assessed indirectly by measuring physiological arousal to different stimuli.

Vocational/Industrial Testing

Psychological testing is used in many ways in employment settings. Students who are about to embark on their first career as well as people who are interested in career change can be helped by the use of tests that have been developed specifically for career guidance. These tests take many forms: they can help people to understand their own preferences for types of work environments and tasks, or they can help construct a profile of a person's skills and abilities. One such test that is given every year on a massive scale is the Armed Services Vocational Aptitude Battery (ASVAB), which is taken by all new military enlistees as well as by about one million high school students in the United States every year. As many such career guidance tests do, it combines an aptitude component with an interest inventory, with the goal of guiding the examinee into a career track that will be interesting as well as suitable for the person's skills.

Another vocational application of psychological testing is as an employment-screening tool. Many employers require job applicants to take psychological tests as a condition of employment, although they are often euphemistically referred to as "pre-employment profiles" rather than the psychological tests they really are. In addition to specific skills tests that have clear relevance to the position of interest (such as a typing test for a secretarial applicant, or a computer programming test for a programming applicant), employers sometimes require applicants to undergo personality assessments. While there have been many legal challenges to this practice over the years, it is still commonly used. Employers are now prohibited under federal law from requiring pre-employment polygraph testing, except for certain occupations.

Also in the vocational arena, testing is sometimes used as a condition of continued employment (not unlike the situation of the Chinese civil servants thousands of years ago), or of advancement. This is most common for government employees (such as security screeners or police officers), but also occurs within the private sector.

The vocational uses described above are all examples of the use of psychological testing to determine if the candidate is well-suited to the job. Psychological testing methods are also used to ensure that the demands of the job are suitable for the people who will be doing the job. Appropriate use of psychological testing can ensure that equipment and processes to be used in a job setting are suitable for the skills and preferences of the individuals who will be using them; "human error" can be minimized by tailoring the demands of the job to the characteristics of the person.

Methods of Psychological Testing

Objective vs Subjective Tests

One central distinction that differentiates among psychological tests is whether they are essentially objective or subjective measures. If a test requires judgment or interpretation to turn the responses into a score or result, then it is considered to be subjective. When an examinee provides a description of a Rorschach inkblot, for example, it takes the judgment of a trained scorer to translate that description into a characterization of the examinee. In the case of an objective test, the responses of the examinee feed directly into the score via a mathematical algorithm. For example, a person taking the MMPI fills out an answer sheet that is run through a computer, which then provides the scores. Objective measurement is most often associated with tests where respondents select from a predetermined set of choices (as in a multiple-choice

test, or rating on a 7-point scale), while subjective measurement is normally required when the respondents construct their own responses.

Projective Tests

Projective tests are commonly used in the measurement of personality. In a projective test, respondents must interpret or describe an ambiguous stimulus (as in a Rorschach inkblot or a Thematic Apperception Test photo), or come up with a drawing in response to a minimal prompt ("Draw a person"), or say a word in response to a stimulus word (as in Jung's Word Association Test). Because of the substantial interpretation required on the part of the scorer, this type of test tends to be fairly low in reliability.

Self-Report vs Report by Others

Another important dimension of psychological testing is whether the information about the subject of the test is coming from the subject him- or herself, or from another person. Clearly, a report from another person provides information about how the subject appears to an observer, and only indirectly provides information about the subject's own thoughts, feelings, and self-perceptions. In many cases, though, information provided by an external observer is more appropriate for the purposes of the test than a self-report would be. For example, the diagnosis of ADHD (Attention Deficit Hyperactivity Disorder) in children is often based on a test in the form of a behavior checklist given to a child's parents and/or teachers. Because the goal in this case is the diagnosis of a deviation from normal, age-appropriate behavior, external observers such as parents and teachers can be the most suitable informants. Another example of the value of data from knowledgeable others comes from the decades-long longitudinal study begun by Lewis Terman in the 1920s. Terman recorded personality characteristics of school-age children as rated by their parents and teachers during the 1921–1922 school year. These ratings turned out to be a reliable predictor of the children's longevity across the life-span.

Most psychological tests, though, use data provided by the subject him- or herself, except in the case of testing that is focused on the question of how self-image differs from external perceptions by others.

Interview Approaches

Some psychological tests rely on an interview technique. A trained interviewer conducts an interview with the subject of the test. Such interview approaches are often characterized as either structured interviews or open-ended interviews. While an open-ended interview is not completely free-form (as a social conversation might be), the structured interview requires that a specific set of questions be asked using fixed wording, and the responses are scored according to a predetermined rating system. For example, there is a structured interview instrument that was developed for assessing the Type A Behavior Pattern.

Physical Indicators

There are many forms of psychological tests in current use that rely on directly measuring some aspect of a person's neuro-psychological functioning, or some other biologically based characteristic. Table I includes descriptions of a variety of such tests. While we now discredit the technique of phrenology, an approach developed in the early 1800s in which a person's characteristics were established by examination of the shape of the skull and the location of its protuberances, over the past decades we have developed a host of new techniques that probe the mind by measurement of various physical characteristics. Some of these techniques have been in use for decades or more, such as the measurement of galvanic skin response (electrodermal conductivity) as an index of anxiety, or the measurement of heart rate as an index of arousal. These are the kind of measures that are used in polygraph analyses. Other techniques are on the cutting edge of current technology: for example, the use of functional magnetic resonance imagery (fMRI), where brain activity is recorded as a person performs some mental task.

Risks and Dangers of Psychological Testing

Given the power of psychological tests, there are many dangers inherent in their use, and great potential for abuse. There are potential problems that can arise from poorly constructed tests, from bias on the part of those involved with the testing, and other potential problems that arise from insufficient attention to ethical requirements.

Reliability and validity are critical to the usefulness of any test, and the absence of these attributes poses risk to any user of the test. A reliable test will yield consistent outcomes—it will provide its results with relatively small error of measurement. There are many statistical techniques that allow for the determination of a test's reliability, and techniques of test construction have been developed that can ensure good reliability. The use of an unreliable psychological test does pose risks, since the result obtained may not be correct, but it is not difficult to avoid unreliable tests given that reliability can be easily assessed. Validity is both more complex and more

Table I Biological/Neuroscience Measures of Individual Differences

Measure	*Description*
Skin conductance, heart rate, blood pressure	Reflect activity of the autonomic nervous system; often are too broad to be useful measures of personality.
PET (Positron Emission Tomography)	Uses radioactively tagged molecules to probe brain function, such as radioactive glucose to examine changes in energy metabolism which are associated with activity. Other compounds can also be tagged radioactively and used to examine other brain processes. But metabolic changes may be slow and delayed.
fMRI (functional Magnetic Resonance Imaging)	Uses very large magnetic fields to probe the movements of molecules. fMRI takes advantage of differences in the properties of oxygenated and deoxygenated hemoglobin, thus yielding a signal that is related to brain activity (since neural activity uses oxygen).
EEG (Electroencephalography)	Measures electrical potentials at the scalp that are caused by large populations of neurons becoming active simultaneously. The P300 wave occurs in response to novel stimuli and may be prove useful in differences in reactions to novelty.
MEG (MagnetoEncephalography)	Similar to EEG, but instead of recording electrical potentials, it records the magnetic fields that result from the electric currents in the brain.
Neurochemical assays	Chemical analyses for the presence of certain neurotransmitters, transmitter metabolites, or hormones. The sites of assay can be in the cerebrospinal fluid or in the blood. In animal studies, assays can be directly in the brain (by microdialysis).
Postmortem analysis	For examining individual differences in anatomy (both gross and cellular) and in the numbers and locations of neuroreceptors (after death).
Candidate gene studies	Search for specific genes that correlate with specific characteristics, although multiple genes likely contribute to any psychological trait. With the succcesful unravelling of the human genome, this biological approach is likely to gain prominence in the years ahead.

difficult to ensure, so its potential absence poses greater risk. Validity is commonly defined as the extent to which an instrument measures what it purports to measure. There are several different categories of validity, and multiple approaches to determining the degree of validity of a given test.

Bias, which interferes with validity, can arise from the actions of the test developer, the test taker, the test administrator, or the test interpreter. There are many such influences that are generally recognized, and well-designed tests are constructed in a manner that minimizes the extent to which the outcome is affected by extraneous factors.

Bias on the part of the test taker can be defined as the effect of any influences that make a response by the test-taker not fully accurate or honest. Some of these factors are intuitively obvious: for example, people tend to present themselves in a positive light, by favoring those responses that are more socially desirable. Another straightforward example is when the test-taker misinterprets the meaning of an item (due to language or cultural differences) and responds accordingly. To preserve validity, these biases should be anticipated by the developers and users of the test. There are more subtle forms of bias as well, that are less blatant and require appropriate modification. For example, there is a pervasive phenomenon of an acquiescence response set, where examinees are somewhat more likely to respond "yes" or "I agree" or "that describes me" than to respond "no" or "I disagree" or "that does not describe me." Careful wording of the items, and including equal numbers of positively coded and negatively coded ("reverse-coded") items, can normally neutralize this bias. A modern technique for test construction called Item Response Theory uses a mathematical analysis of item scores, focusing on the probability that a person with the trait or ability being assessed will give a particular answer to a given item.

Bias can be inadvertently introduced by the examiner, especially if the examiner and the test-taker differ on characteristics of ethnicity and gender. The examiner may communicate hostility or low expectations to the test taker. But even if the examiner behaves in a perfectly appropriate way in administering the test, the demographic or interpersonal characteristics of the examiner may influence the performance of the test-taker. These effects can be subtle and are not necessarily easily remedied or overcome.

A potentially subtle form of bias on the part of the interpreter can occur when instruments that have been developed and standardized on one population group are then applied to a different cultural, racial, gender, or

ethnic group. Clear examples of this type of bias occur when tests are focused on a characteristic where community norms differ between cultural groups. For example, if a test assesses an individual's level of extroversion by including a measure of how far the examinee chooses to stand from the examiner, the measure will be flawed if it fails to adjust for appropriate norms that are part of the individual's cultural background.

Any professional who administers a test, scores it, or receives its results incurs multiple ethical obligations. Both the American Psychological Association and the American Educational Research Association have formal ethical standards documents, providing guidelines that cover many aspects of the testing situation. These ethical standards concern issues such as the privacy of test scores, the requirement that test takers give informed consent before testing, the right of test-takers (and their legal representatives in some cases) to be provided with their results in language they can understand, the appropriate treatment of people who are undergoing testing, the restricted distribution of test instruments, the required training and credentials for those administering tests, and the special ethical considerations that arise with court-ordered testing.

In addition to the set of unique obligations that the testing situation imposes, broader ethical guidelines require that test data used in research be as prudently safeguarded and as carefully analyzed as any other forms of data. Psychological testing can provide a wealth of information about individuals, but like any other powerful tool, it needs to be used carefully and appropriately so that it is beneficial rather than destructive.

Psychometrics of Intelligence

Peter H. Schonemann
Purdue University, West Lafayette, Indiana, USA

Glossary

common factors Latent variables implied by Spearman's (and later Thurstone's) factor analysis model. On partialling out all common factors of the observed variables, only uncorrelated specific factors are left.
congruence coefficient Cosine.
correlation Measure of linear relationship between two variables varying between −1 and 1 (0, no linear relationship; 1, perfect linear relationship).
criterion A variable of practical interest that a test is intended to predict.
dominant eigenvector The eigenvector associated with the largest (dominant) eigenvalue of a symmetric matrix.
eigenvector A vector mapped into a scalar multiple of itself by a square matrix. The scalar is called (the associated) eigenvalue.
general ability (*g*) An unobserved variable implied by a mathematical model proposed by Spearman to account for positive correlations among intelligence tests. In contrast to a PC1, *g* is not a linear combination of the observed tests.
intelligence Technically undefined, the term refers to a broad spectrum of "cognitive" skills presumed relevant for educational and economic success.
IQ total test score on an IQ test, normed to have a mean of 100 and a standard deviation of 15 or 16.
IQ test A test presumed to measure intelligence.
item A subtest of a test, usually scored 1/0 (pass/fail, binary item). The total test score is the sum of the item scores.
latent Implied but not observed overtly.
linear combination (linear composite) Weighted average.
matrix A rectangular array of real numbers.
partial correlation A correlation that remains after the influence of one or more other variables has been statistically removed (partialled out).
PC1, first principal component A linear combination of the observed tests that has largest variance among all possible linear combinations (subject to the constraint that the defining weight vector be of unit length).
reliability A measure of stability of test scores under repeated application to the same subjects; usually expressed as a correlation.
scalar A real or complex number.
validity A measure of the extent to which a test measures what it is designed to measure; often expressed as a correlation.
vector A linear array of real numbers set out either as a row or as a column.

Psychometrics, which literally means "measurement of the soul," is a subdiscipline of psychology devoted to the development, evaluation, and application of mental tests. It is useful to distinguish between two branches of psychometrics, a theoretical and an applied branch. They do not interact as much as might be expected. Here, both branches will be tracked side by side since it is impossible to gauge the merits of a theory without knowing what benefits it produced in practice.

This article discusses developments in test theory and factor analysis, with emphasis on applications to intelligence. This topic originally spawned interest in psychometrics, spurred on its early growth, inspired most of its lasting achievements, and, in the end, also revealed its limitations. It also has had the most profound social impact.

Introduction

The history of psychometrics spans approximately a century, beginning in earnest in approximately 1904/1905, when Binet and Spearman laid the foundations for future developments. This era was followed by a period of consolidation and growing acceptance of IQ tests and college admission tests in the United States.

Under Thurstone in the 1940s, psychometrics became academically respectable but also progressively more dogmatic and mechanical. The field reached its creative apogee under Cronbach and Guttman in the 1950s. Then, it began to stagnate and eventually regressed back to its racist roots in the 1920s.

In this article, matrices are denoted by capital letters, and scalars are denoted by lowercase letters. Column vectors are denoted by boldface lowercase letters, and row vectors are denoted by boldface lowercase letters followed by a prime denoting transposition.

Auspicious Beginnings: Charles Spearman and Alfred Binet

Galton, Wundt, and Wissler

The applied branch of psychometrics goes back at least to the days of Wundt and Galton (1880s). Inspired by the example of the physical sciences, both scholars attempted to measure basic sensory and physiological aspects of human behavior first, such as reaction time, visual acuity, and the like, to lay the grounds for the investigation of more complex variables later.

Galton, together with some of his younger colleagues, especially Karl Pearson and Udny Yule, also contributed to the foundation of the theoretical branch by developing basic correlational techniques that soon were to play a central role in both branches of psychometrics.

At the turn of the 20th century, Wissler applied these new techniques to school grades and some of the mental tests available at the time. The results proved disappointing. The sensory and physiological measures correlated moderately with each other, as did school grades, as indicators of more complex forms of mental ability. However, the correlations between both sets of variables were virtually zero. At this critical juncture, and almost simultaneously, two events breathed new life into the seemingly moribund new science.

Alfred Binet

On the applied side, in 1905 Alfred Binet (with Simon) published a new mental test that violated all canons of the Galton/Wundt school. Instead of trying to synthesize measures of more complex behaviors from simpler, more easily measured sensory variables, Binet set out to measure a highly complex mental trait of undisputed practical importance—intelligence—directly. The test he devised comprised a large number of items designed to sample various aspects of the implied target variable. This variable soon acquired the technical-sounding acronym IQ. It was defined, eventually, in terms of the total item score (which skipping some of the intervening mental age arithmetic that never applied to adults anyway). Binet's test became the prototype of most IQ tests and also of the scholastic aptitude tests still in use today. The problems with this approach begin after one constructs a second IQ test that does not correlate perfectly with the first, since then it is no longer clear which one is the true measure of intelligence.

Charles Spearman's General Ability (*g*)

To cope with this problem, in 1904 Spearman developed an entirely new theory aimed at supplanting the widely used but murky term intelligence with a clear-cut operational definition. Starting with the observation that most measures thought to relate to intelligence, such as school grades, tended to correlate positively, he reasoned this means they all measure the same latent variable, namely intelligence. To account for the fact that the correlations, although generally positive, were not perfect, he appealed to the recently developed machinery of partial correlations: If all positive correlations in a test battery are due to a single underlying variable—which he called *g*, short for general ability, to steer clear of the term intelligence—then its statistical removal should produce a matrix of partial correlations that are all zero. If this should turn out to be true for all batteries of "intelligence tests" worthy of the name, then this latent variable *g* could serve as an unequivocal definition of intelligence, which thus would have been "objectively determined and measured" (the title of his 1904 paper). The globality clause is usually omitted in modern accounts of Spearman's work, although it is absolutely critical for the stringency of this argument. After testing his theory on 12 previously published small data sets, he found it consistently confirmed: Dodd noted that "it seemed to be the most striking quantitative fact in the history of psychology."

Spearman left no doubt about how he felt about the social relevance of his presumed discovery: "Citizens, instead of choosing their careers at almost blind hazard, will undertake just the professions suited to their capacities. One can even conceive the establishment of a minimum index to qualify for parliamentary vote, and above all, for the right to have offspring" (Hart and Spearman, 1912).

Early Criticisms

This initial phase of exuberance soon gave way to sobering reappraisals. In 1916, Thomson noticed that the same type of correlation matrix that Spearman's theory predicts on postulating one common factor is also implied by a diametrically opposed theory that postulates infinitely many common factors (Thomson's sampling theory). To make matters worse, in 1928 E. B. Wilson, a polymath whose stature Spearman instantly acknowledged, wryly observed in an otherwise favorable review of Spearman's

"Ability of Man" (1927) that Spearman's theory did not suffice to define *g* uniquely because it postulated more independent factors than observed tests. As a result, many widely different "intelligence scores" can be assigned to the same subject on the basis of his or her observed test scores. This "factor indeterminacy" issue further undermined Spearman's claim of having defined intelligence objectively as *g*. For a while, it became the focus of lively debate, which soon died down after Thurstone entered the stage.

Eventually, it also became apparent empirically that the early accolades bestowed on Spearman's presumed discovery had been premature. As it turned out, the number of common factors needed to account for the observed test correlations did not stop at one for larger batteries, as the theory required; rather, it increased with the number of subtests in the battery. Typically, approximately one-third as many common factors as tests are needed to reduce the partial correlations to zero.

The fact that his claim of having empirically defined and measured intelligence turned out to be untenable in no way diminishes Spearman's stature for having been first to recognize and address this fundamental challenge and for dealing with it in the spirit of an empirical science.

1910–1930: Consolidation: World War I, Louis Terman, and Carl Brigham

Classical True Score Theory

Spearman's closely knit theory contained a theory of test scores as a special case that, for a considerable period of time, provided the needed definitions for constructing and evaluating new tests. This so-called classical true score theory (CTT) results on applying Spearman's factor model to only two tests and assuming that both contain the underlying common factor—now termed "true score"—in equal amounts (perfectly parallel tests). Under these assumptions, it is not difficult to derive plausible definitions of test reliability and test validity in correlational terms. Since both concepts are derived from the same underlying model, they are closely related. For example, CTT permits to predict how test reliability increases as one increases the number of items comprising the test (Spearman–Brown prophecy formula) and how test validity varies with the reliability of a predictor test, the criterion measure, or both (correction for attenuation). Kuder and Richardson used CTT to derive one of the most popular reliability estimates still widely used today. Cronbach later renamed it coefficient alpha.

Louis Terman

On the applied side, Terman promoted Binet's version of intelligence that is tied to a particular test. Availing himself of the concepts and techniques of CTT, he adapted it to an English-speaking clientele. He shared with many others of his generation, but in marked contrast to Binet, the eugenic prejudices of the early English pioneers (Galton, Pearson, Spearman, and others). This thought collective took for granted that intelligence—whatever it might be—(i) exists and can be measured and (ii) is primarily genetically predetermined (the figure usually given, until very recently, was 80%). Therefore, Terman and his disciples strove to purge their "intelligence tests" as much as possible of environmentally induced impurities (such as educational background) that might mask the underlying, presumed immutable genetic contribution. Note that the first premise conflicts with the outcome of Spearman's efforts.

World War I Army Tests

World War I provided an opportunity to put psychometric theories into practice when the need arose to assess, on short notice, the military qualifications of millions of inductees with widely different social and educational backgrounds. Under the stewardship of a former American Psychological Association president, Robert Yerkes, a committee was charged with the development of intelligence tests suited to the particular needs of the U.S. Army. These efforts resulted in two different tests, the Army Alpha and Army Beta tests. By necessity, both were conceived as group tests (in contrast to the classical Binet test and Terman's American adaptation that had to be administered individually). The Army Alpha was essentially a group version of the Stanford–Binet that relied on the assumption that the testee was fluent in English. The Army Beta was intended as a "nonverbal" substitute for linguistically handicapped inductees whose innate intellectual potential might be masked by traditional verbal tests.

Charles Brigham

World War I offered an opportunity for both branches of psychometrics to promote the fruits of their labors. It also produced a huge database waiting to be mined after the war for new findings to further improve the new technology. This task fell to a young assistant professor, Charles Brigham, who published his findings in a book titled "A Study of American Intelligence," with a foreword by Yerkes.

Brigham's conclusions were in tune with the zeitgeist and seemed perfectly timed to answer steadily mounting concerns over untoward consequences of unrestricted

immigration. He found that the average intelligence of American soldiers was frightfully low. On stratifying his data by country of origin, he further found that "according to all evidence available . . . the American intelligence is declining, and will proceed with an accelerating rate as the racial admixture [having shifted, as he observed, from 'Nordic' to 'Alpine'] becomes more and more extensive" (Brigham, 1923, p. 210). Partly in response to these ominous tidings, the U.S. Congress enacted more restrictive immigration laws in 1924.

These laws were not revoked when Brigham later, to his credit, recanted his earlier prophecies (Brigham, 1930):

> *This review has summarized some of the more recent test findings which show that comparative studies of various national and racial groups may not be made with existing tests, and which show, in particular, that one of the most pretentious of these comparative racial studies—the writer's own—was without foundation.* (p. 165)

The Scholastic Aptitude Test

Brigham went on to develop the first standardized college admissions test [the Scholastic Aptitude Test (SAT)], which in essence was an IQ test tailored to the needs of the decentralized education system in the United States, again stressing the need to tap into innate potential uncontaminated by educational experience. Just as Spearman would have wished, the SAT soon became virtually mandatory for access to higher education in the United States.

Predictive Validities of College Admission Tests

Over the decades, these tests have been refined by infusing ever more sophisticated theoretical and computational advances. However, this did not help improve them in terms of traditional measures of test efficiency. For example, it has been well-known virtually since its inception that the SAT has validities for First Year College GPA (GPA1) that hover around 0.4, approximately 10 correlation points below those of High School Rank (HSR). A tabulation published by the College Board shows that over the time span from 1964 through 1982, the HSR validities varied little (between 0.46 and 0.54, thus explaining approximately 25% of the criterion variance). For the SAT, they range between 0.37 and 0.46 (17%). To make matters worse, Humphreys showed in 1968 that the ACT validities drop into the 0.20s (4%) once the prediction interval is extended to the eighth semester GPA (GPA8). Similarly, it has repeatedly been shown (e.g., by Horn and Hofer and by Sternberg and Williams) that for long-range criteria of practical interest, such as graduation, the validities of the GRE are virtually zero. These findings cannot be dismissed as being due to random error. In contrast to the dubious figures reported for commercial IQ tests, such as the Wechsler and the Stanford–Binet, the sample sizes for the SAT, ACT, and GRE often range in the millions.

From Model to Method: 1930s–1940s—Louis Thurstone

Multiple Factor Analysis

Thurstone's reign of psychometrics extends back into the late 1920's when he published a number of papers devoted to applications of testing models to psychophysics and social psychology, especially attitude measurement. However, he scored his greatest triumph when he extended Spearman's failed factor theory of intelligence from one common factor to more than one common factor (multiple factor analysis). In the process, he transformed factor analysis from a substantive theory into a "general scientific method" susceptible to widespread abuse.

The underlying idea seems straightforward. If, after partialling out one common factor, one finds the resulting partial correlations are still not zero, one might consider partialling out a second common factor, and perhaps a third, until all remaining partial correlations are deemed close enough to zero (multiple factor analysis). In hindsight, this idea seems so obvious that it may not surprise to learn that it had already occurred to others (e.g., Garnett in 1919) long before Thurstone took credit for it in 1947.

Simple Structure

Some additional technical work was required before this simple idea could become useful in practice. Virtually single-handedly, and with considerable ingenuity, Thurstone developed both the theoretical and the technical refinements needed to transform what Spearman had originally intended as a substantive theory of intelligence into a general scientific method.

His most important theoretical contribution was his concept of simple structure intended to resolve the so-called rotation problem. This problem does not arise with Spearman's model because it invokes only one common factor. If there is more than one common factor (e.g., two), then the same observed correlations can be described in infinitely many different ways so that a choice has to be made.

This problem is most easily understood geometrically. If there are two common factors, both can be viewed as the orthogonal axes of a two-dimensional coordinate system used to describe a swarm of test points in a plane. This

swarm of points can be described by many other coordinate systems, even if the origin is kept fixed and the two axes are kept orthogonal to each other. If one chooses a new pair of orthogonal axes by rotating the old system, then the coordinates of the test points—that is, their numerical representation relative to the chosen coordinate system—will change but not the relations among the points, and it is these that constitute the empirical observations. Thus, the question arises which coordinate system to select so as to maximize the scientific utility of the resulting numerical representation of the empirically observed relationships.

Thurstone solved this problem by appealing to the principle of parsimony that is usually attributed to Occam: Explanatory causes should not be multiplied beyond necessity. This means, in the present context, that each test should require as few nonzero coordinates ("loadings") as possible so as to explain it with the smallest possible number of common factors. Hence, after starting with an arbitrary coordinate system, an attempt should be made to rotate it in such a way that each test has as many near zero coordinates as possible. Thurstone called this ideal position "simple structure". If there are only two common factors, such a coordinate system is easily found by visual inspection. However, as the number of common factors increases, this task becomes more difficult. Only with the help of modern computers was this "orthogonal rotation problem" eventually solved to everyone's satisfaction. Thurstone later generalized this rotation problem to correlated factors. The between-factor correlations could then be analyzed for "second-order factors" (hierarchical factor analysis).

Using this methodology, Thurstone arrived at a comprehensive theory of mental tests that dominated American psychometrics during the 1940s and 1950s. Most psychometricians agreed with Thurstone that Spearman had been on the wrong track when he postulated a single common factor of intelligence. Of course intelligence is multidimensional, they argued. All one had to do to see this was apply Thurstone's general scientific method to any battery of intelligence tests. Proceeding in this way, Thurstone derived between 5 and 7 primary mental abilities (PMAs), Eysenck derived 4, R. B. Cattell derived 2 (crystallized and fluid ability), and Guilford derived no less than 120 intelligence factors. However, in practice, Thurstone's test, the PMA, did not perform markedly better than other tests that had been constructed without the benefit of factor analysis.

Consequences

In retrospect, it seems clear that Thurstone's approach was actually a step backward compared to that of Spearman. One reason why Thurstone, Cattell, Eysenck, Guilford, and numerous other psychometricians gave widely differing answers to Spearman's question—what do we mean when we say we "measure intelligence"?—was that they could not even agree on the number of intelligence factors. Yet, whatever the phrase meant, both Spearman and elementary logic tell us that it cannot possibly refer to a multidimensional concept of intelligence. Only unidimensional variables can be "measured" in the sense that exactly one real number is assigned to each subject so that, at a minimum, the empirical order relations (implied by statements of the type "A is more intelligent than B") are preserved. If there were two different intelligences, then all such statements would have to be qualified with a reference to the particular intelligence that is being measured.

In hindsight, it is not surprising that the Thurstone era of exploratory factor analysis, imposing as it seemed at the time, left few empirical imprints still remembered today. Where Spearman had set himself a clearly defined substantive problem, Thurstone promised a research technique uncommitted to any particular subject area, a technique that, moreover, could never fail. No correlation matrix can ever falsify what amounted to a tautological claim that a given number of observed variables can be reasonably well approximated by a smaller number of common factors. Statistical tests of the simple structure hypothesis, although available, were carefully avoided.

Although Thurstone's empirical results are virtually forgotten today, his gospel of a research automaton capable of dispensing scientific progress without requiring any ingenuity, technical skill, or even familiarity with a substantive area proved hugely popular and subsequently resurfaced in various statistical disguises.

1950s–1960s: Apogee—Louis Guttman and Lee Cronbach

Psychometrics reached its apogee in the 1950s under the leadership of Guttman and Cronbach. Both had strong commitments to both branches of psychometrics and were heavily engaged in empirical research.

Louis Guttman

Guttman was without question technically the most accomplished and creative psychometrician in the history of psychometrics. Early in his career he addressed fundamental problems in (unidimensional) scaling. He is most widely known for the joint scale that bears his name. In test theory, he subjected the seemingly innocuous notion of reliability inherited from CTT to searing logical criticism, anticipating later developments by Cronbach and others.

The Importance of Falsifiability

In marked contrast to Thurstone, Guttman never tired of stressing the need to test strong assumptions (e.g., simple structure). Turning his attention to factor analysis, he emphasized that neither parsimony pillar supporting Thurstone's edifice, small rank and simple structure, can be taken for granted. These hypotheses are not just strong but most likely false. A recurrent theme in Guttman's papers is the need to replicate empirical findings instead of simply relying on facile significance tests ("star gazers").

With his radex theory, he proposed a family of alternative structural models unconstrained by these assumptions. In 1955, he also revived interest in the dormant factor indeterminacy issue, recognizing it as a fundamental problem that undermines the very purpose of factor analysis. Thurstone, in contrast, had never faced up to it.

Facet Theory

Later in his career, Guttman returned to Spearman's question, What is intelligence?, which he sought to answer with his facet theory. This research strategy starts with a definition of the domain of the intended variable. Only after this has been done does it become feasible to determine empirically, with a minimum of untested auxiliary assumptions (such as linearity, normality, and the like), whether the staked out domain is indeed unidimensional as Spearman had claimed. If it is not, then one has to lower one's aim and concede that intelligence, whatever else it may be, cannot be measured.

Lee Cronbach

Cronbach also went his own way. As author of a popular text on testing, he was familiar with the problems practicing psychometricians had to face and not easily dazzled by mathematical pyrotechnics devoid of empirical substance. Just as Guttman before him, he also questioned the simplistic assumptions of CTT. Searching for alternatives, he developed a reliability theory that recognized several different types of measurement error—thus yielding several different types of reliability—to be analyzed within the framework of analysis of variance (generalizability theory).

Mental Tests and Personnel Decisions

Most important, in a short book he wrote with Goldine Gleser in 1957, the authors radically departed from the traditional correlational approach for gauging the merits of a test. Instead of asking the conventional questions in correlational terms, they asked a different question in probabilistic terms: How well does the test perform in terms of misclassification rates?

It is surprising that this elementary question had not received more attention earlier. In hindsight, it seems rather obvious that, since use of a test always entails a decision problem, its merit cannot be judged solely in terms of its validity. How useful a test will be in practice also depends on prior knowledge, including the percentage of qualified applicants in the total pool of testees (the base rate) and the stringency of the admission criterion used (the admission quota).

Base Rate Problem

That knowledge of the correlation between the test and the criterion alone cannot possibly suffice to judge the worth of a test is most easily seen in the context of clinical decisions, which often involve very skewed base rates, with the preponderance of subjects being assessed as "normal."

For example, assume the actual incidence (base rate) of normal is 0.90, and that for "pathological" it is 0.10. Suppose further that the test cutoff is adjusted so that 90% of the testees are classified as normal on the basis of their test scores and 10% as pathological. If the joint probability of actually being normal and of being correctly classified as such is 0.85, then one finds that the so-called phi coefficient (as an index of validity) is 0.44. This is quite respectable for a mental test. However, on using it, one finds the following for the probability of total correct classifications (i.e., the joint probability of actually being normal and also being so diagnosed plus the joint probability of actually being pathological and being so diagnosed): $0.85 + 0.05 = 0.90$. This value exactly equals the assumed base rate. Thus, the proportion of total correct classifications achieved on using the test could also have been achieved without it by simply classifying all testees as normal.

The moral of his tale is that the practical utility of a test is a joint function of, among other things, validity, base rate, and admission quota. Validity by itself tells us nothing about the worth of a test. Meehl and Rosen had made much the same point a few years earlier. Cronbach and Gleser expanded on it systematically, tracing out the consequences such a decision-theoretic perspective implies.

To my knowledge, the only currently available complete tables for hit rates (the conditional probability that a qualified testee passes the test) and total percentage correct classifications, as joint functions of validity, base rate, and admission quota, are those published in Schonemann (1997b), in which it is also shown that no test with realistic validity (<0.5) improves over random admission in terms of total percentage correct if either base rate exceeds 0.7.

Notwithstanding the elementary nature of this basic problem and its transparent social relevance, the Social Sciences Citation Index records few, if any, references to it in *Psychometrika*. This is surprising considering that much of modern test theory, with its narrow focus on item analysis, may well become obsolete once one adopts Cronbach's broader perspective. In contrast, some more applied journals did pay attention to the work of Meehl, Rosen, Cronbach, and Gleser.

1970s–1980s: Eugenics Revisited—Arthur Jensen

Some purists may wonder why Jensen is included in this review, since the psychometric elite tends to ignore his work. On the other hand, he also has many admirers. Brandt (1985) calls him "the world's most impressive psychometrician" (p. 222). Whatever one may think of his work, Jensen has clearly had a profound impact on the recent course of psychometrics.

How Much Can We Boost Intelligence and Scholastic Achievement?

Jensen achieved instant notoriety when he challenged the received view that intelligence is primarily a function of environment, not genes. This position had gained ground during World War II, gradually replacing the earlier eugenic thesis to the contrary. To appreciate the progress that the field had made since Spearman, note that logically neither stance makes much sense as long as intelligence still remains undefined.

In his *Harvard Educational Review* paper, Jensen proclaimed that previous attempts to narrow the black/white gap on IQ tests were doomed to failure because, according to him, blacks are deficient in the particular genes required for complex information processing. Although this message initially met with some skepticism, it slowly mutated into the new received view, virtually uncontested by psychometricians and statisticians and deemed worthy of a full-page ad in the *Wall Street Journal* that several prominent psychometricians signed.

Undeterred by his detractors, Jensen set out to back up his unorthodox thesis with extensive empirical evidence. He tabulated IQ scores for various ethnic groups, designed an apparatus for measuring complex reaction times, and contributed suggestions on how best to measure the genetic portion of the IQ test variance. In the end, all these efforts converged on the same conclusion: Spearman had been right all along—g does exist and intelligence can be measured. In addition, it is ubiquitous and of utmost importance in virtually all spheres of life. Just as the early pioneers had claimed, it is primarily genetically predetermined. True, blacks are disadvantaged in this respect. However, this is no cause for alarm, as long as costly but futile efforts to bring them up to the level of whites (such as Head Start) are replaced with more realistic alternatives to guard against "dysgenic trends" toward "genetic enslavement" (Jensen, 1969, p. 91f).

The psychometric and statistical establishment initially reacted with quiet scorn to these heresies, fearing perhaps unwanted public scrutiny of psychometrics more generally. What it did not do, in any case, was to squarely face up to Jensen's challenge and simply show what was wrong with his reasoning.

Jensen's *g* Ersatz versus Spearman's *g*

What was wrong with it was that Jensen, who greatly admires Spearman, had quietly abandoned Spearman's original theory by replacing his g factor with the first principal component (PC1): "For example, the g [the first principal component] extracted from the six verbal subtests of the Wechsler Adult Intelligence Scale has a correlation of 0.80 with the g extracted from the five Performance subtests, in the standardization sample" (Jensen, 1979, p. 17).

To understand why this seemingly innocuous change actually amounts to a grotesque perversion of Spearman's theory, one has to know how principal components differ from common factors. The technical difference is most easily demonstrated with recourse to elementary matrix algebra. Since a correlation matrix of p tests is symmetric, its eigenvalues are always real and can be ordered. The dominant eigenvector of R, if used as a weight vector, results in a linear combination, PC1, that has largest variance among all possible linear combinations of the observed tests (subject to the constraint that the weight vector be of unit length). Note that this is a definition of a PC1, not an empirical discovery. The variance of the resulting PC1 is given by the dominant eigenvalue c.

Artifacts

Now let us see what happens when the correlation matrix R is "positive" throughout—that is, it has only positive elements, which was the point of departure for Spearman. For the sake of argument, let us assume all correlations are equal to $r\,(>0)$. This greatly simplifies the algebra without unduly violating reality. In this case, R can be written as a sum, $R = r\mathbf{e}\mathbf{e}' + (1-r)I$, where r is the correlation, $\mathbf{e}$ is a column vector of p ones, and I is the identity matrix of order p. The left-hand summand is a matrix of rank 1. It has dominant eigenvalue $r\mathbf{e}'\mathbf{e} = pr$ [since $R\mathbf{e} = (r\mathbf{e}\mathbf{e}')\mathbf{e} = r(\mathbf{e}'\mathbf{e})\mathbf{e} = pr\mathbf{e}$], while all other eigenvalues are zero. The right-hand summand, $(1-r)I$, leaves all eigenvectors intact and simply adds $1-r$ to all eigenvalues. Hence, the dominant eigenvalue of R is

$pr + (1 - r)$, which equals the variance of the PC1. The remaining $p - 1$ eigenvalues are all equal to $1 - r$.

As a result, the percentage of variance of the observed tests accounted for by the PC1 of R is $100[r + (1 - r)/p]$, which tends to $100r$ as p increases. The ratio of the largest eigenvalue to the next largest eigenvalue is $pr/(1 - r) + 1$. This ratio quickly increases as the number of tests, p, increases. Concretely, if $p = 10$ and $r = 0.5$, then this ratio is $p + 1 = 11$. If $p = 20$ and $r = 0.33$, it also is 11. This means that a PC1 always explains much more variance in a positive data matrix R than any of the remaining $p - 1$ PCs, as soon as p is reasonably large.

This is the reason why Jensen was so successful in convincing the uninitiated that "g" (as he calls the PC1 in gross abuse of language) is a powerful variable wherever he looks. The problem is that a PC1 is not g as Spearman had defined it in 1904. Partialling out the PC1 does not leave zero partial correlations. Rather, every one of Jensen's PC1s is a local description of the data at hand. Spearman, in contrast, was searching for a g that underlies all intelligence test batteries, not just a particular one. Jensen obtains a different g every time he analyzes a new R.

Congruence Coefficients

Jensen finesses the question whether all his g's are the same by pointing to so-called congruence coefficients as "a measure of similarity" between the dominant eigenvectors extracted from different batteries: "*Congruence coefficients (a measure of factor similarity)* are typically above 0.95, indicating virtually identical factors, usually with the highest congruence for the g factor" (Jensen, 1998, p. 363, italics added).

Usually these cosines are high. The problem is that they tell nothing whatsoever about "factor similarity": Two sets of variables can have identical within-set correlations while all between-set correlations are zero. In this case, the congruence coefficient will be 1 and the correlation between both PC1s will be zero.

This is Jensen's second sleight of hand: It is not at all difficult to tabulate the cosines between dominant eigenvectors extracted from randomly generated positive R's and a vector of 1's (**e**) of the same order. When this was done, the cosines varied between 0.995 and 0.999 when the parent distribution was uniform and between 0.949 and 0.998 when it was chi-square 1 (Schonemann, 1997a, p. 806). This means that Jensen's g ersatz is simply the average test score of whatever tests he analyzes. It is not g, but a travesty of Spearman's g.

Unfortunately, there are few examples in the psychometric and, more significantly, the statistical literature of anyone seriously challenging Jensen on methodological grounds (rare exceptions are Kempthorne and Schonemann). Typically, he is challenged on ideological grounds because critics do not like his conclusions.

Retrospective

Looking back, it is difficult not to notice that psychometrics did not live up to the promise of its auspicious beginnings. After Thurstone had shifted the focus from substantive theory to general scientific method, the field progressively lost its moorings and began to drift toward "ideational stagnation" (Sternberg and Williams, 1998, p. 577). On the applied side, steadily declining technical standards eventually empowered prophets of dysgenic doom to revive the eugenic myths of the 1920s, virtually unopposed by psychometricians and statisticians alike. On the theoretical side, Thurstone's implied message "that knowledge is an almost automatic result of gimmickry, an assembly line, a methodology" (Koch, 1969, p. 64) easily won out against Guttman's stern admonition that the essence of science lies in painstaking replication, not in facile significance tests. Numerous "general scientific methods" came and went, ranging from multidimensional scaling ("a picture is worth more than a thousand words") to latent trait theory, item response theory, linear structural models (LISREL), and meta-analysis and log-linear models. None of them has markedly improved the practical utility of mental tests, let alone helped answer any of the basic theoretical questions, such as "What is intelligence?" Just as Spearman noted years ago, "Test results and numerical tables are further accumulated; consequent action affecting the welfare of persons are proposed, and even taken, on the grounds of—nobody knows what!" (Spearman, 1927, p. 15).

Public Sector Performance

Tony Bovaird
University of the West of England, Bristol, United Kingdom

Glossary

economy Provision of inputs of a specified level of quality at the lowest cost.
effectiveness Usually conceived to be the extent to which objectives have been achieved, but sometimes considered to be the ratio of outputs to outcomes. (Cost-effectiveness is usually conceived of as the level of achievement of objectives per dollar spent.)
efficiency The relationship between inputs (of a given quality) and outputs (of a given quality), or the rate at which inputs are converted into outputs. Technical efficiency relates physical inputs to physical outputs (e.g., staff productivity, which relates staff inputs to organizational outputs).
equity The achievement of the desired level of fairness or social justice, sometimes expressed in terms of the level of equality achieved (e.g., in relation to equality of opportunity, access, cost, use, or outcomes). It is often compared between specific groups in society, such as low-income groups, women, and ethnic minorities (horizontal equity), or between people in the same group but in different circumstances (vertical equity).
input A resource used to execute a policy or provide a service.
outcome The impact of the organization's activities on the welfare of stakeholders (which may be intended or unintended).
output The result of the activities of an organization; in the public sector, this is often the level of service provided. Where the level of service is difficult to measure, the level of activity is often used as a proxy.
performance indicator (PI) A variable whose value suggests the level of achievement of inputs, outputs, outcomes, equity, or sustainability or the level of achievement of the ratios between these concepts (such as economy, efficiency, or effectiveness). Such indicators are often imprecise, particularly because they may be jointly produced or subjective in nature.
performance measure A performance indicator that meets stringent tests of clarity, relevance, validity, reliability, causality, and ability to be aggregated.
performance management system A set of structures and processes for making decisions on the basis of the information from the performance measurement system.
performance measurement system A set of structures and processes for the production of performance information about a public sector organization or policy or project.
public sector The set of organizations whose activities are financed from public money and controlled, directly or indirectly, by elected politicians.
quality The level of achievement of a set of characteristics desired by stakeholders. An overall summary of the achievement of these separate characteristics is sometimes made (e.g., conformance to specification, fitness for purpose, or meeting of user expectations).
sustainability The extent to which current levels of performance are likely to be feasible into the future, given known constraints in terms of resources (physical and financial) and expected economic, social, environmental, and political conditions.
value for money An overall index of the level of achievement of economy, efficiency, and effectiveness (sometimes weighted mainly toward economy and efficiency).

The issue of public sector performance continues to be topical, but the concept is used in many different ways. Here, it is taken to mean how well the public sector meets the expectations of its different stakeholders (i.e., those people who significantly affect or are affected by a policy or the actions of an organization). The increasing interest in performance measurement, particularly during the second half of the 20th century, has been linked to the growth of public sector expenditure. Interest has especially focused on systems of performance measurement and management that will support performance improvement in the public sector. There is no single definition of public sector performance or of the dimensions of performance measurement. However, most stakeholders give some

importance to measures of economy, efficiency, and effectiveness, and many stakeholders add elements such as equity, quality, and sustainability. The characteristics of an appropriate system of performance measurement are contested, but the main thread in most approaches is the need to support appropriate performance management processes. Contractualization of public sector activities in many countries in the 1980s gave particular momentum to performance measurement, often aping private sector practices and usually giving heavy weight to efficiency. In the 1990s, public sector reforms became more oriented to improvements in public governance, but performance measurement has been slow to catch up with these developments.

Introduction

The concept of public sector performance has become common in both everyday and academic discussion, but it is used in many different ways, partly because there are no official definitions. Politicians often seem to view it as meaning the reinforcement of their ideological preferences or keeping the electorate happy. Service users are usually more concerned about service availability, quality, or price, whereas citizens seek reassurance that services will be available when needed but costs will be low in the meantime.

Here, it is taken to mean how well the public sector meets the expectations of its different stakeholders. It is therefore inherently a subjective term, although many stakeholders may use objectively based performance measures to assess it. It is also a multifaceted concept, rather than singular, since many stakeholders will have different perspectives.

The increasing interest in performance measurement, particularly during the second half of the 20th century, has been linked to the growth of public sector expenditure. At first, the main interest was from economists, keen to find ways of comparing the productivity of activities in the public sector with those in the marketized sector. Recently, there has been increased interest in systems of performance measurement and management that will support performance improvement initiatives in the public sector.

Although there is no single definition of public sector performance or its dimensions, most stakeholders give some importance to measures of economy, efficiency and effectiveness, albeit with varying weights. In addition, many stakeholders wish to add elements such as equity (sometimes differently expressed in terms of social justice, fairness, equality, etc.), quality (sometimes emphasizing particular dimensions of quality, such as reliability, accessibility, responsiveness, and due process), and sustainability (sometimes narrowly defined, e.g., as environmental sustainability, but often widely defined, e.g., as resource sustainability or electoral sustainability).

The economics literature considers the economic performance of the public sector as a whole (public finance theory), resource allocation between activities (welfare economics), and the design of optimal performance incentives between the individual and the organization (principal–agent and contract theory). Political science is particularly interested in the potential conflicts between social values and economic efficiency and in the political processes by which these conflicts are managed. Organizational theorists tend to consider public sector performance measurement as a set of socially constructed processes by which different stakeholders seek to increase their power within the governance systems to which they belong. On the other hand, policymakers (including politicians) and practitioners tend to view performance measurement simply as the process of producing performance information for use in their decision making.

This article approaches the subject from a management perspective, drawing on aspects of the theoretical perspectives but focusing primarily on how they throw light on practical issues surrounding the use of performance measures in developed countries.

Background

The roots of performance measurement grew from two very different traditions. The performance of individuals was first measured systematically in the "scientific management" approach associated with Frederick W. Taylor. The performance of organizational units was originally measured in the Soviet Five Year Industrial Plans, which started in 1928. This latter tradition was part of the more general turn to "planning," which was a key element of the modernist movement in the 20th century. Planning in Western Europe has its roots in spatial planning (Garden Cities and the industrial philanthropist colonies before World War I; town and country planning and mass housing programs after World War I; and regional planning, transportation planning, and health and education planning after World War II). An intrinsic part of planning involves comparing plan outcomes to plan targets, although not always with high degrees of sophistication.

In the 1950s, the monitoring of financial performance became more systematic in both private and public sector organizations, sometimes extending beyond budgetary control to unit costing. In the mid-1950s, Peter Drucker was influential in arguing for "managing by objectives" and "managing for results," giving a key role to performance measures. This paved the way in the 1960s for the development of the planning, programming, and

budgeting systems in the United States that emphasized nonfinancial measures of performance.

In the 1970s, the concept of value for money (VFM), incorporating "economy, efficiency, and effectiveness," came into vogue, particularly in the United States and United Kingdom. During the 1980s, VFM was increasingly incorporated into external audit regimes in many areas of the world, often with a particular emphasis on efficiency.

In the 1980s, performance measurement in the public sector became seen as critical to the success of the reform movements of the time, which became known collectively as the new public management (NPM). In the NPM, it was suggested that responsibility for budgets and for performance should be delegated down the organization to the managers whose decisions were most likely to impact performance. The corollary was that performance indicators would be agreed with these managers so that they could be held accountable for their decisions. Another strand of the NPM was a move to contract management (e.g., compulsory competitive tendering in the United Kingdom), whether internally in the organization or through externalization of services, which gave particular momentum to performance measurement, often aping private sector practices and usually giving heavy weight to measuring efficiency and unit costs.

In the 1990s, there was increasing interest in measuring quality of services (partially in order to defend public services against the cost-cutting pressures evident in externalization initiatives). In many European public sector organizations, this led to the utilization of the Excellence Model of the European Foundation for Quality Management (EFQM). This model has five "enablers" to excellence [for each of which performance indicator (PIs) could be developed] and four areas of results (people results, customer results, society results, and key performance results, with the latter category referring to internal indicators of success). At the same time, the Balanced Scorecard spread quickly from its roots in private sector performance reporting to many public sector agencies throughout the world. Its key innovation was the insistence that organizations should report not one bottom line (no surprise in the public sector) but at least four results areas (evidencing clear overlaps with the EFQM results areas)—financial results, customer results, internal business processes, and learning and growth. In each of these areas, organizations were encouraged to state objectives and matching performance indicators.

Recently, public governance has begun to rival the NPM as a paradigm for public sector management. It emphasizes the understanding of public decision making as a multistakeholder activity and not just a government activity, as a "fuzzy" negotiative process rather than a set of clear and firm events, and as a social and political process rather than simply managerial. Consequently, it suggests much more focus on measuring outcomes (particularly quality of life changes for key stakeholders) and measuring the quality of the processes by which decisions are made through the interactions of stakeholders. In this way, it gives more importance to the measurement of "value added" in economic, social, political, and environmental terms, and not only value added to direct service users. Performance measurement has been rather slow to catch up with these developments.

Types and Examples of Measures

Many different categorizations of performance indicators have been developed for use in public administration. One powerful set that has driven the relationships between central and local government in the United Kingdom was developed by the Audit Commission, which divided PIs into those that illustrated achievement in terms of strategic objectives, cost/efficiency, service delivery outcomes, quality, and fair access. Most such approaches are essentially based on finding PIs for all stages in the production of welfare model. This model suggests a simple causative chain as follows:

$$\text{Inputs} \rightarrow \text{outputs} \rightarrow \text{outcomes}.$$

Moreover, PIs are typically developed for the ratios between these categories: for example, the ratio between inputs and outputs (efficiency and productivity), the ratio between outputs and outcomes (effectiveness), and the ratio between inputs and outcomes (cost-effectiveness). Some of these categories are often broken down further; for example, process indicators are often developed to assess how well activities contribute to outputs, whereas quality and equity are often seen as particular elements of effectiveness. Because the production of welfare model is very general, the specific PIs that different stakeholders derive on the basis of it may vary significantly. For example, under effectiveness a service user group may emphasize the achievement of service reliability or speed, whereas professional staff may focus on conformity to the procedural standards established for the service.

It is widely accepted that some types of performance measurement are particularly difficult; for example, PIs for quality of service and for outcomes are generally seen as more problematic than PIs for quantity of service and for output levels. However, there have been major advances in recent years in developing and using PIs even in these areas. For example, the EFQM Excellence Model has helped in the measurement of quality and the Audit Commission has developed and piloted approximately 40 quality of life PIs for local government in England and Wales.

One category of performance has been rarely measured and used; that is, PIs for the achievement of equity goals. Nevertheless, PIs are indeed possible in this area. For example, in New Zealand there is legislation compelling local authorities to report who uses and who pays for each local authority service, and in the United Kingdom many local authorities have an annual equalities report, which reports achievements against an equalities plan. This suggests that the problem here is more political than technical.

What Is a Good Performance Measurement System?

Performance measurement systems can serve a range of purposes so that judgments of what is a good system must depend on its purpose. For example, some systems are designed essentially to give strategic direction to staff (through targets based on measures of strategic performance), others seek to enhance staff and organizational capabilities (through "stretch targets" based on performance measures), and yet others seek to support evidence-based management (through providing PIs for benchmarking exercises) and organizational learning (through providing measures of "what works"). Performance measurement can support each of these purposes.

However, there is another purpose for performance measurement in organizations that creates real problems—control of organizational behavior. Since staff will usually be alert to (and resent) this purpose, it typically gives rise to undesirable distortions in performance measurement, reporting, and behavior. Indeed, where the control purpose is paramount and the sanctions for poor performance are significant, this can result in the perverse control syndrome. In this syndrome, when top management specifies very precise PIs and clearly gives high priority to them, staff are likely to report successful performance against these PIs, whatever the real state of performance and whatever damage it does to the underlying mission and values of the organization. In practice, there are many ways in which staff can distort the values of PIs that get reported in any performance measurement system. It is therefore important that control is only one of the purposes of a performance measurement and reporting system, if such a system is not to be dysfunctional.

A good performance measurement system must also be able to help in all three phases of evaluation of the organization's activities: appraisal of options, monitoring of current activities, and review of past experience. However, the level of detail in monitoring is typically less than in appraising options, whereas review often uses the most detailed performance information, including data collected on a one-off rather than a regular basis.

These three phases of evaluation occur at all organizational levels, from top strategic decisions to front-line decisions on priorities in treating individual service users. It is therefore important to find performance measures that can be cascaded downward (and upward) in the organization so that there is consistency between the way in which strategies are assessed by top management (before, during, and after their implementation) and how operational decisions are evaluated elsewhere in the organization.

A further critical decision in designing performance measurement systems is the balance between self-assessment and external assessment. Although external assessment has the benefit of seeming more independent, internal assessment is usually better informed about the context of the service or activity, more sensitive to its important parameters, and more likely to convince those who will later need to implement its lessons. However, it may lack credibility to an external audience. Since external assessment is usually expensive, most performance measurement is likely to be done by self-assessment. In these circumstances, it is essential that proper auditing of the data is undertaken within the organization; otherwise, all managers will be under pressure to ensure that the data they report show their own organizational unit in a favorable light, which will contaminate the whole organization's information system and systematically disable its ability to identify the key problems and learn what are the appropriate solutions.

There is a major debate about whether a performance measurement system should attempt to provide a balanced and comprehensive picture of the organization's performance or whether it should focus on assessing performance in relation to the organization's priority objectives and make reports only when performance levels drop below predetermined critical values. The former approach is believed to allow a better informed strategic overview to be formed. It has the disadvantages, however, of being expensive, cumbersome, and often rather slow. The latter approach is quicker, cheaper, and more focused but may result in some important developments not being noticed in time, and some organizational units may "hide," being too small to merit review.

Finally, PIs within a performance measurement system are usually assessed against a number of criteria. In particular, they are expected to be clear (readily understandable to all users), relevant (related to the desired objectives and outcomes of the organization), valid (measuring what they purport to measure), reliable (likely to produce similar results when measured again in similar circumstances), able to be unambiguously interpreted (when they change in value), additive (across stakeholders and organizational units), not able to be manipulated (by the behavioral decisions of those whose performance is measured), and reasonably cheap to collect. Unfortunately, very few PIs ever pass all these tests, so all PIs in practice have conceptual limitations.

Issues in Performance Measurement

There are a number of major issues in performance measurement that are the subject of ongoing debate and research. Perhaps the most critical issue is the extent to which performance measurement and reporting are inevitably biased by the interests of the stakeholders concerned—the principal–agent dilemma. Economic analysis has not derived a conceptual solution to this issue, and it seems unlikely that it ever will. The most promising avenue for solving this dilemma appears to be "political"—the finding of appropriate checks and balances by means of which the undertaking of performance measurement and reporting is less likely to be biased. However, it should be clear that evaluation is inextricably bound with assessment against values, which must include the values of all stakeholders: Evaluation can never be value free. The approaches to performance measurement inherent in the EFQM and Balanced Scorecard approaches can be seen as attempts to give other stakeholders a clearer opportunity to put forward their interpretation of how performance in an organization can be viewed.

Another major debate concerns whether it is important to have a single overall measure of performance for a public sector organization. For many decades, the private sector was believed to have a major advantage because the measure of profit gives it a bottom line—a single performance measure. However, overall measures of performance have been undermined recently, in both private and public sectors, by Balanced Scorecard approaches. Moreover, there have been interesting new developments in England and Wales, in which all the public sector inspectorates have been pressed by government in recent years to score public agencies against the achievement of "corporate objectives," which typically include objectives for social inclusion, diversity, environmental protection and enhancement, antipoverty, antidiscrimination, and (less often) fair employment. Consequently, all corporate strategies and business plans in public agencies have been assessed against multiple "top line" objectives. Nevertheless, central government in the United Kingdom has also developed aggregate scores for local authorities (the so-called comprehensive performance assessment), health trusts (the star ratings system), and universities (albeit two-dimensional, with separate scores for research and teaching). However, few other countries seem interested in this one-dimensional approach.

The final issue concerns the amount of resources to be devoted to performance measurement. For many decades, it has been argued, particularly by academics, that the public sector has devoted too little effort to understanding its performance levels and that a learning organization would put more resources into performance measurement. However, the NPM reforms have changed this situation. Indeed, the United Kingdom has seen the emergence of an "audit society." Hood *et al*. have estimated that there are now more regulators, auditors, and inspectors in the United Kingdom than there are taxi drivers. Many now argue that the pendulum has swung too far in the opposite direction and it would be better to put more resources into improving performance rather than simply measuring it.

The Future of Public Sector Performance Measurement

Finally, the literature suggests the following future directions for performance measurement:

- Support for evidence-based policy and management
- Measuring outcomes and quality of life rather than outputs
- Measuring the capacity for innovation and dynamic change
- Measuring achievement of public governance principles and processes
- Using public management for problem solving rather than just dial watching
- More self-assessment (e.g., in EFQM), with appropriate auditing of data.

Q Methodology

Paul Robbins
The Ohio State University, Columbus, Ohio, USA

Glossary

concourse The possible range of opinions and subject positions on a specific topic.
condition of instruction The contextual statement against which the Q-set is sorted by respondents; for example, "Most agree/Most disagree" or "Most like myself/Most unlike myself."
factor array A model Q-sort, used for interpretation, that has been abstracted from the Q-sorts that significantly load on each factor.
factor rotation Judgmental or theory-driven rotation of factor axes in analysis. This contrasts with "objective" rotational procedures, including varimax and quartimax.
operant subjectivity A model of subjectivity that assumes individual viewpoints are self-referent and are expressed and behaved contextually.
Q factor Structured products of Q factor analysis from clusters of statistically similar Q-sorts.
Q-set A subsample of the concourse, individual stimuli for ordering/ranking by study respondents; usually quotes or statements but also may be a set of photographs, pictures, or other objects.
Q-sort The ordered ranking of the Q-set by an individual participant usually using a quasi-normal distribution, expressing the individual's ranking of individual statements/items relative to the condition of instruction (e.g. "most agree").

Q methodology uses a controlled technique to elicit subjective viewpoints in order to make them explicit and comparable. Unlike more common "R" methods, such as traditional ranking opinion surveys that are based on variance analysis and sample averages, Q is less concerned with comparing patterns of opinion between groups than it is with determining what these patterns are to begin with and determining their structure within individual people. It is therefore used to understand the relationship between subjective opinions/claims/understandings as they vary throughout populations. Based on a by-person factor analysis technique and a somewhat standardized protocol for data collection, Q reveals common patterns (factors) of subjectivity, allowing comparison of individual opinions based on their relationship to these idealized patterns. Since it elicits the patterns of opinion directly from the sampled individuals, rather than using a preassumed or a priori set of opinions formed by the researcher, Q method has been effectively employed not only by social scientists but also by practitioners in fields ranging from health science to public policy. Despite its long history, some unsettled issues remain in Q method, including the determination of the numbers of factors in a population, the use of normalized distribution in Q-sorts, and the question of the minimum number of loaders/study subjects required for factor stability.

History

Q method is a technique for the study of subjectivity pioneered in the 1930s, emerging in recent years throughout the human sciences and increasingly common across a range of disciplines. William Stephenson, a psychologist and physicist, first introduced Q in the 1930s in a letter to the editor of *Nature* in which he first described person versus trait correlation. Stephenson explained that traditional factor analysis technique, in which a population of n individuals is measured with m tests/stimuli, might be inverted so that n different tests/stimuli are measured by m individuals. In this way, factor analysis was altered so that individual people, rather than test items, become variates. The factors that emerged would suggest common and empirically grounded structures/relationships between individuals.

Stephenson's Q methodology extended this insight beyond by-person factor analysis, however, specifically using this technique to query individual people and have them rank matters of opinion in relation to one another. Stephenson published his definitive work on the subject, *The Study of Behavior: Q-Technique and Its Methodology*, in 1953, 20 years after this initial contribution, stressing the technique as part of a larger, more comprehensive philosophy. Q method allows a respondent to assemble a model of her or his own subjectivity, preserving its internal and self-referent characteristics during analysis. This work remains a seminal contribution to Q methodology as the science of subjectivity.

The technique has been adopted by researchers in political science, sociology, and psychology, and it has enjoyed popularity in professional practices ranging from marketing to the health sciences. The technique, moreover, has its own professional society and its own journal, *Operant Subjectivity*, which explores applications of the technique and discussion of statistical issues in the method.

Defining Subjectivity in Q Research

The systematic study of subjectivity outlined by Stephenson and later Q methodologists is undergirded by a few key assumptions about the nature of subjectivity. Subjectivity is assumed to be (i) communicable and (ii) operant.

In the first case, the subjectivity of individuals is understood to be self-reflexive, where individuals have a discursive awareness that enables coherent explanation of beliefs and motivations. In this sense, subjectivity refers simply to the distinction between "your" point of view and "mine," as articulated in communication. This assumption is not necessarily compatible with some understandings of the subject articulated in critical theory and psychoanalytic approaches to behavior but does provide a sound basis for the practical exploration of people's points of view.

In the second case, subjectivity is viewed as operant: behaved, self-referent, and contextual. It is behaved and self-referent in the sense that it is performed anytime someone articulates his or her point of view or agrees or disagrees with others. It is contextual in the sense that people's opinions on individual matters are interrelated and realized/articulated together as a coherent whole.

This last assumption suggests a departure from methodologies that inquire into the opinions of subjects based on isolated and apparently unconnected questions, as most opinion research and pollemetrics do. To understand someone's self-referent subjectivity requires propositions and queries that are internally related and whose interconnections are as important as their individual characteristics. Q methodology is specifically designed to query subjectivity in this way.

Measures of Subjectivity: Q versus R

Q method is most commonly compared with so-called R methods, the title of the latter derived from Pearson's product–moment correlation *r*. For Q methodologists, R method refers to any form of standard opinion or subjectivity research in which individuals are queried along a number of individual tests ("Too much money is spent on public education," "The Labor Party is good for local business," etc.), with which they assert scaling agreement or disagreement to varying degrees ("strongly agree," "slightly agree," slightly disagree," etc.). R analysis might then descriptively assess the proportion or character of the population agreeing or disagreeing with such a test: "45% of women strongly agree with statement *X*, while only 10% of men do." Alternately, R analysis can determine significant statistical factors of the population that assemble along particular test/question clusters or latent variates through correlation and factor analysis.

Q versus R Factor Analysis

Q method is not simply an inversion of traditional R factor analysis to group test stimuli or traits, although it does entail such an inversion. Demonstrated simply, factor analysis of a basic data matrix (Fig. 1) in social science typically involves the correlation down columns of *N* traits across a population of *n* persons. This procedure produces

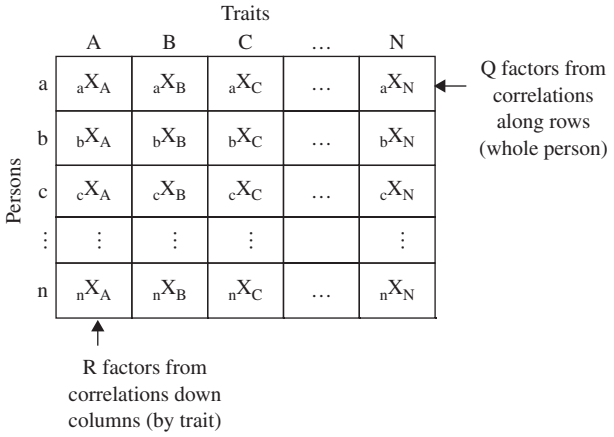

Figure 1 Basic data matrix.

a correlation matrix and a set of factors, against which specific traits can be evaluated based on their clustering or loading. Q analysis (as a factor technique and not a method) is the by-person factoring of correlations of traits, thereby identifying statistically correlated groups of people (i.e., whole individuals, not traits).

Such statistical analysis, in and of itself, may not be useful or meaningful insofar as the tests may be of differing orders or scales. For example, a survey might determine the heights, weights, and ages of a population. Traditional factor analysis might be performed on the population, determining patterns across the population for traits. Inverted "Q" factor analysis, determining correlations within individuals across the many traits, would be meaningless since the measures for height, weight, and age are incomparable. If, however, a survey determined the responses of an individual or a sample of people to opinion questions, and where each trait was a claim or opinion ranked or rated for level of agreement or importance to oneself, then such an inversion becomes useful and powerful. The internal relationships of opinions/issues to one another within people's personal frames of reference become measurable as groups of individuals (factors) of shared and common subjectivity.

Q Method versus R Method Assumptions

Q method was designed to elicit such factors of subjectivity directly from the population rather than a priori measures determined by researchers. If a researcher were interested in environmental opinions in a population, for example, traditionally he or she might produce a questionnaire designed to elicit scores on a predetermined scale. By answering questions one way on an environmental survey, for example, a given subject might score as a "visionary green," a "maybe green," or a "hard brown." The proportion and characteristics of these populations might then be described or examined. These designations (green, brown, etc.) and the threshold scores that designate them are determined, using traditional R approaches, by the researcher before the fact. The assumption is that there is an existing, coherent, subjective pattern out there in the world that scales from "green" to "brown."

Q method begins from a significantly different perspective and seeks as its goal to determine what structure of subjectivity is "out there" in the world, the very structure that R research assumes to exist before the fact (some people are greens and some are browns in the previous example). A Q method study of the same issue would, in contrast, assemble questions on environmental issues and related concerns, allow subjects to rank them, and, through the kind of analysis described later, determine what patterns exist, only later considering a given individual's similarity to those factors. Such a study, continuing from the previous example, may confirm the traditionally assumed pattern of "green" and "brown" viewpoints. It may determine, conversely, that such an axis of differentiation is meaningless, and that real differences lie between those concerned about health and those concerned about wildlife, for example, or some other variation that otherwise would be rendered invisible through the a priori categorization of opinions.

Structures of Subjectivity versus Populations of Subjects

Fundamentally, Q and R differ in the kinds of questions that are asked and the assumptions made in analysis. The two techniques are not contradictory methods but can in fact be highly compatible. Any issue in social science may be explored, for example, through exploratory Q method research, seeking to find empirically the variations of opinion that might inhere in key issues. These may later be explored through sampled survey techniques following an R format.

The main difference is that Q seeks to determine the structures of subjectivity and their variance, whereas R methods seek to characterize populations of subjects. R method can reliably ask and answer the question, "What proportion of women support gun control?" Q method, on the other hand, can reliably answer the question, "What are the variations of opinions about guns, and what are their internal logics?" The differences between each method suits a different phase of research, a different research agenda, and a different political and social project.

Steps in Q Method

Q method is carried out in a series of reasonably consistent steps: (i) The domain of subjectivity is determined; (ii) a concourse of statements is obtained or recorded; (iii) all the representative ideas of the concourse are sampled and included in a much smaller Q-set of statements or stimuli (pictures, words, etc.); (iv) Q-sorts of the statements are arranged by subjects, who rank the statements based on a condition of instruction (e.g., "most agree/most disagree"); (v) subjects are asked to comment in open-ended interview after sorting to explain their reasons and logic for the sorting of items; (vi) the Q-sorts are intercorrelated, two by two, and subjected to a by-person factor analysis; (vii) the factor structure is simplified by axis rotation and interpreted; and (viii) wherever possible, the resulting accounts of study subjectivities are returned to study subjects for review, comment, and reconsideration. Q method software programs have been developed to perform many of the statistical functions described here; software programs include PQ Method and PCQ, which are available from their designers through the Q Web site (www.qmethod.org).

Defining the Domain of Subjectivity

The domain of subjectivity is simply the broad area or topic of concern to the researcher, such as school funding, water quality science, lawn chemicals, or mad cow disease. In selecting the domain of subjectivity, it is useful to consider the breadth and openness of the area and the interest of the researcher. Selecting the domain of attitudes about forests might be more productive than specifying attitudes about deforestation, for example, especially for initial exploration of the range of subject positions in the area.

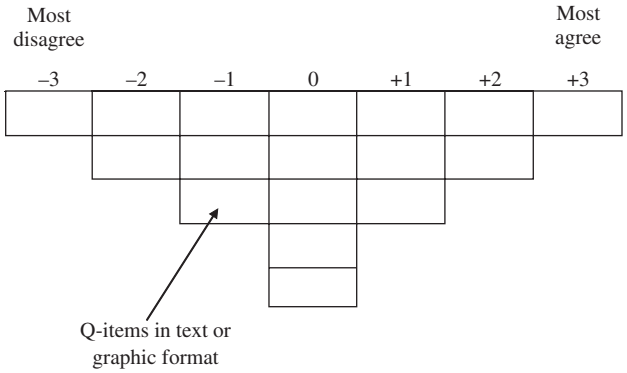

Figure 2 Example of typical normalized Q-sort structure.

Identifying/Sampling a Q-Set

Around the domain of subjectivity, a series of statements is next assembled. The selection of the sample (also known as a Q-set—items to be sorted by the subject), in terms of both composition and quantity, depends on the broader purpose and study design. In some cases, a sample of statements might be drawn purposefully from transcripts of intensive interviews or other techniques. Such a "naturalistic" sample is selected to represent a range of convergent and divergent views on varying facets of a topic of importance to all those interviewed.

Conversely, the statements may be drawn at random from a larger set of secondary quotes. Primary and secondary source materials may also be mixed to produce a comprehensive concourse. Similarly, a standard "deck" of quotes and statements, drawn from previous research, may be used for comparative purposes between groups or over time. The well-known California Q-set is one such standardized tool used in a range of personality studies. This option strays somewhat from the principle of drawing from context, however, which is important to many Q researchers. Moreover, the use of contextual or indigenous items in no way invalidates the generalizability of Q study results since these arguably represent localized reflections of more general patterns of subjectivity.

The number of statements in the concourse is also variable. Mathematically, the factor analysis can be performed with very few statements and some successful studies have utilized as few as 10 items. The maximum number of sorted items is reported to be more than 1000, although as a practical matter, a smaller sample of statements is equally effective.

The use of nonnarrative/text stimuli is also possible, although less prevalent in practice. Colors, photos, music, and even odors have been used in Q-sorts to good effect, especially in the examination of aesthetics, environmental perception, and landscape preference. This is also of particular use when working with groups or populations with highly divergent literacy skills.

Eliciting Q-Sorts from Respondents

The items in the deck are then presented to respondents, who rank order them based on a condition of instruction. The sample of respondents may be drawn randomly from a larger population or may be purposively selected to represent key positions, decision makers, or groups, depending on research goals and hypotheses.

The condition of instruction might be simple (e.g., "Which statements most reflect your feelings?") or more specific (e.g., "Which approaches to development provide more benefit to the local community?"). In a robust study, multiple sorts may be performed using the same items under varying conditions of instruction.

The items are then arrayed, usually along a normal distribution, as shown in Fig. 2, in which items placed in the middle are viewed as "indifferent" or less characteristic. This assumes that items at the extremes are the most salient or significant.

The actual shape and structure of the distribution curve of the Q-sort arguably matter very little since the factors of subjectivity tend to be broad and robust enough to be reproduced under a variety of configurations. Whether the distribution is +5/−5 or +3/−3, for example, has little effect on final results.

Correlation and Factor Analysis

As outlined by Brown, the steps that follow are fairly standardized. Correlation coefficients are computed based on the sorts, and for each pair of Q-sorts a Pearson product−moment correlation coefficient (r) is calculated. The matrix of these intercorrelations is usually not used by itself in analysis but is a step toward the factor analysis that follows. Although a range of newer and more sophisticated techniques are available for extracting factors, factor analysis is typically performed using the centroid or simple summation method. From this, a number of factors will be produced, each with its

own eigenvalues and percentage of explained variance. The factors in the unrotated matrix represent abstracted trends/clusters of similar Q-sorts—in other words, common or idealized subjectivities.

The number of factors prior to rotation is a matter of theoretical as well as practical concern. Statistically, a rule of thumb may be employed to retain all factors with eigenvalues greater than 1.00. This may force the analyst to overlook theoretically and substantively important factors, however, and should be employed with caution. Generally, each factor is examined in its structure and its relevance in the sample population. The factor may, for example, reflect strongly the views of a single, important individual and therefore be retained for a full and robust examination.

Factor Rotation

The factors are next rotated in multidimensional space to align the individual Q-sorts along idealized and abstracted subjective patterns and commonalties. Axis rotation is performed to produce greater clarity and perspective and in no way changes the positional relationships among the factors in multidimensional factor space. Unlike correlation and factor analysis, factor rotation may be executed by a variety of statistical algorithms but may also be performed entirely by manual or judgmental rotation in a less standardized and more theoretically driven fashion. This allows the testing of "hunches" and the exploration of "interesting possibilities."

Typically, the method of rotation is an "objective," statistically derived scheme, such as varimax rotation, in which the purpose, following McKeown and Thomas, is to "maximize the purity of saturation of as many variates (Q-sorts) as possible" along the fewest number of factors derived earlier. In this case, factors are aligned in an orthogonal fashion along perpendicular axes so Q-sorts that load high on one factor will load low on another, maximizing the distinction and differentiation of subject positions while minimizing the correlation among factors.

Such an approach may be less than satisfactory, however, for theoretical reasons, for testing hypotheses, or for revealing meaningful patterns. In many cases, the Q-sort of a key individual or group of individuals may be understood by the researcher as an ideal, important, or definitive type. By rotating the factors to align with those ideal sorts, it is possible to examine the degree of deviation from these opinions among other individuals and groups, for example.

The case of theoretical rotation is shown in Fig. 3, in which a theoretical varimax rotation aligns centroids using Q-sorts from locals and state officials concerning issues in forest management. In this case, the varimax rotation was discarded in favor of a theoretical rotation,

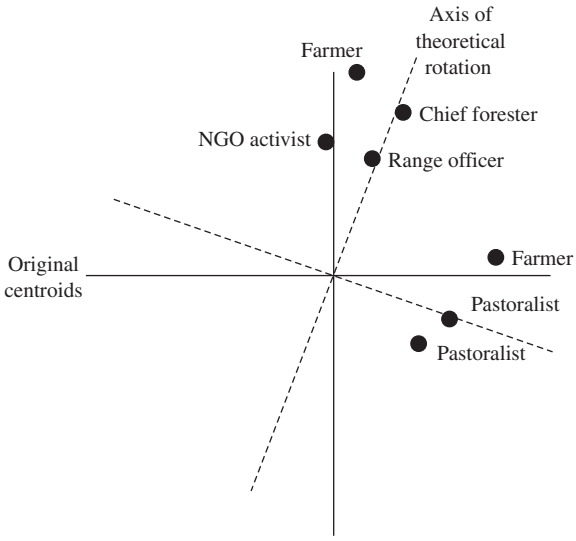

Figure 3 Example of theoretical rotation diagrammed in two-factor space.

wherein the subjectivity of specific specimens (the sorts of foresters and pastoralists) provides "ideal types" and can be examined both in contradistinction to one another and relative to that of other individuals and groups.

Factor Interpretation

Interpretation involves both an examination of the constituent items that make up each factor and the relationship of individual Q-sorts to each factor. In the first case, the factor arrays, those combined elements that represent abstract or idealized subject positions, are of the greatest interest to the Q researcher since they reflect, as Brown (1980, p. 247) notes, "attitudes as attitudes, quite independently of whoever may have provided them." These will take the form of a coherent story, with significant sorted elements making up strong negative and positive components in each factor/story. The factors can be understood as significant and empirically derived viewpoints that exist in the population.

Similarly, each individual Q-sort is scored with a loading on each factor. Some individuals, with high loadings on a single factor, will represent relatively "pure" articulations of a subject position, and their viewpoint is often used to define this factor. Others, however, may straddle multiple positions. This is both methodologically and theoretically desirable insofar as the definition of subjectivity underlying Q method assumes the possibility that predefined and conceptually simple descriptors of subjectivity (e.g., left/right, green/brown, and authoritarian/egalitarian) do not exist in real populations and that the complexity of subjectivity allows for multiple positions and subjectivities.

Iteration with Respondents

The final step of a Q study should involve a presentation to the study subjects of the derived factors in textual or graphic form. This not only allows assessment of the results (e.g., "How close does this factor describe your point of view?") but also opens the possibility for ongoing interpretation of what factors mean. This is especially the case when respondents' Q-sorts load significantly on more than one factor. It is also particularly useful if the technique is being used in social or therapeutic projects in which comparison and ongoing dialogue are research goals (e.g., participatory development projects).

Other Approaches to Q

Q method can also be applied "after the fact" to treat data not derived in the fashion outlined previously. R method questionnaires, for example, that incorporate Likert scale ratings or, more easily, ranking questions can be recoded as individual Q-sorts and subjected to Q factor analysis without violating the assumptions of Q methodology in any fundamental way. Such *ex post facto* uses of Q, however, should open the door to study designs that more explicitly allow survey respondents to model their own subjectivity in the ranking process. Nor is this approach universally accepted in the field since many researchers view Likert ratings as inherently incapable of capturing relevant meaning.

Example: Views of Water Quality Regulation

Maddock conducted a Q-based research project to determine the variation of subjective viewpoints among a commission of diverse stakeholders seeking to create total maximum daily load (TMDL) regulatory structures to manage non-point source pollution. The topic was ideal for Q method since the range of interests (industry, farming, regulatory, scientific, and environmental) was wide, and the traditionally assumed differences between the individuals and groups involved (e.g. "green" versus "brown" views of the environment or "left" versus "right" politics) did not seem to hold.

The study used 23 statements as items for sorting. These statements were drawn directly from in-depth interviews among the various groups and placed on large index cards for easy management and handling. The deck included a range of statements from a variety of perspectives, including the following:

> *The majority of decisions made on this TMDL were not technically based, they were politically based, they were modified to meet the politics.*
>
> *Nobody causes more erosion than farmers. So for how long can they justify regulating the construction industry for example, which is about 5% of the load, and leave farming which is 90% of the load?*
>
> *Non-point source modeling is uncertain. We shouldn't get caught up in the numbers but move ahead to the water quality goals.*
>
> *The knowledge, quantitative tools and models are accurate, but what we need is intense data collection to support calibration and verification.*

The sorts were administered over several weeks and then correlated and subjected to factor analysis. The results of analysis produced four meaningful and significant factors. A fifth factor, although statistically feasible, was determined to add little to the explanatory power of the model and, by reducing the number of defining variables, increased error. Following a varimax rotation, the characteristics of the factors were explored.

The factors reflected four general points of view among commission members: (i) a "technocratic" view, which held that science was accurate and reliable, that participatory structures were troublesome, and that agriculture and construction were the central water quality problems; (ii) a "scientific uncertainty" view, which held that although science was not fully reliable, participatory decision making was ineffectual, and it also held agriculture to blame for current pollution; (iii) a "participatory science" view, which held that science is unreliable and value laden, that participatory decision making is prerequisite to a solution, and that point source polluters and industry were central causes of degradation; and (iv) a "science is political" view, which held no faith in quantitative models and which held that participation was necessary, with little emphasis on pollution causes. A wide range of subject positions was evident, as was the absence of clear or simple binary divisions between views of science, participation, and causes of pollution.

Equally revealing, however, were the surprising constituencies and divergences of these factors across and between interest groups typically viewed as monolithic. As shown in Table I, stakeholder group affiliation did not necessarily dictate or define the specific opinion factor, especially within groups typically or popularly associated with monolithic views, as in the case of environmentalists. What accounts for variation? How are participatory processes and the uses of science implicated in opinion formation within and between groups? These results lead to further hypotheses and motivate further research. Such results are the hallmark of rigorous Q-based research.

Debates and Unsettled Issues in Q Methodology

Despite, and perhaps because of, the method's long history of ongoing development, several methodological

issues remain under discussion. The appropriate number of Q-sorts to support robust factors is a matter of debate, as is the necessity of normalized distribution of Q-sorts. Optimal methods for the formation and rotation of factors is also a point of methodological development. Much discussion also focuses on the question of representativeness among factors and populations. In this last case, some observers mistakenly equate the small sample populations with poor representation and generalizability in Q study results. This is far from the case, however, and reflects, according to adherents, a misunderstanding of what is being generalized in Q study—characteristics of subjectivity rather than characteristics of populations. More productively, many discussions center on the role of Q method in helping to establish free and just communication and decision making more generally, leading to the possibility of "discursive democracy." For a current tracking of such discussions, the Q method Web site is a key source, as is the journal *Operant Subjectivity*, both published and maintained by the International Society for the Scientific Study of Subjectivity.

Qualitative Analysis, Anthropology

D. Jean Clandinin
University of Alberta, Edmonton, Alberta, Canada

Glossary

context Refers both to the situations (places, times, relationships) in which participants live and to the situations in which data is collected.
data (field texts) The material or information collected from research or study participants.
method The techniques or procedures a researcher uses to collect data. Methods are consistent with the philosophic assumptions of a particular methodology.
methodology The fundamental epistemological and ontological view embodied in the research stance.
participant (informant) The people from whom data are collected; the term "subject" is used in quantitative research.
research reports (research texts) The reports written to convey to an audience research findings and their interpretations.
researcher signature The construction of a writer's identity and the development of an authorial presence within a text; a term attributed to Clifford Geertz. In research texts, a researcher signature points to the researcher's participation in producing the text.
voice The ways participants' experiences are expressed in both field texts and research texts.

Anthropologists have begun to question the kinds of methodologies appropriate to studying human experience; in this regard, it is of interest to explore the turn to qualitative methodologies in anthropology. Under the broad heading of qualitative research, there are a number of forms of research methodologies, each with a central purpose of enabling researchers to attend to human experiences. However, within each methodology, the research purpose may be grounded within different theoretical and epistemological conceptions of human experience. These methodologies are being used and developed in anthropology as well as in other disciplines.

Introduction

Broadly defined, the discipline of anthropology is the study of humans, their origins, and their religious beliefs and social relationships. Although there is agreement about such a general definition of anthropology, most anthropologists agree with Clifford Geertz, who has spoken of a crisis in anthropology. Anthropology, of all the human sciences, is the most self-questioning discipline. Within anthropology, there is a fragmentation; a period of instability has emerged, brought on by the growing realization of the complexity of trying to study human experience. Increasingly, anthropology is being defined relative to another discipline or field of study. For example, cultural anthropology, medical anthropology, economic anthropology, and paleoanthropology have emerged as unique areas as anthropologists have recognized and attempted to study human experience systematically. As researchers within anthropology have moved away from a belief in what Geertz described as "a single and sovereign scientific method and the associated notion that truth is to be had by radically objectivizing the procedures of inquiry," there has been a turn toward qualitative research methodologies.

The term "qualitative" turns the attention of researchers toward trying to understand the qualities of something. Usually, qualitative, in a research context, is a term defined to contrast with "quantitative." This distinction between quantitative and qualitative research is frequently problematic and only partially helpful. Whereas qualitative means a researcher is attending to the qualities of an experience, sometimes attending to qualities can involve quantifying aspects of an

experience. In general, as stated by Norman Denzin and Yvonna Lincoln, "qualitative researchers stress the socially constructed nature of reality, the intimate relationship between the researcher and what is studied, and the situational constraints that shape inquiry." Qualitative research, as a set of research practices, is composed of many methodologies. That said, however, in general, as framed by Denzin and Lincoln, "qualitative research is multimethod in focus, involving an interpretive, naturalistic approach to its subject matter. This means that qualitative researchers study things in their natural settings, attempting to make sense of, or interpret, phenomena in terms of the meanings people bring to them." In the following discussions, the term "qualitative research" points to the centrality of attending to peoples' experiences and, more particularly, to the ways researchers understand and compose meanings about those experiences.

History of Qualitative Research

Denzin and Lincoln offered one helpful way to understand the history of the development of qualitative research—that is, as a series of moments. Each temporal period, or moment, marks a shift in the ways qualitative research is defined. The five moments are defined as traditional (1900–1950), modernist (1950–1970), blurred genres (1970–1986), crisis of representation (1986–1990), and postmodern (1990–present). Each succeeding moment or time period includes its successors, with the result that, in present time, traces of all of the ways qualitative research have been defined are present.

Kinds of Qualitative Analysis

An exhaustive review of all qualitative methodologies being used in anthropology is beyond the scope here, but the most common qualitative methodologies are grounded theory, ethnography, phenomenology, narrative inquiry, and case study. Each qualitative methodology, with its attendant analysis, focuses on the qualities of experience, although in different ways (for example, descriptive analysis, categorical analysis, thematic analysis, or narrative analysis).

Grounded Theory Methodology

Grounded theory methodology is a research methodology with a central purpose to study the experience of participants in order to develop a theory grounded in the data gathered from participants. The qualitative analysis draws mainly on interview data from numerous participants in order to construct a grounded theory. Based on that grounded theory, a researcher is able to construct hypotheses and make predictions about other experiences.

Ethnographic Methodology

Ethnographic methodology is a research methodology with a central purpose to study a group of individuals within the setting in which they live and/or work and to construct a portrayal of those individuals that describes the shared patterns of group behavior, beliefs, language, and so on. An ethnographic analysis draws on a range of data including field notes, interview transcripts, documents, and artifacts in order to delineate themes, issues, and group behaviors that have developed over time in the local setting. There are unique types of ethnographies, including realist ethnography (objective, scientifically written), confessional ethnography (report of an ethnographer's fieldwork experience), autoethnography (reflective examination of an ethnographer's experience), microethnography (focused on a specific aspect of a group), critical ethnography (focused on the shared patterns of a marginalized group with the aim of advocacy), and feminist ethnography (focused on women and cultural practices that serve to disempower and oppress) (Cresswell, 2002).

Phenomenological Methodology

Phenomenological methodology has as its central purpose to study a phenomenon that a number of individuals might share and to discern the core or essence of the experience of the phenomenon. Phenomenology is a methodology grounded in lived experience that attempts to transcend lived experience in order to situate and comprehend a particular lived experience. A phenomenological analysis draws primarily on interview data.

Narrative Inquiry Methodology

Narrative inquiry methodology has as its central purpose to study the storied experience of one person or a number of individuals. Narrative inquirers describe the lives of individuals, collect and tell stories about the lives of individuals situated within cultural, social, and institutional narratives, and write narratives of the experiences of those individuals. A narrative inquiry draws on a range of data (field texts), including conversation transcripts, interview transcripts, artifacts, photographs, field notes, documents, memory box items, autobiographical writing, and journal writing.

Case Study Methodology

Case study methodology has as a central purpose to study a bounded system, an individual, whether that individual is a person, an institution, or a group, such as a school

class. The purpose is to provide an in-depth understanding of a case. There can be different kinds of case studies, including intrinsic, instrumental, or multiple cases. There can be multiple forms of data, including artifacts, documents, and interview transcripts. There are at least seven presentation styles: realistic, impressionistic, confessional, critical, formal, literary, and jointly told.

Key Considerations in Qualitative Design

These are central considerations in all forms of qualitative analysis.

Starting Points in Qualitative Analysis

In its most general sense, the starting point for all qualitative methodologies in anthropology is human experience. Although each kind of qualitative methodology adopts a particular purpose and allows a researcher to attend in a particular way, the overall research purpose is to understand the meanings of human experiences.

Role of the Researcher

In qualitative research, considerations regarding the role of the researcher are central throughout a study. Because the researcher is the central instrument in all phases of the research process, from framing the question, to sampling, to gathering data, to analyzing and interpreting data, and to preparing the research reports, it is crucial that researcher knowledge is considered. Central to the process of qualitative research is the researcher living out his/her autobiography and speaking from the perspective of a particular background. In some qualitative methodologies, researchers are advised to undergo a process of self-examination and analysis in order to bracket out their subjectivity and to attempt to set aside their biases. In other more relational qualitative methodologies, such as narrative inquiry, researchers are advised to give an account of how they have shaped the research process. In addition, the struggle to share the experiences of others from within (that is, alongside the research participants), as well as to be able to observe participants with some detachment, is present for all qualitative researchers.

Participant and Site Selection

Selection of participants and research sites is crucial to any form of qualitative analysis. People and sites are selected not on the basis of random sampling but as instances that might best help a researcher understand the particular experience under study. Such sampling is called purposeful sampling. Nine purposeful sampling strategies are used in most forms of qualitative analysis: maximal variation sampling, when a range of participants with the most variation in experience is chosen; extreme case sampling, when the extremes of participants are chosen; typical sampling; theory or concept sampling, when a clear understanding of the concept or theory is in place; homogeneous sampling, based on membership with defining characteristics; critical sampling of exceptional cases; opportunistic sampling that permits a researcher to take advantage of unfolding events; snowball sampling; and confirming/disconfirming sampling.

Participant Voice

Another consideration in qualitative analysis is the place of the voices of the participants. This is a particularly compelling issue in anthropology because issues of power and speaking for others are particularly important. Dependent on the kind of methodology, participants are more or less involved in framing the research puzzles and/or questions, in collecting and analyzing the data, and in writing the final research texts. For example, in case study methodology, participants often help frame issues or questions around the case but then act as sources of data. In narrative inquiry, participants frequently play a collaborative role in actively shaping and reshaping the research puzzle and carry through to working on final research texts. In grounded theory, participants are sources of data (that is, informants) and then serve to validate data through member checks. However, in all forms of qualitative analysis, the way participants' voices will be included is a key consideration. When researchers are working in cross-cultural settings in anthropology, issues of language and culture are especially sensitive. When researchers rely on interpreters, they become vulnerable to added layers of interpretive complexity.

Kinds of Data

The most common data format in qualitative analysis is interview data. A relatively new form of data is conversational data. In interviews, the researcher poses the questions and the participant answers by framing responses in the researcher's terms. In conversation, researcher and participants co-construct data by sharing their experiences. Conversation or dialogue shifts the power differential between researcher and participants to a more mutual, equally vulnerable relationship.

In some forms of qualitative analysis, other kinds of data are also collected, such as field notes based on participation and/or observation (along a continuum from observer to observant participant to participant observer), documents, individual artifacts (such as photographs and memory items), journal writing, and community artifacts.

Depending on the research methodology and the methods by which data are gathered, the kinds and range of data will vary.

Data Saturation

A related issue is what constitutes enough data. This is most frequently called data saturation. In most qualitative research, the amount and variety of data collected are usually almost overwhelming before researchers decide they have enough. Data saturation is reached in different ways, depending on the qualitative methodology used. Sometimes saturation is said to be reached when no new information is being gathered, as in grounded theory and phenomenology. However, in relational forms of qualitative research such as narrative inquiry, the length of time and the depth of the researcher–participant relationship are better guides to knowing when enough data have been collected. As Barbara Myerhoff writes of ethnographic fieldwork, "There is no definite or correct solution to the problem of what to include, how to cut up the pie of social reality, when precisely to leave or stop." The question of "enough" data relies in many ways on researcher judgment or time constraints imposed by participants, researcher, or an outside constraining force such as a funding agency.

Key Considerations in Qualitative Analysis

Data Preparation and Organization

When data have been collected within the parameters of the selected methodology and using methods congruent with the methodology, data must be prepared for analysis. Interview tapes must be transcribed, dated, and labeled as to context and participant identities. Artifacts must be dated and labeled as to context. The data can then be organized in four ways: by type (for example, by sorting interview transcripts as distinct from journal records), by site (for example, by the place of the data collection), by participants, and by time intervals. In a narrative inquiry, a researcher would tend to organize by participant. However, if the inquiry stretches over a long time frame, a researcher may also organize by temporal period—that is, by the data collected with participant A during the first 6 months and subsequent time intervals, by the data collected with participant B during the first 6 months and subsequent time intervals, and so on.

A related issue is deciding whether the qualitative analysis will be completed by hand or whether a computer program will be used in the analysis. This decision will partially affect how the data are prepared and organized. Some forms of qualitative analysis are better suited to computer analysis; examples include grounded theory methodology (using such computer programs as NUD*IST or NVIVO) or some ethnographic methodologies (using a computer program such as Ethnograph). More relational methodologies, such as narrative inquiry, do not easily lend themselves to computer data analysis, although having the data entered into text processing programs allows word searches that are helpful in locating connected themes.

Exploring the Data

When the data have been prepared and organized, the next consideration surrounds the ways researchers immerse themselves in the data. Given that the overall purpose of qualitative research is to understand human experience, it is essential that the researcher read and reread the data, studying the participants' words and silences, gaps, and hesitations in the transcripts, studying photographs and artifacts for multiple meanings and possible interpretations, and reading the field notes in order to try to remember the experience of being in the setting with the participants. Frequently, researchers listen and relisten to the audiotaped materials as they read the transcripts. This process allows a researcher to attend closely to the speech, sounds, and emotions being conveyed. As researchers engage in this immersion process, they begin to interpret the data as they write notes about what they are attending to and/or write theoretical memos about what they are beginning to theorize from the data. As they begin the reflexive and recursive process of analyzing and interpreting the data, they may begin to code the data. In this process, they may begin to foreshadow emerging issues, categories, themes, and/or threads in the data.

Coding the Data

Depending on the research purpose and the methodology being used, data can be coded descriptively, categorically, thematically, or narratively. For example, in most forms of ethnography, data are coded in order to provide thick descriptions of the culture under study. Though data can be coded in many ways in ethnography, in the broad view, ethnographic analysis is the exploration of cultural elements and their relationships as conceptualized by individuals. Data coding can begin when the researcher begins collecting data. Within ethnography, there can be at least four kinds of ethnographic analysis: domain analysis involves a search for the larger units of cultural knowledge (domains), taxonomic analysis involves a search for the internal structure of domains, componential analysis involves a search for the attributes that signal differences among symbols in a domain, and theme analysis involves a search for relationships among domains and how they lead to culture as a whole. The coding occurs

on two levels: at the level of small details of a culture and at the level of the broader features of the cultural landscape.

In grounded theory methodology, there is a continuous interplay between analysis and data collection using a constant comparative method whereby particular data points are constantly compared to other data points in order to form categories and concepts. In case study methodology, the process of coding data occurs over the entire research process. In intrinsic case studies, the researcher codes data to document the importance of a case within the context of the situation, and issues, contexts, and interpretations are developed. The coding is undertaken with an eye to seeking patterns of data to develop issues.

In phenomenology, the process of coding data begins with researcher immersion in the data and continues through incubation, illumination, and explication phases. The overall purpose of phenomenological analysis is to delineate the major essences of a particular phenomenon. In order to do this, the data are coded into categories. These coded categories are then read and reread recursively into the data. In an interpretive process of delineating categories and themes through a process of condensation, essences of a particular experience are illuminated and explicated.

In narrative inquiry, coding is completed with an eye to developing narrative accounts of participants' experiences. Coding occurs within a metaphoric three-dimensional narrative inquiry space, with attention to the personal/social dimension, the temporal dimension, and the dimension of place. Coding of events or actions that lead to narrative themes within a participant's life, narrative plotlines of a participant's life, and narrative threads are all possibilities. As threads, themes, or plotlines within an individual life become evident through coding of individual actions or events, institutional, cultural, family, and/or social narratives that shape a life become apparent and are also coded.

Coding data in all qualitative methodologies is an interpretive process. Although there are particular methods for seeking consistency in the process of coding the data, in qualitative analysis, a great deal depends on the meaning the researcher sees in particular pieces of data.

Interpreting the Data

When data are tentatively coded, they are then sorted into themes (in grounded theory), thick descriptions (in many kinds of ethnography and case study), essences (in phenomenology), and narrative threads or plotlines (in narrative inquiry). The process is a highly interpretive one, guided by what the researcher sees as emerging from the data. As noted earlier, the subjective role of the researcher is central to the process. There are various ways that researcher subjectivity can be accounted for, including a process of bracketing, creating an audit trail that other researchers can follow to verify interpretations, and having other researchers code and interpret some of the data to create interrater reliability. Other ways to verify the coding and interpretive processes include member checking, whereby codes and interpretations are checked with the involved participants for accuracy. Still other processes involve triangulation, whereby multiple kinds of data or data from multiple sources are cross-verified for adequacy of coding and interpretation. However, in narrative inquiry, which is a relational form of qualitative analysis, interim interpretations are also negotiated with participants in order to ensure that an interpretation resonant with participants is being created. Interpretation of data is frequently a messy process. Sometimes as data are interpreted, researchers realize that more data are needed before an adequate interpretation can be made. In these cases, researchers need to return to the field to gather more data from participants. The process is rarely linear; researchers move from living in the field and collecting field texts to coding and interpreting field texts and writing research texts. Issues of participant voice are central to data interpretation and to all attempts to compose an understanding of human experience.

The Place of the Research Literature

What is already published in the research literature is salient at every step of the research process. Although it is important to try to understand a particular aspect of human experience on its own terms in qualitative research, it is also important to read as widely as possible about that aspect of human experience, prior to beginning the research. Situating the research question within the literature allows a more informed framing of the question. Some qualitative researchers frame research questions using particular formalistic categories such as race, class, or gender, whereas other researchers begin with research puzzles or enigmas situated within the participants' and the researchers' experiences. However, for a researcher at any point along this continuum, it is important to have read broadly in the area of research interest. At the point of coding and interpretation, it is also important to situate the data alongside existing research. During coding and interpretation, other research literature may become relevant because of the emerging interpretations of the experiences of participants.

Key Considerations in Writing Qualitative Research Texts

As with all kinds of social science inquiry, research texts drawing on qualitative analysis require evidence,

interpretive plausibility, logical constructions, and disciplined thought. However, within each particular kind of qualitative analysis, there are some unique features concerning forms of representation, the audience, ethical issues, and criteria for assessing qualitative research texts.

Forms of Representation

Forms of representation (data displays) vary across qualitative methodologies. However, issues of form, voice, and researcher signature are central to each qualitative analysis. Forms of representation include thick descriptions and portraits for case study and ethnography; narrative accounts for narrative inquiry; midlevel theories for grounded theory, and descriptions of essences for phenomenology. Some qualitative researchers use arts-based forms of representation or forms called "bricolage" (from the French, *bricolere*, to putter about), a term meaning using anything that is convenient and available, now used in anthropology to denote the more improvisatory way that data can be represented in order to offer multiple meanings. Within each form of representation, unique features vary, depending on the research purpose. Although research reports have fairly standard formats when quantitative methodologies are used, research reports produced when qualitative methodologies are used are often quite different in form, depending on the researchers' interpretive frame and purpose. Researchers frequently experiment with form in order to find ways that best represent the participants' experiences. Qualitative methodologies in anthropology lead researchers to work *ad hoc* and *ad interim* as they compose their research texts.

Questions of Audience

The audience for whom research reports are prepared also influences the forms of representation. Funding agency requirements and university requirements for theses and dissertations influence the forms of representation. Journal and book formats determine, to some extent, the ways that visual and textual materials can be included. Although some journals allow flexibility in form, others do not. As electronic publishing becomes more common, qualitative researchers may continue to push audiences to take seriously more experimental forms of representation, including arts-based forms, bricolage, and a range of narrative forms.

Ethical Issues

Ethical issues and tensions are apparent throughout research employing qualitative methodologies. Qualitative researchers are governed by institutional research ethics boards, but issues of confidentiality and anonymity take on added significance when human experience is being studied. These issues need to be carefully negotiated with participants at the outset of the study. They may also need to be renegotiated at the request of participants and/or researchers at different times throughout the study. Furthermore, many qualitative researchers negotiate interim research texts with participants to ensure that the participants' experiences are represented in a resonant way. Although the guiding principle of all research ethics is to do no harm, the intensity of participant/researcher relationships during qualitative research frequently requires an attentiveness to the participants' experiences that is not necessary when quantitative methodologies are used. In qualitative research with some cultural groups and age groups, such as aboriginal cultural groups and children, additional issues around informed consent also need to be considered.

Criteria for Assessing Qualitative Research Texts

Although it is generally agreed among qualitative researchers that the criteria for judging qualitative research are not validity, reliability, and generalizability in the ways those terms are understood in quantitative methodologies, the criteria for judging qualitative research are still under development. Triangulation, member checking, and audit trails that allow external researchers to reconstruct the research process are used in some qualitative methodologies. Criteria such as plausibility, persuasiveness, authenticity, and verisimilitude are under consideration. Resonance with the experience of readers is another criterion currently in use as a way to judge the quality of research.

Features of Qualitative Analysis

In addition to variability across qualitative research methodologies, there are some features of qualitative analysis that cut across all qualitative methodologies in anthropology. Results of qualitative analysis are always bound by a particular time frame, particular contexts, and particular participants' experiences. There is no one generalizable truth that cuts across experience in general. That said, however, there is a continuum across qualitative methodologies that speaks to how bound by individuals' experiences the results are. For example, at one end of the continuum, a grounded theory methodology does generate a middle-level theory that speaks to others' experiences within a limited range. At the other end of the continuum, a narrative inquiry methodology gives an account of the experience of only those participants

in the study, although there may be resonance with other readers' experiences.

Qualitative analysis does not yield one ultimate truth but offers multiple possible interpretations of human experience. The purpose of qualitative research is to offer insights into the nature of human experience, and results are always open to other interpretations and other understandings. Qualitative analysis is a recursive process that moves back and forth across data gathering, coding, and interpretation. Because of the unfolding recursive nature of qualitative research, it is not always apparent what will emerge. Researchers working with qualitative methodologies need a tolerance for ambiguity and the ability to follow promising avenues in data collection and interpretation that may not have been evident when research questions were initially formulated. This requires tenacity and a willingness to stay with the research, often for extended periods of time.

Given the reliance on language to represent lived human experience, the writing of research texts is also a recursive reflexive process. Researchers need to stay open to imagining alternate forms of representation that may emerge from the interpretations of the data. Clifford Geertz wrote that the research texts needed in anthropology are "tableaus, anecdotes, parables, tales: mini-narratives with the narrator in them." Many qualitative researchers establish sustained response communities to allow them continual feedback as they code and interpret data and write research reports. The complex, multilayered, ambiguous, and unfolding process of research undertaken using qualitative methodologies is one that requires researchers to stay engaged and thoughtfully aware of the idea of trying to understand and represent the complexity of human experience.

Glossary

archival techniques The use of source materials stored in any media format (books, manuscripts, paper, electronic files, or cultural artifacts) to gather information about human activity or to pursue humanistic ends.
case study A particular example of a phenomenon, ranging from a single individual to a larger institution or from a single event to a longer process, separated for close, multidimensional study.
documentary The collection or creation during fieldwork of informational items or artifacts in any medium, including written, audio, or visual records.
fieldwork Any human-centered method of study involving direct interaction with individuals, groups, or entities (past or present) in their natural surroundings.
participant observation A technique of fieldwork in which the researcher joins in the activities of those being studied, while simultaneously documenting the experience.
unstructured (ethnographic) interviewing A technique of fieldwork in which the researcher asks for and documents information from a research participant, who is allowed to respond at will.

Qualitative research methods include any techniques, except those focused primarily on counting, measuring, and analyzing statistical data, to study any social phenomenon. Qualitative social research grew out of and retains the human-centered and literary focus of the humanities. A qualitative study typically involves fieldwork, in which the researcher, rather than remaining in the office or laboratory, goes instead to the settings where the people being studied live, work, play, and so forth. The techniques employed range from passive, such as observation and gathering existing artifacts or records with minimal interaction with others, through active, including creating new documentation, interviewing people, and participating in their lives. Such methods have application in all of the social sciences, but have had a particular trajectory in the research conducted by political scientists.

Current Status of Qualitative Methods

Discussions of qualitative methods often divide the scientific world into two camps, those who accept a natural-science approach and insist on quantification as central to the development of positive facts and those who prefer a qualitative approach to human understanding of social phenomena. At one level, these two camps are imaginary, based on the stereotypes researchers assign to each other. At this level, the argument is often correctly characterized as superficial and unwarranted, and further discussion of qualitative methods could end here. The truth, however, is more complicated than that. If long-standing conflict is conceived as a symptom that tends to arise in the presence of larger philosophical dissension in the social sciences, then qualitative methods deserve closer examination. This is especially the case for political science, which has been unusually slow to find more than token accommodations for qualitative methods in its repertoire of research techniques.

New Knowledge in a Scholarly Venue

The leading edge of research for any discipline tends to appear in current papers from colloquia, symposia, and scholarly conferences. The American Political Science Association (APSA) produces the largest body of such research, with members concentrated in North America but also present in many other countries. A close examination of the electronic databases for the APSA annual meetings since 1999 (available online and through the

association) reveals several obvious qualities. The first is how difficult it is to find qualitative work. A casual browser of the conference program is unlikely to run across any. Electronic keyword searches, however, do yield results. Where social science research predominates in the APSA, papers with titles or abstracts containing qualitative terms cluster in just a few of the better established divisions (for example, the sections on presidency research, on race, ethnicity, and politics, and on foreign policy). Another quality of the work found through the APSA database is the wide variety of techniques reported in the scattering of papers scheduled for delivery, ranging from participant observation, ethnographic interviews, and other field research, to case studies, documentaries, and archival reports, to narrative and rhetorical analyses, to critical/cultural readings of texts. Finally, social scientists using these techniques may adopt in their reports an apologetic or defensive tone regarding their methods, acknowledging that any conclusions must be tentative and generalizations must be postponed. The reports imply that only other means (quantification and statistical analysis) can create positive knowledge.

The emergence of a new section of the APSA dedicated to qualitative methods may seem to present evidence of an advancing interest in the area, perhaps following the classic pattern of subdiscipline formation. However, the definition of "qualitative" in research papers sponsored by the APSA section bearing that name remains primarily quantitative in its background assumptions and in its foreground logic. It is elsewhere, such as in the relatively new APSA sections on comparative democracy and on human rights, that a humanistic epistemology of qualitative work seems not only accepted but also strongly encouraged. In sum, as an example of one of the leading edges of knowledge creation in political science, the recent APSA conferences include qualitative methods as a minor, although perhaps advancing, element.

Established "Facts" in Textbooks

The trailing edge of academic research is usually found in reference books and textbooks, where scholars summarize the widely accepted or little disputed facts of the discipline. Here the story of qualitative methods might be seen as a slow progress toward inclusion, if not acceptance. The seven-volume *Handbook of Political Science*, published in the mid-1970s by Addison-Wesley for a scholarly readership, did include a volume on case studies. But the volume on methods, *Strategies of Inquiry*, treats the stuff of qualitative work, such as manuscript and other archival material, as a source of statistical data, rather than as an appropriate starting point for other modes of understanding political life.

The progress of qualitative inquiry since the mid-1970s can be traced in textbooks for U.S. political science methods courses, where qualitative approaches have played a minor role. They were hardly present before the mid-1970s. First published in 1974, W. Phillips Shively's primer on methods designed for undergraduate students focuses entirely on quantitative methods, after introductory chapters on theory and research questions. Qualitative methods did get mentioned a decade later. The same author's edited textbook from the mid-1980s is a good example: of seven chapters illustrating political science research processes, five, including two labeled "field research," are quantitative. Of the two remaining studies, one concerns John Stuart Mills' political theory and the other uses historical archives.

By the mid-1990s, references to qualitative methods might remain absent from some textbooks, but became a chapter in, or an addendum to, other, new editions of university political science methods textbooks. For example, the third edition of *Political Science Research Methods* by Jean Johnson and Richard Joslyn recites the received history of political science origins, from the time when scholars in the humanities began documenting history and describing government, an approach that held sway until roughly the 1950s. By this account, modern political science then grew from behaviorism and came to rely on statistical methods (becoming "behavioralism," which, unlike behaviorism, attends to unseen attitudes and affinities to quantify political behavior). Such political science textbooks today imagine research following the same story line, with nominally "qualitative" methods as preliminary steps preparing the way for the arrival of quantitative work. Despite recent changes, the coverage of qualitative methods has remained marginal, at least in textbooks used to teach the discipline in the United States.

Qualitative Methods as "Traditional" Political Science

Qualitative methods in political science did develop from philosophy and history, which provided the earliest scholarly venues for studying politics. The methods and assumptions of these humanistic disciplines remain closely associated with qualitative methods. Political theorists continue to analyze documents, and theoretical approaches continue to be central not only to political philosophy but also to the study of institutional and legal settings for politics.

Document Analysis in History

Political historians continue to value archival methods as more than data mining. One way that historical work manages to hold its own is by paying close attention to

social statistics from other sources. Frances Fox Piven and Richard Cloward, in their 1971 book, *Regulating the Poor*, discuss critical history in the presence of data, citing the quantitative studies of others to make a larger historical argument of their own. Although documentary and archival techniques persist, along with purely theoretical work, textbooks describe such scholarship as "traditional" in political science, as a backward or static set of research practices. In its methods and assumptions, political science has been consistently qualitative primarily when verging on other disciplines, such as philosophy, law, history, and sociology (Theda Skocpol has been especially important in bridging between political science and the latter two, and Piven and Cloward bridged from social work and sociology). And even within such work, controversy has emerged about its scientific justification.

Comparative Case Studies

Another early genre of qualitative political science techniques, comparative case studies, developed along with historical and theoretical approaches and came into its own by the middle 20th century, dedicated primarily to comparing the governments either of different countries, or especially in the United States, of different states. Although debates went on between those who preferred a more theoretical political science and those who preferred a more professional, government- and citizen-focused political science, the central methodological assumption of both parties emphasized measurement, with natural science providing the ideal model. This quantitative current advanced among those conducting case studies by the 1970s, such as Arend Lijphart (and later Ada Finifter). Quantification spread so extensively that recent case-study-methods books focus on quantitative procedures rather than on qualitative processes or interpretation.

The 1970s Critical Movement

The social unrest emerging from the late 1960s through the 1970s had a deep and broad influence on other social sciences, including sociology, anthropology, and communication, but less so on political science. The antibehaviorist movement beginning in the late 1960s proposed a politically responsible science based on values and engaged in the life of society, and Marvin Surkin and Alan Wolfe documented the emergence from the movement of an APSA caucus that did critique the constricting effects of behavioral methods. The 1971 history of the poor by Piven and Cloward illustrates the relation of activism to scholarship of the period. But polemics aside, the early results of the movement, found in its journal, *Politics & Society*, were not primarily empirical. Instead, the journal published philosophical discussions, alternative policy studies, and the like, with the shared aim of providing thoughtful interventions from an engaged political science. Only later did the journal emphasize more empirical work, welcoming a wide mix of methods. In recent conference papers, the APSA section on new political science retained an interest in the social consequences and policy impacts of research, as against a commitment to any particular methods.

Social Scientific Techniques of Qualitative Inquiry

In the social sciences, interpretive and similar modes of qualitative inquiry depend principally on field research, which attempts to enter into group life self-reflexively. Political scientists conduct qualitative fieldwork using two main techniques, participant observation and unstructured interviewing.

Participant Observation

In a well-known example of participant observation, Richard Fenno for several years made trips with U.S. congressional representatives to their home districts and watched over their shoulders to understand how they related to their constituents. The resulting 1978 book, *Home Style*, contains information largely beyond the reach of other techniques—about the context and sequence (time and process), as well as the personal dimension, of politics. However, Fenno describes participant observation as exploratory, and he issues several caveats about the limits of its potential contribution to knowledge. Given such a tentative assertion of fact creation, it is not surprising that, despite the wide respect for Fenno and for his book, participant observation has remained at the margins. In the introduction to his collected essays more than a decade after *Home Style* came out, he laments that such work is not quantifiable and is "hard to discipline."

Interviewing

Another field technique, unstructured interviews, usually involves open-ended conversations documented either by tape recording and transcription or by note taking, followed by writing up field notes after each session. Scholars then do multiple, close readings of the texts to look for patterns, sometimes aided by qualitative analysis software, which allows the researcher to tag ideas, relate them to other places where they occur or to other ideas, and develop a map of group understanding. Because ideas are expressed in many ways, not relying on the specific terms or phrases used in quantitative content analysis,

such software is only an aid, like index cards. The scholar must still accomplish the qualitative tasks of exploring, thinking, and writing about a (usually extensive) body of text.

Early on, researchers such as Harriet Zuckerman used the unstructured interview in political science to focus on the study of elites. Doug McAdam, however, published *Freedom Summer*, his study of young people involved in the U.S. civil rights movement, and Bill Gamson's *Talking Politics* explores the experiences of citizens. McAdam began with a questionnaire and followed up with interviews, but other research reverses the process, beginning with qualitative interviews, and then taking a quantitative direction once the analysis begins. A typical study, such as one John Kornacki included in his anthology, uses interviews to discover how members of a legislative body develop patterns of informal leadership, but reports the results in tables that reduce the texts to a few key questions. (The reduction would typify a different technique, i.e., structured interviewing, which occupies a middle ground between surveys and interviews, something like a questionnaire administered face to face). The study also describes its results as general, with little self-reflection, and uses a footnote to mention its methods. The footnotes also reveal that the interviews were part of a larger, funded project based on a systematic (quantitative) survey. Unlike field techniques as practiced elsewhere in social inquiry, their use in political science often springs from or leads into this sort of data processing and analysis.

Philosophical Controversies

Impact of Critical Theory and Cultural Studies

Interpretive methods of empirical research have their philosophical underpinnings in schools of thought that reject the attitude of detachment and the operationalizing strategies that characterize quantitative social science of the 20th century. Critical theory, which developed in the 1940s among Max Horkheimer, Theodor Adorno, and others of the Frankfurt School, and cultural studies, which grew in the 1960s from the British literary and social analyses of Raymond Williams, Richard Hoggart, and the Birmingham School, have wielded a large influence over intellectual life of the past quarter century. These critical/cultural approaches, however, have made only some headway in political science. One anthology, for example, illustrates the difficulty that political scientists face when incorporating cultural approaches into the mainstream of the discipline. Compiled for scholars of comparative politics, a field the authors say has lost its bearings, the collection characterizes three competing traditions: structuralist, rationalist, and culturalist. The latter receives the least extensive treatment in the volume, and in the key theoretical chapter on culture, Marc Ross observes that "cultural contributions to political analysis are relatively rare and far less developed" and that "few graduate students take culture very seriously." Other chapters mention the cultural turn in political science, but the consensus is that such work is lacking rigor.

There are pockets in political science that foster overt constructivism, the notion that the key to understanding politics is the meanings people (groups, institutions, and governments) assign to events and other aspects of political life. Scholars in international relations, for example, have found that norms play an important part in political transformations around the world. An influential example of constructivist thinking is Alexander Wendt's 1999 book, *Social Theory of International Politics*, which attempts to span the divide between constructivist and positivist epistemologies by arguing, for example, that whether nations view each other as friends, rivals, or enemies determines the fundamental ways they act toward each other. Such work, however, is the exception. This state of affairs is due largely to the theoretical status quo in the discipline, especially in the United States. In the intellectual hierarchy, as encountered in the rankings of journals, departments, and other status-granting institutions of the discipline, pride of place has been reserved for a positive orientation. When Kornacki asked political experts to set an agenda for studying the U.S. Congress, for example, the specific ideas they came up with were mainly quantitative: surveys of the members, data on resources available to them, and similar information regarding personnel working for them. An interpretive orientation, despite long roots, has not created a major challenge to this way of thinking. The earlier protest movement within the discipline, despite its forceful introduction in the ferment of the early 1970s, and the critical and cultural orientations emerging in the 1980s have made little headway. Even in works of political history, a logical home to humanistic thinking, the current approach is marked by efforts to find metrics for temporal and sequential analysis.

The Quantitative Reaction and Ensuing Controversies

The discussion of qualitative methods within political science has continued despite the limited approaches. A key event of the 1990s was the publication of a textbook, *Designing Social Inquiry: Scientific Inference in Qualitative Research*. The authors, routinely reduced in reviews and course syllabi to their surname initials

KKV, propose that qualitative and quantitative methods are fundamentally alike. Any differences are stylistic only, because both aspire to do systematic science by following valid rules of causal and descriptive inference. The authors, Gary King, Robert Keohane, and Sidney Verba, then propose ways for qualitative researchers to apply quantitative tools to that end. Tested extensively before publication, the textbook circulated widely thereafter, going through several printings. From the time it appeared in Samizdat copies and then went into print, it has been viewed with admiration. For instance, partisans of rational choice theory, which builds historical explanations and political predictions of human action based on the notion that people maximize utility, point to KKV as a source of inspiration. The textbook also met with some antagonism, which appeared prominently in the bulletin *PS: Political Science & Politics*, and later played in the background of other controversies.

In 2000, anger against the exclusion of qualitative methods flared up online with the circulation of a letter from "Mr. Perestroika," representing what many assumed to be one or more younger political scientists or graduate students. The debate, which continued in the *Voices* column of the APSA bulletin from 2000 on, focused on the structure of the APSA, such as the presentation of a single slate of officers for election, as well as on the editorial practices of its flagship journal, the *American Political Science Review*. Although financed by dues from all APSA members, the journal favors statistical research designs, its detractors say, while ignoring not only their qualitative work but also the normative and practical world of politics. The critique was met with some openness in the APSA, which expanded the discussion through its publications and conferences. As part of these arguments, recent examinations of political science methods employed in journals and taught in graduate programs, which also appeared in the APSA bulletin, seemed to suggest that qualitative methods are losing ground. In the top journals, qualitative articles have been in steep decline since 1975 and are increasingly segregated from and rarely cited in quantitative studies. At the same time, qualitative methods courses play a very small role in doctoral curricula, according to a study by Peregrine Schwartz-Shea, who concludes that the message to graduate students is clear: political scientists value quantitative over other methods.

The controversies over qualitative research are not new. Gabriel Almond documented their emergence in the 1970s and earlier, tracing back to the origins of the discipline, when political science detached itself from the humanities and relocated to the social sciences during the early 20th century. These debates may be central to the disciplinary identity of political science, as scholars attempt to define themselves in contrast to their forebears. If this is so, then conflict over qualitative methods will likely continue to wax and wane as it has done in the past. Whether or not qualitative approaches to knowledge have advanced in political science during the past quarter century, they remain at the margins. This appears to be due to the positive philosophical orientation of the discipline. Although they have provided a staging ground for complaints against that orientation in intermittent debates, qualitative methods of research, analysis, and writing, in current practice, serve principally as a tool for exploratory work and as a foil to police the boundaries of mainstream political science.

Qualitative Analysis, Sociology

Dorothy Pawluch
McMaster University Hamilton, Ontario, Canada

Glossary

analytic induction A procedure for verifying theories and propositions based on the assumption that the research should formulate explanations that apply to all cases of the phenomenon under study.
ethnography The process of intensively studying a social group by immersing oneself in the day-to-day lives of people in the group; also the product or outcome of such research.
naturalistic inquiry An approach to empirical research that emphasizes the need to study social actors *in situ*—that is, in their natural environment rather than in settings that are manipulated, contrived, or artificially arranged.
sympathetic introspection A term coined by Charles Horton Cooley to describe a methodology for gaining access to the meanings and interpretations of those social actors one is studying.
theoretical saturation The point in a qualitative study at which the researcher is learning from an examination of new cases nothing new that will add to the understanding of a particular phenomenon.
triangulation A technique for checking different types of data (e.g., field notes, interview transcripts, and documentary evidence) against each other in order to assess or refine a particular interpretation or inference drawn from the evidence.

Qualitative analysis in sociology is rooted in a particular view of the social world and how best to study it. The goal in qualitative analysis is not to count or measure but to capture the subjective meanings of situations that undergird human group life and to understand the social processes by which those meanings are constructed.

The Interpretive Tradition in Sociology

The Chicago School

Qualitative analysis in sociology can be traced back to the Chicago school of the 1920s and 1930s. Influenced by the sociology of Max Weber and Georg Simmel, a number of sociologists at the University of Chicago—including W. I. Thomas, Robert Park, and Ernest Burgess—encouraged students to learn about social life by going out into their own city (the field) and observing it. Chicago became a laboratory for the direct observation of social phenomenon. A series of classic ethnographic studies came out of the Chicago school, including W. I. Thomas and Florian Znaniecki's "The Polish Peasant in Europe and America," Louis Wirths's "The Ghetto," Harvey Zorbaugh's "The Gold Coast and the Slum," Clifford Shaw's "The Jack Roller," Paul Cressey's "The Taxi-Dance Hall," and Nels Anderson's "The Hobo."

Symbolic Interactionism

The methodological tradition of ethnographic fieldwork that the first generation of Chicago school sociologists established and that a second generation, notably Everett Hughes, continued was buttressed theoretically through the 1940s and 1950s by the work of Herbert Blumer. Most of the key elements in Blumer's writing originated in the ideas of George Herbert Mead, a University of Chicago pragmatist philosopher with whom Blumer and others in the Chicago school studied. However, it was Blumer who took Meadian notions about the relationship between the individual and society and fashioned them into a clear theoretical statement (symbolic interactionism) that continues to inform much of the qualitative analysis conducted today. The three basic premises of symbolic

interactionism, as Blumer laid them out, are as follows: (i) Human beings act toward things (objects, situations, people, and themselves) on the basis of the meanings that these things have for them, (ii) the meaning of things arises out of interaction, and (iii) the meanings of things are handled and modified through a process of interpretation that individuals engage in as they deal with the things they encounter.

Apart from his articulation of symbolic interactionism, Blumer was pivotal in laying out a methodological approach that was consistent with symbolic interactionist premises, an approach that respected the processual nature of human group life and treated human beings as active, interpreting, and interacting agents. Arguing that to try to catch the interpretive process by remaining aloof as an "objective" observer and refusing to take the role of the acting unit is to risk the worst kind of subjectivism, Blumer urged naturalistic observation of the empirical world. The object of social research, as he saw it, was to get close to the social world and dig deeply into it, achieving an intimate familiarity with the perspective of social actors.

Theoretical Divergence and Convergence

Since the 1960s, a number of other interpretive perspectives have emerged, including phenomenology, ethnomethodology, dramaturgy, and, recently, social constructionism, postmodernism, poststructuralism, feminism, and critical and standpoint theory. These perspectives differ over a range of ontological, epistemological, political, and ethical issues, perhaps most fundamentally over the degree to which there is even an external "objective reality" accessible to social researchers and, relatedly, what the accounts that researchers produce actually represent. There is a view that interpretive theories have become so eclectic and the differences between them so profound that the qualitative analysis they tend to favor has become unmoored from the distinct theoretical assumptions to which it was once so firmly linked. In this view, qualitative analysis has become nothing more than a rallying call for a group of increasingly disparate scholars who find themselves under the interpretive umbrella.

There is another view, however, that despite the diverse forms that interpretive theories now take and the profound differences between them, at their core they continue to share a common concern with human action, the construction of meaning and the agency of social actors. All share an interest in knowledge about the social world from the inside. Some sociologists, such as David Maines, have argued that the discipline of sociology more generally has moved toward an integration of perspectives, with the premises of symbolic interactionism and its preference for a more naturalistic, qualitative methodology at the center of the convergence. The importance of situations and context for understanding human conduct, the necessity to consider the meanings or definitions that social actors attach to things and situations around them, and the value in understanding social structures as an expression of social processes are being recognized in virtually every area of sociology, although they may not be recognized as distinctly symbolic interactionist insights. This may explain why, since the 1980s, there has been a significant shift within the discipline toward greater use of qualitative analysis. This shift has paralleled trends in other social sciences, the humanities, and fields such as education, nursing, public health, medicine, marketing, and even accounting. A "qualitative revolution" is unfolding.

The Research Process

Analytic Induction

Qualitative analysis in sociology, then, cannot be understood apart from the fundamental assumption that the social world is constituted by the meaning-making practices of social actors. Nor can it be understood apart from the way interpretive sociologists conceive of the research process. In contrast to positivism, which is based on a deductive logic of collecting data to assess preconceived models, hypotheses, or theories, qualitative analysis proceeds largely on the basis of analytic induction. Using inductive reasoning, explanations for social phenomena arise from the data rather than from preconceived categories that force the empirical social world into the operational definitions that researchers construct. Rather than formulating theories that are tested against the social world, qualitative researchers use a "grounded theory" approach, relying on their observations of the social world to generate theory. The theories they construct are consistent with what they see.

Emergent Design

Moreover, in the grounded theory approach, there is a more or less constant interplay between planning, data gathering, analysis, and even writing. These activities are seen not as discrete and sequential steps but as related and intertwined aspects of the research act. The analysis or process of searching for themes or answers to research questions begins as soon as the researcher begins the study. Decisions are made about a primary focus and a series of generalizations are formulated to describe what is happening, generalizations that are then taken into the next observation, interview, or document

examined. Indeed, in a process referred to as theoretical sampling, the researcher may seek out additional cases on the basis of the potential for those cases to test, refine, or extend the generalizations. When cases that do not fit are encountered, either generalizations are revised so that they do or the phenomenon is redefined so as to exclude those cases that do not fit the generalization. This process continues until a point of theoretical saturation is reached. Theoretical saturation is the point at which additional cases no longer contribute to learning anything new about the phenomenon in question. In the end, the process of analytic induction yields a proposition or statement that applies to all the cases examined. Howard Becker describes the process as being in continuous dialogue with the data. The research design remains emergent, fluid, and flexible throughout.

Generic Social Processes

The same constant comparative method that produces grounded generalizations about a particular group or social setting can be extended to produce theory at higher levels of abstraction. Qualitative researchers can make conceptual comparisons across substantive contexts to produce more formal theory. For example, involvement in different subcultures—religious, criminal, professional, and sport—may be compared in a way that allows one to theorize more generally about involvement in any subculture. Prus has argued for the need to use the rich, textured data that qualitative research yields to formulate concepts and to describe processes that transcend the particular settings in which the data were gathered. Generic social processes may be delineated that have transsituational and cross-contextual relevance, tying together a great deal of research that would otherwise remain disconnected or scattered across a range of substantive contexts. In this way, insight is gleaned into the most foundational question of sociology—how human group life is accomplished.

Types of Data

An understanding of qualitative analysis requires an appreciation for the kinds of data that sociologists work with and how they collect these data. Since the goal in qualitative analysis is to grasp as faithfully as possible the lived experience of social actors and the processes by which they construct meanings, there is a preference for data-gathering techniques that bridge the gap between the analyst and the empirical world.

Participant Observation

Central among these techniques has been participant observation, which involves direct observation of ongoing group life. Participant observation, or ethnography, encompasses a broad spectrum of possible roles for the researcher, from passive observer to active participant. Most sociologists strive for a level of contact and involvement that allows them to achieve an intimate familiarity with, or sympathetic understanding of, the group they are studying. Usually this involves not only watching but also talking to the people one is studying either through casual conversation or in the context of a more formal interview. Participant observation is sometimes described as "hanging around." Although accurate on one level, the phrase belies the range of often thorny issues that need to be negotiated—gaining access to the site or group, building trust with its members, ascertaining on an ongoing basis how to present oneself, developing and maintaining relationships with informants, dealing with attachments and emotions, confronting ethical dilemmas, and deciding when it is time to leave the field and how to do so. Throughout the process, the researcher is engaged in continuous stock taking, trying to figure out what is going on, eventually focusing on a particular aspect of what is happening and making decisions about what to do next.

Interviews

In-depth interviews are another common way to collect qualitative data. Interviews may be standardized or structured so that the same list of open- and close-ended questions is posed to each respondent. When the researcher is really interested in the perspective of respondents, however, interviews are more likely to be either semistandardized or unstandardized and informal. In the case of semistandardized interviews, there may be an interview guide (a list of topics to address and possible wording and follow-up questions), but researchers give themselves the latitude to digress as they see fit and to probe into areas that appear to be analytically promising. Unstructured interviews tend to be the most conversational in style. The researcher may have only the roughest idea of where the interview will go, allowing the talk of respondents to drive the course the conversation takes. This requires adept listening skills and a preparedness to improvise and generate questions on the spot as the situation dictates. Apart from interviewing styles, there are decisions to make about who to interview; how to reach them; how to establish rapport; how to word, order, and pose questions; how much personal information, if any, to divulge; whether to play the role of a naive or informed listener; how to record what is being said (tape or notes); and when to stop. If the interview has touched on sensitive subjects, there are concerns about what happens to respondents when the researcher has walked away. Many of these decisions are guided by the researcher's ongoing analysis of the data.

Documents and Other Data-Gathering Techniques

Another technique involves analysis of personal, public, or historical documents—diaries, letters, biographies, autobiographies, photographs, newspapers, archival material, organizational records, actuarial records, official reports, manuscripts, contracts, court proceedings, films, TV programs, graffiti, song lyrics, Web sites, Internet chat rooms, and so on. These sources of data have the advantage of being unobtrusive. They cannot interrupt the flow of interaction and there are fewer concerns about how the researcher's presence may be affecting interaction. During the past two decades, qualitative sociologists have developed yet other techniques, including focus group interviews, life histories (using one person's first-hand account of his or her life), the study of material artifacts, and autoethnographies (mining one's own thoughts, experiences, and biography as a way of shedding light on the lives of others).

Triangulation

In many instances, qualitative researchers work with not one but several sources of data within the context of the same study. In a research tradition where the focus is on the point of view of the experiencing actor, anything that allows for greater sympathetic introspection is seen as potentially useful. Moreover, a multimethod approach offers different lines of sight on the same social situation or process, thereby giving analysts an opportunity to triangulate. Interpretations and generalizations that emerge out of the analysis of one source of data can be checked against other sources, leading not only to richer accounts but also to accounts in which the analyst can have greater confidence.

Interpreting Qualitative Data

Just as there are different theoretical perspectives guiding qualitative analysis in sociology, and different ways to collect data, there are different approaches to the handling, sorting, and interpretation of data. There is no clear set of rules that all qualitative sociologists follow. There are, however, certain practices that are commonly employed.

Memo Writing and Coding

Memos are essentially notes that researchers write to themselves as they are conducting a study. These notes, sometimes kept in the form of a research log, are typically a combination of procedural record, explaining the course that a study takes and the decisions made, and an analytical record consisting of reflections, ideas, impressions, reactions, and insights. Coding, is an analytical strategy aimed at sorting and organizing the data according to key themes, patterns, and concepts.

Open Coding

Coding can occur on different levels and take different forms. Typically, in the earliest phases of the research, codes are descriptive. Working line by line with the data, the researcher identifies the topics covered. What is the data about? The codes are not predetermined but based directly on what appears in the data. In fact, the codes may be *in vivo*, codes that use the very language of those studied. For example, in a study among people living with HIV, the talk in a line of transcribed data might have to do with telling a friend about one's seropositive status. The margin code may read "disclosure to friends" or simply "telling friends." This type of preliminary and unrestricted coding, referred to as open coding, invariably triggers ideas. Analytical observations that appear in the memos at this point are likely to take the form of tentative hunches about commonalities, recurrent themes, possible patterns, and what they may mean. These hunches, however, as they are considered in light of a rereading of already collected and incoming data become the basis for more conceptual, interpretive, or focused coding.

Focused Coding

Focused coding is more directed. Researchers concentrate on those codes with overriding significance, those that seem most interesting and show the most analytical promise, or those that work best at categorizing large portions of the data accurately and completely. They begin to theorize around them. Moving beyond a description of the data, the point now is to go through the data in a more selective way, searching for instances of a particular phenomenon; identifying its properties; searching for variations within it that may lead to the construction of a typology; specifying conditions under which it arises, continues to occur, and changes; considering its consequences; and exploring its relationship to other phenomena.

Returning to our example, a researcher might observe as a result of open coding that there are repeated references in the data to disclosing to others. The observation may lead to a more focused consideration of disclosure. What types of disclosure are individuals talking about—to partners, children, employers, coworkers, or neighbors? In relation to whom and in what circumstances does disclosure become an issue? What are the issues related to disclosure? How are disclosures done? To what extent does how they are done depend on whom one is telling? What are the consequences of telling or not telling? To what extent is disclosure linked to stigma or problem-solving strategies that people with HIV use?

It is this type of coding that often raises questions, reveals gaps in the data, and sends the analyst back into the field to do more theoretical sampling. Memo writing also begins to look different at this stage in an analysis, becoming increasingly more conceptual and taking on the quality of theoretical notes. These notes serve as a bridge from the coded data to the first draft of a completed analysis.

The Importance of Staying Close to the Data

There are variations among qualitative researchers in terms of how strictly they follow these strategies. There are variations in how far from the substantive case an analysis ventures and how theoretical generalizations become. There are also variations in terms of temporal sequencing: Some researchers adopt an analytical stance almost as soon as they have data to consider, whereas others orient themselves more toward analysis after most of the data have been obtained. Qualitative researchers have been criticized for not standardizing and codifying their analytic procedures. Some have responded by calling for greater articulation of the processes involved in the analysis of qualitative date as a first step toward codification. Others see codification as neither feasible nor desirable. In whatever way analysts choose to proceed in coding and interpreting their data, an intimate familiarity with the data is essential. If there is a cardinal rule in the analysis of qualitative data, it is "stay close and be true to the data." Although they are generally working with a huge volume of data in the form of hundreds if not thousands of pages of field notes, interview transcripts, and/or documents, by the time a study has been completed most researchers will have gone through the data several times. The data are read and reread, coded and recoded as the analyst moves with greater certainty, clarity, and depth toward the insights that will ultimately find expression in reports and published papers.

The Use of Computers

The task of analyzing qualitative data has been facilitated by the development of computer software programs. Some programs are generic word processors, text retrievers, or textbase managers, whereas others are designed specifically for qualitative data analysis. Many of the dedicated programs can perform sophisticated functions, such as coding the data automatically, searching for relationships among code categories, and creating hierarchical and graphic networks of codes, allowing for the automatic generation and testing of hypotheses.

The number of dedicated programs available is increasing rapidly, but sociologists who work with qualitative data have tended not to embrace them. There are concerns that the programs encourage simple counting and matching of code categories. Qualitative analysis would become more of a "word-crunching" exercise consistent with the logic of survey research as opposed to the in-depth, theme-based analysis it has always been. Although the programs may contribute to the greater standardization of procedures that some in the field would like to see, they are viewed by others as a threat to the long-standing tradition of imaginative theoretical work and intellectual craftsmanship on which qualitative researchers have prided themselves. Worse, there are fears that the demands of particular programs and what the programs can or cannot do may ultimately affect how a research project is designed and the types of questions that are asked. Although there are still qualitative researchers who do not use any sort of computer program and work largely by hand, there is no question but that computers will play an increasingly important role in qualitative analysis in the future. The hope of most qualitative analysts is that computer programs will enhance rather than control or compromise their studies, and that they will ease the more tedious aspects of working with qualitative data so that researchers can devote more time to interpretation.

Conclusion

rom the vantage point of someone who has never done it, qualitative analysis may appear easy. It is not. Both the data collection and analysis dimensions of the process can be labor-intensive and time-consuming. There may be innumerable challenges and frustrations. The lack of simple procedural recipes requires a capacity to tolerate ambiguity and the patience to hone fine interpretive skills. In a passage that refers specifically to fieldwork but could easily be adapted to fit other aspects of qualitative analysis, Shaffir *et al*. (1980) write,

> *[It] must certainly rank with the more disagreeable activities that humanity has fashioned for itself. It is usually inconvenient, to say the least, sometimes physically uncomfortable, frequently embarrassing, and, to a degree, always tense. Sociologists and anthropologists, among others in the social sciences, have voluntarily immersed themselves for the sake of research in situations that all but a tiny minority of humanity goes to great lengths to avoid.* (p. 3)

It is not unreasonable to wonder why a researcher would ever undertake qualitative analysis. On this point, if no other, there is consensus. Qualitative analysis is worth doing because its intellectual payoffs and personal rewards are great. Coming full circle to the essential assumptions underlying most qualitative analyses, if "society" is about individuals intersubjectively creating the

meanings that constitute the context for all human action, and if our purpose as researchers is to study society, there is simply no other way to do it.

Quantitative Analysis, Anthropology

Dwight W. Read
University of California at Los Angeles, Los Angeles, California, USA

Glossary

clustering procedure An algorithm for grouping data points in such a way that the groups are internally cohesive and externally isolated from one another.
correlation coefficient A measure of the extent to which the values of two variables tend to covary.
descriptive statistics Methods for describing and summarizing patterns through parameter values based on measurements made over all members of a population.
histogram A graph in which a bar represents a value for a variable and the length of the bar is proportional to the frequency of that value in the population.
inferential statistics Methods for relating measurements made over samples to population parameters.
normal distribution A frequently occurring data pattern important for inferential statistics.
population mean, μ The value obtained by averaging all the population values.
population parameter A numerical value based on measurements made on all members of a population.
population standard deviation, σ The square root of the average of the square of the deviation for each measurement in the population and the population mean, μ.
scattergram plot A graph of two variables with each member of a population located at the point determined by variable values for the members of the population.

Quantitative analysis in anthropology has had an uneasy relationship with anthropological research stemming from a fundamental conflict between the underlying assumption of cultural as shared knowledge among culture bearers and statistical methods based on the assumption that patterning is not displayed on individual cases but in the aggregate. Culture as shared knowledge implies that data on cultural systems can be obtained from a few knowledgeable informants, whereas the presumption of patterning in the aggregate assumes that pattering is discerned through the relationships of individual cases to one another and not on single cases. Ethnographies are implicitly based on the assumption that discerning patterning at a cultural level does not require statistical sampling. At the same time, although there are many questions relating to behavior where patterning in the aggregate is the appropriate metaphor, it is often difficult to determine in advance what should be considered as the aggregate. This discordance between the underlying assumptions of anthropological research and statistical methodology implies that effective use of statistical methodology depends on determining ways in which anthropological reasoning can be expanded and enriched through the use of quantitative methods. At the level of the formation of a data set to be brought forward for analysis, this has led to preanalysis of data so as to subdivide an initially heterogeneous data set into data sets homogeneous in terms of both cases included in the data set and the variables measured over those cases. At the level of analysis, methods such as cultural consensus analysis have been formulated in accordance with assumptions about culture as shared knowledge. Anthropological research has made extensive use of statistical methods ranging from simple, single-variable descriptive methods to sophisticated, multivariate statistical modeling.

Statistical Methods and Anthropology: An Uneasy Relationship

As a discipline, anthropology, with the notable exception of biological anthropology and to a lesser extent archeology, has long had an uneasy relationship with

quantitative methods and analysis. The uneasy relationship stems, in part, from a presumed incompatibility between the full richness of human experience as it might be captured and expressed qualitatively in an ethnography and the supposed loss of that richness when behavior is reduced to summary, quantitative measures. Whether or not the uneasiness is valid, the trend in cultural anthropology toward a more humanistic, interpretive, and literary approach has substantially reduced the usage of quantitative methods in anthropology as measured by the percentage of articles that make use of any kind of quantitative analysis or reporting of quantitative data. A study of six of the major journals of anthropology by Michael Chibnik (1999) concludes, "The gap between quantifiers and nonquantifiers in sociocultural anthropology may be widening. There was a striking drop in the use of simple descriptive statistics from 1985–1986 to 1995–1996" (p. 155). Yet anthropological research has a long tradition of both using and developing quantitative methods of analysis and continues to use and develop quantitative methods that are part of statistical methodology.

Broadly speaking, the utility of statistical methods for anthropological research arises from the methods providing a way to represent and analyze patterns in phenomena through quantitative measurements. As a discipline, statistics is concerned with numerically expressed data that are individually idiosyncratic but display patterning in the aggregate. This core concept of patterning in the aggregate identifies and brings together two key methodological features central to the application of statistical methods in general and to anthropology in particular: (i) the use of quantitative measures as the basis for the display and discernment of pattern in phenomena and (ii) the use of an aggregate, or a population, rather than individual cases, as the reference point for discerning and expressing patterning found in measurements made over phenomena.

Of these two features, the first raises the issue of implementation (What are appropriate quantitative measures in anthropology, especially with regard to culture?), and the second raises a conceptual issue relating to a discrepancy between the way cultural patterning is presumed to be distributed with respect to culture bearers versus the statistical concern with patterning found in an aggregate but not on individual cases. Together, these two issues highlight the unease that many anthropologists have found with quantitative methods and analysis.

In fact, there is legitimate concern regarding the fit between the concepts underlying statistical methods and the understanding anthropologists have about the nature of culture and its distribution among societal members. The unease many anthropologists have had with quantitative analysis is not due solely to a shift toward a humanistic and interpretive approach. In part, it stems from a conceptual discordance between the underpinnings of statistical methods and the assumptions anthropologists make about how phenomena of interest to anthropologists are structured. Consequently, this article focuses primarily on the relationship between the conceptual foundation of statistical methods and the conceptual foundation that anthropologists bring forward in their analysis of human societies and human culture. The range of quantitative forms of analysis that have been implemented in anthropology will be discussed briefly.

The Basic Dilemma: Patterning in the Aggregate versus Patterning on Individual Cases

The difference between patterning found in the aggregate and patterning expressed on individual cases lies in the relationship of individual cases to the pattern. By patterning in the aggregate is meant patterning in which individual cases may deviate from the overall pattern that is discerned when the aggregate is considered as a whole. The patterning is defined by the relative position of each case to the other cases included in the aggregate; hence, the patterning is aggregate specific. Consequently, for patterns based on aggregated data, generalizations made from individual cases may differ widely, depending on the individual case that has been selected for generalization. In contrast, patterning expressed through properties of individual cases allows for patterning exhibited on an individual case to be generalized directly to other, like cases. This kind of patterning is often found in the physical world. An experimenter might drop an object with specified mass in a vacuum, for example, and graph the relationship between time and distance the object has traversed due to the effect of gravity acting on the mass. The pattern displayed in the graph of time versus distance is the same, keeping the experimental conditions (such as dropping the objects in a vacuum) unchanged and so the patterning found in a single case of a falling object characterizes the patterning found in other instances of falling objects as well. No aggregate or population needs to be identified to discern the pattern, and so no sampling protocol is required because there is no population to be sampled.

The focus on an aggregate, or population, in statistical methodology as a reference point for discerning patterning is not in keeping with assumptions made in cultural anthropology, however. The data elicitation method of participant/observation that underlines much of ethnographic fieldwork is based on a different notion regarding the locus of patterning for the phenomena of interest.

Discordance between Ethnographic Observation and Statistical Methodology

Discordance between ethnographic observation and statistical methodology stems from assumptions made in cultural anthropology about the distribution of cultural, and to a lesser extent behavioral, patterns across the members of a society. Cultural patterns are presumed to be shared by the members from the same cultural domain; hence, discernment of these patterns does not require the "patterning in the aggregate" feature that underlies statistical methods. Rather than requiring an aggregate to discern patterning, it is assumed that patterning obtained from an individual case—the informant—can be generalized to other cases as noted by W. Penn Handwerker and Danielle Wozniak (1997): "The *socially constructed* nature of cultural phenomena makes the classical sampling criterion of independent case selection not only impossible to attain but also undesirable" (p. 874, italics added).

The notion of patterning found on an individual case representing the patterning to be found on other cases has been the basis of traditional ethnographic research with its focus on the use of a few, knowledgeable informants. Since the cultural pattern obtained through the use of a single informant is assumed to be essentially the same regardless of the informant, the criterion for a "good informant" is someone knowledgeable about one's culture. Discussions in the literature that focus on the choice of informants pay attention to knowledge of one's culture and individual characteristics that make a person a good informant, not on statistical sampling procedures for selecting informants. Even when sampling procedures are used, it is the knowledge of informants and not the use of random samples that is paramount. As observed by Robert Trotter and Jean Schensul (1998), "It is important to talk to individuals who are carefully selected for their expertise . . . rather than randomly selecting someone from the general population" (p. 703). In effect, Durkheim's notion of culture as a collective representation presumes that individual variation in cultural knowledge relates primarily to the extent to which one is knowledgeable about one's culture and not to the pattern of culture per se. Even statistical techniques that have been developed for discerning cultural patterning, such as cultural consensus analysis, operate from the presumption that what distinguishes cultural knowledge is a high degree of consistency from one individual to another, thereby making variation in knowledge from one individual to another of secondary importance.

The discordance between the conceptual basis for statistical methodology and the presumption of shared knowledge underlying cultural phenomena, however, has received relatively little attention in the application of quantitative methods in sociocultural anthropology. The emphasis, instead, has mainly been on methods for discerning pattern in numerical data. Within this framework, considerable work has been done on issues that arise from the viewpoint of statistical methodology, such as Galton's problem with drawing a representative sample of world societies from the population of all societies since societies in a region may be historically related and hence are not independent observations from a statistical viewpoint. In archaeology, however, more attention has been placed on the discordance between the conceptual foundations of statistical methodology and the concepts anthropologists have about the nature of human societies.

Use of Statistical Methods to Extend Anthropological and Archaeological Arguments

In either case, anthropology or archaeology, we may consider the underlying rational for the use of numerical data and statistical methods to be a way to extend and increase the scope of anthropological and archaeological arguments regarding the nature and form of societies and their underlying culture, including the conditions under which societal and cultural change takes place. Use of statistical methods is not a goal in and of itself; rather, the goal is to determine ways in which anthropological reasoning can be expanded and enriched through the use of quantitative methods. Nor are quantitative methods considered to be inherently preferable to more qualitatively based methods (or vice versa). Instead, the choice of method arises from the questions being asked and the form of the data that can be brought forward to bear on those questions.

In ordinary discourse, we make use of both qualitative and quantitative concepts. Consider a statement such as "If a sexually mature female engages in sexual intercourse, she may become pregnant and give birth in 9 months to a baby weighing about 9 pounds." Both quality and quantities are integrated into our commonsense understanding of matters such as reproduction. The relative importance of the qualitative versus the quantitative aspects of this statement depends on the context. For someone talking to teenagers about the risk of unprotected sex, the emphasis would likely be on the qualitative aspects of reproduction: "sexually mature female," "become pregnant," and "give birth." On the other hand, a doctor talking with a teenager who has just become pregnant is likely to focus on more quantitative aspects, such as "give birth in 9 months" and "baby weighing about 9 pounds." Similarly, quantitative anthropology depends on a context in which the questions of interest can be best addressed by quantitative

measures. What constitutes quantitative measures, though, is not self-evident and subject to change as the degree of understanding by anthropologists of a research domain increases.

Measurement Scales

Initial qualitative distinctions made among observations, such as classification of societies into hunting/gathering, horticultural, agricultural, and industrial on the basis of the primary means of production and/or procurement of resources, may later be augmented by an ordinal dimension. We might, for example, rank the kinds of society on the basis of increasing complexity—hunting/gatherer < horticultural < agricultural < industrial—according to some definition of complexity. The indeterminacy of the latter brings to the fore a complex issue, namely the construction of measurement scales. For a measure such as complexity, the underlying difficulty lies in the fact that we typically measure behavior or the consequences of behavior, such as the number of interconnected parts, but the matter of concern may be at more of an ideational level of how a society is conceptually structured rather than at the material level of how a society is organized. The two viewpoints—ideational versus material—have different implications for the application of statistical methods because the former is concerned more with patterning in the form of shared knowledge, hence patterning generalizable from the pattern found on an individual case (such as a well-informed informant), and the later relates to patterning found in the aggregate, hence on patterning falling within the domain of statistical methods.

More problematic than an ordinal scale measurement in anthropological research is the formation of ratio scale measurements. Even when a satisfactory definition of a ratio scale measurement has been made, data collected by others may not permit assigning a ratio scale measurement. Carol Ember and Melvin Ember (1998) illustrate the problems that may arise through an example based on devising and implementing a measurement scale using the concept of an extended family. They suggest the operational definition that an extended family consists of "two or more constituent families united by a blood tie," where a family is a "social and economic unit consisting minimally of at least one or more parents and children" (p. 665). Although the definition provides the basis for determining the instances of social units that are to be considered as a family or as an extended family, it implicitly raises the question as to whether or not the definition should be an emic or an etic construction. Like other, similar operational definitions, the definition suggested by them is an etic one because it is presumed to be universally applicable. In contrast, Ira Buchler and Henry Selby (1968) had previously suggested that "the shape of the family exists *solely in the minds of the informants*, and the ethnographer *merely translates* the results of his rigorous and culture-specific methodology to establish what the family form of X culture may be" (p. 22, italics added). Their comment is echoed in David Schneider's (1984) assertion that "[t]he first task of anthropology, prerequisite to all others, is to understand and formulate the symbols and meanings and their configuration that a particular culture consists of" (p. 196). In brief, even in what appears to be a simple task of operationally defining a quantitative measure, fundamental theoretical issues regarding the nature and form of anthropological research quickly arise and present issues that do not have easy resolution within the domain of quantitative research and statistical methods. The latter presumes that adequate quantitative measures have already been defined or determined because statistical methods do not provide the means for determining or defining satisfactory quantitative measurements.

Even if we accept the kind of operational definition suggested by the Embers, implementation is still problematic, as they point out, when working with ethnographies that are likely to use descriptions such as "most households are extended families" and not the precise census data presumed by their definition of an extended family. Ethnographic comments of the form, "most households are extended families," provide, at best, an ordinal level of measurement scale even though the operational definition can, in principle, be implemented as a ratio scale measurement.

Statistical Methods and Ethnographic Research Questions

With these concerns in mind, we can identify the range of questions and quantitative methods that have been fruitfully used in anthropology for analytical purposes. Table I indicates how a series of statistical methods relate to questions typically asked about anthropological data. As can be seen from the table, a wide variety of methods are employed that address the range of questions that typically arise when doing ethnographic research. Leaving aside the details of specific methods, several broad analytical goals have been incorporated into anthropological research using quantitative methods that are briefly reviewed here.

Patterning

Histograms and variants such as stem and leaf plots are often used to visually display the patterning in the numerical values of a single variable. The patterning is then expressed in terms of qualitative measures, such as the

Table I Research Questions and Relevant Methods[a]

[a] Modified from Table I in Handwerker and Borgatti (1998; p. 556).

shape of a pattern, and quantitatively through the use of summary statistics. Common qualitative distinctions made for the shape of a histogram include unimodal versus multimodal distributions, symmetric versus skewed distributions, and, where relevant, the presence of unusually extreme values or outliers. Numerical expression of patterning primarily focuses on measures of central tendency (mean for ratio scale variables, median for ordinal scale variables, and mode for nominal scale variables). Measures of dispersion include the standard deviation for ratio scale variables. The location of an individual case in the aggregated data (z scores for ratio variables, percentile for ratio and ordinal variables, and percent for nominal data) is, however, less often used, with the exception of percents for nominal data (which can include ordinal and ratio scale variables). When more than one variable is considered, scattergram plots are used for expressing the pattern displayed in the relationship between the variables, although in practice scattergram plots are used less frequently than might be expected even though they provide the primary means for discerning the patterning between two or more variables. Measures of association (e.g., Pearson product–moment correlation for ratio variables, Spearman's rho for ordinal variables, and the phi coefficient for nominal variables) are used to express the strength of the association between pairs of variables.

Statistical Inference and Bootstrapping

Cross-cutting all statistical methods are inferential procedures aimed at relating measurements made on sample data to the population from which the sample data were obtained. Samples are used, for example, to make inferences about population parameters such as the population mean, μ, or population standard deviation, σ. When measured over an entire population, these parameters are exact and not subject to sampling error. Similarly, the overall pattern for the values obtained when a variable is measured over all the members of a population is simply whatever is the pattern displayed in the population of measurements.

Despite the fact that the parameters of interest are computed over measurements made over all members of a population, researchers usually work with samples. Sampling is conducted for pragmatic reasons, such as limited time to take measurements, problems with getting access to all members of a population, cost of taking measurements, and the like. The sample is then used to obtain estimates of population parameters or population patterns based on measurements made over the members of a sample. With estimation comes assessment of the likelihood that a sample value (e.g., the sample mean) is within some specified numerical distance from the population parameter being estimated from sample data (e.g., the population mean, μ). The assessment is expressed in terms of the probability, p, of getting a deviation as small as, or smaller than, the difference between the measurement made over sample data and the population parameter being estimated. Computation of p typically assumes a random sample from the population and a particular pattern, such as a normal distribution, for the data values in the population.

Sampling that fully meets statistical requirements for both estimating population parameters from sample data and computing the value of p is problematic in anthropological research. Often, populations are not well specified, may vary with time (e.g., the members of a community), or may not be specifiable in advance of doing at least some preliminary research. In addition, the shape of the pattern for the population values may not match the shape assumed for computing the value of p. One way to resolve this sampling problem is to use nonparametric statistics that do not depend on the shape of the distribution of values in a population. For many of the more common statistical measurements, there are equivalent nonparametric statistics. The drawback of using nonparametric statistics, though, is that they generally are less powerful than their parametric counterparts; that is, one is more likely to accept a false hypothesis with nonparametric statistics.

One recently devised method for getting around the discordance between the actual pattern for the data from a population and the assumed pattern underlying a particular estimation procedure is to resample from the sample data. Resampling is used to construct a frequency distribution for the measurement, and this constructed frequency distribution is used to assess the likelihood of obtaining a deviation of a specified magnitude. Methods of this kind are called bootstrapping estimation procedures. They provide a way of dealing more realistically with populations that do not match statistical assumptions, although they do not solve the problems that may be introduced through nonrandom sampling. In addition, bootstrapping does not resolve problems that may arise when the population brought forward for analysis is heterogeneous with respect to processes postulated or known to be the basis for patterning observed in the data. Methods for addressing this problem are discussed in the following section.

Model Construction

Methods devised in statistics based on regression analysis (RA) are used as a way to construct a model for a set of variables as predictors (independent variables) of one or more response (dependent) variables. Typically, the goal is to account for the variance in the values of the dependent variable(s) by determining the relationship of the dependent variable(s) to one or more independent

variables. The canonical form of a RA model for two variables, X and Y, where X is the independent variable and Y is the dependent variable, is given by the expression, $y = \mu_{Y|X=x} + \varepsilon$, where the value, y, for the variable, Y, is decomposed into two parts: (i) $\mu_{Y|X=x}$ ("the mean of the values, y, measured on those cases in the aggregate where the variable X takes on the value, x") and (ii) ε ("residual"). The locus of the set of points $(x, \mu_{Y|X=x})$ forms the (deterministic) regression curve for the data points (x, y) measured over the aggregate being analyzed. The regression curve is then expressed explicitly as an equation whose graph is the regression curve. When the regression curve is a straight line, it becomes $\mu_{Y|X=x} = \alpha + \beta x$. This leads to the expression, $y = \alpha + \beta x + \varepsilon$, as a model for a scattergram plot in which the variables X and Y appear to have a linear trend. Typically, the values for the parameters α and β are estimated using least squares estimators. Furthermore, it is assumed that the actual value, y, of the variable Y for a given value, x, of the variable X deviates from the underlying, deterministic relationship, $\mu_{Y|X=x} = \alpha + \beta x$, in a "random" manner—that is, by some amount, ε, with the value of ε obtained on a given member of the aggregate assumed to be a random observation from a normal distribution of values with mean, $\mu = 0$, and fixed variance, σ^2.

In practice, most applications of regression models in anthropology do not rigorously determine whether or not the context in question satisfies all the assumptions of the regression model. Instead, a procedure such as ordinary least squares regression is used to estimate the parameter values in a linear model, and the parameter values are tested for statistical significance. Often, the residuals are not tested for homeoscedasticity (unchanging variance) and whether they are more or less normally distributed, even though this is a fundamental assumption of the regression model.

Because one can construct a regression model for whatever variables are selected as the independent variables and whatever variables are selected as the dependent variables, even when the parameters in a linear model fit to the pattern displayed in a scattergram plot are statistically significant, the pattern need not have anthropological significance. Therein lies the discordance between statistical methods and anthropological theory discussed in the archaeological literature.

Anthropological Significance versus Statistical Significance

One can mechanically apply a regression model to any set of variables and possibly arrive at a model with parameter values that are statistically different than zero—that is, a meaningful model from a statistical viewpoint. However, whether the model has anthropological significance depends on first having selected a population in which the dependent variable(s) has a single, underlying relationship to the values of the independent variable(s). Here is the problem, though. Consider a typical question for which one might use a regression model: Does the value of one variable predict the value, or outcome, of another variable? For example, cross-cultural studies have made extensive use of questions such as the following: Does the mode of production predict the form of social organization? The purpose of the question, however, is not exhausted by the specific result that is obtained. Rather, the underlying intent is to use the pattern of relationship that is found as a way to gain insight into the structuring processes operative in human societies.

Consider in detail a more prosaic example relevant to the goal of admitting students to a university: Does the SAT score of a graduating high school senior predict the grade point average (GPA) that senior may receive should he or she complete a college education and receive a BA degree? An admissions committee may be satisfied with whatever statistical result is obtained for the purposes of making decisions about admission, but from an anthropological perspective the statistical result would simply be an initial step in an analysis aimed at trying to work out the way in which a variety of factors—family background, personal attributes, prior education, ethnicity, and the like—relate to the way students become engaged in university life and how that engagement translates into performance measured by variables such as GPA. Consider the problems that arise for the anthropological analysis when the statistical analysis is not constructed in terms of the kinds of insights anthropologists have developed about human societies.

For simplicity, assume that the relationship between SAT and GPA appears to have a linear trend in a scattergram plot of these two variables. In the form of a model, it is posited that $\text{GPA} = \alpha + \beta\ \text{SAT} + \varepsilon$, where the relationship $\alpha + \beta$ SAT represents the deterministic relationship between SAT and the average GPA, $\mu_{\text{GPA|SAT}=x}$, received by all graduating college students with an SAT given by the value x; for example, if $x = 550$, then $\mu_{\text{GPA|SAT}=550}$ would be the mean GPA for all graduating college students who entered college with an SAT score of 550. The value ε represents the magnitude of all those effects that relate to the actual GPA of a graduating college student deviating from the predicted value based on the deterministic relationship between x and the means $\mu_{\text{GPA|SAT}=x}$. The relationship between SAT score and GPA, however, may result from a number of different "causes." Some students may study hard and have a GPA that reflects their level of involvement with their studies. Other students might decide to be involved in a number of different activities that conflict with intensive studying and so have a lower GPA than

would be the case had they studied in the same manner as the first group. Yet other students may decide that they will be satisfied with a minimal GPA and thus spend little time studying. Each group may have a different set of parameter values for expressing the relationship between SAT score and GPA at time of graduation. Hence, each group has its own model for relating SAT scores to GPA. Taken collectively, the parameter values for all graduating students considered as the aggregate will reflect an average of the parameter values for each group considered separately weighted by the size of each group. Thus, the parameter values will mainly have descriptive value and fail to provide insight into the processes underlying the relationship between SAT scores and GPA.

This example illustrates the underlying problem that can arise with application of statistical methods to anthropological data. At one level, statistical methods can be applied to any aggregate, but in so doing the results may be descriptively accurate but lack interpretation in terms of underlying processes. Interpretation depends on defining an aggregate within which the same structuring process(es) applies equally to all cases within the aggregate. However, therein lies a double bind. On the one hand, one may want to use statistical methods to determine the appropriate aggregates; on the other hand, methods for doing so depend on the aggregates already being determined. Clustering procedures have been advocated as a way to address the problem of heterogeneity, but they make unrealistic assumptions about the way in which phenomena considered by anthropologists are structured.

Clustering Procedures

Clustering procedures have had wide application in anthropological and archaeological data analysis because they are based on the concept of dividing a heterogeneous data set into homogeneous subsets. However, as has been demonstrated with archaeological data (but the problem is not limited to archaeological data), clustering algorithms for determining aggregates typically make computations that assume the variables used for the clustering jointly determine the space within which the clustering may be identified. Clustering procedures have presumed that as more variables are included in the analysis the clustering algorithm will tend to converge on the distinct aggregates that may be present in the data set brought forward for analytic purposes. In brief, clustering procedures assume a paradigmatic data structure in which all variables are equally useful for the determination of clusters or aggregates. However, it is likely that the data set brought forward for analysis has a taxonomic structure in which different variables are relevant for determining subaggregates that reflect underlying structuring processes.

To continue with the SAT example, we might define a series of "background" variables, such as *S*, the time spent on studies, and *E*, the time spent on extracurricular activities. A typical cluster analysis would assume that clusters, or aggregates, should be found in the two-dimensional space defined by *S* and *E*. However, suppose for illustrative purposes that there are two groups of three students—one group having a high value for *S* and the other group a low value for *S* as shown in Fig. 1A, with each group having a different pattern for the relationship between SAT scores and GPA. Initially, we are not knowledgeable of this difference among the students, and so our analysis begins by taking the six students graphed in Fig. 1A as the aggregate. Suppose that we want to determine whether there are subaggregates of students that should be distinguished prior to beginning the analysis of the relationship between SAT scores and GPA by using a cluster analysis based on the variables *S* and *E*. Consider, however, data structured in the following manner with respect to variables *S* and *E*.

With respect to the variable *S*, the students graphed in Fig. 1A form two well-defined clusters; that is, clusters satisfying the criterion of "internally cohesive and externally isolated." Suppose further that the values for the variable *E* are random with regard to the two clusters; hence, some of the students in each of the two clusters might have a large value for *E* as shown in Fig. 1B. Note that the pair of students *C* and *a* in Fig. 1B, although isolated from each other when considering the space determined by the variable *S* alone, are close to each other in the two-dimensional space determined by *S* and *E*. Thus, they form a third cluster in the two-dimensional space. However, the cluster they form has no bearing on the relationship between SAT score and GPA. The cluster appears in the two-dimensional space only because of the way the geometry of the clusters has been altered by introducing a variable for which the distribution of values is independent of the clusters that are present in a space in which this variable does not occur. However, the analysis would proceed under the assumption that

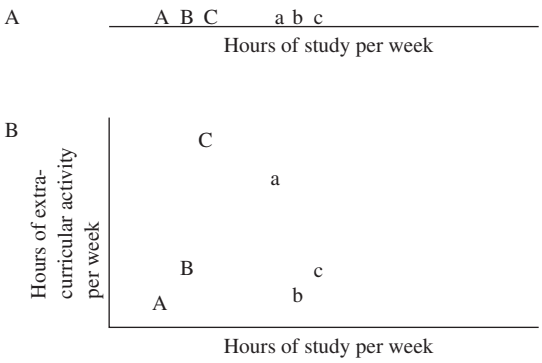

Figure 1

this third cluster found in the two-dimensional space is homogeneous when in fact it is heterogeneous with respect to the relationship between SAT score and GPA. If other variables having a pattern for the distribution of values independent of the two well-defined clusters are introduced, then the distorting effect becomes more pronounced.

The distorting effect is a consequence of having clusters that form a taxonomic, rather than a paradigmatic, structure with regard to the variables selected for measurement. I have demonstrated mathematically that the introduction of variables for which the distribution of values does not reflect clusters that may be present in a low dimension space leads to divergence from the embedded structure when considering the higher dimensional space determined by the full set of variables. This is contrary to the underlying assumption of most applications of clustering procedures as a way to reduce heterogeneity in data brought forward for analysis.

Dimensionality Reduction

With cultural data, measurements made at the level of observable behavior are used to infer processes at a cultural level through dimensionality reduction methods, such as principal component or factor analysis (ratio scale variables), multidimensional scaling (ordinal variables), and correspondence analysis (nominal variables). These procedures are used both descriptively as a way to reduce a higher dimensional space to a lower dimensional space in which most of the original variability in the data is present and inferentially as a way to construct new dimensions that reflect processes underlying the values of the variables as measured. Multidimensional scaling has been used extensively for this purpose in anthropology because it requires only measurements in terms of ordinal scale variables. Consequently, multidimensional scaling has made feasible the analysis of data in the form of paired comparisons ("Is *A* similar or dissimilar to *B*"), triads (" Is *A* more similar to *B* or to *C*"), pile sorts ("Sort the entities into groups of similar entities"), and the like as a way to discern an underlying cultural model for pattern displayed in the data. The culmination of this approach is represented by cultural consensus analysis as a way of determining whether or not responses to questions about a knowledge domain reflect shared, cultural knowledge about the domain or whether interrespondent agreement is better interpreted as resulting from factors such as shared experiences. The underlying assumption of cultural consensus analysis is that cultural patterning represents shared knowledge and hence should be patterning exhibited at the level of individual cases, whereas interrespondent agreement due to similar experiences should only exhibit patterning at the level of the aggregate. Interestingly, quantitative methods make a full circle here since cultural consensus analysis brings quantitative methods back to the underlying assumption of cultural anthropology that was implicitly, if not explicitly, rejected through the application of statistical methods to anthropology. Cultural consensus analysis returns to the notion of patterning on individual cases, but it does so through analytic demonstration, not by assumption.

The problem of data homogeneity is critical to dimensionality reduction applications that intend to go beyond description. Without data homogeneity, the dimensionality reduction procedures are responding to both the data structure within a homogeneous subaggregation and the data structure of the differences between subaggregations. As with the parameters in model fitting to heterogeneous data, dimensionality reduction procedures done over heterogeneous data will be a weighted average of the effects expressed in each of the subaggregates, thus making interpretation of the constructed variables difficult. The solution suggested in the archaeological literature to this problem lies in preanalysis of the data brought forward for analysis before utilizing statistical methods to work out the patterning in the data.

Preanalysis of Data

The problems previously discussed arise through variables that are not well defined over the data set brought forward for analysis, with data sets that lack homogeneity, or both. Four contexts for data analysis can be distinguished according to whether or not the data set is well defined or whether or not the variables are well defined, as shown in Table II. Mode 1 is where quantitative analysis should begin, whereas mode 4 is a common beginning point for data analysis. Preanalysis refers to steps that can be taken to reformulate modes 2–4 to mode 1 prior to beginning quantitative data analysis. In general, a shift from the right to the left in the table may utilize dimensionality reduction procedures, especially for variables that are known to only partially measure the structuring process that is of anthropological interest. A shift from the lower to the upper row typically involves identification of clusters by considering different ways the data structure may be viewed, such as using histograms with single variables or scattergrams with pairs of variables, where the variables may be as originally

Table II Modes of Analysis

	Variables	
Data set	*Well-defined variables*	*Not well-defined variables*
Well-defined data set	Mode 1	Mode 2
Not well-defined data set	Mode 3	Mode 4

measured or as modified through trying to formulate well-defined variables. A key aspect to preanalysis is using an iterative approach in which every time a subdivision of the data set is made the preanalysis is repeated on the newly formed data sets.

The shift from mode 4 to mode 1 depends on both restructuring the data set and reconstructing variables, yet each of these operations depends on the other for its successful implementation. An iterative approach allows for convergence to mode 1 through incremental steps rather than presuming a single algorithm that can simultaneously restructure the data set and reconfigure the variables brought forward for analysis.

Conclusion

Many of the questions asked by anthropologists naturally use quantitative measures, even if expressed in more qualitative terms such as many, most, and few. Often, one wants to know whether or not, when one has more of one thing, if there more of something else. In contrast, qualitative relationships generally take on an either/or form. At a theoretical level, the opposition between material and ideational approaches to modeling social phenomena parallels the opposition between quantitative and qualitative analyses. When societal properties arise in response to external conditions, societal patterning tends to have an underlying quantitative dimension because responses may be sensitive to the quantity and amount of external factors, whether it be individuals optimizing returns as hunters and gatherers or maximizing gains in a market context. In contrast, behaviors that arise out of ideational properties such as identities individuals take on as part of becoming a culture bearer tend to be differentiated by qualitative distinctions, such as kinship relationships and the social grouping to which one belongs. Quantitative analysis has tended to focus on the material side of human social groups or measures of behavior, both of which are more amenable to statistical methodology. To challenge perceptions of the declining use of quantitative analysis in anthropology, more methods need to be developed that are both methodologically rigorous from the standpoint of statistical requirements and conceptually sensitive to the full range of factors—ideational and material—that affect, constrain, and guide the form of human social systems and their associated cultural constructs.

Quantitative Analysis, Economics

Charles G. Renfro
Journal of Economic and Social Measurement, New York, USA

Glossary

business cycle The tendency for an economy to experience perceptibly regular periods of expansion and contraction, often graphically represented as an undulating pattern around an upward trend.

econometrics Originally, in the 1930s, the unification of economic theory, economic statistics, and mathematics. Today, a body of techniques that tend to focus on the methods of estimating the unknown, usually presumed constant parameters of behavioral, quantitative relationships between economic variables.

game theory A body of essentially mathematical techniques seen as governing the competitive behavior of economic agents under conditions of scarce resources and unknown, but essentially probabilistic, outcomes.

index numbers A counting technique that attempts to measure relative quantities or prices of collections of non-homogenous goods and services.

input-output A technique originally developed by Wassily Leontief in the 1930s and 1940s that measures both the distribution of the production of an industry to all purchasers of that production, both intermediate and final purchasers, and the set of purchases by an industry of all inputs to that industry's production from itself and other industries. The result, under certain assumptions, permits an evaluation of the effects of changes in the scale of economic activity.

linear programming A mathematical technique designed to determine the optimal allocation of resources between competitive uses, or else the optimal configuration of activities, under conditions of limited resources.

This article traces the development of the methods of quantitative economic analysis from the earliest days of economics as an identifiable discipline, roughly during the 16th century, to the present day. It places particular stress upon the development of macroeconomic quantitative techniques, reflecting the historical development of economics first as concerned with macroeconomic phenomena and only later with the behavior of individual economic agents. In its approach, this account demonstrates various aspects of the interplay between the process of measurement and the development of theories of economic behavior.

Introduction

In the most basic as well as the broadest sense of the term, quantitative economic analysis refers to the process of quantifying, or measuring, the activities of economic agents, individually or in the aggregate, and then attempting to explain the characteristics of that observed behavior using these measurements, collectively called data. A more precise definition of what constitutes quantitative analysis in economics is in part a question of whether the primary focus is placed upon the purpose of the analysis or the specific techniques used. The techniques employed by economists today are in most cases relatively recent in origin, essentially from the mid-20th century, and are now closely associated with the use of both the modern computer and, increasingly, the Internet. Econometrics, for example, possibly the most well-developed quantitative sub-discipline of economics, dates to only the early 1930s as an identifiable body of techniques with the establishment of the Econometric Society, even if certain of the underlying methods originate at the beginning of the 19th century. When the relative extent of its development is considered, econometrics more specifically belongs to the period following World War II. A similar statement could be made about each of the other quantitative techniques now commonly used by economists, with perhaps one or

two exceptions. These other techniques include input-output analysis, linear and dynamic programming, representational measurement techniques such as index numbers, and in recent years, the developing field of experimental economics.

At the beginning of the 21st century, some 50 years after the first use of the electronic computer by economists, it is tempting to consider quantitative economic analysis almost exclusively in this context. Not only is the computer now employed to make most, if not all, of the necessary computations, but it has also increasingly become the means of organizing, distributing, and even collecting the data used, to the point that today, not just governments and other organizations but even individual economic entities such as supermarkets and other retail establishments have increasingly begun to amass point-of-sale and other data as a by-product of doing business—often for the explicit purpose of performing some type of subsequent analysis. If the techniques now used by economists are the specific focus, there is even less need to consider more than a handful of scholarly contributions prior to 1940. However, this argument, if adopted, not only isolates the study of economics from the methods of empirical analysis used, but also ignores the degree to which these techniques have developed as a consequence of the development of economics as a discipline.

The Interplay of Theory and Measurement

Economics as a discipline is the outcome of more than 400 years of collective effort to explain why economic agents behave as they do, and in what circumstances. During this time, economic concepts have progressively sharpened, but in certain general respects the issues addressed even in the early years are still familiar to the modern economist.

Macroeconomics, the study of the behavior of groups of economic agents, began as an attempt to explain economic growth and industrial development as a consequence of what is today called international trade. As early as the second half of the 16th century, Jean Bodin in France and John Hales in England produced treatises on money and economic development that addressed then-topical issues such as inflation and the effect of the agricultural revolution of that time. With the increasing power of central governments of nation states, the growth of trade during the next 100 years and its promotion, regulation, and taxation increasingly became a matter of policy, leading to the first attempts by writers such as Josiah Child and Thomas Mun during the 17th century to explain its determinants and effects. Of course, these centuries were also the period of the discovery and colonization of the Americas, which additionally helps to explain both the trade expansion and the growing degree of general awareness of its role in commercial life.

Trade was an obvious source of wealth for the individual and the nation, but so was the increased production of goods and services. William Petty, who lived in the second half of the 17th century, may to be regarded as one of the founders of political economy, today called economics, but the important element of his contribution is not only his attempt to interrelate the concepts of money, interest, taxation, and the value of land and labor as productive forces, but also his contributions to the foundation of statistics, particularly economic statistics. The most novel aspect of his argument was to bring empirical economic measurements to bear. He determined, as he said in the preface to his 1690 book *Political Arithmetick*, to "express [himself] in terms of *number*, *weight* or *measure*; to use only arguments of sense, and to consider only such causes, as have visible foundations in nature." In France in the middle of the next century, this theme was taken up by Quesney and the physiocrats who also stressed production but focused on agriculture as the principal source of a nation's wealth. The important methodological similarity was the attempt, in the form of Quesney's *Tableau Economique*, to explain empirically an economy's characteristics, using economic measurements to estimate the relationships. Subsequently, John Sinclair in Great Britain, the first to use the word "statistics," and Charles Alexander de Colonne in France were among those who attempted during the last 20 years of the 18th century to produce detailed compilations of their respective governments' accounts, as well as quantitative statements of economic and social conditions.

The 19th century, in contrast, became more conceptual in approach, following Adam Smith's synthesizing 1776 inquiry into the cause of the wealth of nations, which he famously cast in terms of the beneficial outcome of the selfish actions of individual economic agents. At the start of the century, Robert Mathus struck a discordant note, asserting that in as much as food production grows arithmetically but population geometrically, famine and want are the inevitable lot of mankind. Less well known are his writings on economic rent and related price concepts. The focus of such 19th century economists as Mathus, Mill and Ricardo, and even Marx was the more detailed conceptual explanation of microeconomic phenomena, culminating in the work of Bohm-Bawerk, Jevons, Marshall, Menger, and Walras at the end of the century. By then, production and cost were joined to the concept of marginal utility, leading to an explanation of supply and demand as the joint determinants of prices. Speaking in 1907, Marshall (pp. 7–8) proclaimed a "general agreement as to the characters and directions

of the changes which various economic forces tend to produce," but recognized that "much less progress has indeed been made towards the quantitative determination of the relative strength of different economic forces. That higher and more difficult task must wait upon the slow growth of thorough realistic statistics." In the 19th century, there were attempts to collect statistics on such things as earnings and hours worked, and there were a few methodological innovations, such as Marshall's chain index formula, that are relevant even today. But this work proceeded for the most part as isolated, individual efforts, even if often as the result of governmentally established inquiries and commissions.

The 20th century opened quietly, as Marshall's words indicated, but a shock to economic analysis soon came in the form of the first of two world wars. The years 1914–1918 marked a watershed. The sudden need to mobilize entire societies to support the war effort meant that it immediately became necessary to understand and, ideally, stimulate and control actual economic performance. In the United States, for example, entities such as the War Industries Board were established and, in this case, led to the construction by Day, Stewart, and others of the first reasonably extensive set of single industry production and price indices. But this work proceeded slowly. The fact that the major industrial countries had blundered into a conflict beyond previous imagination meant that few prior preparations had been made. Consequently, only after the war did statistical reports begin to appear in any significant numbers. Even then, immediately afterward, the war was at first seen as a temporary aberration. However, the early postwar years produced widespread unemployment, hyperinflation in Germany, and then, following a boom in the second half of the 1920s, a pervasive depression in the 1930s. This accumulation of circumstances progressively established the general recognition of needs, even if no immediate solutions were forthcoming.

From Occasional Observations to Modern Economic Statistics

Bricks cannot be made without straw. In a parallel sense, quantitative economic analysis presupposes measurement, including not just the process of observing prices, quantities, and other primary observations, but also the construction of economic statistics using these numbers. It is actually difficult to be certain in detail about the early modern history of economic measurement, because this activity is almost invisible in the late 19th and early 20th century economics literature, although particular pioneering efforts can be identified. These include Irving Fisher's 1906 attempt to establish appropriate concepts for the construction of economic accounts, Wesley Mitchell's *Business Cycles* in 1913, as well as King's first calculations from the U.S. Census of estimates of total income and wealth in 1915. Then, beginning in the early 1920s, came contributions by Bowley, Day, Mitchell, Stamp, Stewart, Williams, and Working, among others. Although it involves a certain degree of idealization, the work of these people can be collectively viewed as mapping a progressive movement, during the period from 1906 to the 1930s, from single industry indexes to combined indexes, expressing business conditions or aggregate industry behavior, to the computation of national income measurements and, finally, the basis for the subsequent construction of national income and product accounts, as well as a broad range of other economic statistics.

In order to comprehend what such work involved, it must first be recognized that analytical judgment is an integral component. For example, there are a number of economic concepts, such as inflation and the cost of living, that in the abstract appear to have definite meaning, yet are difficult to measure empirically. Inflation refers to a general rise in prices, but just how to construct a good measure of inflation is a continuing subject of debate: for instance, which prices should be included, and how should they be combined? Similarly, the concept of cost of living raises a number of questions, among them, whose cost of living? The meaning of the resulting statistics clearly depends on what is bought, which in turn obviously depends on who is buying, and possibly other particular circumstances. Each of these concepts is measured using a weighted combination of its constituent elements, the latter being individual prices that collectively express these measurements. The composite value is known as an index number. Obviously, when abstract concepts are involved, the index number measurement problem consists of determining both the constituent elements and the weights.

However, measurement problems do not disappear when simpler cases are considered. The general role of index numbers can be seen immediately by considering such ordinary objects as apples and oranges. Considering these items separately, there is obviously no problem making quantity measurements. So long as quality and type are fixed, price measurement is similarly straightforward, in principle. However, collectively, apples and oranges are fruit, and assigning a single number to measure the quantity or the price of "fruit" is clearly immediately problematic. By extension, the difficulty is much the same when it becomes necessary to add up the quantities of the entire range of goods and services produced by an economy, so as to measure both the total production and the value of that production: ingots of steel, numbers of computers, bushels of wheat, and so on cannot of course be simply added together. The value of what is produced in

principle can be added, but simply knowing the value of production over time does not provide a good measure of economic performance, unless prices remain constant. In a world in which prices of goods and services change at varying rates, it is necessary to measure both production values and aggregate price level changes in order to be able to distinguish the real changes in production.

The Marriage of Concepts and Analytic Tools

During the early 20th century, aggregate economic statistics began to be created as an organized activity, as just indicated. However, the tendency for an industrial economy to experience progressively somewhat regular periods of expansion and contraction was a recognized phenomenon throughout the 19th century, and came to be called the business cycle. As a subject for quantitative analysis, it attracted the attention of Wesley Mitchell and others even prior to World War I. Their attempt to document this phenomenon received considerable support from the postwar development of the production and price indices, together with estimates of employment, unemployment, and other measures of economic performance that existed, including the relatively easily measured stock price indices, such as the well-known Dow Jones indexes. By the process of first gathering performance statistics for production, employment, and other business conditions, next mapping stages of a prototypical cycle, and then classifying these various measures into the categories of "leading," "lagging," and "coincident" indicators, the business cycle can be both monitored and, to a degree, predicted. Or at least that is the theory. In practice, not only is each individual cycle in important respects unique, but a heavy dose of judgment is still needed in order to classify the individual indicator variables, both in their selection and in the specific way the information is combined to explain an economy's performance pattern. Notwithstanding such qualifications, business cycle analysis promised to Mitchell and his colleagues the possibility of ameliorating, if not eliminating, at least some of the negative effects of the cycle.

From this description, albeit brief, it should be evident that one of the characteristics of these business cycle indicators is that they form a relatively parsimonious collection of economic statistics. This trait was beneficial during the first third of the 20th century, when nothing even approaching a complete statement of national income and product accounts was available. But such parsimony also highlights the knowledge gaps that existed then, due to the lack of other economic measurements—such as business expenditures for plants, equipment, and inventories, consumer expenditures, imports, exports, and government purchases. The significance of these gaps is especially easy to appreciate in hindsight, given the degree to which these particular statistics are regularly reported today on the television and in newspapers, not to mention the extent to which they have become critical in the formulation of government economic policies. But their present familiarity can also obscure the fact that the concepts just mentioned—investment, consumption, imports, exports, and government purchases—did not exist as elements of an integrated explanation of the performance of an economy until 1936, with the publication of John Maynard Keynes' *General Theory of Employment, Interest and Money*. In fact, Keynes did not create these concepts out of nothing. During the period from 1920 to the early 1940s, independently of Keynes, the underpinnings of national economic accounts were in the process of being assembled, as indicated earlier. Consumers, governments, and businesses existed, and their purchases were recognized as accounting for the bulk of a nation's production. Nonetheless, until the *General Theory*, what was missing was the conceptual spark that locked these concepts into the now familiar macroeconomic intellectual framework and made it commonplace to think of the change in the aggregate demand for goods and services as integral to any complete explanation of the business cycle.

The immediate effect of Keynes' book was muted. At that point, his analytic framework was new, and it would take a further 10 years for Colin Clark, Simon Kuznets, James Meade, Richard Stone, and others to clothe these concepts with empirical meaning and thus develop a database for future quantitative analysis. Nevertheless, at the beginning of World War II, the combination of Keynes' *General Theory* and the publication in 1940 of his equally influential, if much less well known, *How to Pay for the War* set the stage for the expanded development of quantitative economic analysis in the postwar years. His *General Theory* drew upon many strands of the economic thought developed during the preceding three centuries to provide a conceptual basis for coordinated governmental economic policies. It incorporated a consistent explanation for the behavior of an economy, particularly in the context of a severe recession or depression, and provided a number of policy prescriptions. *How to Pay for the War*, which mapped out the empirical connections more precisely, was also closely associated with the British National Income and Expenditure Accounts that were first produced in 1940. Subsequently, this work helped to stimulate to the creation of national income and product accounts worldwide, particularly in the post war period. In his 1984 Nobel prize lecture, Richard Stone, who received this prize in recognition of the role he played in the development of modern national income and product accounting, described in some detail the development of economic accounting systems from the 17th century to the 1980s.

The Offspring of the Marriage

With the foregoing description as background, it is now possible to consider how an accounting system both translates into an analytic device and supports quantitative economic analysis. It so happens that even the earliest economic accounts, such as those of Petty and Quesnay, directly provide a means of representing at least certain of the characteristics of an economy. The closest modern parallel to Quesnay's *Economic Tableaux*, but a very substantial improvement on it, is the work on the inter-industry structure of the U.S. economy by Wassily Leontief, also first described in 1936. This work complements that of Keynes, providing a way to view the relationships between industries. For each industry included, what is called an input-output table specifies, row by row, the value of the industry's product purchased as an intermediate product by itself and every other industry, as well as direct purchases by final purchasers. These direct purchases, referred to as final demand, are the point of connection with the Keynesian analytical framework. Once such a table is constructed, it is immediately possible, using a simple arithmetic operation, to compute the proportion of each industry's product accounted for by each purchaser, as a consequence deriving a table of decimal coefficients. Although effectively requiring the assumption that these coefficients do not change as production rises and falls, once constructed, this table of coefficients immediately allows the consideration of the effects on industry output of changes in final demand and production levels. Other, related relationships between final demand, prices, and employment can be derived in a somewhat similar manner, extending Leontief's original approach, and in the process providing a reasonably complete quantitative, interrelated representation of an economy. Input-output models have been developed and applied to regional as well as national economies. Leontief's work began in advance of the publication of formal economic accounts by the United States and other governments, and in fact was influential in the development of those accounts, once they began to incorporate industry detail. On their own, input-output models do not, however, provide the means to consider analytically, or as a means of policy analysis, the demand side behavior of economic agents.

The macroeconometric model is another one of the analytic tools that has been developed in order to attempt to explain the behavior of economies, the first of which was created in 1939 by Jan Tinbergen. The national income and product accounts, combined with data on employment and other statistical measures, provide the skeleton for these models, particularly the structural models created during the period from 1950 to the present day by Lawrence Klein and others. These models normally incorporate Keynesian concepts, and combine statistically estimated behavioral equation specifications with accounting identities, as the income and product accounts are called in this context. The result is to provide a representation of, usually, the macro economy at any of several levels, national, multi-national, or regional. However, a number of model structures are possible, and by the end of the 1970s, there were a variety of forms of quantitative economic models, using econometric techniques and reflecting competing beliefs among economists as to how economic phenomena should be represented, as well as progress in the development of both the electronic computer and the underlying database. Models created during the early 1950s through the early to mid-1960s were estimated and solved using desktop electromechanical calculators and were generally no larger than 20–30 equations, but by the late 1960s, models of 200–400 equations were attempted. By the 1980s, computer technology had advanced to the point that models as large as 10,000 and more equations were developed, although most contained less than 1000 equations.

It is obvious that the type of quantitative analysis associated with both econometric and input-output models has been both enabled and stimulated by the invention of the computer, since they often require large quantities of data and intensive calculations in their construction and use. The computer itself is a child of World War II, with the first electronic computer having been created at the Moore School of the University of Pennsylvania for the purpose of computing ballistic trajectories for artillery shells. Although Leontief began his work in advance of its construction, he quickly saw the benefit of this machine to his work: he was the first economist to use the computer, although the particular one he used was in fact electromechanical in operation.

An immediate post-war development that, like the computer, also originated as a technique to serve the needs of the military was the mathematical technique developed by George Danzig in 1947, known as linear programming. Although developed independently, there is in fact a close mathematical connection between Danzig's and Leontief's work, at least given certain assumptions. It is characteristic of the input-output model that, by construction, there is a unique relationship between the sectorial outputs and final demand: the data used constitute observations on what occurred historically, so that this relationship is determined by that history. In contrast, Danzig addressed the situation, originally in the context of U.S. Air Force planning, in which a variety of inputs and outputs are *a priori* mutually compatible, posing the problem of choosing the best activity level: the question is, given distinct sets of inputs and outputs, each of which is feasible, what is the optimum configuration? Interestingly, there is also a connection between both Danzig and Leontief's work and another

area of quantitative economic analysis, known as game theory, the mathematical underpinnings of each coincidentally being the same. Although recently connected in the public mind with the work of John Nash, the central theorem and original development of game theory was due to John von Neumann in 1928; von Neumann also played an important role in the development of the first electronic computers, particularly the modern form known as a stored program computer, an ubiquitous example of which is the now-familiar microcomputer.

During the past 50 years, there have been further extensions of the techniques of econometrics, linear programming, and game theory. Econometric techniques are now applied to the explanation of stock prices and other financial variables; they have been applied by political scientists and historians, among others. Linear programming has been applied to a broad variety of problems, but has also been more generally extended, in the form of nonlinear programming. Game theory, similarly, is a technique with a host of applications beyond economic analysis, and such terms as a "zero sum game" are now a part of everyday language. Broadly speaking, these techniques not only have been developed and applied by economists, but also have been incorporated into the subject areas of such fields as operations research and decision sciences, and even to some degree in the physical and biological sciences. The applications are now extremely widespread.

However, while these developments occurred, economists additionally began to create an increasing number of distinct data sets containing observations on the behavior of individual economic agents. As mentioned previously, economists characteristically attempt to explain the behavior of people in their various roles as economic agents. Just as in the 19th century many economists began to focus on microeconomic behavior as an underlying conceptual explanation for macroeconomic phenomena, once database and computer technology permitted, a similar progression occurred, now focused on empirical research. An initial impediment was that some of the data sets collected, such as those administratively generated by tax authorities and other governmental agencies, are by their nature confidential. However, with the progressive development of the computer, beginning particularly during the late 1960s and early 1970s, it has become increasingly feasible to produce sample data bases, stripped of individual identifying information, that can then be used quite generally in applied economic research. Other governmentally collected data sets of this type include the population census and surveys of consumer purchasing patterns that underlie the construction of government price indexes, industry specific censuses and surveys, and the like, the latter of which also provide data for the construction of input-output tables.

Of course, not all microeconomic applied research has depended upon the availability of such administrative data, or data collected as a by-product of official censuses and surveys: during the past 40 years, there have also been an increasing number of microeconomic data sets collected independently, specifically to enable various types of economic and social research. And, of course, as mentioned earlier, during the past 20 years in particular, businesses have begun to develop point-of-sale and other data sets, derived from their operations, that are increasingly being used for proprietary research. The result has been a general, substantial increase in data resources that are often available for general research purposes.

The modern availability of both microeconomic and macroeconomic data, which during the past 10 years has become increasingly available via the Internet, has obviously supported the development of a broad range of quantitative analysis in economics, to the point that it is now difficult to classify this work, beyond simply saying that both the individual techniques and applications have become profuse. The behavior and decisions of economic agents acting as consumers, investors, importers, exporters, and even government bureaucrats is now quantitatively analyzed by economists on both the microeconomic and macroeconomic level. Economists consider productivity as a measure of the efficiency of production for a given level of human, machine, and other inputs. The way in which consumers choose to purchase goods and services, given their income and accumulated wealth, when prices are set or change is increasingly evaluated quantitatively. More broadly, the effect of the presence or absence of information about the world on the part of economic agents, particularly when this involves costs of acquiring relevant information, generally known as search costs, has become an active area of quantitative analysis. The effects of economic agents' expectations about the future has been seen, particularly during the past 30 years, not only as determining their behavior as individuals but also as potentially affecting the ability of governments to effectively pursue both short-term and long-term economic policies.

There is, however, a distinction to be made between the non-experimental and experimental. Economics has traditionally been regarded as a non-experimental discipline. Obviously, it is generally not possible to institute a particular government policy, observe the results, then roll back the clock, and try some alternative instead. In principle, it is infeasible, if not impossible, to perform controlled macroeconomic experiments. Based upon such considerations, quantitative economic analysis has generally been viewed as limited in its application to data that are generated as a by-product of economic activity. Economic theory, in turn, particularly microeconomic theory, has developed on the basis of postulates about the motivations

and behavior of economic agents that can be characterized as logically abstract, and not based on assumptions tested empirically. Concepts such as utility, profit maximization, and other behavioral precepts abound in the theories of economists, but as theoretical constructs these are essentially assumptions that have been made about the motivations of economic agents.

Notwithstanding limitations, during the past 30–40 years, a new area of economic quantitative analysis has emerged that is generally known as experimental economics. It of course remains true that experimentation with governmental economic policies under anything approaching controlled laboratory conditions is difficult, if not impossible. But the behavior of individuals as consumers, employees, and managers, and in their other roles as economic agents, is potentially subject to experimental observation. Generally, experimental economists have adopted the methodologies of psychologists and others who investigate conscious, and perhaps unconscious, human behavior. This research can in fact be seen as an extension of the prior investigations of economists: since the 18th century, they have considered markets in terms of the behavior of buyers and sellers, and in the past 50 years, game theory has sharpened the concepts; the difference is that in recent years it has proved possible to evaluate this microeconomic behavior experimentally. Strategies of behavior, as well as both the motivation of market participants and the degree of contextual consistency and rationality of that behavior, have been examined. It is too early to begin to evaluate to what degree these new investigations will feed back to the development of economic theory, but there is certainly scope for this. Microeconomic theory has generally been developed axiomatically, with the conclusions during the 20th century increasingly being stated in mathematical terms, resting upon a particular set of assumptions that can be shown to imply those conclusions. For example, consumers have usually been assumed to be "rational" and "consistent" in their behavior. Experimental economics has questioned these assumptions. This assault upon the assumptions may in time lead either to their confirmation or to the formulation of new behavioral theories that rest upon tested assumptions rather than what can at least sometimes be seen as mathematically convenient axioms.

Conclusion

Economists, because they study behavior that involves quantities, prices as well as the number of apples, oranges, tons of steel, bushels of wheat, and the like that may be demanded at a particular price level, have since the early 20th century led social scientists in the development of empirical analytic techniques. Many of the specific techniques developed have also been applied more widely, not only by other social scientists, but also by historians and even certain physical scientists. Particularly in the case of game theory and linear and dynamic programming, scholars with a background in operations research and other such disciplines might even view these techniques as so much a part of their own tradition as to cause them to question the degree to which these are "economic" in origin. However, it is also true that with the development of experimental economics in particular, economists have begun to import others' experimental techniques. Cross-fertilization has become endemic. The purpose of this account is not to make any particular claims, nor stimulate debate as to the origin of a particular technique. Instead its purpose is simply to describe, in rather broad terms, the development of quantitative economic analysis as an activity pursued by economists.

Quasi-Experiment

Linda Heath
Loyola University Chicago, Chicago, Illinois, USA

Glossary

covariate A variable that is related to the independent variable of interest that could bias the estimation of causal relationship between the independent and dependent variable if not controlled.
randomization The process of assigning participants to experimental or control conditions based on a random process. Also called random assignment.
randomized experiment Any experiment in which participants are randomly assigned to experimental and comparison conditions by either the researcher or naturally occurring random processes.
threat to validity A process or factor that could undercut the veracity of the suggested causal relationship between the independent and dependent variables.
validity The veracity of the claims made of research findings.

Broadly speaking, quasi-experiments can be conceived of as research designs that operate without random assignment of participants to condition (generally because random assignment is either impossible or unethical to employ in that particular research area) but that seek to approach the causal strength of true experiments by research design techniques. Because the researcher cannot rely on randomization to create comparability of respondents in the experimental and control conditions, additional controls must be devised and employed to account for potential extraneous differences between the experimental and control conditions. At the simplest level of quasi-experimentation (i.e., the simple time series and the simple nonequivalent control group design), the experimenter simply describes the presence of potential differences between the experimental and comparison group participants and outlines strategies to minimize the occurrence of such differences. In more sophisticated quasi-experimentation, statistical controls and/or extensive design strategies are used to minimize, eliminate, or account for preexisting differences between experimental and control conditions. This article provides an overview of these simple and more complex quasi-experimental designs.

The Logic Underlying Experimental and Quasi-Experimental Research

Historical Context

Two very different research approaches set the stage for quasi-experimentation. The first, classical experimental design, formed the basis for much of the research in the natural sciences and for a great deal of the early work in certain areas of the social sciences (e.g., psychology). By rigorously controlling the experimental setting, researchers could isolate variables of interest and make strong causal claims. Both single participant experiments (such as those done by the early perception researchers Hering and Helmholtz and the early memory researcher Ebbinghaus) and carefully controlled between-subject experiments (such as those done by the learning researcher B. F. Skinner) drew upon the scientific logic that undergirded much of the natural sciences. The second approach that appeared in early research in the social sciences was the case study, a careful analysis of a single person or group of people to inform generalizations about human nature. The early works by Freud and Piaget illustrate this approach.

As the social sciences matured, however, researchers sought to go beyond the case study approach and bring experimental rigor to important social and psychological

issues that defied capture in the scientific laboratory. Both practical and ethical problems stymied these researchers' efforts. For example, in seeking to understand the etiology of mental disorders, researchers could not test hypotheses about early childhood abuses, family patterns, or socialization disruptions within a rigorous experimental design because it was patently impossible for researchers to control all the extraneous variables in a child's upbringing. Even if the practical constraints could have been overcome, the researchers still faced serious ethical limitations about what ills they could inflict on their respondents. Watson's Little Albert (if he really existed) illustrates this ethical problem. Numerous introductory psychology textbooks over the years have reported that Watson conditioned a young boy named Albert to fear white rats via traditional classical conditioning techniques, and that this fear generalized to white hair and Santa's beard. If this story is true, serious ethical concerns about inducing psychological disorders arise. Thus, researchers who sought to introduce scientific rigor to the investigation of serious pathologies and other social problems faced the dual problems of the feasibility of implementing an experimental design and ethical constraints if the design were feasible.

Thus was born the quasi-experimental approach to research design, which trades off some experimental rigor to allow the examination of important areas that defy study using classical experimental design.

The Cost of Forgoing Randomization

The strength of most classical experimental design lies in the process of randomization (the exceptions being in the physical sciences, in which control, not randomization, allows causal inference). By following a random procedure of assigning participants to the experimental and control conditions of the study, the researcher distributes systematic error (unrelated to the topic of study) evenly across conditions in most instances. That is, if the researcher conducting a study of upper body strength enhancement assigns men and women to experimental or control conditions by following a random procedure, without accounting for gender, on average, half of the women will be placed into the experimental condition and half will be placed in the control condition. The same would be true for men, on average. Rare quirky randomization outcomes do occur, but, on average, the outcome of a random process is equal distribution of irrelevant variables across experimental and control conditions.

In situations in which researchers have reason to suspect that a particular outside variable (such as gender) could seriously affect or interact with the variable of interest, they should force that variable to be evenly distributed across conditions by randomizing within levels of that variable (a process known as blocking). However, the strength of randomization is that, on average, it evenly distributes between conditions extraneous variables about which the researchers are concerned and even those variables about which they are not concerned (even if they should be). Thus, handedness, eye color, left brain dominance, and even zodiac sign would all be evenly distributed across conditions, on average, by following a random assignment procedure.

Distributing these irrelevant variables evenly across experimental conditions is important to avoid introducing systematic differences that could masquerade as treatment effects. For example, if new strength-building programs were being tested in a college setting, researchers who created the experimental group entirely from one class and the control group entirely from another class could introduce serious selection differences into the findings if one class was a nursing class that enrolled primarily women and the other was an engineering class that enrolled primarily men. Even if both classes were mathematics classes, the same degree of initial difference could be introduced if one class was a required math course for nursing (and therefore enrolled more women) and the other was a required course for engineering (and enrolled more men). We know that gender is related to body strength, so in this instance the type of selection difference we would be introducing is obvious. Another, more subtle type of selection difference could be introduced even if we used two sections of the identical course as our basis for assignment to experimental or control conditions. Athletes are often allowed to register early for classes in order to avoid times that conflict with their training schedules. If a researcher were to assign students in a 10 AM section of Math 118 to the strength-building condition and assign students in a 4 PM section of Math 118 to the control condition, selection difference could still be introduced into the findings if significantly more athletes were in the 10 AM section compared to the 4 PM section. Even if the researcher blocked on gender and made sure that the gender ratio was identical in each class, thereby controlling for differences attributable to gender, differences associated with athlete status (and therefore presumably level of physical fitness) could still produce spurious results in this design. Even if the researcher blocked on both gender and athlete status, differences could still be introduced into the results if the testing on the dependent variable occurred early in the morning and the students who sign up for 4 PM classes are particularly sluggish during morning hours.

The point is that researchers who employ designs without random assignment of participants to experimental and control conditions risk introducing systematic differences into their findings that can be misinterpreted as effects of the independent variable. Variables that

systematically covary with (or are confounded with) the variable of interest are potentially the true causal variable that produced the results observed in the research. Quasi-experimentation is the art of controlling for as many of these potential confounds as possible or, at least, testing the plausibility of those confounds as the true causal force. The strongest quasi-experimental designs are those that can control for a whole host of potential confounds rather than just laboriously testing one potential confound's effect at a time. Some of the most dangerous confounding variables may be those of which the researcher is totally unaware. Because these variables may never be identified as topics for further analyses, they might be able to introduce considerable confusion into the research literature.

Types of Validity

Validity refers to the truth or veracity of the claims about research findings, as opposed to reliability, which refers to the consistency of the research findings. Validity has many dimensions. At the basic level, internal validity (as described in the classic work by Campbell and Stanley) refers to the truth of the assertion that A caused B. Imagine that we have two groups of people: One group gets high levels of A and a second group gets no A. The group that gets lots of A also displays high levels of B, whereas the group that gets no A shows low levels of B. Internal validity asks, "Is A the cause of the observed variation in B?" Concretely, imagine one group consumes lots of vitamin A and displays high income, whereas a second group consumes no vitamin A and has low levels of income. Is vitamin A the cause of the different levels of income, or is there some other variable that covaries with vitamin A consumption that is really the causal agent for the differences in income levels?

Construct validity of the cause and the effect asks, "What exactly is A, anyway?" and "What exactly is B, anyway?" If a researcher randomly assigns children to a special preschool program or to a comparison condition in which they stay home with their caregivers and later observes that the children in the preschool condition score higher on a test of number recognition, the internal validity of the study might be strong. (We would actually need to know many more details before we could make that judgment.) However, what exactly is the treatment and what exactly is the effect? Is the treatment the enrichment activities provided by the preschool (the most obvious construct) or is it having a nutritious lunch and snack every day, or is it being out of the home for a period every day, giving the caregiver a sorely needed respite? Even when one has determined that something about the preschool assignment led to improved scores on the test of number recognition, the issue of construct validity can remain open to question. Similarly, what does the score on the test of number recognition really measure? Knowledge of numbers? The ability to follow testing instructions? Motivation to take this type of test? Familiarity with this type of test? Again, construct validity questions remain.

Another type of validity is termed external validity and concerns the generalizability of the research findings to other instances, settings, populations, and times. A causal relationship between an independent and dependent variable might be valid for a particular type of person, a particular place, or a particular point in time but invalid for other people, places, or times. For example, researchers might validly conclude that a particular antibiotic kills a particular bacterium in 1999, but this conclusion might not be valid in 2000 (if the bacterium has developed resistance to that antibiotic). Similarly, a drug prevention program might be effective for sixth-graders but not for tenth-graders. Also, the use of powdered formula for infants might convey a health benefit in places with access to clean water but be a health liability in places without clean water supplies.

A final type of validity that is of concern in quasi-experiments is termed statistical conclusion validity by Cook and Campbell in their oft-cited 1979 text. This type of validity addresses the appropriateness of the statistical procedures employed and the degree to which statistical assumptions have been satisfied. Although a researcher might correctly conclude that in the particular research being reported the independent variable did not produce a statistically significant change in the dependent variable as measured, this does not necessarily mean that the independent variable does not cause a change in the dependent variable. Too few participants (resulting in low statistical power), a poorly measured dependent variable (also resulting in a loss of statistical power), or failure to meet statistical assumptions can all mask a causal relationship between variables. On the other hand, exceedingly high statistical power can reveal a statistically significant relationship where no meaningful or practically significant relationship exists.

Different research designs are susceptible to different threats to validity that could compromise the internal validity, construct validity of cause and effect, external validity, and statistical conclusion validity. The strongest design for a particular research project is the one that minimizes the number of serious threats to validity that operate, but identifying that design involves a variety of judgments about the priorities among the different types of validity. Should external validity be compromised to improve internal validity? Should construct validity be so rigorously protected that threats to internal validity occur, or would a lesser level of construct validity that avoids problems with internal validity suffice? Following is a discussion of some of the classic quasi-experimental designs, along with explication of the main threats to

validity associated with these designs. The final decision about which design best suits a particular research situation must take into account the unique research situation and the research goals.

Bivariate Quasi-Experimental Designs

Nonequivalent Control Group Design

One of the most frequently used quasi-experimental designs is the nonequivalent control group design (NECG) (sometimes referred to as the nonequivalent comparison group design or the nonequivalent group design). This design is similar to the randomized experiment but does not employ random assignment to experimental and control conditions. (Recall from the previous discussion that this is an extremely important difference.) Probably the majority of studies that employ a NECG design use just one treatment group and one no-treatment comparison group, with a pretest and posttest observation for each condition. More than one treatment group representing different treatments or different levels of treatment are possible, as are more than one control or comparison groups (such as a placebo treatment group and a pure no-treatment group). Occasionally, researchers employ a NECG design with no pretest observation, although this type of design is extremely weak and termed by Campbell and Stanley a "preexperimental" design rather than a quasi-experimental design.

In the typical NECG study, random assignment of participants to experimental or control conditions is impossible or extremely difficult without seriously compromising the strength of the independent variable. For example, in one of the early studies of the effects of television violence on aggressive behavior, boys in one cottage at a reform school were allowed to watch their normal television programs, and boys in another cottage were allowed only to watch nonviolent programming. It would have been impossible to assign individual boys within a cottage to type of viewing because the cottage had only one television and the repercussions of allowing some boys in the cottage unfettered access to television programming while strictly limiting the access of other boys in the cottage would have introduced serious construct validity problems. Similarly, researchers interested in examining the effects of childhood events such as abuse or parental imprisonment cannot randomly assign children to such conditions.

Another situation that frequently results in NECG research involves an innovation that cannot be tailored to one person, such as a new classroom technique. A researcher with unlimited resources could randomly assign classroom or school to the new technique (thus using classroom or school as the unit of analysis), but researchers rarely have sufficient resources to study the dozens of schools or classrooms that would be necessary for sufficient power with those units of analysis. Consequently, the more common design is for all the classrooms in school A to get the new technique and all the classrooms in school B to continue using the old technique, producing a NECG design.

NECG designs are susceptible to all the threats to construct validity and statistical conclusion validity that apply to randomized experiments, plus the additional selection threats to internal validity that do not present major problems for randomized experiments. NECG designs, however, generally have fewer problems with threats to external validity than do most randomized experiments in the same research area.

By far the most prevalent threat to the NECG design is that of selection. A selection threat refers to the selection differences discussed previously as costs of foregoing randomization. The threat rests on the possibility that the type of participants who are selected for the treatment condition are in some important way different from the type of participants selected for the comparison condition. Imagine an attractive program offered to the first 40 children who sign up. That group would receive the program and form the treatment group. The next 40 children whose parents tried to sign them up after the program was already full would constitute the comparison group. It is not difficult to create a long list of ways that the parents who succeed in enrolling their children in the program might differ from the parents who fail to enroll their children. The first group of parents might be more motivated; might be more attentive to announcements; might have better transportation or better day care options, allowing them to arrive at the enrollment location earlier; might have fewer personal life crises that could detract from their ability to get their child enrolled; and so on. One can easily imagine that even before the treatment began, the children of such parents would have many advantages over the children whose parents cannot get them enrolled.

Some researchers mistakenly believe that having a pretest measure will overcome such selection problems, that they can simply subtract out the pretest difference or otherwise make corrections statistically using a pretest score. This assumption is generally weak, but this assumption is particularly problematic if maturational processes are operating. The pretest observation might fail to capture preexisting differences between the groups that have not yet manifested themselves in a measurable way. For example, if our attractive program from the previous example was a reading readiness program, the pretest measure might not show any differences between the groups if none of the children had yet developed reading readiness skills (meaning the pretest is basically all error). Both

groups could score identically at pretest, but real underlying differences between the groups could already exist (although not in a way that was measured by the pretest instrument). This selection by maturation interaction could distort the findings and produce the appearance of a treatment effect where none existed.

A selection by instrumentation interaction threat to validity could occur if the pretest were paper-and-pencil and the posttest were completed at a computer. For this to create a selection by instrumentation interaction, the participants in one group would need to be more comfortable with one of the measures than participants in the other group. Returning to the example of the first 40 children to enroll in the special program, if those children are more likely to have computers in their homes or to use computers at the local library than are the children in the comparison group, the treatment group might score equal to the comparison group at pretest and significantly higher than the comparison group at posttest for reasons that have nothing to do with the treatment. Many of the other threats to internal validity can similarly operate via a selection by threat interaction in the NECG design.

In addition to selection threats to validity, the NECG design can also encounter validity problems if participants in the different conditions are aware of the alternative condition. The study of boys in reform schools mentioned earlier fell prey to the "resentful demoralization of group with less desirable treatment" threat to validity. The boys in cottages who had their television viewing curtailed, causing them to miss their favorite show (Batman), created such uproar at the institution that the study had to be prematurely ended. The obverse could also happen if the group with the less desirable treatment tries to "show up" the researcher by performing especially well, termed the compensatory rivalry or "John Henry" threat to validity.

If others in positions of power are aware of the different experimental conditions, they can introduce two types of threats to validity. First, the control group might receive other special programs or benefits to compensate for not receiving the treatment in the research project. Such compensatory equalization of treatments can occur if, for example, a grade school principal creates a special activity or club for the students who were not chosen to be in the treatment group. If the compensatory option has the same effect as the identified treatment, both groups should score equally on the posttest, which could lead the researcher to erroneously conclude that the treatment was ineffective. Similarly, the principal could notice the children in the treatment condition improving in performance or behavior and decide to offer the treatment to all the students in the school. This diffusion or imitation of treatment threat to validity could make the identified treatment appear ineffective by raising the scores of the comparison group to those of the treatment group. Such a problem with the research implementation might not be evident from the data analysis, especially if a naturally occurring growth trend in outcome scores would be expected (e.g., in the case of reading scores among schoolchildren).

Simple Interrupted Time Series

The simple interrupted time series design makes use of data systematically collected at regular intervals over an extended number of observations. (The old rule of thumb was 50 or more observations, but recent analytic developments might allow that number to be much lower, especially with more than one observation per time point.) The time series can be based on measures taken yearly, monthly, daily, or even by minute or second. The interruption should be well specified and abrupt to produce interpretable results. For example, one of the classic time series analyses involved the examination of the introduction of a Breathalyzer law on the rates of traffic fatalities. As with most laws, the legislation instituting the Breathalyzer examinations of suspected drunk drivers took effect on a precise day at a precise time that was well publicized. Traffic accidents that result in fatalities can also be well specified as to time and location. The simplest version of this study examined the traffic fatality rate for many time periods before and after the introduction of the new law. A statistically significant change in level or slope of the time series of observations after the introduction of the new law would be interpreted as an effect of the law.

As is probably apparent, the major threat to the validity of the simple interrupted time series design is history. Some other event might coincide with the law change in the Breathalyzer example. For example, another law regarding the number of infractions before license revocation could have occurred simultaneously. Another possibility is that police procedures for dealing with drunk drivers changed, and those procedures, rather than the legal change, caused changes in fatality rates. Another potential history threat would be improved ambulance service, resulting in fewer fatalities even if the number of accidents remained constant.

Another very plausible threat to internal validity in simple interrupted time series designs is instrumentation. If the manner of data collection changes at a time that coincides with the presumed treatment, that change in instrumentation could masquerade as a treatment effect. For example, in response to a crime wave, a city might institute new policing procedures and change the way it records and tracks crimes. Also, in response to community concerns about sexual assaults, a city might open rape crisis centers and provide victim advocates to support victims in filing charges. A researcher who used the rape statistics to examine the effects of the crisis centers without careful consideration of the effects of the victim

advocacy program would risk drawing improper conclusions.

Multivariate Quasi-Experimental Designs

Nonequivalent Control Group Designs with Covariate

Although the NECG design allows the researcher to examine the effects of real-life, socially relevant, high-impact independent variables, the key concern is that some variable other than the putative independent variable is the real causal force on the dependent variable. For example, research on the effects of television viewing on criminal behavior cannot be examined in a true experimental design for a wide variety of ethical and practical reasons. Comparing the criminal paths of people who chose to watch a lot of television as children with those of people who chose to watch less is one variant of the NECG (a sort of epidemiological NECG). The major concern with such a design, however, is that some factor other than television viewing is the true causal variable. For example, children who exhibit high levels of aggressiveness toward their peers might not have many playmates and might retreat into television viewing as a result of their aggressive nature. If this aggressive nature then leads them to commit violent crimes, an NECG analysis could mistakenly appear to reveal that television viewing caused the criminal behavior instead of the aggressive personality. Similarly, time spent watching television is time not spent on other activities that might have a preventative effect on criminal behavior. Again, an NECG analysis could mistake the effects of not participating in those other preventative activities with an effect of television viewing.

The use of covariates in conjunction with the NECG design can reduce some of the risks of misinterpreting findings or misspecifying causal relationships. For example, a researcher who had access to earlier measures of aggressive personality characteristics could use these as a covariate to determine if the relationship between television viewing and criminal activity remained after controlling for aggressive personality characteristics.

The strongest covariate is one that controls for a whole host of potential threats to validity. Regarding the example of the parents who manage to enroll their children in a desirable program, a researcher could use a strong measure of "family functioning" as a covariate for several of those potential troublesome variables. In all cases, however, researchers' understandings of the research area and their careful deliberation about potential threats to validity are necessary precursors to any salutary effects of covariate analysis.

Interrupted Time Series with Control Group or Switching Replications

In the same way that covariates can help eliminate many threats to validity in the NECG design, the use of a comparison series or a series with switching replications can address concerns about threats to validity in the interrupted time series design. For example, in the Breathalyzer study mentioned earlier, researchers addressed a whole array of history threats to validity by including a comparison of traffic fatalities during hours that bars or pubs were open with traffic fatalities during the hours they were closed. If changes in weather, road conditions, or ambulance service had coincided with the introduction of the Breathalyzer law, those changes should be as evident during hours when the pubs are closed as when they are open. The Breathalyzer, on the other hand, should only show effects during the time the pubs are open (and just after). Results showed no changes during hours that pubs were closed and significant changes during hours that pubs were open.

Similarly, an examination of the impact of the introduction of television on crime rates compared cities that received broadcasting licenses just before the Federal Communications Commission froze licenses with those that received licenses just after the freeze was lifted. Early adopter cities showed an increase in theft rates immediately after the introduction of television that was not matched by the late-adopter cities. Immediately after they began receiving television signals, the late-adopter cities showed an increase in theft rates, rising to the level of those of the early adopter cities. Crime data from the late-adopter cities, therefore, served as the comparison series at the first intervention point, and crime data from the early adopter cities served as the comparison series at the second intervention point. This time series with switching replications design is one of the strongest quasi-experimental designs because for a threat to validity to be plausible, it would have to impact the first series (but not the second) at a time that coincided with the early intervention, and it would have to impact the second series (but not the first) at a time that coincided with the late intervention. Few, if any, problems with instrumentation, maturation, selection, history, and so on are plausibly posited to follow such a complicated pattern.

Conclusions

Quasi-experiments allow researchers to deal with serious social problems with scientific rigor that, although not equal to that of randomized experiments, controls for many of the most important threats to validity. In many instances, the gain in external validity from adopting

a quasi-experimental approach outweighs the loss in internal validity. In all cases, however, the researcher should strive to maximize both internal and external validity as much as possible. Thoughtful consideration about ways to identify and test potential confounding variables is crucial. Quasi-experiments can be one important component of a well-conceived program of research on important social issues.

Quetelet, Adolphe

Alain Desrosières
National Institute for Statistics and Economic Studies, Paris, France

Glossary

average Approximating or resembling an arithmetic mean; approximately midway between extremes.
average man A fictitious man, invented by Quetelet, whose characteristics (e.g., size) are the averages of all individuals. It represents, for Quetelet, an ideal of perfection.
International Statistical Congress Created by Quetelet, it met every 2 or 3 years between 1853 and 1875 and included the main statisticians of the world. After 1885, it was replaced by the International Statistical Institute, which still exists.
law of errors The astronomers of the 18th and 19th centuries call the law of errors the probabilistic distribution, which was later called normal law by 20th-century statisticians.
mean A quantity of the same kind as the members of a set that in some sense is representative of them all and that is located within their range in accordance with a set rule.
probability The chance that a given event will occur.
statistical regularities According to Quetelet, some statistical series, such as crimes or suicides, are almost like constants. For him, it was the proof that there could be a *physique sociale*, with forecasting possibilities, as in astronomy.

Adolphe Quetelet lay the foundations of modern statistics in the two meanings of the word: (i) the organized collection and arrangement of quantitative data on the social world and (ii) the interpretation and analysis of data on large numbers by means of mathematical tools. He transposed to the social sciences the formalism of Gauss's law, derived from the theory of errors in astronomy. The concepts of "average man" and the regularity of statistical series are important contributions to the theory of social measurement.

Introduction

The Belgian statistician Adolphe Quetelet (1796–1874) played an essential role in the development and dissemination of "social measurement." He also largely helped to give statistics the importance it has today—"statistics" being understood here in the two standard present-day meanings of the term: (i) the organized collection and arrangement of quantitative data on the social world (usually under an official aegis) and (ii) the interpretation and analysis of data on large numbers by means of mathematical tools. For these purposes, Quetelet brought together and combined several previously distinct scientific traditions: that of the measurements practiced in 18th-century natural science (astronomy and physics) and that of the social surveys and administrative enumerations undertaken at the behest of states—also since the 18th century—within the framework of English "political arithmetic" and German "statistics." This reconfiguration of knowledge sectors and analytical techniques makes Quetelet one of the founding fathers of the social measurement that, in the 20th century, came to prevail in the social sciences and in the invention of new forms of governmentality. Statistics indeed implies the systematic organization of periodic large-scale measurements in the collection phase upstream. In the interpretation phase downstream, it requires the use of mathematical techniques, probabilistic or not, such as the calculation of means or the application of the law of large numbers, which make it possible to establish and identify macrosocial regularities.

Quetelet's initial training was both in the humanities and in the sciences. In 1819, he received a doctorate in mathematics with a thesis on focal conics, a class of curves used in optics. Having developed an interest in astronomy, he succeeded in the 1820s in convincing the authorities of the Kingdom of the Netherlands (to which

Belgium belonged until 1830) of the need to build an astronomical observatory in Brussels similar to those already operating in France and England. In 1823, to prepare the project, he spent a few months in Paris, where he met French astronomers and mathematicians, including Alexis Bouvard, François Arago, Pierre Simon Laplace, Joseph Fourier, and Siméon Denis Poisson. This stay was to have a decisive influence on the rest of his career. Quetelet discovered how the scientists he met used probability theory to assess measurement errors in astronomy. The core of this mathematical methodology was formalized by Carl Friedrich Gauss and Laplace around three closely linked notions: (i) the Gaussian distribution (later referred to as the normal law or distribution) of the measurement errors for an astronomical value, (ii) the choice of the arithmetic mean as the most probable value of the quantity measured, and (iii) the least-squares method as an optimization criterion. Quetelet imported and popularized the first two notions—the Gauss curve and the mean—in the social sciences. The third notion, the least-squares method, was not accepted until the late 19th century, thanks to the British statistician Udny Yule. The Gauss curve, which was assumed to reflect the distribution of measurement errors, was dubbed the law of possibilities. It did not receive the name normal law until the end of the 19th century.

From Astronomy to Social Science

Most of Quetelet's biographers state that he assimilated one major idea from his contacts with French scientists in 1823: the transfer of the most spectacular advances in astronomy—then the queen of sciences—to the social sciences. According to this somewhat simplified version of Quetelet's ideas, mathematical determinism, and hence the predictability of astronomical phenomena, can be transferred to physical and moral (i.e., social) measurements of human beings and, consequently, to the regularities observed in these measurements. Stephen Stigler paints a more nuanced picture of Quetelet's thought. Stigler helps us to understand the intellectual context in which this "knowledge transfer" was possible: The intermediate link in the sequence appears to have been meteorology. At that time, astronomy and meteorology were not as distinct as they are today. Scientists studying time and climate were struck by the complexity of these phenomena and the impossibility of reducing them to simple laws—in the same way as astronomers, for example, did with Isaac Newton's laws of gravity. Many interlocking causes, impossible to enumerate in full, were involved, making it even more necessary to think in terms of probability. Quetelet, it is claimed, remembered this when he later sought to construct a "science of man." He even made the comparison explicitly in 1853, when he organized an International Statistics Congress modeled on the meteorology conferences held to improve navigation at sea.

This interpretation of the cognitive and institutional shift achieved by Quetelet, from natural science to the nascent social sciences, is of great value because it directly introduces the multiplicity of causes and uncertainty in those very areas in which the simplifying determinism of natural science are manifestly inapplicable. Meteorology and social science share the impossibility of arriving at a comprehensive knowledge and measurement of the many factors involved in the phenomena described and, hence, of reducing them to simple laws. The only solution in either field is to multiply the observation loci by interconnecting them via a dense network of exchanges of standardized information. In this convergence between two seemingly different scientific fields, we find the two main features of the statistical approach promoted by Quetelet all his life. The first is the organization of observations, and the second is the treatment of the large numbers thus collected by applying tools derived from natural science: the normal law and the mean. In fact, the main element transferred from Quetelet's Paris visit was the high generality of possible uses of the Gaussian distribution postulated by astronomers to characterize the dispersion of their measurement errors. The Gaussian distribution is supposed to result from the combination of many small, independent effects. However, the novelty of the transfer lay in the radical change in the epistemological status of the normal distribution (for the sake of convenience, this now standard designation is used, despite its anachronism when applied to Quetelet's ideas).

Quetelet was indeed the first to observe that other measurements—for example, the heights of conscripts in a regiment—are distributed in the same "gendarme's cap" (i.e., bell-shaped) pattern. His stroke of genius was to bring together the two similar distributions (those of measurement errors in astronomy and those of conscripts' heights), thus creating a totally new entity: the average man. Astronomers know that a real star lies at the source of their imperfect, scattered observations. By calculating a mean, they can estimate the star's most likely position. Similarly, Quetelet argues that a new but no less real being—the "average man"—is the ideal model behind individuals, all of whom are different. For astronomers, the star's real position is the constant cause of their successive observations, which explains the normal shape of the distribution of measurement errors. Likewise, the average man is the "constant cause" of the height distribution. The reasoning was thus reversed: It is the normal profile of the height distribution that implies the prior existence of a constant cause—that is, the average man, whose most probable height is the mean of the observed heights.

Average Man and the Gladiator Metaphor

In fact, the constant cause argument was derived from Bernoulli's theorem or law of large numbers (1713). Consider an urn containing an unknown but constant proportion of black and white balls. If we draw a sequence of balls from the urn, the proportion of balls of either color converges toward that of the balls in the urn. The proportion in the urn appears to be the constant cause of the shares observed in the draws. A chain of statements established a continuum between Bernoulli's probabilistic formulations, the astronomers' error computations, the measurement of conscripts' heights, and the propensities to crime or suicide and their regularities. The metaphor of the "Gladiator's statue" is one of the ways to concatenate this series.

To promote an understanding of the apparently unexpected convergence between the distribution of measurement errors and that of different individuals' heights, Quetelet conceived the following metaphor, inspired by his youthful interest in the arts and letters. The King of Prussia admires a beautiful statue of a gladiator. He commissions 1000 copies by 1000 sculptors in his kingdom for distribution to his loyal courtiers. The copies are imperfect and, of course, all different, but they all broadly resemble the model. Thus, the model acts as the constant cause of the copies since the 1000 sculptors have sought to imitate it. According to the metaphor, the average man is the equivalent of the original, perfect statue of the Gladiator. Actual human beings are the imperfect reproductions of this average man, described as an ideal of perfection. Quetelet elaborates the metaphor in detail in his "Letter No. 20," included in his main book on probability theory published in 1846, "*Lettres à S. A. R. Le Duc Régnant de Saxe-Cobourg et Gotha, sur la théorie des probabilités, appliquée aux sciences morales et politiques*" ("Letters Addressed to H. R. H. the Grand Duke of Saxe Coburg and Gotha, on the Theory of Probability as Applied to the Moral and Political Sciences"). By transposing the diversity of the sculptors' copies to the diversity of measurements performed on human beings, he even adds another cause of variability: the effect of successive imperfect measurements taken on a single individual. Quetelet thus combines in the same model the two sets of causes of variation: the real differences between individuals and the imperfections of measurement procedures, analogous to those factored in by astronomers since the 18th century.

The Gladiator model thus provided the link between two uses of the notion of mean (or average) that had hitherto been very distinct, including in the vocabulary employed. In the 18th century, scientists distinguished between (i) the "mean proportionals" (*moyennes proportionnelles*) adopted by astronomers as the best possible estimate (calculated from several observations) of a single real but unknown value and (ii) the common values chosen to summarize and proxy a diversity of values of different objects. In the second case, the substitution was justified by figures of speech such as "by and large," "taking one year with another," "more or less," and "the strong carrying the weak" (*le fort portant le faible*), which effectively express the notion of mutual "compensation" implied by this use of the mean. In a sense, Quetelet resorted to epistemological strong-arm tactics by linking the two applications of means. However, he did stipulate an important restrictive condition: The computation of a mean of measurements of different beings is justified, according to him, only if the distribution of the measurements exhibits the profile of the much vaunted law of possibilities (i.e., a normal shape). Only the presence of this form justifies the assumption of a constant cause preceding the contingent and imperfect manifestations of the tangible beings observed. In so doing, Quetelet introduces a distinction between true means, whose computation is justified by the presumed existence of a constant cause, and false means, whose computation and use should be prohibited in cases in which the distribution is not normal, particularly if it is bimodal. Two examples of the latter are often quoted by Quetelet: the distribution of heights of buildings in a town and that of the life spans of a population of children born in a given year. In either case, speaking of a mean would make no sense.

Observed Regularities of Moral Statistics

Quetelet's transfer of cognitive tools relies on a second characteristic of means: their relative stability over time. The average height of conscripts possesses this important property. The height dispersion in any given year is fairly wide. In contrast, the average height of new conscripts is roughly stable from year to year, or at least it varies in a far smaller interval than that of the individual heights of conscripts in a particular year. The stability of the mean, as against the dispersion of individual cases, was to serve as the foundation for the use of statistics in the social sciences. A comparable time invariance was observed for other totalizations supplied by nascent administrative statistics. Exposing regularities justifies the practice of forecasting, which is one of the main tasks that the world of action demands from the world of the social sciences.

The identification of regularities was made possible by the publication of administrative statistics assembled under the heading of what was then known as moral

statistics. Such publications were issued on an increasingly regular basis from the 1830s on. They cover a range of diverse events, such as births, marriages, suicides, and crimes. Although these events may seem to be due to decisions governed solely by individual freedom, their annual numbers, revealed by official statistics, were remarkably stable, as was the average height of conscripts. The "inexorable budget of crime," prophesized by Quetelet, heralds the sociological determinism of Émile Durkheim and his successors. Just as each individual has a height and weight, he or she is also endowed with a "propensity" to marry, commit suicide, or kill another person. The statistics bureaus may be compared to astronomical observatories: They record facts that are stable and thus predictable. The discipline of social measurement established its scientific credentials by modeling them on the unquestioned credentials of astronomy. Indeed, in the 1830s Quetelet was just as busy lobbying for the construction of an observatory in Brussels as in organizing a statistical system that included population censuses as well as the collection of vital statistics (births, marriages, and deaths) and crime and health statistics.

Quetelet's importance in promoting social measurements, both in the social sciences and in the political management of the social world, results from the strength of that association between the state and science. The two sides of the link are (i) the administrative machine and its registrations, stabilized in conformity with codified procedures, and (ii) the simplicity and generality of the law of large numbers, issued from the application of probability theory to astronomical measurements. However, in the process, the State partly changes nature. To the generality arising from judicial law—taken as the social rule applicable to all citizens of a State—was now added the notion of statistical law, observed in society, and accordingly treated as independent of the State. Statistics, synonymous with the State when introduced in Germany in the 18th century, was now emancipated from the State and laid the foundation for an autonomous social domain. The State had to make allowance for these new "laws," which it had not decreed. Sociology, particularly that of Durkheim, was constructed partly in opposition to the science of legal experts and jurists; it relied instead on the statistical regularities that Quetelet was so good at orchestrating. The quantitative social sciences—with their variables whose effects are analyzed—descend directly from the table of constant causes and propensities of individuals, invented by Quetelet. The terms in quotes are shorthand forms for naming new and previously unthinkable aggregates and assemblages. The epistemological status of these social measurements was encapsulated in a box, whose invisible cogs consisted of the recording procedures, and whose outputs, naturalized by statistical language, were propensities or variables producing effects. These could now be measured and separated, for example, by logistic regressions.

Determinism and Free Will

Quetelet's ambition was to import into the social sciences what was the pride of specialists of natural science in the first half of the 19th century—the possibility of starting from systematic measurements to arrive at general laws of phenomena and hence to predict their future course. The most brilliant example of this was the astronomy born of the endeavors of Newton, Laplace, and Gauss. However, the macrosocial "regularities" exhibited by Quetelet concerning marriages, crimes, or suicides seemed to clash head-on with the idealistic philosophy of freedom and individual responsibility that thinkers—religiously inspired or not—were seeking to promote in the same period. If the total number of crimes and suicides perpetrated in a given year is stable and predictable, what remains of the free will of the moral individual? This question was debated by philosophers, theologians, and novelists, particularly in the German world. In 1912, the Belgian Jesuit Joseph Lottin devoted a large volume to "*Quetelet, statisticien et sociologue*" ("Quetelet, Statistician and Sociologist"). He admired Quetelet but went into a lengthy discussion on the link between the moral freedom of the individual and the mean regularities described by Quetelet. From a different perspective, the French Durkheimian sociologist Maurice Halbwachs posed similar questions in 1912 in his supplementary doctoral dissertation titled "*La théorie de l'homme moyen. Essai sur Quetelet et la statistique morale*" ("The Theory of the Average Man: An Essay on Quetelet and Moral Statistics"), which took a more critical stance. Since that period, such criticism has often been directed against quantitative sociology—in particular of the Durkheimian variety—although Quetelet is no longer mentioned. Although the man is frequently forgotten, the dispute over macrosocial determinisms triggered by his work endures. A detailed study of the preoccupation with this issue in 20th-century European literature is found in a 1993 book by the French philosopher Jacques Bouveresse, in which he discusses the influence of Quetelet and his philosophy of statistics on the Austrian writer Robert Musil. Significantly titled "*L'homme probable. Robert Musil, le hasard, la moyenne et l'escargot de l'histoire*" ("Probable Man: Robert Musil, Chance, Averages, and History's Snail"), the book shows that the theme of Musil's novel "The Man without Qualities" (i.e., without specific singularities) was heavily influenced by the German debates over average man and individual freedom.

Implementation of a Coordinated Network of Social Measurement

Although his work sparked an ideological debate of this kind, Quetelet was less a philosopher than a scientific and administrative entrepreneur. By the 1820s, he was working to set up coordinated observations in meteorology. In 1853, he initiated the first meeting in Brussels of the International Statistical Congress to bring together statisticians from the statistical bureaus created (often under his influence) in several countries during the two preceding decades. The goal was to establish a coordinated network that would gather information on population, the economy, and moral statistics using the most standardized definitions, classifications, and recording procedures possible. On several later occasions, he drew attention to the concomitance of two international conferences—one on statistics and the other on meteorology—in Brussels in 1853. In both cases, "governments wanted to reach agreement through their special delegates." The first conference "deals with the general statistics of the different countries and with the means of unifying the official documents intended for the administration and for science," whereas the second "deals with the navy and the agreement that needs to be achieved between the efforts of different nations to arrive at a knowledge of the laws governing the movements of the seas and the atmosphere, the depth and temperature of waters, and, in general, all matters of interest to the navigator" [Quetelet (1860) as quoted in Brian (1989, p. 122)]. This parallel confirms Stigler's suggested interpretation of the 1823 Paris trip. It covers four aspects of the international statistical system that Quetelet was seeking to promote: the establishment of a measurement network, the standardization of procedures in the network, the role of States in this implementation, and their usefulness (the proper administration of society, sea navigation), and not only scientific in the "pure science" sense.

Quetelet in the 20th Century: Posterity and Oblivion

Quetelet's ideas were incorporated into the social sciences of the 20th century, for example, through Durkheim's work, but his name has not been preserved in the pantheon of the founding fathers of sociology or economics, as are those of Durkheim, Max Weber, Adam Smith, and David Ricardo. The reasons for this relative oblivion are philosophical and technical. Intellectually speaking, the theme of the regularity of observed averages, which cast all philosophies of liberty and action to the wind, was perceived by some as highly simplistic. It is striking that after "*Le Suicide*" (1897) and until his death in 1917, Durkheim made no further allusion to Quetelet. However, as discussed previously, Quetelet is important for having promoted the implementation of observation and measurement networks. History shows that statistics—an essential phase in the construction of the social sciences—is destined to become anonymous and invisible after its networks are up and running.

In another area—the techniques of statistical analysis—Quetelet's simple tools (calculation of means and rudimentary test of the stability of time series) were left far behind by the mathematical tools (variance, correlation, regression, and chi-square test) invented in the late 19th century by British biometricians Francis Galton, Karl Pearson, Udny Yule, and Ronald Fisher. These tools focus on the analysis of distributions and on the relations between them. The "normal" law, dear to Quetelet, remained important but was now interpreted in an entirely different manner. Henceforth, attention would focus on the differences and hierarchic relationships between individuals, not on averages supposedly reflecting a macrosocial whole endowed with specific properties of regularity and predictability.

Quetelet is therefore an important figure in two fields: epistemology and the sociology of the social sciences. For the epistemologist, he was the first to theorize the use of official statistical records to deduce the formulation of empirical laws, in the sense of observed regularities that can be extrapolated to the future. When Quetelet's name is mentioned today, it is generally in this connection. In contrast, the sociologist and the historian of the social sciences view Quetelet as the tireless advocate of the establishment of statistical offices and commissions at the national and international levels, followed by the standardization of measurement procedures to allow comparisons in space and time. This second aspect is often forgotten when the history of the social sciences is told exclusively from the standpoint of the history of ideas. Quetelet's distinctive achievement was to fully unite these two dimensions—cognitive and organizational. This undoubtedly explains his success in the 19th century but also his relative fall into obscurity in the 20th century, once his ideas came to be perceived as simplistic and once the forms of institutional organization that he had promoted had become completely routine.

Randomization

Bryan F. J. Manly
Universidade de São Paulo, Piracicaba, Brazil

Glossary

experimental unit A unit (e.g., a human subject) receiving a prescribed treatment as part of an experiment, with a variable of interest measured on the unit as a response to the treatment.
randomization test A test of a hypothesis based on the process of randomization that is used to allocate subjects to treatments.
sample unit The basic unit (e.g., a household) selected for study and measurement as part of a sample survey.
simple random sample A sample selected in such a way that every item available for selection has the same probability of being included in the sample, independently of the selection of any other unit.
stratified random sampling A sampling method whereby the population of sample units that is of interest is divided into groups or strata that are expected to be similar in terms of the variables of interest, and a simple random sample is taken separately from each of the strata.
target population The collection of all sample units that are of interest for a sample survey.

Randomization is a process that is used in the allocation of treatments to experimental units as part of some experimental designs and in the selection of sample units as part of some sampling designs. The intention in both cases is to eliminate biases due to differences between units that are not explicitly taken into account in the study design. In certain circumstances, the process of randomization can also be used as the basis for testing statistical hypotheses by determining whether a set of observed data was likely to have arisen by chance as a result of a random selection of sample units.

Introduction

Since the publication of Fisher's 1935 book on experimental design, it has been recognized that randomization is an important and desirable part of many experiments. The basic idea in this case, as propounded by Fisher, is that whenever there is some choice about assigning experimental units to treatments, the units should be randomly allocated to ensure that the allocation is independent of any preexisting differences between the units, such as the likelihood of a high response. This ensures a fair comparison between the treatments even when there are important differences between the units that the experimenter is unaware of and therefore cannot explicitly allow for in the experimental design.

Fisher first introduced the idea of randomization in his 1925 book on statistical methods in general. Before that time, it seems that there were no widely accepted procedures for the layout and analysis of experiments, and systematic arrangements were commonly used. Fisher was a forceful proponent of randomization, but there was much controversy in the early days about whether it was desirable or not.

Randomization in sample selection has a slightly longer history. According to Folks, the first real definition of random sampling was provided by the American philosopher Peirce, who is quoted as saying in approximately 1896 that "a sample is a random one, provided it is drawn by such machinery, artificial or physiological, that in the long run any one individual of the whole would get taken as often as any other." Strictly, this definition is not altogether satisfactory because it does not specify the independence of the selection of different individuals. It would, for example, apply if two individuals were always either selected or not selected together.

An alternative to random sampling for surveys is purposive selection, whereby samples are chosen to be representative of the population of units of interest. Cochran notes that random sampling and purposive sampling were the two rival methods used for sample surveys by local and national governments in the early 20th century. A commission appointed by the International Statistical Institute seemed on balance to favor purposive selection. However, the method was eventually largely abandoned because it provides no measure of the accuracy of estimation and is not as flexible as random sampling. An exception is the use of systematic sampling, which is sometimes used to obtain "representative" samples over space or time.

Randomization in Experimental Designs

As a hypothetical example of the use of randomization as part of an experimental design, suppose that five drugs for the relief of arthritis pain are to be compared. The subjects available will be 20 men and 20 women, with 10 men and 10 women younger than 60 years old and the other men and women older than 60 years old.

Table I lists the subjects in the four age–gender groups; within each group the order is based on the date of enrollment into the study. It would obviously be possible to allocate out the five drugs systematically to the subjects in each age–gender group, with the first two subjects receiving drug A, the next two receiving drug B, etc. However, there would be concern about that allocation because, for example, drug A will always be assigned to patients enrolled into the study at an early date, and it is conceivable that these patients might have something unusual about them in terms of their response to the drugs.

Therefore, it is sensible to allocate out the drugs in a random order. One way to achieve this is to assign each subject a random number between 0 and 1, as shown in the "random" column in Table I. Such numbers can be obtained either from a table of random numbers, such as is often included in statistics textbooks, or by generating the numbers in a computer spreadsheet (as was done in this case). If the subjects are sorted in order within groups based on the random number, and the drugs are then allocated out in order (A, A, B, B, C, etc.), then this is effectively a completely random allocation. Table II shows the outcome obtained for the example.

If nothing else, this type of random allocation avoids the possibility of any bias, conscious or unconscious, on the part of the experimenters in the allocation of the different drugs. Indeed, it is preferable that the experimenters and subjects do not actually know what the drug allocation was so as to avoid any biases in the measurement of responses to the drugs. It then becomes a double-blind trial.

Sometimes, it is thought that it is possible to improve on a random allocation by altering the allocation to make it

Table I List of Subjects for an Experiment on Pain Relief in the Order (within Groups) of Enrollment into the Study[a]

Group	*Subject*	*Random*	*Group*	*Subject*	*Random*
Female, < 60	1	0.284	Male, < 60	1	0.095
Female, < 60	2	0.044	Male, < 60	2	0.056
Female, < 60	3	0.745	Male, < 60	3	0.174
Female, < 60	4	0.808	Male, < 60	4	0.001
Female, < 60	5	0.593	Male, < 60	5	0.661
Female, < 60	6	0.075	Male, < 60	6	0.065
Female, < 60	7	0.368	Male, < 60	7	0.306
Female, < 60	8	0.627	Male, < 60	8	0.407
Female, < 60	9	0.950	Male, < 60	9	0.514
Female, < 60	10	0.899	Male, < 60	10	0.437
Female, > 60	1	0.132	Male, > 60	1	0.704
Female, > 60	2	0.314	Male, > 60	2	0.852
Female, > 60	3	0.160	Male, > 60	3	0.027
Female, > 60	4	0.862	Male, > 60	4	0.071
Female, > 60	5	0.866	Male, > 60	5	0.798
Female, > 60	6	0.890	Male, > 60	6	0.150
Female, > 60	7	0.008	Male, > 60	7	0.258
Female, > 60	8	0.663	Male, > 60	8	0.499
Female, > 60	9	0.818	Male, > 60	9	0.733
Female, > 60	10	0.202	Male, > 60	10	0.238

[a] The random values are uniform random numbers between 0 and 1.

Table II Random Allocation of the Drugs to Subjects Based on the Random Numbers Assigned to the Subjects

Group	*Subject*	*Random*	*Drug*	*Group*	*Subject*	*Random*	*Drug*
Female, < 60	2	0.044	A	Male, < 60	4	0.001	A
Female, < 60	6	0.075	A	Male, < 60	2	0.056	A
Female, < 60	1	0.284	B	Male, < 60	6	0.065	B
Female, < 60	7	0.368	B	Male, < 60	1	0.095	B
Female, < 60	5	0.593	C	Male, < 60	3	0.174	C
Female, < 60	8	0.627	C	Male, < 60	7	0.306	C
Female, < 60	3	0.745	D	Male, < 60	8	0.407	D
Female, < 60	4	0.808	D	Male, < 60	10	0.437	D
Female, < 60	10	0.899	E	Male, < 60	9	0.514	E
Female, < 60	9	0.950	E	Male, < 60	5	0.661	E
Female, > 60	7	0.008	A	Male, > 60	3	0.027	A
Female, > 60	1	0.132	A	Male, > 60	4	0.071	A
Female, > 60	3	0.160	B	Male, > 60	6	0.150	B
Female, > 60	10	0.202	B	Male, > 60	10	0.238	B
Female, > 60	2	0.314	C	Male, > 60	7	0.258	C
Female, > 60	8	0.663	C	Male, > 60	8	0.499	C
Female, > 60	9	0.818	D	Male, > 60	1	0.704	D
Female, > 60	4	0.862	D	Male, > 60	9	0.733	D
Female, > 60	5	0.866	E	Male, > 60	5	0.798	E
Female, > 60	6	0.890	E	Male, > 60	2	0.852	E

"fairer." An example of the disaster that this can cause is provided by the famous Lanarkshire milk experiment. This took place over 4 months in 1930 in Lanarkshire, Scotland, and was intended to compare the growth of schoolchildren given raw milk, pasteurized milk, or no milk. Unfortunately, within a school the selection of children as "feeders" (receiving milk) or "controls" (not receiving milk) was left to the principal of the school. Initially, a more or less random allocation was made, but unfortunately in the description of the experiment it is stated that "in any particular school where there was any group to which these methods had given an undue proportion of well-fed or ill-nourished children, others were substituted in order to obtain a more level selection." Given this flexibility, it seems that the teachers tended to allocate milk to poorly nourished children whom they thought needed it. This, together with other problems, turned a perfectly reasonable experiment into one in which the validity of the final results is very questionable.

Randomization in Sampling Designs

A well-designed sampling program will always include a clear definition of the sample units, which are the basic units selected for study such as the individual households in a survey of household expenditure, and of the target population, which is the collection of all sample units that are of interest. The sampling plan then describes how the sample units will be selected from the target population.

It is sometimes assumed that human beings are able to take a representative sample of units without needing to be concerned with randomization schemes, and often the word random is applied to any method of choosing sample units that appears to be arbitrary and without purpose. However, statisticians realized in the early 20th century that an arbitrary selection of units is often biased in comparison with what would be obtained by a truly random method. Some early examples are provided by Kendall and Stuart.

Thus, to overcome biases in sample selection, a proper randomization process is always desirable. Often, simple random sampling is used, whereby it is ensured that every unit in the target population has the same chance of being included in the sample, independently of all the other units. This is still often done by a mechanical process. For example, the names of the N units in the target population can be written on N cards, one per unit. These are then put in a container, and n cards are drawn to determine which units will be included in the sample to be taken. This produces an essentially random sample providing that the N cards are mixed up sufficiently in the container.

In practice, it will often be more convenient to use random numbers in a similar way to the random allocation of experimental treatments to patients that was described in the previous section and illustrated in

Tables I and II. One way to do this is to assign each of the N units in the target population a random number between 0 and 1, sort the units in order according to the value of the random number, and then take the first n units in the resulting list as the ones to be sampled. This randomization process ensures that each of the N units is equally likely to appear anywhere in the final list, independently of all the other units, and therefore gives a truly random sample.

Random sampling can be included in sample designs that are much more complicated than what has just been described. For example, stratified random sampling is often used, where the target population of sample units is divided into several groups or strata, such that within each of these strata the units are expected to be similar for the variable or variables of interest. Thus, the households in a city might be stratified on the basis of the suburbs where they occur, on the assumption that this will produce strata within which the households will tend to be similar in terms of their socioeconomic status. A simple random sample would then be taken separately from each of the strata, and the data that are collected from each household would be analyzed taking into account the way that the sample was determined. Stratified random sampling and other modifications of simple random sampling are reviewed by Manly.

Many populations that need to be sampled consist of units that are not easily identified. No list of the items is available, and therefore choosing a random sample is not just a matter of selecting units at random using random numbers or some mechanical process. In these cases, ingenious methods may be needed to attempt to obtain something approximately equivalent to a random sample. Some examples are discussed by Manly.

Inference Based on Randomization

When data are collected using a design that includes some process of randomization, it is sometimes possible to draw conclusions from the data based on the randomization by following a procedure first suggested by Fisher in 1936. The following example illustrates how this can be done.

Suppose that 30 adult females recently diagnosed as having schizophrenia are available for the trial of a new treatment for the disorder. Fifteen of the 30 patients are randomly chosen to be assigned the new treatment, and the others receive the standard treatment. After 1 month, the results for the two treatments are compared.

For each patient, there is a score at the start and the end of the month based on her symptoms, with high scores indicating many symptoms of schizophrenia. The effectiveness of the treatment received is therefore measured by the difference between the final score and the initial score (the change), with a large negative value being desirable. Table III shows these differences for the two groups of patients.

Table III Results from the Trial for a New Treatment for Schizophrenia

New treatment		*Standard treatment*	
Patient no.	*Change in score*[a]	*Patient no.*	*Change in score*
1	−7	1	−11
2	−25	2	−1
3	−3	3	−16
4	−4	4	−14
5	−7	5	12
6	−11	6	−18
7	−9	7	−11
8	−12	8	−9
9	−28	9	−10
10	−17	10	−20
11	−16	11	−23
12	−22	12	−13
13	−22	13	−10
14	−27	14	4
15	−12	15	−27
Mean	−14.80		−11.13
SD	8.36		10.10

[a] The difference between a score for symptoms at the start and end of 1 month of treatment, with large negative values indicating an effective treatment.

The mean change for the standard treatment is −11.13, indicating that there was some improvement on average for the 15 patients given this treatment. For the new treatment, the mean change is −14.80, suggesting that this treatment may be better than the standard treatment for reducing symptoms. However, there is obvious interest in knowing whether the mean difference, $D = (-11.13) - (-14.80) = 3.67$, is large enough to give real evidence that the new treatment is better.

The usual method for assessing the significance of the observed mean difference of 3.67 would involve performing either a two-sample t test or a nonparametric alternative, such as the Wilcoxon rank-sum test. However, an alternative procedure that has the merit of being very easy to understand examines the problem from the standpoint of asking whether the mean difference of 3.67 could reasonably have occurred as a result of the random allocation of the 30 women to the two groups.

The null hypothesis for the test based on the randomization is that the observed change for each woman would be the same, irrespective of the treatment given. If this is true, then the observed mean difference of 3.67

arose simply because of the particular randomization used in the experiment. To determine the probability of obtaining a mean difference as large as 3.67 on this basis, it is simply necessary to use a computer to carry out a very large number of alternative randomizations and find the proportion of times that a mean difference of 3.67 or more occurs. This can be done, for example, using an add-on to the Excel spreadsheet.

When 20,000 alternative randomizations were carried out, it was found that a mean difference of 3.67 or more occurred 15% of the time. Consequently, this size of difference is slightly unusual but not to the extent that it suggests that the difference is not just due to the randomization procedure. In the terminology of a test of significance, the significance level is $p = 0.15$ (the probability of getting a result as extreme as that observed by chance in the absence of a difference between the effects of the treatments). This would not usually be regarded as evidence against the null hypothesis.

More information about randomization-based methods of inference can be found in the texts by Edgington, Good, and Manly. See also the discussion by Lunneborg of the commonly occurring experiment, such as the one described previously, in which subjects are randomly allocated to two groups that are then given different treatment. Lunneborg notes that in certain circumstances conventional and randomization tests comparing the means of treatment will be too conservative, giving too few significant results.

Ranking

Wade D. Cook
Seymour Schulich School of Business, York University, Toronto, Canada

Glossary

consensus ranking This term is used to describe the ranking of a set of alternatives that is in best agreement with the rankings supplied by a set of voters.
data representation This term refers to the manner in which one displays ordinal responses (e.g., pairwise comparisons and vectors).
intransitivity Inconsistency in preference specifications whereby the voter prefers for example **a** to **b**, and **b** to **c**, but also **c** to **a**.
ordinal data Data or information in the form of binary pairwise comparisons, or as rank positions on an *N*-point scale.
round robin tournament Refers to any competition or comparison in which each pair of members (teams, individuals, objects) competes exactly once.

The theory of ordinal ranking, data, and consensus involves (1) the evaluation of methods for formatting data when only ordinal preferences can be specified, (2) the resolution of possible inconsistencies in that specification, and (3) the derivation of a consensus of opinion when multiple sets of preferences are present.

Introduction

Data in real world decision problems appear in many different forms. Generally, data can be classified as falling into one of four groups.

(1) *Nominal data* are measurements that simply classify the units of the sample into categories. An example would be the political party affiliation of each individual in a sample of 50 business executives.

(2) *Ordinal data* are measurements that enable the units of the sample to be ordered with respect to the variable of interest. An example would be the size of car rented by each individual in a sample of 30 business travelers; compact, subcompact, midsize, or full-size.

(3) *Interval data* are measurements that enable the determination of how much more or less of the characteristic being measured is possessed by one unit of the sample than another. An example is the temperature at which each of a sample of 20 pieces of heat-resistant plastic begins to melt.

(4) *Ratio data* are measurements that enable the determination of how many times as much of the characteristic being measured is possessed by one unit of the sample than another. An example is the sales revenue for each firm in a sample of 100 U.S. firms.

In this article, attention is confined to ordinal data.

Information or data in the form of individual preferences are common in a wide variety of real-world comparisons and choice situations. When a consumer is asked, for example, to rate or compare several flavors of pudding, it is natural that an ordinal response be given: "I prefer the flavor of chocolate to that of vanilla, the flavor of strawberry to that of chocolate." It can be unreasonable in such situations to expect an individual to be able to quantify his or her responses to these stimuli (flavors) on an absolute cardinal scale (chocolate rates at 6 while vanilla rates at 5). Another example is the fitting of lenses by an optometrist. At each trial, the optometrist presents to the patient two lenses from which the patient chooses the one through which he or she sees the clearest. In this case, the patient is not even required to provide an ordinal ranking of the lenses, but simply to express ordinal preferences between two samples at a time. The result of this set of pairwise comparisons is the identification of the most suitable lens.

The analysis of stimuli impacts, therefore, constitutes an important area where the data are inherently ordinal.

Such ordinal preference data have been the subject of study for over two centuries. Initially, a problem arising in the theorizing on preferential elections of the 18th century, it has evolved into the social choice theory of today. An important group of problems involving ordinal data and ranking concern the aggregation of preferences provided by a set of individuals into a group preference function or a consensus. Numerous authors have investigated problems of ranking and consensus, including Blin and Whinston, Cook *et al*., Kemeny and Snell, and Kendall.

Dealing with problems involving ordinal data provided by individual responses, generally involve three issues. The first issue pertains to the format in which data concerning a set of alternatives should be collected. This depends upon the application under investigation and the number of alternatives at hand. The second issue, in some settings, involves resolving inconsistencies in preferences supplied by the respondent. Such inconsistencies arise when the data format chosen involves pairwise comparisons of alternatives. Finally, when multiple respondents supply preferences concerning a set of alternatives, there is the issue of combining these preferences into a consensus ranking of those alternatives.

Problem Settings

Using Consumer Preferences to Evaluate Products

Opinions of consumers play a dominant role in the development and marketing of new products. Private enterprise relies on such opinions to aid in targeting their products toward particular segments of society according to age, sex, economic status, and so on. Because of the enormous financial implications associated with new product development and changes to product formulations, the obtaining and processing of consumer perceptions are crucial elements in the product's success or failure.

To have a particular problem setting as a backdrop, consider the situation faced by a researcher who is collecting consumer responses pertaining to preferences among five formulations of a pudding mix, which a company is considering for production. Denote the alternative formulations as $a, b, c, d,$ and e. The formulations vary in texture, flavor, smoothness, and the like. The company is attempting to determine which formulation would be most favorable with the public and which segments of the public should be targeted as the primary market for the product in question. In simple terms, therefore, the ultimate purpose of the survey is to arrive at a preferred product from among the five options, or more generally to obtain a ranking of the products.

This problem has been the focus of extensive research in the field of marketing for decades. Hundreds of papers have been written on the subject, and scores of models for characterizing and evaluating consumer preferences have been advanced. A number of major issues must be confronted in dealing with this problem, including choosing an appropriate data format, resolving inconsistencies in responses from consumers, and deriving a compromise or consensus of opinions among multiple respondents.

Aggregating Voter Responses in a Preferential Ballot Election

In a preferential election, each voter selects a subset of k candidates from a ballot of m choices, and rank orders these k candidates from most to least preferred. Such a voting format is common in municipal elections where a number of candidates are required to fill various positions.

A number of models for aggregating preferential votes have arisen from parliamentary settings. These methods all utilize the set of values v_{ij}, giving the number of jth place votes received by the ith candidate on the ballot. Models that go under such names as the American, English, and West Australian systems, for example, have different ways of utilizing these statistics to arrive at a final list of winners. A sample of these methods is discussed below.

Ranking Players in a Round Robin Tournament

Many sports events involve the direct competition of one individual or team against another. While many variations exist, one form of competition, the round-robin tournament, characterizes several games. Consider the case of a chess tournament, where a group of players competes in a pairwise fashion. Each match between a pair of players results in a win of one player over the other or in a draw, and generally every pair is involved in exactly one match.

The outcomes of all matches can be represented by a binary preference matrix of a form similar to that presented in the previous application. The rows and columns are labeled by the players $P_1, P_2, \ldots, P_N$, and the entries $a_{p_i p_j}$ are 1s, 1/2s, and 0s, depending on whether P_i won against P_j, tied, or lost.

$$A = \begin{array}{c|cccc} & P_1 & P_2 & \cdots & P_N \\ \hline P_1 & 0 & 1 & \cdots & 0 \\ P_2 & 0 & 0 & & \\ \vdots & & & & \\ P_N & 1 & 0 & \cdots & \end{array}$$

Ultimately, it is necessary to determine a clear winner out of the competition. As observed in the previous application, however, cycles can occur. Cycles are present here, not because of an inconsistency in stating preferences, but rather that player P_1 defeats P_2 who defeats P_3 who defeats P_1. Such a phenomenon is often the rule rather than the exception, partially because the teams or players are generally evenly matched.

While standard procedures have been adopted to score players in tournaments such as chess, many different approaches have been developed and studied in the literature that attempt to rank players in a manner that best captures the outcomes from the matches. Some of these account for the strength of the players: a win against a strong player is valued more than one against a weak player.

In cases where not all pairs of players or teams compete, opponents must be ranked using an incomplete set of outcomes. Here it may be necessary to evaluate indirect results from matches. If P_1 beats P_2 and P_2 beats P_3, but P_1 and P_3 never compete, P_1 could be viewed as superior to P_3 because of the chain of outcomes, which may be assumed to be transitive. On the other side of the scale, there can be multiple matches: two players may compete several times. Furthermore, this number of matches may be different for some pairs of players than for others.

The problem of ranking players in a tournament is then clearly one where binary pairwise comparison data must be evaluated. In its most generic form, it can be viewed in the same manner as the problem of resolving intransitivities in a consumer's stated preferences. At the same time, in a multiple-match tournament, consensus issues also arise.

Representation of Ordinal Preferences

A number of different models for dealing with ordinal preference have been developed. Three of the most common are presented below.

Object-to-Object Representation

One of the most common frameworks for eliciting individual preferences is the pairwise comparison method in which each pair of alternatives or objects is compared in an ordinal sense. Specifically, preferences concerning n alternatives are represented in an $n \times n$ pairwise comparison matrix $A = (a_{ij})$ where

$$a_{ij} = \begin{cases} 1 & \text{if alternative } i \text{ is preferred to } j \\ 1/2 & \text{if } i \text{ and } j \text{ are tied} \\ 0 & \text{otherwise.} \end{cases}$$

In the case of 4 alternatives, a, b, c, d, where a is in second place, b in first, c in fourth, and d in third, the preference matrix is given by

A_1:

0	a	b	c	d
a	0	0	1	1
b	1	0	1	1
c	0	0	0	0
d	0	0	1	0

Alternatively, if a is in first place, b in fourth and c and d are tied for second and third positions,

A_2:

	a	b	c	d
a	0	1	1	1
b	0	0	0	0
c	0	1	0	1/2
d	0	1	1/2	0

It is noted that this representation is equivalent to the matrix representation of Kemeny and Snell, where $a_{ij} = 0$ if i and j are tied, $a_{ij} = 1$ if i is preferred to j, and $a_{ij} = -1$ if j is preferred to i.

Vector Representation

Cook and Seiford offer a vector representation $A = (a_1, a_2, \ldots, a_n)$, where a_i is the rank or priority assigned to alternative i. The vector representation of the preference relation given by A_1 above is (2, 1, 4, 3). That is, alternative a is ranked second, b first, c fourth, and d third. The priority vector corresponding to A_2 is (1, 4, 2.5, 2.5). The 2.5 designation indicates that alternative c and d are tied for second and third place.

Object-to-Rank Binary Matrix Representation

Blin has suggested an alternative to the Kemeny and Snell model for complete orderings. Armstrong *et al.* have extended this to include ties (weak orderings). Specifically, an ordering is defined by matrix $P = (p_{ij})$, where

$$p_{ij} = \begin{cases} 1 & \text{if alternative } i \text{ has rank } j \\ 0 & \text{otherwise.} \end{cases}$$

It is assumed here that i takes on the values 1, 1.5, 2, 2.5, $\ldots$, $n-1$, $n-0.5$, n. The P-matrices corresponding to A_1 and A_2 above would then be given by

P_{A1}:

	1	1.5	2	2.5	3	3.5	4
a	0	0	1	0	0	0	0
b	1	0	0	0	0	0	0
c	0	0	0	0	0	0	1
d	0	0	0	1	0	0	0

and

$$P_{A2} = \begin{array}{c|ccccccc} & 1 & 1.5 & 2 & 2.5 & 3 & 3.5 & 4 \\ \hline a & 1 & 0 & 0 & 0 & 0 & 0 & 0 \\ b & 0 & 0 & 0 & 0 & 0 & 0 & 1 \\ c & 0 & 0 & 0 & 1 & 0 & 0 & 0 \\ d & 9 & 9 & 9 & 1 & 0 & 0 & 0 \end{array}$$

Geometric Interpretations

Ordinal preferences represented as priority vectors have a convenient description in a geometric sense. A necessary (but not sufficient) condition that a ranking vector satisfies is

$$\frac{p(p+1)}{2} \le \sum_{i \in K_p} a_i \le \frac{2np + p - p^2}{2}, \quad p = 1, \ldots, n$$

for every subset K_p, of the indices, of cardinality p.

In Figs. 1 and 2, this condition is utilized to illustrate the space of rankings for $n = 2$ and 3. In each case the rankings lie on the $(n-1)$ dimensional simplex given by

$$\sum_{i=1}^{n} S_i = \frac{n(n+1)}{2} \quad x_i \exists 0 \quad \text{for all } i.$$

The complete rankings are the extreme points that result from imposing the additional constraints

$$\frac{p(p+1)}{2} \le \sum_{i \in K_p} x_i \le \frac{2np + p - p^2}{2} \quad \text{for } p = 1, 2, \ldots, n-1.$$

(For $n = 2$ and 3 these additional constraints reduce to 1 # x_i # n for all i.) The tied rankings correspond to midpoints of the faces. (The ranking in which all objects are tied is the midpoint of the polyhedron.) See Figs. 1 and 2. It should also be noted that the space of rankings for $n-1$ objects is naturally embedded in (as a face of) the space for n objects. This is illustrated for $n = 4$ in Fig. 3.

Resolving Intransitivities in Pairwise Comparison Preferences

When preferences are expressed in a pairwise comparison format, as discussed above (object-to-object representation), the problem of providing a ranking of the alternatives being considered is often hampered by intransitivities in specification (e.g., a is preferred to b, b to c, and c to a).

In the application to ranking players in a tournament, as discussed above, this issue was raised. The tournament ranking problem has attracted considerable attention since the early work of Zermelo.

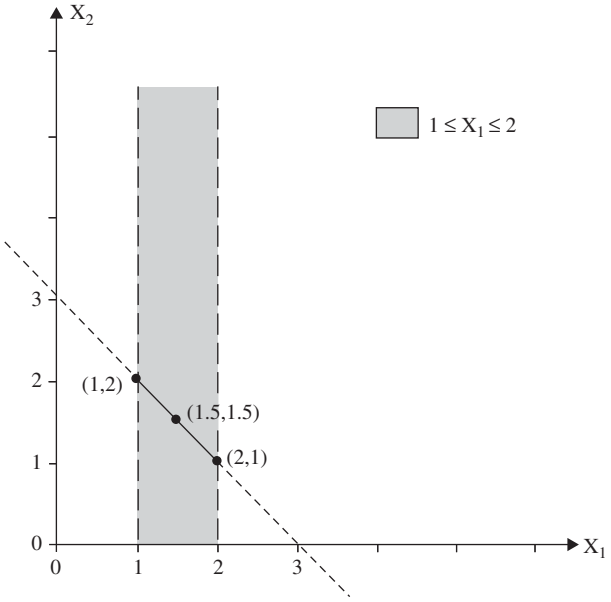

Figure 1 Ranking space for 2 objects.

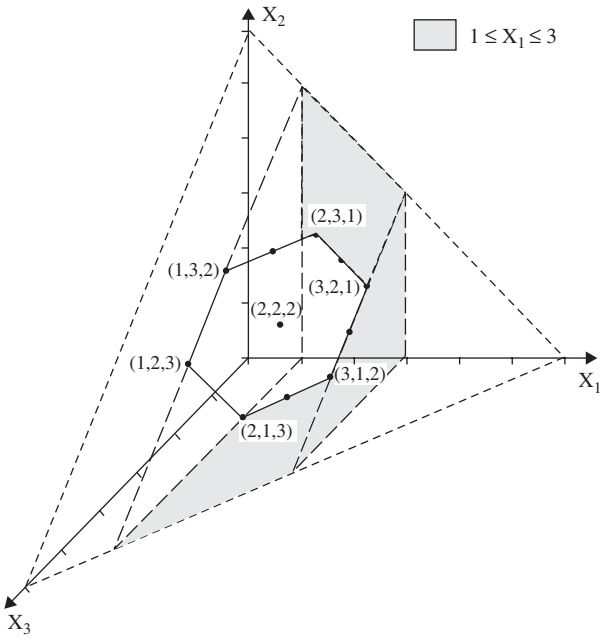

Figure 2 Ranking space for 3 objects.

The Kendall Scores Method

Numerous techniques have been suggested for deriving a ranking of the "players," with perhaps the most simple being the Kendall scores approach, which we briefly discuss here. The "score" of an alternative i is defined as the number of alternatives to which i is preferred, or (in sports) the number of players that were beaten by player i. This method was first proposed by Kendall.

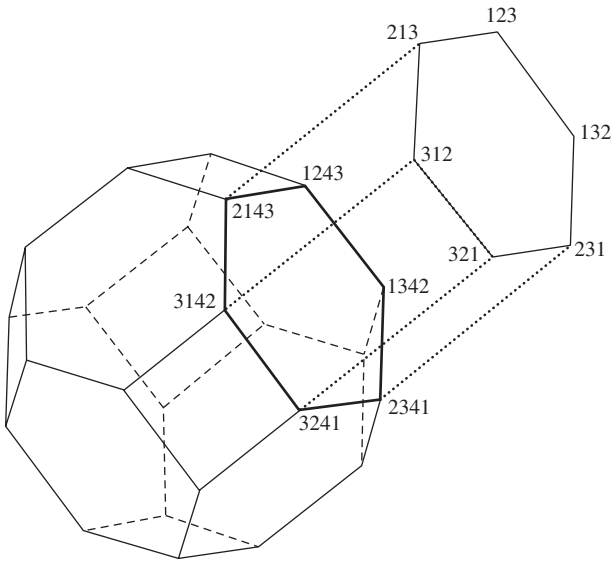

Figure 3 Ranking space for 3 objects embedded in space for 4 objects.

An Example

Consider the preference matrix

$$A = \begin{array}{c|ccccc} & a & b & c & d & e \\ \hline a & 0 & 1 & 1 & 1 & 0 \\ b & 0 & 0 & 1 & 1 & 0 \\ c & 0 & 0 & 0 & 1 & 1 \\ d & 0 & 0 & 0 & 0 & 1 \\ e & 1 & 1 & 0 & 0 & 0 \end{array}$$

The KS vector for this preference structure is $(3, 2, 2, 1, 2)^{\mathrm{T}}$; that is, the sum of the elements of the first row is 3, that of the second row is 2, and so on. If the criterion for ranking the alternatives is "i is ranked higher than j if the score of i is greater than that of j and only if the score of i is at least as high as the score of j," then the resulting possible rankings are (a, b, c, e, d) or (a, b, e, c, d) or (a, c, b, e, d) or (a, c, e, b, d) or (a, e, b, c, d) or (a, e, c, b, d). Thus, six possible rankings result from this preference structure. In general, if there are k strings of tied scores where the ith string consists of n_i alternatives, then the number of possible rankings that are consistent with this set of scores is $(n_1)!(n_2)! \cdots (n_k)!$. In this example, there is one string with three alternatives tied; hence, there are $3! = 3 \times 2 \times 1 = 6$ rankings.

To demonstrate the possibility of multiple rankings, consider preference structures of order 5. There are $2^{10} = 1024$ possible 5×5 preference structures. Table I presents the frequencies of the numbers of possible KS rankings for those preference structures.

The preference structures with a single ranking number $5! = 120$, with KS equal to a permutation of the vector (1, 2, 3, 4, 5). The 24 preference structures each with 120 possible rankings represent the case where the KS vector is (2, 2, 2, 2, 2).

Breaking Ties: The Iterated Kendall Method

Given the high probability of ties among the Kendall scores, the question arises as to how to reduce the number of possible rankings. One approach is the Iterated Kendall ranking method. In this procedure, those alternatives with tied scores are pulled out from the preference structure and constitute a preference structure or substructure of their own. An attempt is made to rank order this substructure according to KS, and this procedure is repeated as far as possible. Formally, the method involves three steps:

1. Rank order the alternatives according to Kendall scores. If there are no ties, the resulting ranking has no violations and the procedure terminates. Otherwise, go to step 2.
2. Break the ties among any k tied alternatives by considering only the $\binom{k}{2}$ outcomes of these k choices, and then performing the ranking as in step 1.
3. If there are ℓ alternatives that are tied among themselves, select any one of these ℓ, and place it first in the subranking. The tie among the rest of the $\ell - 1$ alternatives is broken by performing step 2.

Applying this method to the above example, define the substructure that includes alternatives b, c, and e only. This substructure is

	b	c	e
b	0	1	0
c	0	0	1
e	1	0	0

The KS vector of this substructure is (1, 1, 1), and unless a winner is picked according to step 3, the tie still cannot be broken, and therefore we cannot eliminate any of the six rankings. Even though we can easily construct an example where this iterated method can reduce the number of possible rankings, in many cases it will not work.

Table I Frequencies of Multiple KS Rankings

No. of possible rankings	*Frequency*
1	120
4	480
6	400
120	24
Total	1024

Another approach is to rank order tied alternatives according to a Hamiltonian order.

DEFINITION 1. The ranking $(a_1, a_2, \ldots, a_n)$ is said to be a Hamiltonian order if and only if a_1 is preferred to a_2, a_2 is preferred to $a_3, \ldots, a_{n-1}$ is preferred to a_n. That is, the rank order of any consecutive pair of alternatives agrees with their pairwise comparison results in the preference structure.

Out of the six KS rankings in our example, only three rank the tied alternatives (b, c, e) in a Hamiltonian order. These rankings are (a, b, c, e, d), (a, c, e, b, d), and (a, e, b, c, d). Furthermore, since e is preferred to a and d is preferred to e, there is only one complete Hamiltonian ranking, (a, c, e, b, d). Therefore, by applying the reasonable Hamiltonian requirement to the tied alternatives, it is possible to reduce the number of KS rankings by one-half. By applying this rule to the entire set of alternatives, we could single out a unique KS ranking.

Ad hoc Consensus Methods

As discussed above, many problem settings require finding a consensus among a set of declared preferences.

Numerous approaches have been suggested in the literature for aggregating individual rankings in order to arrive at such a compromise or consensus. While some of these approaches can be linked to a particular piece of literature, e.g., Borda, others have simply evolved over time via parliamentary procedures, preferential voting needs, etc. In this section, some of these "*ad hoc*" approaches are very briefly examined.

These *ad hoc* methods can be grouped under two headings—elimination and nonelimination methods.

Nonelimination Methods of Consensus

Borda's Method of Marks

This approach, due to Borda, and later discussed at length by Kendall, is based on deriving the total of the ranks for each alternative as assigned by the voters. Consider the following 3-alternative, multivoter example

23 *votes*:	1	2	3
17 *votes*:	3	1	2
2 *votes*:	2	1	3
10 *votes*:	2	3	1
8 *votes*:	3	2	1

Total for

a: $23 \times 1 + 17 \times 3 + 2 \times 2 + 10 \times 2 + 8 \times 3 = 122$

b: $23 \times 2 + 17 \times 1 + 2 \times 1 + 10 \times 3 + 8 \times 2 = 111$

c: $23 \times 3 + 17 \times 2 + 2 \times 3 + 10 \times 1 + 8 \times 1 = 127$

The consensus here by Borda's Method is then $b > a > c$ or $A^* = (2, 1, 3)$.

Several modifications of the Borda Method have been developed, including those due to Cook and Seiford.

Simple Majority Rule or Condorcet's Method

Condorcet proposed a method whereby alternative x should be declared the winner if for all $y \neq x$, x is preferred to y by more voters than the number who prefer y to x. Similarly, y would be ranked second if for all $z \neq x$ or y, y is preferred to z by more voters than the number who prefer z to y. Consider the following example.

	Alternative		
	a	b	c
Voter#1	1	2	3
Voter#2	2	1	3
Voter#3	1	2	3
Voter#4	2	3	1
Voter#5	1	3	2

$a > b$ by 4 voters

$b > c$ by 3 voters

$a > c$ by 4 voters

Thus, the consensus ranking by simple majority rule is $a > b > c$ or $A^* = (1, 2, 3)$.

One problem cited by Condorcet, and one that is often encountered in applying this method is the occurrence of intransitivity, giving rise to the so-called "paradox of voting" or Condorcet effect. Example 1 above illustrates this phenomenon. There, $a > b$ by 33 voters out of 60, $b > c$ by 42 voters, and yet $c > a$ by 35 voters. Thus, a cycle arises, and the simple majority procedure breaks down. It has been shown that in the case of a uniform distribution of 3 alternatives, intransitivity occurs 8.8% of the time. For 4 alternatives, this probability is approximately 16%. Niemi and Weisberg and others have obtained estimates of such probabilities for a number of combinations of voters and alternatives.

Several "Condorcet completions" have been developed to deal with such intransitivities.

Elimination Methods

These methods gained popularity in parliamentary settings.

Runoff from Top Method

One such procedure consists of each individual first voting for the prospect he most prefers, and if there is no majority on a first ballot, a second vote is taken after eliminating the prospect with the fewest "first choice" votes on the first ballot. This appears to be identical with what is sometimes

called the "West Australian System" and very close to what is sometimes called the "English System," particularly for only three prospects.

Runoff from Bottom Method

This approach has approximately the same appeal as the runoff from top method. On each successive ballot the voters choose the prospect to eliminate.

The American System

The system sometimes identified as the "American System" is apparently designed only for use with preferential ballots which collect full rankings on the first round. Here, if there is no majority of first choice votes, the option with the fewest first choices is eliminated along with all those ballots whose first choice was the eliminated option.

Pairwise Majority Rule

Finally, there is the basic method defined by pairwise majority rule, which has special practical as well as theoretical appeal as long as it results in a determinate outcome. Some other methods have sought to make simple modifications to the majority rule approach. In Copeland's method, the prospect of x is more preferred the greater the number of prospects which lost to x relative to the number to which x loses.

Distance-Based Consensus Methods

In this section, aggregation or consensus among a set of preferences is examined from the point of view of a distance function. This concept has intuitive appeal in that a consensus is defined to be that set of preferences which is closest in a minimum distance sense to voter responses. This idea was first advanced by Kemeny and Snell, and was later adopted by Blin and by Cook and Seiford.

The approach is to define a distance function on the set of all preference orders which satisfies certain desirable properties. These properties or axioms are related to social choice properties. For purposes of presentation, the vector model of Cook and Seiford will be used as the preference representation.

Cook and Seiford propose that any distance function d_{cs} on the set of all priority vectors should satisfy the axioms:

Axiom 1. $d_{cs}(A, B) \geq 0$, with equality iff $A \equiv B$.

Axiom 2. $d_{cs}(A, B) = d_{cs}(B, A)$.

Axiom 3. $d_{cs}(A, C) \leq d_{cs}(A, B) + d_{cs}(B, C)$, with equality holding if and only if ranking B is between A and C. A, B and C are said to lie on a line in this case, hence d_{cs} is additive on lines.

Axiom 4. (Invariance) $d_{cs}(A, B) = d_{cs}(A', B')$, where A' and B' result from A and B, respectively, by the same permutation of the alternatives in each case.

Axiom 5. (Lifting from n to $(n+1)$-dimensional space). If A^* and B^* result from A and B by listing the same $(n+1)$st alternative in last place, then $d_{cs}(A^*, B^*) = d_{cs}(A, B)$.

Axiom 6. (Scaling) The minimum positive distance is 1.

It can be shown that the unique distance function which satisfies this set of properties is the ℓ^1 norm

$$d_{cs}(A, B) = \sum_{i=1}^{n} |a_i - b_i|.$$

Consensus among a set of voter priority vectors $\{A^\ell\}_{\ell=1}^m$ is then given by the vector $B^* = (b_1^*, b_2^*, \ldots, b_n^*)$, which solves the minimization problem

$$\sum_{\ell=1}^{m} d_{cs}(A^\ell, B^*) = \min_B \sum_{\ell=1}^{m} d_{cs}(A^\ell, B) = \min \sum_{\ell=1}^{m} \sum_{i=1}^{n} |a_i^\ell - b_i|.$$

A similar axiomatic structure has been proposed by Kemeny and Snell for pairwise comparison priorities and for the Blin model (see the work of Armstrong *et al.*). The Kemeny and Snell distance is defined as

$$d_{KS}(A, B) = \sum_i \sum_j |a_{ij} - b_{ij}|,$$

where A and B are pairwise comparison matrices. The Blin distance function is given by

$$d_{cs}(P, Q) = \sum_i \sum_j |p_{ij} - q_{ij}|,$$

where P, Q are object to rank binary matrices.

To better understand the distance models presented above, it is useful to examine an interesting connection that can be derived by starting with the Blin model and extending it to include degree of disagreement. Two of these extensions lead directly to the Kemeny and Snell and the Cook and Seiford models, respectively. Approaching the design of the latter two models from this direction lends an important insight into the level of complexity vis-à-vis the solution of these models.

Rank-Based Distance

One point of departure from the simple Blin representation is to define a function in which the aggregate disagreement between voters is measured according to the location of the alternatives relative to the various rank positions.

DEFINITION 2. The position j forward indicator vector $P^+(j)$ and the position j backward indicator vector $P^-(j)$

are those vectors whose kth components are given by

$$(P^+(j))_k = \begin{cases} 1 & \text{if object } k \text{ is ranked in a} \\ & \text{lower position than } j, \\ 0 & \text{otherwise} \end{cases}$$

$$(P^-(j))_k = \begin{cases} 1 & \text{if object } k \text{ is ranked in a} \\ & \text{higher position than } j, \\ 0 & \text{otherwise,} \end{cases}$$

respectively.

The consensus model arising from this position based extension of the Blin function is one of determining a permutation matrix $X = (X_{ij})$, which minimizes

$$\sum_{\ell=1}^{m} d_p(A^\ell, X) = \sum_{\ell=1}^{m} \langle n(n-1) - \sum_{j=1}^{n} [P_\ell^+(j), X^+(j)\rangle + \langle P_\ell^-(j), X^-(j)\rangle]].$$

This is equivalent to the linear assignment problem

$$\text{Max} \sum_{\ell=1}^{m}\sum_{j=1}^{n}\sum_{i=1}^{n}\left[\left(\sum_{t=j+1}^{n} p_{it}\right)\left(\sum_{t=j+1}^{n} x_{it}\right) + \left(\sum_{t=1}^{j-1} p_{it}\right)\left(\sum_{t=1}^{j-1} x_{it}\right)\right],$$

Subject to

$$\sum_{i=1}^{n} x_{ij} = \sum_{j=1}^{n} x_{ij} = 1, \quad x_{ij} \geq 0 \quad \text{for all } i,j.$$

Object-Based Distance

In a fashion similar to that presented above, one can construct an alternative-based distance function.

Definition 3. The alternative i forward indicator vector $0^+(i)$ and the alternative i backward indicator vector $0^-(i)$ are those vectors whose kth components are given by

$$(0^+(i))_k = \begin{cases} 1 & \text{if alternative } k \text{ is ranked} \\ & \text{lower than alternative } i, \\ 0 & \text{otherwise,} \end{cases}$$

$$(0^-(i))_k = \begin{cases} 1 & \text{if alternative } k \text{ is ranked} \\ & \text{higher than alternative } i, \\ 0 & \text{otherwise.} \end{cases}$$

The consensus model arising from this object based extension of Blin is the quadratic assignment problem:

Maximize

$$\sum_{\ell=1}^{m}\sum_{i=1}^{n}\sum_{k=1}^{n}\sum_{j=1}^{n} p_{ik}^{-\ell} x_{ij} \sum_{t=j+1}^{n} x_{kt},$$

Subject to

$$\sum_{i=1}^{n} x_{ij} = \sum_{j=1}^{n} x_{ij} = 1, \quad x_{ij} \geq 0 \quad \text{for all } i,j,$$

where

$$\bar{p}_{ik}^{\ell} = \sum_{t=j_i(\ell)+1}^{n} p_{kt}^{\ell}.$$

Some Comparisons

An issue which a number of authors have addressed has to do with the likelihood of different criteria giving rise to the same outcome (same winner or same consensus ranking). Fishburn, for example, has carried out a simulation study comparing Borda's method with that of Copeland. In this particular study, various combinations (n, m) were examined (n = number of voters and m = number of alternatives) from $n = 3-21$ and $m = 3-9$. For each such combination, 1000 cases were generated. A uniform distribution of ranked votes was assumed in carrying out the simulations. In comparing the two consensus methods, the issue was whether the winning candidates matched (2nd, 3rd, ..., etc. place standings were not compared).

Fishburn has found, for example, in the case of 21 voters and 3 alternatives, that in 81.8% of the 1000 cases examined, all winners via Borda (i.e., the set of alternatives tied for 1st place) were also the winners in Copeland and vice versa. In 12.8% of the cases at least some Borda winner matched a Copeland winner (but not all winners under Borda matched all Copeland winners). Finally, in the remaining 5.4% of the 1000 cases, no Borda winner was a Copeland winner.

The 3-Alternative Case

In the 3-alternative case, the six possible linear ordering of the 3 alternatives are assumed to follow a Dirichlet distribution. Figure 4 illustrates the shape of this distribution for $n = 3$. This single peaked distribution is particularly instructive in that there is a relative independence among options. At the same time, it is sufficiently general to permit a number of possible shapes.

For the 3 alternative case, and under the assumption of Dirichlet distributed rankings, it can be shown that the pairwise majority rule model always results in a transitive ranking. Thus, Copeland and majority rule are equivalent. It can also be shown that all of the aforementioned runoff or elimination methods will yield the same consensus ranking as well.

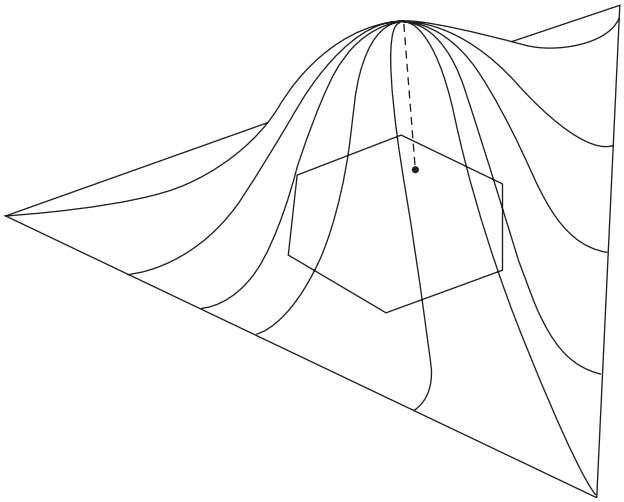

Figure 4 The Dirichlet distribution.

The General Case

Cook *et al*. examine the general case for n alternatives. For this case, let $\{R^\ell\}_{\ell=1}^{n!}$ denote the space of ordinal rankings, and $\{P^\ell\}_{\ell=1}^{n!}$ the corresponding proportions of voters (probabilities of the $n!$ rankings being chosen). Further, define the index set $M_{ij} = \{\ell \,|\, a_i^\ell < a_j^\ell\}$. Here, a_i^ℓ denotes the position assigned to alternative i by the ℓth voter. That is M_{ij} is the set of all rankings in which alternative i is preferred to alternative j. Note that $M_{ij} 1 M_{ji} = \phi$ and $M_{ij} \chi M_{ji} = \{1, 2, \ldots, n!\}$. With this notation, voter responses are said to be transitive if there exists an ordering of the n alternatives (assume this is say the natural ordering $(1, 2, \ldots, n)$) such that

$$\sum_{\ell \in M_{ij}} P^\ell > \sum_{\ell \in M_{ji}} P^\ell \quad \text{for all } i,j \text{ where } i<j.$$

Clearly, if such a transitivity property holds, then the consensus under pairwise majority rule (and Copeland's model) is the natural ordering

$$(r_1, r_2, \ldots, r_n) = (1, 2, \ldots, n).$$

In order to evaluate the Borda model, it is necessary to define another form of transitivity. Partition the index set M_{ij} into a series of different sets or levels. Formally, we define for alternatives i and j $(j\ i)$ the set of difference c (or level c) by

$$L_c = \{\ell \,|\, a_i^\ell - a_j^\ell = c\}.$$

Note that $M_{ij} = \cup_{c=-1}^{1-n} L_c$ and $M_{ji} = \cup_{c=1}^{n-1} L_c$.

Definition 4. Voter responses are said to be weighted transitive if there exists an ordering of the n objects such that

$$\sum_{c=1}^{n-1} c \sum_{\ell \in L_{(-c)}} P^\ell > \sum_{c=1}^{n-1} c \sum_{\ell \in L_c} P^\ell,$$

for all i, j where $i < j$.

Theorem 1. Under the condition that voter responses follow a Dirichlet distribution, transitivity on levels is always present, and Simple Majority Rule, Borda's method and Copelands method are equivalent.

Concluding Comments

Ordinal data in day to day decision making settings is a naturally occurring phenomenon. To deal with such data, numerous formats for its representation and models for aggregating responses have been developed. Many papers and books have been written on this subject including Cook and Kress. Many of the methods for dealing with data of this type have arisen over centuries in parliamentary voting settings. Others find their genesis in mathematical and social science settings, where axiomatic structures have been advanced to properly characterize consensus of opinions. This article attempts to capture some of these ideas.

Rapid Assessment Process

James Beebe
Gonzaga University, Spokane, Washington, USA

Glossary

bogus empowerment Letting people think they have control over outcomes and the power to act on their own judgments when they actually do not have this control or power; occurs whenever someone is asked for their input but there are no intentions of using it.

ethnography A descriptive study of an intact cultural or social group or an individual or individuals within the group, based primarily on participant observation and open-ended interviews; based on learning from people as opposed to studying people.

iterative process A process in which replications of a cycle produce results that approximate the desired result more and more closely. For rapid assessment, the process describes the cycle of data analysis and data collection, designed to produce a preliminary understanding of a situation from an insider's perspective.

participants Persons interviewed as part of the rapid assessment process. The term can be used interchangeably with "informants" or "respondents" when these terms are not modified with the words "individual" or "key." The term "subjects" is generally avoided.

rapid appraisal, rapid rural assessment, rapid rural appraisal (RRA), participatory rural appraisal (PRA) Different types of rapid qualitative research based on small multidisciplinary teams using semistructured interviews and direct observations to collect information in processes that can be completed in less than 6 weeks. As often implemented, these approaches may lack some of the methodological rigor of rapid assessment.

rapid assessment process (RAP), rapid assessment Intensive, team-based qualitative inquiry using triangulation, iterative data analysis, and additional data collection to quickly develop a preliminary understanding of a situation from the insider's perspective. Rigor is achieved by the use of multidisciplinary teams for both data collection and analysis; explicit use of an iterative process for data collection, analysis, and additional data collection; a defined role for "insiders" in the research team; member checking; documentation of the process, and attention to ethics.

triangulation A term from navigation and physical surveying that describes an operation for determining a position by use of bearings from two known fixed points. Triangulation is used as a metaphor by social scientists for the use of data from different sources, the use of several different researchers, the use of multiple perspectives to interpret a single set of data, and the use of multiple methods to study a single problem.

Rapid assessment allows a team of at least two researchers to develop a preliminary understanding of a complicated situation in which issues are not yet well defined. Rapid assessment is especially relevant when an insider's perspective is needed, and there is not sufficient time or other resources for long-term, traditional qualitative research. Rapid assessment is a type of participatory action research. It shares many of the characteristics of ethnographic research. However, rapid assessment, uses intensive, team interaction and multiple cycles of data collection followed by data review/analysis, instead of the prolonged fieldwork normally associated with traditional qualitative research. Results can be used for planning, monitoring, and evaluating activities and for the design of additional research. Rapid assessment will almost always produce results in a fraction of the time and at less cost than is required by traditional qualitative research.

Introduction

Rapid assessment is defined as intensive, team-based qualitative inquiry using triangulation, iterative data analysis, and additional data collection to quickly develop

a preliminary understanding of a situation from the insider's perspective. Data is collected by talking with people and getting them to tell their stories. The acronym for the rapid assessment process, "RAP," expresses well the need to communicate with participants using their vocabulary and rhythm and one definition of "rap" is "to talk freely and frankly." "Rapid" means a minimum of 4–5 days and, in most situations, a maximum of 6 weeks. Responding to the need for almost immediate results involves compromises and requires special attention to methodological rigor. "Process" means a series of actions or operations conducive to an end. A process approach suggests that at least as much attention is given to the way results are obtained as to the results. References to rapid appraisal, rapid rural assessment, rapid rural appraisal, participatory rural appraisal, and the acronym RAP have been widely used in the literature to identify different rapid qualitative research methods. Not everything labeled "rapid assessment" meets the methodological rigor of the rapid assessment process.

Evolution, Current Status, and Relationship to Other Approaches to Rapid Qualitative Research

Rapid assessment has its roots in farming systems research of the late 1970s. Farming systems research was based on a holistic consideration of people along with their plants and livestock and started with the assumption that local systems consisted of mutually related elements that constitute a whole. A systems approach initially considers all aspects of a local situation, but quickly moves toward the definition of a model that focuses on only the most important elements and their relationship to each other from the perspective of the local participants. In the initial research on local farming systems, neither research tourism or questionnaire survey research were able to produce solid and timely results. A 1979 paper by Peter Hildebrand described a farming systems research approach based on teamwork called "sondeo." His paper, along with others, had been presented at the 1979 Rapid Rural Appraisal conference at the Institute of Development Studies at the University of Sussex. Because of the title of the conference, "rapid rural appraisal," along with variants, including "rapid appraisal" and "rapid assessment," became associated with rapid qualitative team-based research. The publication of the *Proceeding of the 1985 International Conference on Rapid Rural Appraisals* by the Khon Kean University in 1987 made information available to a wider audience. Robert Chambers and his colleagues at the Institute of Development Studies have been at the forefront of formulating and disseminating information on rapid research methods for the past two decades. Significant publications have included Chamber's *Shortcut and Participatory Methods for Gaining Social Information for Projects*, Krishna Kumar's *Rapid Appraisal Methods*, Nevin Scrimshaw and Gary Gleason's *Rapid Assessment Procedure: Qualitative Methodologies for Planning and Evaluation of Health Related Programmes*, John Van Willigen and Timothy Finan's *Sounding: Rapid and Reliable Research Methods for Practicing Anthropologists*, and James Beebe's *Basic Concepts and Techniques of Rapid Appraisal* and *Rapid Assessment Process: An Introduction*. Despite differences in details, all of the different rapid qualitative research methods are based on small multidisciplinary teams using semistructured interviews, direct observation, and other techniques to collect information, with the entire process being completed in less than 6 weeks.

There is increasing use of rapid qualitative research methods as planning and evaluation tools in a variety of fields. More than 50 examples illustrate the range of topics that have been investigated using rapid research methods in areas as diverse as agriculture, community and rural development, conservation and natural resources, health and family planning, and marketing. These examples also illustrate how groups and organizations that have used these methods, and the extent to which the methods have been adapted to meet different needs. Increased recognition of a need for qualitative research has encouraged the use of rapid research methods as resources available for traditional long-term qualitative research have declined. A growing consensus on the need for participatory approaches to research activities has also contributed to expansion of rapid research methods. Chambers has observed that anticipatory language has become obligatory "donor-speak." Current issues concern the extent to which rapid qualitative methods should be participatory as well as how participation is implemented. The contrast of rapid assessment with participatory action research, and especially participatory rural appraisal (PRA) associated with Robert Chambers, illustrates these issues. In response to different needs, these approaches have evolved in different ways, with participatory action research focusing more on the empowerment of local participants who do research to satisfy local needs, and rapid assessment focusing more on methodological rigor and the involvement of decision makers at different levels. The two approaches complement each other and share methodological techniques. Rapid assessment differs from numerous forms of participatory action research by explicitly recognizing that in many situations local participants do not have control over the resources necessary for change. Rapid assessment intentionally involves decision makers in the research process and attempts to ensure sufficient rigor for credibility with decision makers.

The lack of methodological rigor has been one factor in the limited use of rapid qualitative research methods for research published in peer-reviewed journals. Publication in peer-reviewed journals continues to be viewed as validating research that contributes to the body of knowledge. Chambers has lamented that calling research methods rapid has "been used to justify and legitimize sloppy, biased, rushed, and unself-critical work." Rapid assessment explicitly deals with methodological rigor.

Questions raised by some anthropologists regarding the legitimacy of rapid research methods have limited their use. Almost all descriptions of ethnography refer to a requirement for prolonged fieldwork. There has been an unfortunate tendency to equate time with quality and to dismiss rapid results with pejorative phrases such as "quick and dirty." The case for prolonged fieldwork advanced by anthropologists such as H. Russell Bernard and Harry F. Wolcott is based on tradition and the argument that it takes times to develop intellectualized competence in another culture, to be accepted, to develop rapport, to be included in gossip, and to get information about social change.

Basic Characteristics

"Rapid" means producing results in 1 to 6 weeks. There is growing consensus among practitioners that completion of data collection, data analysis, additional data collection and the preparation of a report requires at least 5 days. "Rapid" does not mean "rushed." Schedules must be flexible to allow the team to take advantage of the unanticipated. Rapid assessment uses the techniques and shares many of the characteristics of ethnography, but differs in two important ways: (1) more than one researcher is always involved in data collection, with data triangulation based on teamwork, and (2) more than one researcher is involved in an iterative approach to data analysis and additional data collection. The intensive teamwork is necessary because of the shortened fieldwork.

Data Collection: Triangulation and Intensive Teamwork

The Team and Teamwork

Between two and six individuals are usually on the RAP team, and teams need to be multidisciplinary, diverse, and include at least one "insider" as well as "outsiders." The assumption is that two sets of eyes and ears are better than one and that the use of different techniques can help make the best use of the extra eyes and ears as part of intensive teamwork. The assumption is also that two heads are better than one in figuring out what has been seen and heard and for deciding on the next steps. Sensitivity to cultural differences is essential and team diversity improves cultural sensitivity and helps establish credibility with local communities. Whereas traditional research methodology has focused on helping outsiders to better understand insiders' knowledge, there is a growing appreciation of the role insiders should play in the design, implementation, and publication of research. The ability of the RAP team to quickly develop a preliminary understanding of a situation, from the perspective of the local participants, is facilitated by having an insider on the team. The insider needs to be a full team member and must be involved in planning, data collection, data analysis, and the preparation of the report.

Rapid assessment depends on teamwork and cannot be done by one person. All team members should be involved in data collection and data analysis, including the preparation of the report. Teamwork by a multidisciplinary team increases sensitivity to the insiders' categories and definitions. Because of the importance of team interaction, the RAP team should be together most of the time.

Directed Conversation (Semistructured Interviews)

The most important way of learning about local conditions is to get local people to tell what they know. The goal is to get people to talk on a subject and not simply answer questions. This process is often identified as a "semistructured interview," but it is better thought of as directed conversation. Directed group discussions involve the entire team interacting with each other as well as with the respondent. This is not sequential interviewing by individual team members. Relaxed, semistructured interviewing provides respondents with time to think and helps elicit stories.

Experience has shown the value of opening the conversation with a carefully articulated "grand tour" question. All RAP team members need to be active listeners. The grunts and noises the team members make as active listeners, such as the "umms," "uh-huhs," and "mmmmmms," improve rapport and encourage people to speak longer. The conversation is kept moving and on-track with probes that do not inject the views of the team. Nondirective probes are culture specific and need to be identified prior to conducting the first interview. Examples of nondirective probes that work in a United States cultural setting might include "Give me a description of . . . Tell me what goes on when you . . . Describe what it's like to . . . Say more, keep talking." The RAP team will likely want to develop short guidelines based on a few big issues. Guidelines are used instead of a list of questions prepared in advance of the conversation. Despite the guidelines, the direction of the study should emerge as information is collection. Guidelines should be viewed as a reminder of issues that should

not be missed, rather than as an agenda to be diligently worked through.

The RAP team purposefully selects individuals for directed conservations. Consistent with qualitative research, they are identified as "participants" or "respondents" and not as "subjects." They are not a sample. They are selected not because they are believed to be average, but because they are believed to represent the diversity found in the local situation. The RAP team should seek out the poorer, less articulate, more upset, and those least like the members of the RAP team.

Other Techniques for Data Triangulation

In addition to semistructured interviewing other specific research techniques for use in a given rapid assessment are chosen from among a wide range of techniques, based on the specific topic being investigated and the resources available. Observations and team interaction with respondents, based on what is seen and heard, are necessary. All interviews should be conducted in a relevant setting where listening can be combined with observing. Anthropologists note that participant observation can range from actually living and working in the field as a member of group over an extended period of time, to simply being an observer. The essential requirements for participant observation are that people must feel comfortable with the presence of the team. Even during a rapid assessment, there are opportunities for observing. Team members should try to be present at relevant times outside of normal business hours, including early morning and late evenings and weekends. Sharing of meals with respondents provides opportunities for combining observations with informal discussions and follow-up.

Groups of respondents as well as individual respondents can be interviewed using techniques associated with focus group research. Folktales, myths, songs, proverbs, riddles, and jokes can provide insights to local situations. Drawing diagrams and "rich pictures" allows respondents to express themselves in ways that are often more valid than talk. Maps drawn by respondents can be used for collecting data and planning action.

Field Notes, Transcripts, and Logs

Among social scientists, there is considerable disagreement on what constitutes field notes and how they should be organized. Because more than one person is involved in collecting and processing field notes, all parties need to agree on the format. The term "field notes" probably should be reserved for the usually handwritten notes prepared as data is being collected. Field notes must be readable by the person who wrote them and should clearly differentiate between (1) what has actually been said by the respondents and observed by the team and (2) comments by the researchers, including reflections, thoughts about conclusions, and other notes. Field notes need to include detailed observations and direct quotations, as opposed to summaries. Carefully done field notes can help the team avoid imputing false meaning. Field notes should include information about the interview process and should identify things that need to change during subsequent interviews. All team members should take notes, including the team member who is directing the conversation at any given moment. Note taking becomes a way to control the speed of the conservation and gives both the team members and the respondent time to think. Field notes should also include descriptions of the settings, who else was present, the overall demeanor of the respondent, and nonverbal communications such as a smile or yawn.

Interviews should always be taped unless the respondents specifically object to the use of a tape recorder. The written version of what has been recorded is usually identified as a "transcript." Ideally, transcripts should be made available to the team within 24 hours. Transcripts are not field notes. Even when there are not plans to transcribe interviews, tapes can be used to fill in missing information. Tape recorders should be expected to fail and should never be used in place of note taking.

The "log" is a combination of the field notes, the transcripts, and the reflections of the researchers in a format ready for analysis. When transcripts are not available, the log created from the different field notes of the team. Logs are most useful if they are typed (double-spaced), with every sentence beginning on a new line and with very wide margins on both sides. Many researchers place codes in the left margin and comments in the right margin. Anything in the log that is not a direct observation should be clearly identified. Logs should be prepared within 24 hours of the interview. Preparation of the log allows the team to carefully examine what has been heard and to consider explicitly the insider's perspective. This review also provides an opportunity to consider changes that need to be made in the next round of data collection, including changes in the way the interview was implemented.

Iterative Analysis and Additional Data Collection

Rapid assessment explicitly divides research time between blocks used for collecting information and blocks when the RAP team does data analysis and considers changes in the next round of data collection. Beginning on day 1, time is scheduled for team interaction. Usually more time is spent on team interaction than on data collection. An iterative process is defined as a process in which replications of a cycle produce results that approximate the desired result more and more closely. The constant shifting between data analysis and additional

data collection is an iterative, or recursive, process. For rapid assessment, the replication of the process of data collection, followed by analysis and additional data collection, contributes to the goal of understanding the situation under investigation from the perspective of the local participants.

Just as there is no one best way for data collection, there is no one best way for analysis. An approach that has worked for many rapid assessments and that can serve as a beginning point for modification is based on Matthew Miles and A. Michael Huberman's model. This model involves (1) coding the data and adding marginal remarks, (2) displaying the data, and (3) drawing conclusions. For rapid assessment, as for qualitative research in general, analysis is an ongoing process that begins with, or even before, the first round of data collection and continues through the preparation of the report.

Coding

The logs, combining the field notes of all members of the RAP team and, when available, the transcripts of the directed conversations, are the source of the data for understanding the situation from the perspective of the respondents. The first step in the analysis process is to read the logs several times. The next step is dividing the log into thought units and applying codes to these units. A unit of thought may be a sentence, paragraph, several paragraphs, or even an individual word. Coding can be thought of as cutting the logs into strips and placing the strips into piles. The codes are the labels that the RAP team gives to the individual piles. Developing a coding system is based on trial and error. The coding system should remain flexible enough that codes can be added, combined, and removed as needed. The RAP team looks for threads that tie together bits of data and seeks to identify recurring words or phrases. These words often become the labels for the codes. Not everything in the log is coded and a single unit of thought will often have multiple codes. The team can always change the codes. Experience suggests it is better to start with only five or six codes and to then subdivide these when necessary.

After codes have been assigned, the next step is to consolidate everything relating to each code. Materials from all interviews, as well as other observations relating to codes, can then be considered together. Cut-and-paste functions of word-processing programs facilitate this process, but should be done with care to ensure that thought units are associated with specific interviews. Adding margin remarks is closely related to the coding process and occurs both before and after materials have been rearranged according to their codes. Margin remarks are usually written into the margin of the log after it has been typed and can include RAP team reactions, questions about the meaning of statements, and notes about connections between parts of the data, etc.

Data Display

The second aspect of analysis is data display. Development of data displays should begin during the coding and continued throughout the research process. Data displays are often drawn on large sheets of paper such as flip charts, and include matrices, graphs, words, and drawings of objects linked by lines, suggesting relationships. "Rich pictures" can be used as data displays.

Drawing Conclusions

The third element in the data analysis process is conclusion drawing and verification. Miles and Huberman suggest that people can make sense of the most chaotic events, but that the critical question is whether the meanings they find in qualitative data are valid. They identify 13 tactics for generating meaning. The first six of these are descriptive and provide a good beginning point for rapid assessment. The first three identify connections and concern (1) patterns and themes, (2) seeking plausibility, and (3) clustering. The next three sharpen understanding and include (4) metaphor making, (5) counting, and (6) making contrasts and comparisons.

Member Checking

Before conclusions are final, the RAP team should share them with the people who provided the information and check for their agreement. This can be done either formally or informally. The local people can provide corrections to facts and their own interpretation of the situation. This process is often called "member checking."

Preparation of the Report by the Entire RAP Team

The joint preparation of the rapid assessment report by the entire team continues the intensive team interaction. The preparation of the report should start while there is still time for additional data collection. The involvement of the entire team, including the local members, provides the report with more depth than is often found in reports prepared by a single individual.

The RAP Sheet

One of the major challenges for rapid assessment is promoting flexibility and creativity without diminishing rigor. Rigor can be enhanced by agreement on basic principles, and then documentation, as part of the rapid assessment report, of the specific techniques used. The documentation on what was actually done can be summarized in a checklist, called a "RAP sheet." The RAP sheet is attached to the report and can include information about team members, hours of data collecting, hours of team interaction discussing the data, types of information collected by direct observations, the number of individuals interviewed, methods of selection of respondents, places of

interviews, and specific information about the diversity of the respondents interviewed. The RAP sheet allows the reader of the report to judge the quality of the work.

How Much is Enough?

Every RAP team will face the question of how much information is needed, how much time should be spent in the field, and how many interviews are sufficient. The data is sufficient when themes begin to repeat. Experience shows that when interviews have been relaxed and sufficient time has been spent by the team making sense out of the data that are collected, themes often began to repeat after 8 or 10 interviews. The actual number of interviews needed can be significantly more than this, but is usually not less. It is usually easier for the team to recognize when data is insufficient than when enough data has been collected.

Ethics, Participation, and Bogus Empowerment

There is widespread consensus on the value of participation. As discussed earlier, rapid assessment is a participatory research approach. However, ethical issues related to participation are often ignored. These issues are almost always aggravated by an inappropriate belief that problems must be identified and solved at the local level, without the involvement of outsiders. Unlike some forms of participatory action research, RAP does not assume that the study population can unilaterally solve its own problems. Decision makers and authorities higher in the system who control resources often need to be members of the RAP team in order to feel committed to the outcome of the research and as stakeholders are more inclined to take action. Even when outside decision makers are not part of the research effort, it is critical that the research effort be designed with sufficient rigor to allow outsiders to have confidence in the results.

The most serious negative consequence of an excessive focus on participation is shifting responsibility for change onto the poor and outsiders relinquishing their responsibilities. Even when such a shift does not occur, discussing problems can raise unrealistic expectations in local communities that the problems will be addressed. Closely related to raising unrealistic expectations is what Joanne Ciulla has called "bogus empowerment." Several aspects of bogus empowerment are especially relevant to rapid assessment. Both the RAP team and those responsible for bringing in the RAP team must keep their promises. The best way to do this is to make promises that can be kept. Everyone involved in rapid assessment needs to be clear about the often limited power of the local community and must avoid the temptation of engaging in hyperbole about the democratic nature of the situation. Rapid assessment also can be an accessory to bogus empowerment by encouraging people to believe falsely that actions will be taken in response to their input.

Learning to RAP

For individuals who have had limited experience with qualitative techniques, there is a need to provide a strong rationale for, and an introduction to, qualitative research. For individuals with a background in qualitative research, there is a need to enhance their understanding of ways in which rapid assessment differs from traditional approaches. There is general consensus among practitioners that rapid assessment is best learned while participating as a team member with someone with experience. However, because rapid research methods are "organized common sense," they can be self-taught. From reading reports by others, it is possible to learn about the methodology and to acquire realistic expectations. Copies of reports, information on the availability of workshops about rapid assessment, additional references, and useful tools are available on the rapid assessment website (www.rapidassessment.net). Rapid assessment uses many of the techniques of traditional qualitative research, and reference books on qualitative research can be very useful. To begin experimenting with rapid assessment, all that the RAP team needs to remember is that the goal is to talk with people and to get them to tell their stories, as opposed to answering the questions of the team.

A combination of brief introductions to qualitative research techniques and a willingness to listen intently and genuine respect for others can help a RAP team get started. Everyone on the RAP team needs to recognize that (1) they do not know enough in advance to even know what questions to ask and (2) they do not know enough to provide answers, but (3) they do know enough to want to empower others to solve their own problems.

Plausible Directions for the Future

The accelerating rate of change in the world and a lessening of financial support for long-term research have driven the increasing interest in rapid assessment. Limited resources often are better used to provide needed services rather than to support traditional research. There is growing recognition of the relationship between leadership and the creation of organizations based on participation. Rapid assessment can be an important tool for leaders because of its ability to promote participation and to help create learning

organizations. Rapid assessment has tremendous potential. The major challenges to rapid assessment include overselling it, confusing "rapid" with "rushed," and failing to implement it rigorously. If these challenges can be met, rapid assessment may be an idea whose time has come.

Rare Events Research

Will Lowe
Harvard University, Cambridge, Massachusetts, USA

Glossary

relative risk The proportional increase in the probability of an event between two values of an independent variable.
response-based sampling A biased sampling scheme in which data are selected on the dependent variable.
risk difference The difference in the probability of an event between two values of an independent variable.

State collapse, the outbreak of war, and cases of rare diseases are events that occur very infrequently in a population, but are of considerable interest when they do. Rare events cause particular problems for statistical models, such as logistic regression, that are used to understand and predict them: a small random sample is unlikely to contain enough instances of the rare event to make reliable inferences, but a sample large enough to ensure a reasonable number of rare events may be prohibitively expensive to collect. Schemes that ensure samples with a balance of event types are easily found, but except in special circumstances, applying standard estimators to data generated this way leads to inconsistency. In addition to sampling scheme issues, maximum likelihood estimators are well known to be biased in samples of less than 200 observations. Less well known is that small sample problems can occur when one value of the dependent variable is rare, even in very large data sets. Bias and inconsistency in parameter estimation lead to unsound estimates of the quantities of substantive interest: estimates of conditional probability, relative risk, and risk difference. Rare events research methods are designed to resolve these closely related issues by showing how to fit models while maintaining consistency under biased sampling schemes and by generating appropriate small sample corrections.

Introduction

We focus on the following simple system. $P(Y, X)$ is a joint distribution over event types and covariate values. $P(Y)$ is a discrete distribution over M possible event types, any one of which may be rare. In the case of predicting the outbreak of war, $M = 2$ and the probability of war $P(Y = 1)$ is much smaller than the probability of peace $P(Y = 0)$. $P(X)$ is a distribution of possibly real-valued independent variables thought to be useful for predicting or explaining Y. Although $P(X)$ is typically unknown, we are willing to entertain a parameterized model of the relationship between Y and X, $P(Y \mid X; \beta)$. Because this model very often takes the form of a multinomial logit, we shall concentrate on results for this model class.

Substantive interest centers on the fitted model's estimates of $\pi = P(Y \mid X)$ because these quantify the effect of covariate changes on Y, both by themselves and as part of relative risk and risk difference statistics. We are interested in consistent, and preferably efficient and unbiased, estimates of β primarily as a means to this end.

In the next section the choice of biased sampling schemes available for rare events researchers is reviewed. The following section considers a range of estimators for β that are consistent under biased sampling schemes. In addition to sampling scheme issues, rare events data suffer from finite sample bias in maximum likelihood estimation. We consider two debiasing parameter estimators to address this problem. Separate issues arise in the estimation of π itself; three estimators for this task are considered. With a fitted model finally in hand, the final section shows how risk quantities can be estimated under varying amounts of information about $P(Y)$.

Sampling Schemes for Rare Events

In the following, the distribution of a sample under some sampling scheme is called H(Y, X). In the simplest case of simple random sampling from the population, H(Y, X) = P(Y, X). Alternatively, it may be more practical to define blocks of observations based on values of X and take subsamples within them. In this case, H(Y, X) = P($Y \mid X$) H(X) $\neq$ P(Y, X). Both of these schemes are exogenous sampling schemes. They share the property that maximizing the joint likelihood function P(Y, X; β) with respect to β is equivalent to maximizing only the conditional part, leading to

$$\text{argmax}(\beta): \sum_{i=1}^{N} \ln P(y_i \mid x_i; \beta). \tag{1}$$

This estimator yields maximum likelihood estimates with entirely classical properties. The equivalence holds when there is selection on X because although H(X) $\neq$ P(X), β does not depend on P(X), allowing P(X) to drop out.

Unfortunately exogenous sampling schemes can be highly inefficient for studying rare events. In small sample sizes, the rare events may not appear at all, or not sufficiently often to provide reliable parameter estimates. Indeed, the rarer the event, the more information is provided by its occurrence. In logistic regression, for example, the covariance for β is

$$\text{Var}(\hat{\beta}) = 1 \Big/ \sum_{i=1}^{N} \pi_i(1-\pi_i)\mathbf{x}\mathbf{x}'. \tag{2}$$

In a model with well-chosen covariates, π_i, and therefore $\pi_i(1-\pi_i)$, will be larger for rare events than for common ones. Thus, the variance shrinks more for rare observations, and does so in proportion to how rare they are. Sample sizes large enough to guarantee a reasonable number of rare events may also be prohibitively expensive to collect and will be unbalanced, exacerbating finite sample bias.

An alternative endogenous sampling scheme is to divide Y into blocks and sample within each block. Because Y is a decision, outcome, or response variable, sampling schemes that select on Y are referred to as response-based sampling. For response-based sampling, H(Y, X) = P($X \mid Y$)H(Y). This makes standard maximum likelihood approaches inconsistent. To see this, note that for a sample of size D,

$$P_D(Y \mid X) = P_D(X \mid Y)\frac{P_D(Y)}{P_D(X)} \tag{3}$$

converges in distribution to

$$P(X \mid Y)\frac{P(Y)}{P(X)} = P(Y \mid X). \tag{4}$$

The corresponding sample version

$$H_D(Y \mid X) = H_D(X \mid Y)\frac{H_D(Y)}{H_D(X)} \tag{5}$$

does not converge to

$$P(X \mid Y)\frac{P(Y)}{P(X)} = P(Y \mid X). \tag{6}$$

This is because H(Y) $\neq$ P(Y) by design and will not converge to it, irrespective of sample size. Consequently, P($Y \mid X$) cannot be consistently estimated from response-sampled data without a correction that makes use of information about P(Y) from outside the sample.

Estimators for Response-Based Samples

A wide range of estimators are available for maximum likelihood estimation in response-based samples. However, in the special but substantively important case of multiplicative intercept models such as logistic regression, these choices reduce to two: weighting and intercept correction.

The Weighting Estimator

The weighted exogenous sampling maximum likelihood estimator (WESML) replaces Eq. (1) with

$$\text{argmax}(\beta): \sum_{i=1}^{N} w_i \ln P(y_i \mid x_i; \beta), \tag{7}$$

where w_i = P(y_i)/H(y_i). With a slight abuse of notation, P(y_i) refers to the probability of seeing an observation with the same Y-value as that of the ith sample value. H(y_i) is the corresponding probability under a response-based sampling scheme. Thus, when $M = 2$, and one-quarter of the sample data are expected to have $Y = 1$, P(y_i) = 0.25 whenever $y_i = 1$ and 0.75 otherwise.

The WESML estimator is consistent and asymptotically normal. Replacing the expected proportions from the response-based sampling scheme H(y_i) with their sample values makes the estimator more efficient. Although WESML is essentially a weighted version of the regular maximum likelihood approach, regular standard errors should be computed using White's heteroskedasticity-consistent variance matrix.

The Intercept Correction Estimator

Three other estimators are available for response-based samples: Manski and McFadden have provided a conditional maximum likelihood, and described a more efficient full information approach. A generalized method of moments estimator is also available. All these methods are consistent and asymptotically efficient. Rather than pursue the detail of each estimators, it is most useful to note that for multiplicative intercept models, the three estimators coincide. Morever, they may be computed by fitting the model to response-based sample data as if they were exogenously sampled, and then adjusting the model's intercept parameter. In the case of $M = 2$, the new intercept takes a particularly simple form:

$$\hat{\beta}_0 - \ln\left[\left(\frac{\mathrm{P}(Y=0)}{\mathrm{P}(Y=1)}\right)\left(\frac{\mathrm{H}(Y=1)}{\mathrm{H}(Y=0)}\right)\right]. \qquad (8)$$

In fact, in this class of models, non-intercept coefficients are consistently estimated under both exogenous and response-based sampling schemes. The intercept correction estimator is consistent and asymptotically efficient. By comparison, WESML is slightly less efficient but less sensitive to model mispecification. For this reason it may be preferable for social scientific applications.

Although both WESML and intercept correction assume perfect knowledge of P(Y), their statistical properties are the same when an independent sample is available from which P(Y) may be consistently estimated.

Response-Based Sample Design

Researchers using response-based sampling methods for rare events data should normally choose H(Y) to be an equal division among Y categories. For, although an optimal splitting value for rare and common response categories will always exist, it is essentially impossible to determine in advance. Luckily, Monte Carlo studies suggest that a sampling procedure giving each value of Y an equal number of cases in the sample is seldom far from optimal across a range of parameter values and estimators, including WESML. A balanced sample has the added advantage of minimizing finite sample problems in maximum likelihood estimation.

Finite Sample Corrections

Standard maximum likelihood estimators for β in multiplicative intercept models yield consistent and asymptotically efficient estimates. However, in finite samples they are biased. Two related methods for correcting finite sample bias in generalized linear models are available.

McCullagh and Nelder provided a somewhat complex but easily calculated direct correction to the maximum likelihood estimate of β by using a second regression. This correction has the advantage of reducing variance as well as bias. One disadvantage of this correction is that because it is applied after estimation has finished, it provides no protection from the infinite parameter values that arise from perfectly separable data, a particular risk for small samples and rare events.

Approximately the same debiasing effect can be obtained by fitting a model using Jeffreys' non-informative prior and taking the maximum *a posteriori* value of β. A non-Bayesian interpretation of this method is as the minimization of the penalized likelihood

$$\text{argmax}(\beta)\colon \ln \mathrm{P}(Y \mid X;\, \beta) + \frac{1}{2} \mid I(\beta) \mid, \qquad (9)$$

where $I(\beta)$ is the Fisher information matrix. This method guarantees finite parameter estimates even when data are perfectly separable.

Bias, like inconsistency in response-based sampling, primarily affects the intercept term. For example, in a model with a single fixed covariate coefficient and intercept, the intercept bias is approximately, $(\bar{\pi} - 0.5)/N\bar{\pi}(1-\bar{\pi})$, where $\bar{\pi}$ is the average estimated conditional probability in the sample. For events of probability less than one-half, this bias is negative. Consequently, the intercept, and therefore the estimated marginal probability of $Y = 1$, will be too small.

Whichever approach is taken, debiasing corrections should always be used in place of the standard maximum likelihood estimate.

Estimating P($Y \mid X$; β)

The preceding corrections affect parameter estimates. However, the aim of parameter estimation is to generate reasonable estimates of π conditioned on covariates. But there is a separate choice to make when estimating π. In a non-linear model such as logistic regression, simply inserting a debiased estimate of β into a logistic regression model does not generate a similarly unbiased estimate of π. This is a quite general problem with unbiased estimators; an unbiased estimator may not exist, and if it does, functions of unbiased estimator may not be unbiased themselves.

An Approximately Unbiased Estimator

In order to reduce bias in π_i it is necessary to subtract

$$C_i = (0.5 - \pi_i)\pi_i(1-\pi_i)\mathbf{x}'_i\mathrm{Var}(\beta)\mathbf{x}_i \qquad (10)$$

from each estimated conditional probability. However, considerably better estimators of π, in a mean square error sense, are available.

A Semi-Bayesian Estimator

An easily computable alternative is King and Zeng's semi-Bayesian estimator. Logistic regression assumes a linear predictor determines the mean value of an unobserved logistic distribution $p(Y^*)$. When this distribution generates a value greater than zero, a one is observed, otherwise a zero. π is then equal to $p(Y^* > 0)$. In a Bayesian treatment, uncertainty about β, as expressed in its posterior covariance, must be integrated out of estimates of π as

$$\pi = \int \mathrm{P}(y \mid x, \beta)\mathrm{P}(\beta)\, d\beta; \tag{11}$$

where P(β) is assumed to be normally distributed with the mean and variance of the distribution of $\hat{\beta}$. Identifying the sampling distribution of $\hat{\beta}$ with a posterior distribution leads to the same numerical results as when a non-informative prior is used, for example, using Firth's estimator. Of course, the interpretation is quite different, but here the estimator's performance is evaluated in terms of its sampling properties.

For distributions of β with significant variance, this integration leads to a wider distribution of Y^*, so a larger proportion of $p(Y^*)$'s support will be greater than zero than if a single value of β had been used. Consequently, the semi-Bayesian estimator increases the estimated value of π. Surprisingly, the amount of probability increase is approximately C_i. Intuitively, C_i grows with sampling distribution, and its direction is provided by the first term. Thus, for rare events, the debiasing estimator decreases π_i and the semi-Bayesian estimator increases it, in about equal degrees.

Of these estimators, the semi-Bayesian estimator, which trades bias for substantially decreased variance, is to be preferred on mean square error grounds. The unbiased estimator is preferred only if there is a compelling reason to demand unbiased estimation. Finally, Monte Carlo studies suggest that the maximum likelihood estimator, that is, uncorrected π, is superior to the unbiased estimator, inferior to the semi-Bayesian estimator in terms of mean square error, and provides a compromise between the two with respect to bias.

Risk Statistics

When a model of $\mathrm{P}(Y \mid X; \beta)$ is finally in hand, it can be used to compute quantities of substantive interest. The three most important quantities are the following:

- absolute risk: $\mathrm{P}(Y \mid X = b)$
- relative risk (RR): $\mathrm{P}(Y \mid X = b) / \mathrm{P}(Y \mid X = a)$
- risk difference (RD): $\mathrm{P}(Y \mid X = b) - \mathrm{P}(Y \mid X = a)$.

An important auxiliary quantity is the odds ratio (OR):

$$\mathrm{OR} = \frac{\mathrm{P}(Y = 1 \mid X = b)/\mathrm{P}(Y = 0 \mid X = b)}{\mathrm{P}(Y = 1 \mid X = a)/\mathrm{P}(Y = 0 \mid X = a)} \tag{12}$$

$$= \frac{\mathrm{P}(X = b \mid Y = 1)\mathrm{P}(X = a \mid Y = 0)}{\mathrm{P}(X = a \mid Y = 1)\mathrm{P}(X = b \mid Y = 0)}, \tag{13}$$

where the second line follows by Bayes theorem.

The Odds Ratio

Unlike the risk statistics, the odds ratio is not straightforward to interpret substantively, although this is often attempted. Also unlike the risk statistics, the odds ratio has the advantage of being calculable directly from response-based samples. The preceding reformulations are possible because it is invariant to addition to or rescaling of either marginal. Consequently, it is unaffected by sample distributions of Y that do not match their population. The odds ratio is also easy to extract from a fitted logistic regression model: $\mathrm{OR} = e^{(X_b - X_a)\beta}$. Moreover, this extraction is always safe to perform: even an uncorrected and therefore inconsistently estimated model fitted under response-based sampling restricts its inconsistency to the intercept term, which is not used in the extraction process.

Given the straightforward corrections for response-based sampling designs and finite sample corrections described previously, it is no longer necessary to work with the odds ratio in place of risk statistics. However, it remains an important intermediate factor in risk computations when P(Y) is not known with certainty.

Uncertainty about P(Y)

If P(Y) is known, the weighting or intercept correction estimators should be used to fit a model, and risk quantities computed directly. In rare cases, P(Y) is in fact known with certainty, for example, when a population census is available, or when the response in question is generated by a computer algorithm, e.g., a statistical estimator, which can be run on all available data at low cost. The majority of applications, however, do not enjoy this situation. In this majority of cases, P(Y) is not known for certain, and four cases can be distinguished.

P(Y) Can Be Estimated from Auxiliary Data

In this case, an independent sample is available from which P(Y) can be consistently estimated. This does not affect the statistical properties of any of the estimators

described previously. Risk statistics may be computed directly from the model.

P(Y) Is Vanishingly Rare

In second case, $Y=1$ is treated as vanishingly rare. Rearranging the definition of OR, it can be seen that

$$\mathrm{OR} = \mathrm{RR}\left[\frac{1-\mathrm{P}(Y=1\,|\,X=a)}{1-\mathrm{P}(Y=1\,|\,X=b)}\right]. \qquad (14)$$

Taking the limit as $\mathrm{P}(Y=1)\to 0$, $\mathrm{OR}\to\mathrm{RR}$. A traditional approximation suggests using the odds ratio in place of the relative risk when $Y=1$ is very rare. But this can no longer be recommended; not only does the odds ratio overestimate the relative risk, but $\mathrm{P}(Y=1)$ is known not to be 0, and better methods are available. This approach is more clearly a problem with the risk difference, where the same limit necessarily leads to an estimate of 0 (no effect).

P(Y) Is Completely Unknown

In a third case, P(Y) is assumed to be completely unknown. Manski showed that if P(Y) can lie anywhere on [0, 1], the relative risk is bounded by

$$[\min(1,\mathrm{OR}),\max(1,\mathrm{OR})], \qquad (15)$$

where the odds ratio is used as an effect size bound. Under the same conditions, the risk difference is bounded by

$$\left[\min\left(0,\frac{\sqrt{\mathrm{OR}}-1}{\sqrt{\mathrm{OR}}+1}\right),\max\left(0,\frac{\sqrt{\mathrm{OR}}-1}{\sqrt{\mathrm{OR}}+1}\right)\right] \qquad (16)$$

Unsurprisingly, due to the extreme level of uncertainty, estimates of relative risk and risk difference overlap 1 and 0, respectively (no effect).

P(Y) Is Bounded

In the fourth case, P(Y) is known only to lie on the interval $[\pi_a,\pi_b]$. In this case, a tighter set of bounds than the previous case is possible. The relative risk lies on

$$[\min(\mathrm{RR}_a,\mathrm{RR}_b),\max(\mathrm{RR}_a,\mathrm{RR}_b)], \qquad (17)$$

where RR_a is the risk ratio evaluated at $\mathrm{P}(Y=1)=\pi_a$.

Computing the risk difference is slightly more involved. Let π_K be the value of P(Y) that would generate the risk difference $K=\left(\sqrt{\mathrm{OR}}-1\right)/\left(\sqrt{\mathrm{OR}}+1\right)$. When π_a and π_b are either both greater than or both less than π_K, then the risk difference lies on

$$[\min(\mathrm{RD}_a,\mathrm{RD}_b),\max(\mathrm{RD}_a,\mathrm{RD}_b)]; \qquad (18)$$

otherwise, it lies on

$$[\min(\mathrm{RD}_a,\mathrm{RD}_b,K),\max(\mathrm{RD}_a,\mathrm{RD}_b,K)]. \qquad (19)$$

Conservative error bars can be placed on all these bounds by using the sampling distribution of β to generate outer bounds from the underlying model via simulation.

Glossary

deterministic model A mathematical model that gives the exact value for an outcome as a function of parameters.
frame of reference Contains sets of objects and agents that can be brought into contact with each other to produce a reaction or a response.
parameter A variable whose values govern or determine other values in mathematical models.
probabilistic model A mathematical expression that gives the probability of an outcome from a defined set of possible outcomes as a function of parameters.
relative invariance A comparison between two objects that is independent of the agents, and vice versa, within a frame of reference.
specific objectivity The property of invariance of comparisons of objects and of agents within a specified frame of reference.
sufficient statistic A function of data in a probabilistic model is a sufficient statistic with respect to a parameter if, given this statistic, the resultant distribution does not depend on that parameter.

Georg Rasch had a distinctive impact on social measurement. A mathematician who turned to statistics in the 1930s to earn a living, Rasch worked for 50 years during an exciting era for statistics. A member of the International Statistics Institute and charter member of the Biometrics Society, he knew all of the most influential statisticians of that era. His main works were published in 1960 and 1961, with a retrospective summary in 1997. His 1960 book, *Probabilistic Models for Some Intelligence and Attainment Tests*, summarized his original empirical work; his 1961 paper from the IVth Berkeley Symposium on Mathematical Statistics and Probability, "On General Laws and the Meaning of Measurement in Psychology," abstracted a class of probabilistic models from his empirical work that satisfied requirements for measurement; and his 1997 paper "On Specific Objectivity: An Attempt at Formalising the Request for Generality and Validity of Scientific Statements" in the *Danish Yearbook of Philosophy* articulated a general framework for invariant scientific reference.

The author recorded an interview with Rasch in June 1979 that is the basis for this article (Rasch died in 1980). Unreferenced quotes are from that interview.

Development as a Mathematician

Elementary and Secondary Schooling

Rasch was born in 1901 in Denmark. His mother, who died early in her life, seemed to have little impact on him. His main influence was his religious father, who had taught mathematics in a nautical school. When Rasch was ready to enter secondary school, three factors converged to lead him into mathematics. First, his father concluded that Rasch should continue his schooling, apparently because he was not practical; second, he came across his father's trigonometry books and was intrigued by them; third, he had an excellent teacher in arithmetic and algebra who persuaded Rasch's father to go to substantial extra expense to send him to a cathedral high school in Odense specializing in mathematics rather than a closer one specializing in languages.

After three years in high school, in September 1919, Rasch became a student of mathematics at the University of Copenhagen. There, Rasch immediately began working with his professors, and while still an undergraduate published a joint paper with Professor Niels Nielsen.

University Studies

Rasch then worked with Professor Nørland, an association that lasted for some 20 years. His first task was to study the preserved library of another Danish mathematician, J. L. W. V. Jensen, who claimed he had proved a theorem proposed by the German mathematician Rieman that would have given a great deal of information about how prime numbers are distributed. Though Rasch never found the proof, he did publish papers based on this search. He completed his masters degree in 1925 and his doctor of science degree in 1930.

> *My old teacher, Lehn, was quite right when he declared that the son of Mr. Rasch was a born mathematician. Not the best one in the world, by no means, but the interest in mathematics and the need for making research in mathematics has followed me from very early days. Although I have been known as a statistician, my original training and my original gift is in mathematics.*

Rasch published an elegant proof of Wishart's theorem concerned with the distribution of variances and covariances in multi-dimensions, and from his doctoral dissertation, *Matrix Calculus and Its Application to Difference Equations and Differential Equations*, published "The Theory and Application of the Product Integral" in a German journal. This paper was acknowledged in work in atomic and group theory research.

On completing his doctorate, Rasch was qualified to be appointed as a full professor in mathematics. He applied unsuccessfully for two such positions. Rasch believed these rejections were due to his association with Nørland, because the professorships were given to students of Harold Bohr, a mathematician and brother of the nuclear physicist Niels Bohr.

Start in Statistics

Analysis of a Data Set

If Rasch had been able to get a professorship in mathematics, his career would have taken a very different path, and his contribution to social measurement may never have appeared. His mathematical ability and training, however, were central to the contribution that he did make. Rasch did not become a full professor until 1960, when he was appointed as a professor of statistics in the faculty of social sciences at the University of Copenhagen on the basis of the work he had done by taking this very different career path.

Not having a faculty position in the 1930s meant times were difficult for Rasch, as they were for many people in that period. Rasch's ability in mathematics and networks with fellow students lead to improved personal circumstances and to his hesitant start in analyzing very different kinds of data. Again, a number of events converged. First, two medical acquaintances asked him to look at their data on reabsorption of cerebrospinal fluid. Although he did not know even the method of least squares, by trial and error he fitted an exponential curve to the data. He displayed his results in a way that anticipated his way of doing so for the rest of his career—revealing regularities in the data, if they existed, as straight lines.

> *When I just had the curvatures determined and then calculated the points corresponding to their position, the plots of the observed points through these calculated points gave the nicest straight lines I could ever wish. That was to them sensational. Out of this came a paper by Stűrup, Fog and Rasch. That was my first experimental paper.*

Second, appreciating that mathematics was relevant to them, Fog and Stűrup invited Rasch to teach them and some of their colleagues further mathematics. The same group persuaded him that he could read a statistics book more readily than they could and that he could teach them statistics. Through this group, he also became a consultant at the Hygienic Institute in Copenhagen.

Third, and again through personal contacts in which Rasch's mathematical ability was invoked to critique a doctoral dissertation, Rasch was invited by the head of the State Serum Institute, Dr. T. Madsen, to join the institute as a consultant.

Fourth, Nørland and Madsen, who knew each other, decided that for Rasch to make a worthwhile contribution in statistics, he needed proper training. They obtained a Carlsberg scholarship for Rasch to study with Ragner Frisch, an econometrician in Oslo, for 3 months and a Rockefeller Foundation scholarship to study with R. A. Fisher in London for a year, beginning in September 1935. Fisher's work had a major impact on Rasch.

Studies in Statistics

Although the direction Rasch took seems to have occurred through a series of coincidences, in each case he excelled in using his mathematics ability, and even though he did not have direct training in the work he was doing, he greatly impressed with what he could do with data, culminating in his opportunity to study with the most significant statistician of the time (perhaps of all time). Rasch believed that Fisher's realization of the concept of sufficiency was the high mark of Fisher's many contributions.

> *Many may consider it just a mathematical trick, but I think it's much more than that .... Now in my language today, the sufficiency concept is very remarkable. It plays an important role in, as we shall see, the probabilistic theory of specific objectivity.*

Return to Denmark: The Study of Individuals

On his return to Denmark, the range of data Rasch analyzed expanded. He analyzed psychological test data in the same distinctive way he had analyzed biological data. He critiqued the population studies of the biologist Julian Huxley.

Fairly early I got around to the problem of dealing with individuals. I had tried to do that for the growth of children already before I came to London. But meeting Julian Huxley showed me that this was really an important line of my research. I continued to stick, as far as I could, to the study of individuals ever since. It meant quite a lot to me to realize the meaning and importance of dealing with individuals and not with demography. Later on I realized that test psychologists were not dealing with the testing of individuals, but what they were studying was how traits, such as intelligence, were distributed in a population. From the data on children's growth, which was individual, and through my connection with Huxley, and then the move to psychological testing, has a continuous line.

The Multiplicative Poisson Model

Design for Invariant Comparisons

Rasch's next big opportunity occurred when, following preliminary analysis of errors in reading words in texts, a special design was used to collect new data. The design held that the texts students read should not be so difficult that they became frustrated and distracted, nor so easy that they were not challenged. The number of errors by each student should be on the order of 5 to 10%. This meant that the same text could not be given to all students. The design of the data collection took the form shown in Table I with students in higher grades given more difficult texts than those in lower grades. This design led Rasch to his models for measurement.

Table I Design of Reading Experiments—Taken from Rasch (1960, p. 5)

	Grade					
Test	*2*	*3*	*4*	*5*	*6*	*7*
ORF	+	+				
ORU		+		+		
ORS			+	+	+	
OR5			+	+	+	+
OR6					+	+

With the probability of an error being relatively low and the opportunity to make one relatively large, Rasch hypothesized that the Poisson distribution

$$\Pr\{X = x;\, \lambda\} = e^{-\lambda}\frac{\lambda^x}{x!}, \tag{1}$$

where X is the random variable for the number of errors, in which $E[X] = \lambda$ is the mean number of errors, would characterize the data. However, rather than seeing this as the characterization of a population, he resolved the parameter λ into two components, one for the person and one for the text: $\lambda_{vi} = \delta_i/\xi_v$ where δ_i is the difficulty of text i and ξ_v=0 is the ability of person v giving

$$\Pr\{X_{vi} = x;\, \delta_i, \xi_v\} = e^{-\delta/\xi_v}\frac{(\delta_i/\xi_v)^x}{x!}, \tag{2}$$

in which $E[X_{vi}] = \delta_i/\xi_v$.

Rasch called Eq. (2) the multiplicative Poisson model (MPM). It is evident that the mean number of errors is proportional to the text's difficulty, δ_i, and inversely proportional to the person's ability, ξ_v. This means, for example, that if the difficulty of text j is given by $\delta_j = k\delta_i$, then text j is k times more difficult than text i. This statement is analogous to the kinds of statements that are made in measurements in physics, to which Rasch related his work.

The Poisson distribution has the property that the probability of the sum of two Poisson distributions (e.g., $X_{v(i+j)} = X_{vi} + X_{vj}$) is governed by a parameter that is the sum of the parameters of the individual distributions (e.g., $\lambda_{v(i+j)} = \lambda_{vi} + \lambda_{vj}$). In the case of a person reading two texts, the multiplicative structure has the property that the difficulty of the combined texts is simply the sum of the difficulties of the individual texts: $\lambda_{v(i+j)} = \delta_{(i+j)}/\xi_v = (\delta_i + \delta_j)/\xi_v$, giving

$$\Pr\{X_{v(i+j)} = x;\, \delta_i, \delta_j, \xi_v\} = e^{-(\delta_i+\delta_j)/\xi_v}\frac{((\delta_i + \delta_j)/\xi_v)^x}{x!}, \tag{3}$$

in which $E[X_{v(i+j)}] = (\delta_i + \delta_j)/\xi_v$.

Rasch noticed that this structure, too, had an analogy to physical measurement—just like two masses in the laws of classical physics, two texts could be concatenated with the same response law prevailing. However, rather than taking concatenation as his starting point for measurement, as is done in representational measurement theory, he took a different route.

Eliminating the Person Parameter

The MPM has the property that the probability of the score x_{vi} by person v on text i, conditional on the person's total score on the two texts i and j being $r_v = x_{vi} + x_{vj}$, is given by the binomial distribution

$$\Pr\{X_{vi} = x;\, \delta_i, \delta_j, \xi_v \mid r_v\} = (r_v x_{vi})(\pi_{ij})^x(1 - \pi_{ij})^{r_v - x_{vi}}, \tag{4}$$

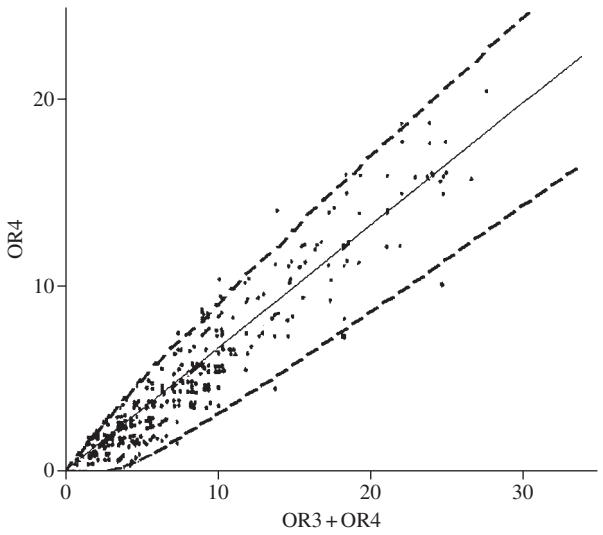

Figure 1 Graph showing the hypothesis line, the confidence interval, and observed points for the score of persons on one text relative to the total score on two texts. Adapted from Rasch (1960).

in which $\pi_{ij} = \delta_i/(\delta_i + \delta_j)$ is the probability of observing an error on text i. Equation (4) has no person parameter. The statistic r_v is sufficient for the person parameter ξ_v—that is, all the information that the data can provide about the parameter ξ_v is contained in r_v. Thus, r_v can be used directly to estimate ξ_v. However, for Rasch this was not the main issue. Instead, he saw two other points to the model. First, it meant that the relative difficulties of the texts could be estimated independently of the abilities of the persons. Second, it provided immediately an opportunity to check the fit of the model using a hypothesized straight line with confidence limits around it. Taken from Rasch's 1960 book, Fig. 1 shows such a check for scores on one text given the total score on two texts.

Rasch showed that with the MPM, relevant comparisons could be made even if all of the persons did not read all of the texts. More than that, Rasch turned this solution to a practical problem into a requirement for measurement.

The Dichotomous Model

Construction of the Model

Rasch's mathematical orientation was central to his formulation of his model for dichotomous responses. Rasch appreciated that there was a dichotomous response for each word in the count of the number of errors for a text as a whole:

> *The discovery of the model actually was an achievement in connection with the reading tests and the study of the multiplicative Poisson models. I chose the multiplicative Poisson because it seemed a good idea mathematically if it would work. It turned out that it did work. Then I wanted to have some good motivation for using it, and not only the excuse that statistically it worked perfectly. I wanted to have a good reason for trying that after I had used it.*

Rasch derived the model for dichotomous responses in which an error ($x = 1$) was counted, that produced the MPM for texts as a whole. If the correct response is counted ($x = 1$) rather than an incorrect one as in the case of reading, then the relationship $\lambda_{vi} = \delta_i/\xi_v$ is written inversely as $\lambda_{vi} = \xi_v/\delta_i$, $\delta_i > 0$, giving the dichotomous model

$$\Pr\{X_{vi} = x; \delta_i, \xi_v\} = \frac{(\xi_v/\delta_i)^x}{1 + \xi_v/\delta_i}, \qquad (5)$$

where $X_{vi} = x \in \{0,1\}$.

Rasch had earlier worked with intelligence tests, so when he had the dichotomous model, he analyzed existing data from two tests out of curiosity.

> *The first thing I did was, in fact, to analyze the Raven's tests. They worked almost perfectly according to the multiplicative model for dichotomous items. That was my first really nice example using the newly discovered model. Now I compared the Raven's test and the results of an analysis of the military tests which had been taken over as a routine intelligence test for recruits. The intelligence tests did not conform and I showed it to the head of the military psychologists group.*

Constructing Items to Conform to the Model

Rasch showed from the deviations of the data from the model that the 72 items fell into seven groups. The head of the military psychology group immediately understood Rasch's point, and instigated the construction of tests in which the items in each group were intended to conform to Rasch's new model.

This was a remarkable instruction. Rasch had tried his model on only two sets of data at the time: in one set, the Raven's progressive matrices, which is a non-verbal intelligence test, the model worked; and in the other set, which was the military's own test, it did not. Rather than abandoning the model at this point, and complicating it to better account for the data of the latter test, new items were to be constructed with the explicit intention that they conform to the model. Rasch's analysis of the data and conclusions with the model must have been extremely compelling. After the construction of these tests and analysis of their responses, Rasch wrote,

> *It is tempting, therefore, in the case with deviations of one sort or other to ask* whether it is the model or the test that

has gone wrong. *In one sense this of course turns the question upside down, but in another sense the question is meaningful. For one thing, it is not easy to believe that several cases of accordance between model and observations should be isolated occurrences. Furthermore the application of the model must have something to do with the construction of the test; at least, if a pair of tests showed results in accordance with our theory, this relationship could easily be destroyed by adding alien items to the tests. Anyhow, it may be worth while to know of conditions for the applicability of such relatively simple principles for evaluating test results [emphasis in original].* (Rasch, 1960/1978, p. 51)

This model is now more conventionally written and studied in the form

$$\Pr\{X_{vi} = x; \sigma_i, \beta_v\} = \frac{\exp x(\beta_v - \sigma_i)}{1 + \exp(\beta_v - \sigma_i)}, \qquad (6)$$

where $\beta_v = \ln \xi_v$ and $\sigma_i = \ln \delta_i$. Although it is the simplest possible model for a dichotomous response, it has generated extraordinary literature, both theoretical and empirical.

The Model for Any Number of Response Categories

Invariance as a Property of a Model—Not Just Data

The requirement that the comparisons of items should not depend on specific persons, and vice versa, was not new. Thurstone articulated the same requirement in a number of important papers in the 1920s. However, for Thurstone, the requirement of invariance was left as a requirement of data. Invariance was important for Rasch as well, but Rasch made it a property of a mathematical model. His ability and training in mathematics were important in first setting up the opportunity to do so, and then in identifying a class of models with this property. Equally importantly, this property made it possible to carry out mathematical derivations to understand other implications of the requirement of invariance.

The Insight into the Implications of Invariance

I saw the importance of finding an answer to the following question: which class of probabilistic models has the property in common with the multiplicative Poisson model, that one set of parameters can be eliminated by means of conditional probabilities while attention is concentrated on the other set, and vice versa.

In identifying a class of models for the probabilistic case that gives invariance, two related components are involved. First, the probability distribution itself needs to have the property of sufficiency for its parameters. The family of distributions that have sufficient statistics, which following Fisher's work were well defined, are known as the exponential family. Second, the structure of the parameters must give the possibility of separating the person parameters from the item parameters.

The General Response Model

In 1961, Rasch presented a very general class of distributions with the property of sufficiency in which the dichotomous and MPM models are special cases, which took the form

$$\Pr\{X_{vi} = x; \sigma_i, \beta_v\} = \frac{\exp(\varphi_x \beta_v + \psi_x(-\sigma_i) + \chi_x \beta_v \sigma_i + \kappa_x)}{\sum_{x=0}^{m} \exp(\varphi_x \beta_v + \psi_x \sigma_i + \chi_x \beta_v \sigma_i + \kappa_x)}. \qquad (7)$$

where φ_x and ψ_x were scoring functions of the categories, κ_x were category coefficients, and $X_{vi} = x$ was a response in any one of $m + 1$ categories to an item. To give measurements, which required the parameters to be scalar, Rasch quickly specialized this general model to the form

$$\Pr\{X_{vi} = x; \sigma_i, \beta_v\} = \frac{\exp(\varphi_x(\beta_v - \sigma_i) + \kappa_x)}{\sum_{x=0}^{m} \exp(\varphi_x(\beta_v - \sigma_i) + \kappa_x)}. \qquad (8)$$

There has been substantial development of this model for rating and performance assessments in items with formats with ordered response categories. Andersen (1977) proved that the sufficiency condition actually imposed the constraint

$$\varphi_x - \varphi_{x-1} = \varphi_{x+1} - \varphi_x, \qquad (9)$$

and Andrich (1978) interpreted the scoring functions φ_x and the category coefficients κ_x in terms of familiar concepts in psychometrics, thresholds τ_x, $x = 1, \ldots, m$ that partitioned the continuum into categories, and discriminations α_x, $x = 1, 2, 3, \ldots, m$ at the thresholds. Specifically,

$$\varphi_x = \alpha_1 + \alpha_2 + \alpha_3 + \cdots + \alpha_x \quad \text{and}$$

$$\kappa_x = -(\alpha_1\tau_1 + \alpha_2\tau_2 + \alpha_3\tau_3 + \cdots + \alpha_x\tau_x).$$

Without loss of generality, let $\alpha_x \equiv 1$, $x = 1, 2, \ldots, m$, giving $\varphi_x = x$ and $\kappa = -(\tau_1 + \tau_2 + \tau_3 + \cdots + \tau_x)$, which reduces Eq. (8) to

$$\Pr\{X_{vi} = x; \sigma_i, \beta_v, \tau_x\} = \frac{\exp(x(\beta_v - \sigma_i) - \sum_{k=0}^{x} \tau_k)}{\sum_{x=0}^{m} \exp(x'(\beta_v - \sigma_i) - \sum_{k=0}^{x'} \tau_k)}, \quad (10)$$

where $\tau_0 \equiv 0$. This model has been generalized further to the case in which different items may have different thresholds:

$$\Pr\{X_{vi} = x; \sigma_i, \beta_v, \tau_x\} = \frac{\exp(x(\beta_v - \sigma_i) - \sum_{k=0}^{x} \tau_{ki})}{\sum_{x=0}^{m} \exp(x(\beta_v - \sigma_i) - \sum_{k=0}^{x} \tau_{ki})}. \quad (11)$$

Interestingly, in this model the successive categories for an item are scored with successive integers, just as is commonly done in elementary analyses of ordered category data as in Likert-style questionnaires and in performance assessment. However, this scoring is not a result of equal distances between thresholds defining the categories, but of equal discriminations at the thresholds. This is the same condition that makes the total score in the dichotomous Rasch model the relevant statistic from which the person parameters can be eliminated when estimating the item parameters. Data with ordered categories are ubiquitous in the social sciences. They are used often by analogy to measurement in the physical sciences. Equations (10) and (11) make practical statistically advanced analyses of such data.

The Two-Way Frame of Reference

The Probabilistic Case

To formalize his mathematical reasoning in measurement, Rasch made explicit a two-way frame of reference as follows. Suppose that there is a set of objects O_v, $v = 1, 2, 3, \ldots \in \mathrm{O}$ and a set of agents A_i, $i = 1, 2, 3, \ldots, \in \mathrm{A}$, which may come into contact with each other in pairs to give responses $X_{vi} = x \in \mathrm{X}$ within some frame of reference $\mathrm{F} \equiv [\mathrm{O}, \mathrm{A}, \mathrm{X}]$, summarized in Table II. The random variable X_{vi} can be a vector. Although Rasch wrote the two-way frame of reference in general, in the case of measurement, the objects and agents are characterized by scalar parameters.

The formulation from which he derived Eq. (9), in which two agents A_i and A_j are brought into contact with object O_v to provide the response $X_{vi} = x$, Rasch specified as

$$\Pr\{(x_{vi}, x_{vj}), \delta_i, \delta_j, \xi_v | f(x_{vi}, x_{vj})\} = \vartheta(x_{vi}, x_{vj}, \delta_i, \delta_j) \quad (12)$$

Table II Rasch's Two-way Frame of Reference of Objects, Agents and Responses

		Agents				
Reactions	X_{vi}	A_1	A_2	$\cdot$	A_i	$\cdot$	A_I
Objects	O_1	x_{11}	x_{12}	$\cdot$	x_{1i}	$\cdot$	x_{1I}
	O_2	x_{21}	x_{22}	$\cdot$	x_{2i}	$\cdot$	x_{2I}
	$\cdot$	$\cdot$	$\cdot$	$\cdot$	$\cdot$	$\cdot$	$\cdot$
	O_v	x_{v1}	x_{v2}	$\cdot$	x_{vi}	$\cdot$	x_{vI}
	$\cdot$	$\cdot$	$\cdot$	$\cdot$	$\cdot$	$\cdot$	$\cdot$
	O_V	x_{V1}	x_{V2}	$\cdot$	x_{Vi}	$\cdot$	x_{VI}

so that the probability statement should not depend on the person parameter ξ_v. For example, in the case of the dichotomous model of Eq. (6), Eq. (12) specializes to

$$\Pr\{(x_{vi}, x_{vj}); \delta_i, \delta_j, \xi_v \,|\, r_v = x_{vi} + x_{vj}\} = \frac{\exp(-x_{vi}\delta_i - x_{vj}\delta_j)}{\exp(-\delta_i) + \exp(\delta_j)}. \quad (13)$$

Equation (4) with respect to the MPM has the same structure.

Rasch articulated the requirement of invariance between parameters in the two-way frame of reference in terms of comparisons:

> *The comparison between two stimuli should be independent of which particular individuals were instrumental for the comparison; and it should also be independent of which other stimuli within the considered class were or might also have been compared.*
>
> *Symmetrically, a comparison between two individuals should be independent of which particular stimuli within the class considered were instrumental for comparison; and it should also be independent of which other individuals were also compared, on the same or on some other occasion.* (Rasch, 1961, p. 332)

The Determinate Case

Rasch extrapolated the requirement of invariant comparisons from the probabilistic case to the determinate case and to the connection with measurement in physics. As indicated previously, Rasch already saw these connections from the multiplicative Poisson model.

In the determinate case, Rasch replaced the response space X of the probabilistic case with a reaction ρ_{vi}, $v = 1, 2, 3, \ldots; i = 1, 2, 3, \ldots, \in \mathrm{R}$, giving the frame of reference $\mathrm{F} \equiv [\mathrm{O}, \mathrm{A}, \mathrm{R}]$. Suppose again that the objects, agents, and now reactions, are characterized by scalar parameters ξ_v, α_i and ρ_{vi}, where $\rho_{vi} = \rho(\xi_v, \alpha_i)$ is a function of the object and agent parameters. The equation that reflects a local

comparison of agents 1 and 2 and depends on object v in the reaction is given by

$$u(\rho_{v1}, \rho_{v2}) = u(\rho(\xi_v, \alpha_1),\ \rho(\xi_v, \alpha_2)) = \vartheta(\alpha_1, \alpha_2 \mid \xi_v). \tag{14}$$

The equation that then reflects a global comparison of agents 1 and 2 and that is invariant with respect to the object v is given by

$$u(\rho_{v1}, \rho_{v2}) = u(\rho(\xi_v, \alpha_1),\ \rho(\xi_2, \alpha_k)) = \vartheta(\alpha_1, \alpha_2). \tag{15}$$

With usual conditions of continuity and differentiability on the functions u, ρ, and ϑ, Rasch established that the existence of strictly monotonic functions $\xi' = \varphi(\xi)$; $\alpha' = \psi(\alpha)$; $\rho' = \chi(\rho)$, which transform the reaction function $\rho(\xi_v, \alpha_i)$ into an additive relation of the form

$$\rho'_{vi} = \xi'_v + \alpha'_i \tag{16}$$

is a necessary and sufficient condition for Eq. (15) to hold. The same equation arises for the invariant comparison of objects relative to agents. The exponential transformation is strictly monotonic, and therefore, after transformations $\rho^*_{vi} = \exp \rho'_{vi}$, $\xi^*_v = \exp \xi'_v$, and $\alpha^* = \exp \alpha'_i$ of the variables in Eq. (16),

$$\rho^*_{vi} = \xi^*_v \alpha^*_i. \tag{17}$$

The comparison between agents 1 and 2 through the interaction with an object in the frame of reference F is then obtained as the ratio

$$\frac{\rho^*_{v1}}{\rho^*_{v2}} = \frac{\xi^*_v \alpha^*_1}{\xi^*_v \alpha^*_2} = \frac{\alpha^*_1}{\alpha^*_2}. \tag{18}$$

Rasch referred to a frame of reference F that provides invariant comparisons of agents with respect to objects, and vice versa, as specifically objective: objective because the comparisons were invariant, and specifically objective because they depended on the specified frame of reference.

Rasch showed the connection of his derivations to measurement in physics. In particular, in 1977 he dissected the general gas equation in the form

$$p = \frac{r}{v}(t + \gamma) = \frac{r}{v} T, \tag{19}$$

in which r and γ are constants, p (pressure) and v (volume) are positive real numbers, t is the temperature measured in centigrade degrees and T is the temperature measured on the absolute Kelvin scale to show its conformity to Eq. (17). Rasch was aware that such laws prevailed in physics.

Fundamental Measurement and the Laws of Physics

According to Krantz *et al*. (1971), the results of Eqs. (16) and (17) are entirely compatible with the axiomatic treatments of representational or fundamental measurement, which in general terms is also known as additive conjoint measurement. In addition to being compatible, it seems to answer a key question in physical measurement observed by Ramsay (1975) in a review of the Krantz *et al*. book (Rasch had made the same observation):

> *Also somewhat outside the concerns of the rest of the book, this chapter is unique in considering the representation of relations between measurable structures explicitly. It deals with the fact that virtually all the laws of physics can be expressed numerically as multiplications or divisions of measurements. Although this rule has been known for a long time and forms the basis of the techniques of dimensional analysis widely used in engineering and physics, it remains a phenomenon for which no satisfactory explanation has been forthcoming* (Ramsay, 1975, p. 58).

Rasch's conclusion—that for invariant comparisons to be possible in the case of determinate relationships among variables, it is necessary to have structures that are additive or, equivalently, multiplicative, within acceptable transformations—seems to go a long way toward explaining Ramsay's observation that the laws of physics are multiplicative.

Rasch and Fundamental Measurement

Rasch began his formulations with invariant comparison, and concluded them with the requirement of an additive or, equivalently, a multiplicative structure. Rasch speculated as to whether the comparison is the most elemental basis of knowledge. He believed that the comparison of objects must involve some reactions to some agent (and vice versa) and that the identification of a specifically objective frame of reference was essential for scientific inference.

Although Rasch strove for necessity and sufficiency in the relationships he formulated, he did not publish rigorous proofs of his results. He carried out proofs to his satisfaction, shared them with students and colleagues, and presented them in more or less detail in informal papers. Early in his work he did not seem to be aware of existing results in group theory that could have made his proofs simpler. Toward the end of his life, he was made aware of them, and showed great interest in them. In addition, it seems Rasch was not aware of the axiomatic approach to representational measurement theory or fundamental measurement.

Implications of Rasch's Insights

Implications for Practice

Axiomatic treatment of deterministic fundamental measurement is important in the understanding of

measurement. However, it has had relatively little impact on the practice of measurement in the social sciences, because data in the social sciences are generally not deterministic. Rasch's models provide an opportunity to test data generated in the social sciences against criteria of fundamental measurement, with the data in the measurement of reading and intelligence being exemplary. His models are now applied in a range of social science settings, including sociology, health care, social medicine, and marketing, as well as in education and psychology, from where they originated. When the criterion of fundamental measurement is the motivation for the application of one of his models, items are constructed with a view that they conform to the chosen model, and the emphasis on the data fitting the model rather than the other way around. This continues the tradition set by Rasch. Software programs are now available that make the analysis of data using Rasch models relatively routine.

Expansion of Rasch's Work

Rasch had a reputation for reading relatively little; he also wrote relatively little. However, the material he wrote was careful and compelling in giving a view that was different from the traditional. He was also a passionate advocate of the concept of invariant comparisons within a specified frame of reference and of the classes of models that had this property in lectures and personal interactions. This advocacy inspired others to take up his work. In Denmark, his approach to psychometrics is now the standard approach. He had a direct impact on a generation of his students, including his successor Erling B. Andersen, who advanced both the theory and practice of Rasch models. Outside of Denmark, he inspired Benjamin D. Wright at the University of Chicago and Gerhard Fischer at the University of Vienna to work on the models. They introduced many of their colleagues and students to Rasch's work and together they have further developed this class of models. These developments have included different ways of deriving the models, developing algorithms for estimating parameters in the models, and establishing means for detecting deviations of data from the models.

Rating Scale Model

Erling B. Andersen
University of Copenhagen, Copenhagen, Denmark

Glossary

conditional maximum likelihood estimates Estimates that are based on maximizing a conditional likelihood function.
goodness-of-fit test A test for judging the closeness of the observed data to those predicted by the model.
likelihood ratio test A test that is derived by the ratio of the likelihood under the model and the likelihood without assuming a model.
marginal maximum likelihood estimates Estimates that are based on maximizing a marginal likelihood function.
residual Difference between observed quantities and their expected values under the model, divided by the standard error of this difference.
symptom checklist for discomfort A set of items used by psychiatrists to measure the degree of discomfort/depression of their patients.

The rating scale model is a latent structure model for polytomous responses to a set of test items. The basic structure of the model is an extension of the Rasch model for dichotomous responses, suggested by Georg Rasch in 1961. It is called a rating scale model because the response categories are scored such that the total score for all items constitutes a rating of the respondents on a latent scale. It is assumed that the category scores are equally spaced, giving the highest score to the first or the last category. Thus, the phrasing of the response categories must reflect a scaling of the responses, such as "very good," "good," " not so good," and "bad."

Presentation of the Model

The rating scale model is a special case of the polytomous model, first presented by Rasch in 1961. It was reconstructed as a rating scale model by Andrich in 1978. A similar model was presented by Andersen in 1977. The main assumption for the rating scale model, apart from being a polytomous Rasch model, is that the scoring of the response categories must be equidistant (i.e., their values must increase by a constant). Both Andersen and Andrich presented convincing arguments for specifying this condition. In 1983, Andersen discussed a somewhat more general model, which is still a polytomous Rasch model but with less restrictive scoring of the response categories.

Consider n polytomous test items, $i = 1, \ldots, n$. The response U_i on test item i can take the values $h = 1, \ldots, m$. The response function for item i, category h, is

$$P_{ih} = \text{Prob}(U_i = h).$$

The response pattern for an individual is defined as

$$\mathbf{U} = (U_1, \ldots, U_n).$$

It is sometimes convenient to introduce the selection vectors

$$(u_{i1}, \ldots, u_{im}) = (0, \ldots, 1, 0, \ldots, 0),$$

where $u_{ih} = 1$ if response h is chosen on item i, and 0 otherwise.

The response function is assumed to depend for each individual on the value of an ability parameter θ, describing the individual. Accordingly, we write

$$P_{ih} = P_{ih}(\theta).$$

Under the rating scale model, the response functions have the form

$$P_{ih}(\theta) = \frac{e^{w_h\theta - a_{ih}}}{\sum_{h=1}^{m} e^{w_h\theta - a_{ih}}}, \qquad (1)$$

where $w_1, \ldots, w_m$ are the category scores, which prescribe how the m response categories are scored,

and a_{ih} are item parameters connected with the items and categories. Figure 1 shows the four response functions for a typical item with four possible responses. The category scores are chosen to be 3, 2, 1, and 0, and the item parameters are chosen to be $(a_{i1}, \ldots, a_{i4}) = (1.0, 0.75, 0.25, 0.0)$.

As can be seen in Fig. 1 and verified from the analytical form of the model in Eq. (1), the response function for the category with the highest category score tends to 1 as $\theta \to \infty$ and to 0 as $\theta \to -\infty$, whereas the response function tends to 0 as $\theta \to \infty$ and to 1 as $\theta \to -\infty$ for the category with the lowest category score. It follows that individuals with high abilities will, with very high probability, choose category 1, whereas individuals with very low abilities most likely will choose category 4. For middle values of the ability, there are moderate probabilities for all four categories to be chosen. The role of the item parameters is to shift the response function to the left for small values of a_{ih} and to the right for larger values of a_{ih}. Thus, the higher the value of a_{ih}, the lower the probability of choosing category h for the category with the largest category score and the higher the probability of choosing category h for the item with the lowest category score. For the category with middle category scores, the probability of choosing category h will increase with a_{ih} for high θ values and decrease for low θ values with high probability for large θ values and with low probability for small θ values.

The rating scale model is based on the assumption that the category scores $w_1, \ldots, w_h$ are equidistant; that is, the differences

$$d_h = w_h - w_{h-1}, \quad h = 2, \ldots, m,$$

are all equal. This assumption was first suggested in Andersen in 1977 based on certain properties connected with the sufficient statistic for θ, where θ is regarded as an unknown parameter to be estimated. When Andrich introduced the rating scale model in 1978, he showed that $w_h = h$ could be interpreted as the number of the categories in which the response occurs or as thresholds being exceeded. Any linear transformation

$$w'_h = c_0 + c_1 w_h$$

is, of course, equivalent to w_h since this only entails a redefinition of the scale of the θ axes.

In order to derive the probability of observing the response $\mathbf{u} = (u_1, \ldots, u_m)$, the assumption of local independence is needed—namely that given the value of θ, the responses on the n items will be independent. Thus, the required probability is

$$\begin{aligned} f(\mathbf{u} \mid \theta) &= \text{Prob}(\mathbf{U} = \mathbf{u} \mid \theta) \\ &= \prod_{i=1}^{n} \text{Prob}(U_i = u_i \mid \theta) \\ &= \frac{\prod_{i=1}^{n} \exp\left(\theta \sum_{h=1}^{m} w_h u_{ih} - \sum_{h=1}^{m} a_{ih} u_{ih}\right)}{C_i(\theta, \mathbf{a})}, \end{aligned} \tag{2}$$

where

$$C_i(\theta, \mathbf{a}) = \sum_{h=1}^{m} \exp(\theta w_h - a_{ih}).$$

The selection vector notation for u_{ih} is used in Eq. (2) to express which w_h and a_{ih} come into play when category h is chosen by the individual. A rating scale model can thus be described as Eq. (1) combined with local independence.

Equation (2) can be rewritten as

$$\begin{aligned} f(u \mid \theta) = \exp\left(\theta \sum_{i=1}^{n} \sum_{h=1}^{m} w_h u_{ih} - \sum_{i=1}^{n} \sum_{h=1}^{m} a_{ih} u_{ih}\right) \\ - C^{-1}(\theta, \mathbf{a}), \end{aligned} \tag{3}$$

where

$$C(\theta, \mathbf{a}) = \prod_{i=1}^{n} C_i(\theta, \mathbf{a}).$$

Since, obviously, $C(\theta, \mathbf{a})$ is just a normalization factor independent of the responses $(u_1, \ldots, u_u)$, Eq. (3) shows that the score

$$t = \sum_{i=1}^{n} \sum_{h=1}^{m} w_h u_{ih} = \sum_{i=1}^{n} w_{ih}$$

is sufficient for θ, where w_{ih} is the score of the category h the individual chooses on item i. This result is clear from ordinary exponential family theory. It can also be seen directly from Eq. (3), which is the likelihood function pertaining to θ and t. Note that the total score for a given individual is simply the sum of the category scores of the chosen response categories. The category

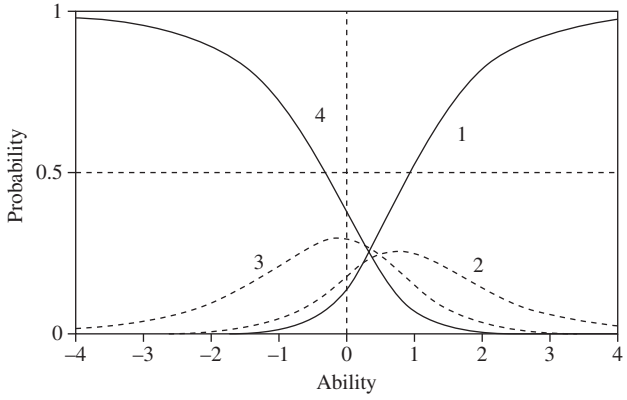

Figure 1 Response functions for four categories of an item (with parameter values 1.00, 0.75, 0.25, and 0.0). Reproduced with permission from W. van der Linden and R. K. Hambleton (eds.) (1997). "Handbook of Modern Item Response Theory," pp. 67–82, © Springer-Verlag.

scores accordingly can also be regarded as a scoring of the n responses into the total score. In 1977, Andersen showed that equidistant scoring was the only one allowing for a smooth variation over t values when a response was changed by changing just one category on one item.

The model is rather general with regard to the item parameters. For inference purposes, there is no real advantage in assuming a more specified structure of the item parameters (i.e., the a's), but for many applications it is natural, as well as in accordance with the theory behind the model, to assume a certain structure. One may assume, for example, that

$$a_{ih} = w_h a_i - \sum_{\ell=1}^{h} d_\ell,$$

where $d_1, \ldots, d_{m-1}$ are threshold parameters, making the item parameters a_{ih} smaller (or larger for negative d_ℓ), depending on the thresholds

$$d_h^* = \sum_{\ell=1}^{h} d_\ell.$$

In 1961, Rasch, in his first formulation of the model for polytomous items, argued that the item parameters a_{ih} should have the same multiplicative form

$$a_{ih} = v_h d_i^*$$

as the term θw_h, and even that the factor v_h corresponding to category h should be the same as the category scores, although he assumed that w_h was a parameter to be estimated.

The description of the model is completed by introducing the ability density $\varphi(\theta)$, which describes the variation of θ in the given population. The marginal distribution of any response pattern u is thus given by

$$f(\mathbf{u}) = \int f(\mathbf{u} \mid \theta)\phi(\theta)\, d\theta,$$

or, according to Eq. (3),

$$f(u) = \exp\Big(-\sum_i \sum_h a_{ih}u_{ih}\Big) \int \exp\Big(\theta \sum_{i=1}^{n} \sum_{h=1}^{m} w_h u_{ih}\Big) \times C^{-1}(\theta, \mathbf{a})\phi(\theta)\, d\theta. \quad (4)$$

Extensions of the rating scale model are provided by Fischer and Parzer and also by Glas.

Parameter Estimation

The item parameters a_{ih} can be estimated by conditional maximum likelihood (CML) or by marginal maximum likelihood (MML). From Eq. (1), it follows that only $n(m-1)-1$ parameters are unconstrained since $\sum_h P_{ih}(\theta) = 1$ and one a_{ih} can be changed by changing the θ scale.

CML Estimation

From Eq. (3), it follows that the marginal distribution of t (i.e., the probability of observing score t) is equal to

$$f(t \mid \theta) = e^{t\theta} C^{-1}(\theta, \mathbf{a}) \sum_{(t)} e^{-a_{ih}u_{ih}}, \quad (5)$$

where the summation (t) is overall response vectors with

$$t = \sum_i \sum_h w_h u_{ih}.$$

The last factor in Eq. (5) is usually denoted $\gamma_t(\mathbf{a})$ so that using

$$\gamma_t(\mathbf{a}) = \sum_{(t)} e^{-a_{ih}u_{ih}},$$

the distribution of t can be written as

$$f(t \mid \theta) = e^{t\theta} C^{-1}(\theta, \mathbf{a})\gamma_t(\mathbf{a}). \quad (6)$$

Hence, the conditional probability of observing response pattern u, given t, is

$$f(\mathbf{u} \mid t) = \frac{\exp\big(-\sum_i \sum_h a_{ih}u_{ih}\big)}{\gamma_t(\mathbf{a})}.$$

Now consider N individuals, who respond independently on the n items. If $(u_{ij1}, \ldots, u_{ijm})$ is the selection vector for individual j's response item i, the joint conditional distribution L_C is

$$L_C = \prod_{j=1}^{N} f(u_j \mid t_j) = \frac{\exp\Big(-\sum_i \sum_h a_{ih} \sum_{j=1}^{N} u_{ihj}\Big)}{\prod_{j=1}^{N} \gamma_{t_j}(\mathbf{a})} = \frac{\exp\Big(-\sum_i \sum_h a_{ih} y_{ih}\Big)}{\prod_t [\gamma_t(\mathbf{a})]^N t}, \quad (7)$$

where N_t is the number of individuals with score t, t_j is the score for individual j, and y_{ih} is the total number of responses h on item i.

Differentiation of the logarithm, $\ln L_C$, of Eq. (7) with respect to a_{ih} gives the conditional likelihood equations

$$\frac{\partial \ln L_C}{\partial a_{ih}} = \frac{y_{ih} - \sum_t N_t \partial \ln \gamma_t(a)}{\partial a_{ih}}.$$

Hence, the CML estimates are obtained as solutions to

$$y_{ih} = \frac{-\sum_t N_t \partial \ln \gamma_t(a)}{\partial a_{ih}}. \quad (8)$$

These likelihood equations have a unique set of solutions except for extreme sets of response patterns. Since Eq. (7) is an exponential family, it follows from a result by Barndorff-Nielsen that there is a unique solution unless the observed set of y's is a point on the

convex hull of the set of y's with positive probability given the observed frequencies over score values. Unfortunately, it is not possible to describe the set of extreme response patterns in close form, as is the case for the dichotomous Rasch model.

The conditional likelihood equations are usually solved by a Newton–Raphson procedure, which also provides standard errors for the parameters. The CML method was suggested by Rasch in 1961 and developed by Andersen in 1972. The recursive procedure needed for the calculation of γ functions is also described by Andersen.

MML Estimation

For MML estimation of the a's, the marginal likelihood L is needed. This likelihood is defined as the marginal probability of the responses u_j for $j = 1, \ldots, N$ (i.e., for the N respondents).

From Eq. (4), assuming independence,

$$L = \prod_{j=1}^{N} f(u_j) = \exp\Big(-\sum_i \sum_h a_{ih} y_{ih}\Big) \prod_t \Big[\int e^{\theta t} C^{-1}(\theta, \mathbf{a}) \phi(\theta)\, d\theta\Big]^{N_t}, \tag{9}$$

where again y_{ih}, $i = 1, \ldots, n$, $h = 1, \ldots, m$ are the item totals, and N_t is the size of score group t. In order to maximize Eq. (9), assumptions concerning the form of $\phi(\theta)$ are needed. It may thus be assumed that $\phi(\theta)$ belongs to a parametric family with two parameters b_1 and b_2. The log-likelihood function then becomes

$$\ln L = -\sum_i \sum_i a_{ih} y_{ih} + \sum_t N_t \ln \int e^{\theta_t} C^{-1}(\theta, \mathbf{a}) \phi(\theta \mid b_1 b_2)\, d\theta. \tag{10}$$

From this likelihood simultaneous estimates of the a_{ih}'s, b_1, and b_2 can be obtained.

The maximization of Eq. (10) requires numerical integration of functions such as

$$\frac{e^{\theta t} C^{-1}(\theta, \mathbf{a}) M \phi(\theta \mid b_1, b_2)}{M b_j}.$$

In case of a normal latent density, integration does not seem to be a serious numerical problem.

If one tries to maximize Eq. (10) for an unspecified latent density, only a set of discrete values for the ϕ function can be identified. In fact, nonparametric estimation of ϕ can be defined using the maximum likelihood estimate

$$\hat{\pi}_t = \frac{N_t}{N} \tag{11}$$

for the marginal probability of obtaining score t. The likelihood then becomes

$$\ln L = \ln L_C + \sum_t N_t \ln\left(\frac{N_t}{N}\right). \tag{12}$$

For this nonparametric estimation of ϕ, it was first shown by Tjur that the results from MML and CML estimation coincide.

Goodness of Fit

Multinomial Tests

The most direct goodness-of-fit test is based on the multinomial distribution of response patterns, given the model holds true. Given n items with m response categories for each item, there are n^m possible response patterns ranging from $(l, \ldots, l)$ to $(m, \ldots, m)$. Let u be a typical response pattern; then the joint distribution of all response patterns has the same likelihood as the multinomial distribution

$$\{n_u\} \sim \text{Mult}(N, \{\pi_u\}), \tag{13}$$

where n_u is the observed number of response pattern u, N is the total number of respondents, and π_u is the probability of observing response pattern u given by Eq. (3).

For estimated cell probabilities, π_u, the fit of the multinomial model (Eq. 13) is tested by the likelihood ratio test quantity

$$Z = 2 \sum_u n_u [\ln n_u - \ln(N \hat{\pi}_u)]. \tag{14}$$

Under suitable regularity conditions, Z is approximately χ^2 distributed with

$$\text{df} = n^m - 1 - q \tag{15}$$

degrees of freedom, where q is the number of estimated parameters in the model. An equivalent test is the Pearson test statistic

$$Q = \sum_u \frac{(n_u - N\hat{\pi}_u)^2}{N\hat{\pi}_u}, \tag{16}$$

which is also approximately χ^2 distributed with a number of degrees of freedom given by Eq. (15). For the rating scale model in Eq. (4), there are $n(m-1) - 1 + s$ parameters to be estimated, where s is the number of parameters in $\phi(\theta)$. Hence, the number of degrees of freedom is

$$\text{df} = n^m - n(m-1) - 1 - s.$$

A critical condition for the approximation to the χ^2 distribution is that the expected number $N\pi_u$ for the response patterns are not too close to zero. For many practical applications, the approximation is rather safe if we require that $N\pi_u > 3$ for all u. On the other hand, it

is clear that even for moderate values of n, especially if $m > 2$, a requirement such as $N\pi_u > 3$ is difficult to meet.

If the number of possible response patterns is very large—for example, $4^{20} = 1.0995 \cdot 10^{12}$, which is the number of possible patterns for $n = 20$ and $m = 4$—it is not likely that any expected number will satisfy the requirement, and we have to search for alternative tests. If the number of response patterns is moderately large, such as 243 (for $n = 5$ and $m = 3$), most response patterns will have low observed counts, but some response patterns may meet the requirement $N\pi_u > 3$. In this case, one possibility is to group the response patterns with low counts into groups with similar response patterns and let grouped observed and expected numbers appear in Eq. (14) or Eq. (16) as a single item.

The degrees of freedom for Z and Q will then be equal to

$$\mathrm{df} = N_G - 1 - q,$$

where N_G is the total number of terms corresponding to grouped or single response patterns appearing in the test quantities.

For a small set of items, where the number of response patterns is very limited, such as for $n = 5$ and $m = 2$, grouping can be avoided; however, in most cases a grouping is necessary.

A Likelihood Ratio Test

If a goodness-of-fit test cannot be based on the multinomial distribution over response patterns, one may use the statistical test suggested by Andersen in 1973.

Let $y_{ih}^{(t)}$ be the item totals for all respondents with score t; that is, $y_{ih}^{(t)}$ is the number of respondents with score t who respond h on item i. Then, the conditional likelihood (Eq. 7) can be factored as

$$\begin{aligned} L_C(\mathbf{a}) &= \prod_t L_C^{(t)}(\mathbf{a}) \\ &= \frac{\prod_t \exp\left(-\sum_i \sum_h a_{ih} y_{ih}^{(t)}\right)}{[\gamma_t(\mathbf{a})]^{N_t}}, \end{aligned} \tag{17}$$

where $L_C^{(t)}$ is the likelihood of all responses belonging to individuals with score t.

The CML estimates $\hat{a}_{ih}$ are the values of a_{ih} that maximize L_C given by Eq. (17). These estimates are the overall CML estimates. It is possible, however, to maximize the individual factors $L_C^{(t)}$ in L_C. This will result in a number of different sets of estimates called score-group CML estimates.

For practical reasons, one would often like to group the scores in interval groups such as $t_{g-1} < t < t_g$, but such a grouping does not affect the following argument.

If the model holds true, the score group estimates should only differ randomly from the overall estimates. If the model does not hold, the factors L_C in Eq. (17) would depend on the distribution of the abilities in the score groups. In 1973, Andersen suggested the use of the likelihood ratio test

$$Z_C = 2 \ln L_C(\hat{\mathbf{a}}) + 2 \sum_t \ln L_C^{(t)}(\hat{\mathbf{a}}^{(t)}). \tag{18}$$

In this test statistic, the maximum of $\ln L_C$, with the overall estimates $\hat{a}_{ih}$ inserted, is compared with $\ln L_C$ with the score group estimates $\hat{a}_{ih}^{(t)}$ inserted. Clearly, Z_C is larger than zero, and the larger the value of Z_C, the less likely it is that the model fits the data. Under suitable regularity conditions,

$$Z_C \sim \Pi^2(\mathrm{df}),$$

where

$$\mathrm{df} = [n(m-1) - 1](T - 1),$$

where T is the number of score groups.

One has to be particularly careful with the approximation to the limiting Π^2 distribution in this case since many score group totals $y_{ih}^{(t)}$ are likely to be small. Hence, a grouping of scores into score intervals is necessary except for the case in which there is a very small number of items.

A goodness-of-fit test based on Z_C given by Eq. (18) is less sensitive to model deviations than a test based on the multinomial tests Z or Q. However, as mentioned previously, it is often the only practical possibility. The types of model deviations that are likely to be detected by the test statistic Z_C were discussed by Andersen in 1973 and Glas in 1989. Glas suggested the use of Wald-type tests based on the score group total $y_{ih}^{(t)}$. The likelihood ratio test statistic Z_C checks only the part of the rating scale model contained in Eq. (2) since the conditional likelihood is independent of Eq. (θ) and, hence, of the form of the latent density (Eq. 8). However, since the probability $f(\mathbf{u} \mid \theta)$ of response pattern U, given by Eq. (4), can be factored as

$$f(\mathbf{u} \mid \theta) = f(\mathbf{u} \mid t) \cdot f(t \mid \theta),$$

where $f(\mathbf{u} \mid t)$ and $f(t \mid \theta)$ are given by Eq. (6) and the formula before Eq. (7), the total likelihood L factors into the conditional likelihood L_C and a term containing the marginal probabilities $f(t) = \pi_t$ of the scores, where π_t is given by

$$\pi_t = \gamma_t(\mathbf{a}) \int e^{\theta t} C^{-1}(\theta, \mathbf{a}) \phi(\theta)\, d\theta.$$

Hence, a two-stage procedure can be adopted: in the first stage the item parameters are estimated based on L_C and the model fit is checked based on Z_C, whereas in the second stage the form of $\phi(\theta)$ is checked based on

the multinomial distribution of the score t over its range. The relevant goodness-of-fit test statistic in stage two would then be

$$Z_T = \sum_t N_t[\ln N_t - \ln(N\hat{\pi}_t)], \tag{19}$$

where $\hat{\pi}_t$ is π_t with its parameters estimated. It is safe, although not theoretically optimal in stage two, to use the CML estimates from stage one as estimates for the a_{ih}'s.

If a goodness-of-fit test has an observed level of significance so low that the model must be rejected, it is important to be able to identify data points contributing significantly to the lack of fit. Residuals are the appropriate tools for this purpose.

Residuals

For the multinomial tests Z, given by Eqs. (14) and (16), the residuals are defined as

$$r_u = \frac{(n_u - N\hat{\pi}_u)}{\text{s.e.}\{n_u - N\hat{\pi}_u\}}. \tag{20}$$

The standard error, s.e.$\{n_u - N\hat{\pi}_u\}$, is the square root of

$$\text{var}[n_u - N\hat{\pi}_u].$$

The precise form of this variance was derived by Rao as

$$\text{var}[n_u - N\hat{\pi}_u] = N\pi_u(1-\pi_u)(1-h_u),$$

where h_u, with $0 < h_u < 1$, is a correction term that depends (on matrix form) on the response probabilities and their derivatives. Note that the variance is smaller than the multinomial variance $N\pi_u(1-\pi_u)$. The correction term h_u can be large, even close to 1, especially if a substantial percentage of the respondents choose response pattern u.

For the test statistic Z_C, there are two possibilities for residuals. The first possibility is to standardize the differences

$$y_{ih}^{(t)} - E[Y_{ih}^{(t)}], \tag{21}$$

where the mean values are estimated using the overall estimates. Since Eq. (21) set equal to 0, for all i and h, represents the likelihood equations for the score group CML estimates, large values of these residuals would point to model deviations. The variance of the expression in Eq. (21) can, in principle, be derived from the response pattern variances and covariances, but actual computations are time-consuming. As a second possibility, the overall CML estimates and the score group CML estimates can be compared directly in the differences

$$\hat{a}_{ih}^{(t)} - \hat{a}_{ih},$$

for all i, h, and t.

It was proved by Andersen in 1995 that approximately

$$\text{var}[\hat{a}_{ih}^{(t)} - \hat{a}_{ih}] = \text{var}[\hat{a}_{ih}^{(t)}] - \text{var}[\hat{a}_{ih}].$$

Thus, it is very easy to obtain the residuals

$$r_{ih}^{(t)} = \frac{(\hat{a}_{ih}^{(t)} - \hat{a}_{ih})}{\text{s.e.}\{\hat{a}_{ih}^{(t)} - \hat{a}_{ih}\}}. \tag{22}$$

Example

In order to illustrate the use of the rating scale model, 14 items from the Symptoms Check List for Discomfort scale were analyzed by Bech *et al*. in 1992. To obtain the scaling, psychiatric patients were presented with a number of items corresponding to problems or complaints that people experience. For each item, the patients were asked to describe how much that particular problem had bothered or distressed them during the last week. The response categories were as follows: (1) extremely, (2) quite a bit, (3) moderately, (4) a little bit, and (5) not at all. For present purposes, categories 1–3 were merged.

The following 14 items were selected for illustrative purposes:

1. Blaming yourself for things
2. Feeling critical of others
3. Your feelings being easily hurt
4. Feeling hopeless about the future
5. Feeling blue
6. Feeling lonely
7. Thoughts of ending your life
8. Having to do things very slowly
9. Difficulty making decisions
10. Trouble concentrating
11. Your mind going blank
12. Lack of sexual interest
13. Trouble falling asleep
14. Feeling low in energy

If a rating scale model fits the patients' responses to these 14 items, each patient's total score would represent a degree of discomfort and thus implicitly provide a scaling of the patient's discomfort/depression. Table I shows the item totals and score group totals for the equidistant scores

$$w_h = m - h, \quad h = 1, \ldots, m.$$

The minimum and maximum obtainable scores across the 14 items with this scoring of response categories were 0 and 28 (i.e., 14×2).

The minimum score corresponded to no symptoms, whereas a high score reflected a high degree of discomfort

or a high indication of psychiatric problems. The CML estimates are given in Table II.

The CML estimates show, as do the item totals, that items 2, 4, 5, 9, and 12 contributed most to a high discomfort score, whereas items 6–8, 13, and 14 were less often used as indicators of discomfort. Thus, in a rating scale model the item parameters reflected how strongly a given item tended to provoke a response contributing to a high score.

For $n = 14$ items with $m = 3$ response categories, there are approximately 5 million possible response patterns. For this case, a goodness-of-fit test based on the multinomial distribution over response patterns was not possible. However, it was possible to use the test statistic Z_C given by Eq. (18) based on score groups. To ensure that the required approximations could be expected to hold, the following interval grouping of the score t was selected: 0–7, 8, 9–11, 12–13, 14, and 15–28. Figure 2 shows the score group CML estimates plotted against the overall estimates. The main structure was satisfactory, but there were obvious deviations from the ideal identity line. The test statistic Z_C had observed value

$$Z_C = 174.45, \quad df = 135,$$

with a level of significance of approximately 0.1%. It was questionable, therefore, to accept the model and, consequently, a rating scale based on all 14 items.

To inspect the lack of fit more closely, the residuals in Eq. (22) were plotted against the item number. An inspection of this plot (Fig. 3) reveals that the significant residuals were concentrated in items 5, 13, and 14. Hence, a set of items without these three items should be expected to fit the model better. When the goodness-of-fit test was repeated for this set and the residuals were plotted again, the level of significance for the Z_C test became 0.06, and the residual plot looked satisfactory. If item 8 was also excluded from the set, the goodness-of-fit test Z_C had the observed value $Z_C = 124.50$, with 114 degrees of freedom. This corresponded to a level of significance of approximately 25% and was judged to be a very satisfactory fit. It seemed that the rating scale model fit the data well with 11 of the original 14 items included in the scoring of the responses and very well with 10 items included. Table III provides a summary of the goodness-of-fit tests.

To illustrate the use of a normal latent density, consider the test statistic Z_T given by Eq. (19). In Table IV, the observed score group counts N_t and their expected values

Table I Item Totals, y_{ih}, and Score Group Counts N_t

14	16	16.77	−0.194
15	14	15.63	−0.428
16	11	14.58	−0.979
17	5	13.54	−2.455
18	9	12.39	−1.040
19	12	10.80	0.408
20	10	7.78	0.925

$N_t\hat{\pi}_t$ for a normal latent density are given. The estimated mean and variance were found to be

$$\hat{\mu} = -1.35 \quad \text{and} \quad \hat{\sigma}^2 = 2.96$$

The observed value of Z_T was $Z_T = 54.63$, with 18 degrees of freedom. This result was significant at 0.1%. Hence, a latent structure model seemed to fit the data but a normal latent density did not. The residuals given in Table IV (i.e., the differences between observed and expected values divided by their standard errors) show that the lack of fit is primarily due to a clear overrepresentation of score 0 as compared to the model. Thus, the model to a large extent described the shape of the score distribution but was not able, it seemed, to describe the frequency of the (not very interesting) respondents with score 0.

Glossary

biregional input–output table An input–output table that describes two regions; usually, the first region is a particular area such as a county, and the second region is "the rest of the country."
final demand The sum of the value of consumption by households, purchases by the government, purchases as investments, mostly by companies, and exports.
intermediary deliveries The delivery of goods from a certain industry to other industries or to the same industry in another region.
internal deliveries The delivery of goods from a certain industry within the same industry.
multiplier A value that shows the effect of a certain impulse as a result of the estimated recirculation of spending within the area concerned.
primary input Sum of labor costs, capital costs, payments to the government (e.g., taxes), and import costs.
technical coefficients The proportion in which a specific input is required to produce one unit of output.
transactions matrix A representation of the monetary value of the flows of goods between industries, the final demand, and the primary input within an economy.

Regional input–output analysis depicts the flows of goods (and services) between industries in the economy of a region. In the early history of input–output analysis, only national input–output tables were used; however, as interest increased in regional economic analysis, regional input–output tables were developed. In dealing with a regional input–output table, regional multipliers can also be derived. Depending on the geographic subdivision pertaining to the table, they show the effects of a certain impulse on the region, on other regions, or on the national economy. A great advantage of input–output models is their internal consistency. All effects of any given change in final demand can be recorded. This article gives an overview of the potential of this method as well as a numerical illustration.

Introduction

Input–Output Analysis

Input–output analysis is an established technique in quantitative economic research. It belongs to the family of impact assessment methods and aims to map the direct and indirect consequences of an initial impulse into an economic system across all economic sectors. It is essentially a method that depicts the systemwide effects of an exogenous change in a relevant economic system.

Input–output models are based on the idea that any output requires a corresponding input. Such input may comprise raw materials and services from other industries but also labor from households or certain amenities provided by the government. The output consists of a sectoral variety of products and services. A conventional input–output table is based on double-entry

bookkeeping: the totals of the columns equal the totals of the rows. Input–output tables may relate to the global economic system, the national economy, and also regional systems.

With the help of regional input–output tables, interdependencies and linkages between industries, households, and the government in and between regions can be examined. This method has found many applications worldwide and is one of the foundation stones of policy impact analysis.

Examples

One example of the use of input–output modeling can be found in a 1998 Australian study by McKay in which the impact of foreign students on the local economy of the city of Wollongong was estimated. Since large amounts of money are often invested in the image of a university and its home city, it is interesting to know what the expected or calculated effects of the expenditures to attract (foreign) students are on the local economy. In this study, it appeared that the effects on the local economy were significant because $1 of investments appeared to create $1.8 of household income and a large number of jobs were created.

Another example is the impact of a certain industry, such as forestry, on other industries. Because the forestry industry uses inputs from other industries and labor from the households in the area, and because it delivers products to several industries, an input–output analysis is a proper analytical instrument. With the use of an input–output table, the impact of a growing forestry industry and also a decreasing industry can be estimated. McGregor and McNicoll performed this exercise in the United Kingdom. In a simulation experiment, they assumed a reduction in output of the forestry industry to zero. Of course, the largest impact is seen in the forestry industry, but the households and the banking, finance, and insurance sectors, as well as the energy and water industries, also encounter major negative effects.

Input–output analysis has become a dominant analytical method in applied economic research. Its strength is its overall consistency at a systemwide level and its power to estimate all direct and indirect implications of an initial stimulus. This potential has been broadly recognized in the history of input–output modeling.

Historical Background

The input–output theory was developed by Wassily Leontief in the late 1920s. He was born in 1906 in Saint Petersburg, and in 1932 he developed the first input–output table of the U.S. economy. Until World War II, the theory was not in demand because many researchers thought it was too mathematical and too data demanding. During World War II, however, the value of the theory was more appreciated as it became very useful to identify bottlenecks in military production chains, such as determining when additional workers were needed.

At that time, input–output tables were used at a national level. Later, regional and international tables were developed. In 1973, Leontief won the Nobel Prize in economics for this groundbreaking and influential work in the assessment of input–output transaction tables. This methodology has become one of the standard tools for economists.

Input–Output Model

The basic information dealt with in the input–output model concerns the flows of products from each industrial industry considered a producer (output) to each of the industries considered a user (input). These flows are often physical or material in nature, but they are usually expressed in monetary terms and described in an interindustry transactions table. The rows of the table describe the distribution of a producer's output throughout the economy. The columns describe the inputs required by a particular industry to produce its output. The "sales to final markets" is included in an additional "final demand" column. Other inputs for the production, such as labor, are included in an additional "primary input" row. The table can describe national flows but also international or regional flows of products.

The usual sources of data for input–output tables are the national (or regional) economic accounts. These accounts are often collected on a regular (yearly) basis by means of surveys among individual firms. For national input–output tables, for example, national income and products accounts and interindustry or input–output accounts are used. The data requirements for building a comprehensive input–output model are formidable.

Input–output theory can be applied to modeling experiments and used for descriptive analyses. Modeling experiments use economic multipliers to map all relevant effects. Descriptive analyses describe, for example, the spatial relationships between regions or the structure of the industries in a certain region.

The Structure of an Input–Output Table

Because the input–output table describes the flows of products between and within industries for a certain region, the table can be divided into four quadrants (Fig. 1):

1. The upper left quadrant of the table contains the internal and intermediary delivery of goods from the industries to their own or to other industries.

From	To	Industry 1	Industry 2	Industry 3	Industry 4	Households	Government	Investments	Export	Total (X)
Industry	1	z_{11}	z_{12}	z_{13}	z_{14}	c_1	g_1	i_1	e_1	X_1
	2	z_{21}	z_{22}	z_{23}	z_{24}	c_2	g_2	i_2	e_2	X_2
	3	z_{31}	z_{32}	z_{33}	z_{34}	c_3	g_3	i_3	e_3	X_3
	4	z_{41}	z_{42}	z_{43}	z_{44}	c_4	g_4	i_4	e_4	X_4
Primary input factors	Labor	l_1	l_2	l_3	l_4					L
	Capital	k_1	k_2	k_3	k_4					K
	Government	o_1	o_2	o_3	o_4					O
	Import	m_1	m_2	m_3	m_4					M
Total (Z)		Z_1	Z_2	Z_3	Z_4	C	G	I	E	

Figure 1 Elements of an input–output table.

2. The bottom left quadrant shows the primary costs, such as import and labor costs.
3. The upper right quadrant contains the final demand consisting of the demand of households and government, investments, and export.
4. The bottom right quadrant shows the portion of the primary costs that directly apply to the final sales.

As previously mentioned, the values of the cells are often expressed in monetary terms. Because the goods, produced by the different industries, are very heterogeneous, monetary terms are the best way to compare the flows. In some cases, such as when a table describes flows of energy, prices are not interesting. In these cases, energy terms are used.

The notation used in Fig. 1 is as follows:

Internal and intermediary deliveries

z_{ij} is the value (in monetary terms) of the delivery from industry i to industry j in a certain period for a certain economic system.

X_i is the total value of the goods produced by industry i.

Z_j is the total value of all inputs required by industry j.

Final demand

c_i is the value of consumption by households of goods from industry i.

g_i is purchases by the government of goods from industry i.

i_i is purchases as investment, mostly by companies, from industry i.

e_i is exports by industry i.

Primary input factors

l_j is labor costs of industry j.

k_j is capital costs of industry j.

o_j is payments to the government by industry j.

m_j is import costs of industry j.

Summarizing, the rows of the input–output table contain the internal deliveries (e.g., the agricultural industry that delivers products to other companies within the agricultural industry) as well as intermediary deliveries (e.g., the agricultural industry delivering to the food industry). Furthermore, the rows contain deliveries to the final demand, such as the consumers, the export sector, or the government. Each row sums up to the total output of an industry.

The columns contain deliveries from other industries as well as from the own industry to the pertaining industry (e.g., from the building industry to the agricultural industry). The columns also contain the rest of the necessary inputs, such as labor, imports, and indirect taxes.

Regional Input–Output Tables

As mentioned previously, initially only input–output tables concerning the national economy were used.

However, decades after the first national table was constructed interest arose in regional economic analysis. Therefore, regional input–output tables had to be envisaged and developed. According to Miller and Blair, there are two basic features of a regional economy that affect the characteristics of a regional input–output table.

First, the technical coefficients (describing the proportion in which a different input is required to produce one unit of output), which at the national level are composed of average data of individual producers, have to be adapted to regional specificities. Although at the national level the average technical coefficients of all regions are given, the production process of similar goods in distinct regions can differ substantially. For example, energy can be produced using water power, wind power, or coal. The required input differs very much; therefore, the national input–output table should be adapted using region-specific data. Information such as household income and the output of industries at the regional level is used to modify the national data.

Second, smaller economic areas are more dependent on trade with other areas both for the sales of outputs (export) and for the purchase of inputs (import). One can imagine that a city cannot produce all the inputs that are needed for its production, and that it cannot sell all the goods that it has produced. On the other hand, if we take the world as an economic area, it becomes clear that no import or export will exist at a global level.

When examining the spatial level of detail within input–output tables, we can distinguish between national, intraregional, and interregional tables. The intraregional table describes the relations, the flows of products, between firms in one region. The transactions with industries in other regions of a country are seen as export or import to a foreign country. The interregional table discerns different industries in different regions. It divides the transactions according to the industries concerned. When an interregional table describes two regions, it is called a biregional table. The construction is easier because the second region is "the rest of the country," which means that the two regions sum to the total national economy. Biregional tables give detailed information concerning the relations between firms within the region but also of the relations between firms within the region and firms within the rest of the country. Clearly, the step to multiregional tables is straightforward but, of course, more demanding from a data perspective.

Multipliers

Direct and Indirect Effects

An important characteristic of input–output models is that they provide a detailed industry-by-industry breakdown of the predicted effects of changes in demand. It is sometimes useful, however, to provide a summary statement of these forecasts by examining direct and indirect effects. This can be done by constructing multipliers based on the estimated recirculation of spending within the region; recipients use some of their income for consumption spending, which results in further income and employment. This generated effect appears at three levels. First, the direct effect of production changes. For example, an increase in tourists staying in a hotel will directly increase the output of the hotel industry. Indirect effects result from various rounds of respending of, for example, tourism receipts in linked industries. If more hotel rooms are rented, then more breakfast products or cleaning services are needed. This will have an indirect effect on these industries. The third level of effects consists of the induced effects. These effects only occur in a closed input–output model. In this case, the household industry is converted into an endogenous industry, which means that it responds to a change in income. The induced effects also include changes in economic activity resulting from household spending of income earned directly or indirectly as a result of tourism spending, for example. These households may be employees of restaurants, who spend their income in the local economy.

The three most frequently used types of multipliers estimate the effects on (i) outputs of the industries, (ii) income earned by households due to new outputs, and (iii) employment expected to be generated because of the new outputs.

An output multiplier for the tourism industry can be defined as the total value of production in all industries of the economy that is necessary to satisfy $1's worth of final demand for the output of the industry. Income multipliers describe the impacts of final demand changes into changes in income received by households. Finally, the employment multiplier describes the number of jobs created because of one new job.

Multipliers can be derived as follows:

Output multiplier: (direct effect + indirect effect)/direct effect

Households income multiplier (type I): (direct effect + indirect effect)/direct effect

Households income multiplier (type II): (direct effect + indirect effect + induced effects)/direct effect

Employment multiplier: (direct jobs created + indirect jobs created)/direct jobs created

The size of the multiplier depends on several factors. First, it depends on the overall size and economic diversity of the region's economy. Regions with large, diversified economies that produce many goods and services will have high multipliers because households and businesses can find most of the goods and services they need in their own region. Also, the geographic scale of the region and

its role within the broader region play a role. Regions of a large geographic coverage will have higher multipliers, compared to similar small areas, because transportation costs will tend to inhibit imports (imports can be considered as leakage and have a negative effect on a multiplier). Regions that serve as central places for the surrounding area will also have higher multipliers than more isolated areas. Furthermore, the nature of the specific industries can have a significant effect. Multipliers vary across different industries of the economy based on the mix of labor and other inputs and the tendency of each industry to buy goods and services from within the region (less leakage to other regions). Tourism-related businesses tend to be labor-intensive. Therefore, they often have larger induced effects because of household spending rather than indirect effects. Finally, the year of the development of the input–output table should be taken into account. A multiplier represents the characteristics of the economy at a single point in time. Multipliers for a given region may change over time in response to changes in the economic structure as well as price changes. When comparing the sizes of the multipliers, it is important to distinguish the different effects that are taken into account.

Regional Multipliers

When working with a regional input–output table, regional multipliers can also be derived. Depending on the kind of table, relevant economic effects on the region, on other regions, or on the national economy can be computed. These effects are interesting, for example, when the government has to decide upon a new location for a military base or for a new main post office. If the government wants to use this relocation to stimulate a certain region, the regional effects on employment or income are relevant.

The effect of a change in final demand within a region (region 1) on the region, the regional (output) multiplier, can be derived as follows:

$$M_a = \frac{(X_1^1 - X_1^0)}{\text{impulse}},$$

where M_a is the regional multiplier, X_1^1 is the total output of region 1 after the impulse, and X_1^0 is the total output of region 1 before the impulse. The essence of an interregional input–output model is that it includes impacts in one region (region 2) that are caused by changes in another region; this effect is measured by the spillover multiplier. Later, we explain in more detail how the multipliers can be computed.

Advantages and Disadvantages of Regional Input–Output

The major advantage of input–output models is their internal consistency. All effects of any given change in final demand can be recorded. Important, and sometimes restrictive, assumptions made in the input–output model are that all firms in a given industry employ the same production technology (usually assumed to be the national average for that industry) and produce identical products. Because the tables are produced for a certain period, the model can become irrelevant as a forecasting tool when production techniques change. Other disadvantages are that the model assumes that there are no economies or diseconomies of scale in production or factor substitution, and that they do not incorporate the existence of supply constraints. Finally, input–output models are essentially based on a linear production technology; doubling the level of agricultural production will double the inputs, the number of jobs, etc. This reveals something of the inflexibility of the model. Thus, the model is entirely demand driven, implying that bottlenecks in the supply of inputs are largely ignored.

There are also some practical problems in (regional) input–output theory. The development of a new input–output table is very labor-intensive and expensive. This is mainly due to the fact that most information is gathered using microsurvey questionnaires. Another problem of this method is that interviewees, firms or households, are not able to give perfect answers. Sometimes, they do not understand the question, or they do not want to tell the truth and therefore the data are not always perfect.

Another problem is that the data are expressed in monetary terms. This is done because it is impossible to compare physical units, but monetary values may increase and decrease due to price changes. Still, input–output analysis is seen as a very clear and important method, which has its limitations but is often embedded as a module in more extensive models.

Numerical Example

Here, a simple illustration of input–output analysis is presented. This example presents an input–output table (Fig. 2) describing an economy with two regions that both have two industries, industry A and industry B. From Fig. 2, we can read, concerning the output, that industry A from region 1 delivers 10 units to its own industry, the internal deliveries. The industry also delivers 5 units to industry B in region 1, 6 units to industry A in region 2, and 2 units to industry B in region 2. Final demand, which goes directly to consumers, investments, and the government, consists of 15 units. Finally, 4 units are exported.

The input consists of 10 units of internal deliveries and a total of 14 units of intermediary deliveries. Furthermore, 6 units are imported and 12 units go to the value-added account, the labor payments, taxes, and profit.

From the transactions matrix, we move to the technical coefficients matrix (Fig. 3). The technical coefficients

		Region 1		Region 2				
		Industry A	Industry B	Industry A	Industry B	F	E	X
	Industry A	10	5	6	2	15	4	42
Region 1	Industry B	6	7	4	5	10	15	47
Region 1	Industry A	4	2	12	6	8	4	36
Region 2	Industry B	4	2	8	10	12	10	46
Region 2	M	6	4	2	2			
	V.A.	12	27	4	21			
	X	42	47	36	46			249

F = Final demand; E = Export; X = Total input or output; M = Import; V.A. = Value added

Figure 2 Transactions matrix.

$$\begin{vmatrix} 10/42 & 5/47 & 6/36 & 2/46 \\ 6/42 & 7/47 & 4/36 & 5/46 \\ 4/42 & 2/47 & 12/36 & 6/46 \\ 4/42 & 2/47 & 8/36 & 10/46 \end{vmatrix}$$

Figure 3 Matrix with technical coefficients (A).

matrix A can be obtained by dividing the row of internal and intermediary deliveries by the column of total output (X).

The first element of the matrix indicates that 10/42 units of input from industry A from region 1 are necessary per unit output. If industry A is the agricultural industry and industry B can be seen as the service industry, it means that the agricultural industry in region 1 needs 10/42 units of input from its own industry to produce 1 unit of output. The second element of the table indicates that the agricultural industry also needs 5/47 units of input from the service industry in region 1, 6/36 units of input from the agricultural industry in region 2, and 2/46 units of input from the service industry from region 2.

Then the (inverse) Leontief equation can be applied: $X = [I - A]^{-1} \times (F + E)$, where X is the total output column, I is the identity matrix, A is the technical coefficients matrix, F is the final demand vector, and E is the export vector.

For this example, the total output can be calculated as follows:

$$X = \left\| \begin{vmatrix} 1 & 0 & 0 & 0 \\ 0 & 1 & 0 & 0 \\ 0 & 0 & 1 & 0 \\ 0 & 0 & 0 & 1 \end{vmatrix} - A \right|^{-1} \times \begin{vmatrix} 19 \\ 25 \\ 12 \\ 22 \end{vmatrix}$$

$$= \begin{vmatrix} 0.76 & -0.11 & -0.17 & -0.04 \\ -0.14 & 0.85 & -0.11 & -0.11 \\ -0.10 & 0.04 & 0.67 & -0.13 \\ -0.10 & -0.04 & -0.22 & 0.78 \end{vmatrix}^{-1} \times \begin{vmatrix} 19 \\ 25 \\ 12 \\ 22 \end{vmatrix}$$

$$= \begin{vmatrix} 1.43 & 0.21 & 0.45 & 0.18 \\ 0.31 & 1.24 & 0.37 & 0.25 \\ 0.28 & 0.14 & 1.70 & 0.32 \\ 0.27 & 0.13 & 0.56 & 1.40 \end{vmatrix} \times \begin{vmatrix} 19 \\ 25 \\ 12 \\ 22 \end{vmatrix} = \begin{vmatrix} 42 \\ 47 \\ 36 \\ 46 \end{vmatrix}$$

Here, the computed X is identical to the last column of the transactions matrix, as it should be. Now, we can simulate an impulse in this small economy and compute the multipliers.

The multipliers we are searching for are the elements of the inverse Leontief matrix. For example, the value 0.31 in the second row means that a unit increase of demand in industry A of region 1 leads to an increase of 0.31 in industry B in this region. The overall effect of a unit increase in this sector is the sum of the values in the first column of this matrix: $(1.43 + 0.31 + 0.28 + 0.27) = 2.29$. This is the value of the output multiplier for sector A in region 1. Thus, an increase in final demand of 10 units for sector A in region 1 would have a total effect of 22.9 on the whole economy, 17.4 of which would materialize in region 1 and the rest in region 2.

Glossary

entropy maximization Extension of the traditional gravity model, used to model spatial interaction as a stochastic, rather than deterministic, process.
geographic information system Computerized environment for collecting, processing, analyzing, and displaying spatial data.
GIScience Theory and science behind the tools and technologies of geographic information systems (GIS) and the application of GIS in scientific research.
linkages Interdependencies between sectors that comprise an economy.
location–allocation models Operations research models designed to identify the optimal location of a facility given the location of markets, suppliers, and raw materials; the goal of such models is to determine the location that will minimize costs or maximize profits.
multiplier Direct and indirect impacts of changes in final demand.
space economy The spatial structure of regional economies; geographic distribution of inputs and outputs, spatial variation in prices and costs, and geographic patterns resulting from economic processes.
spatial autocorrelation Tendency for observations of social and economic variables to be correlated according to their geographic location; empirical regularity in which the value of one geographic observation is influenced by the value of other (usually nearby) observations.
spatial interaction Movement of goods, people, information, and capital; geographic patterns resulting from economic processes of supply and demand, competition, and distance.

In this introductory review of methods commonly used in the field of regional science, the discussion focuses on those fields and subareas within which regional science has made and continues to make the greatest impact, in theory, in practice and in policy. Economic and spatial methods and their potential applications are considered, and some basic planning applications are discussed. Because of the traditional spatial focus of regional science, the tools and technologies of geographic information science have been quick to take hold.

Introduction

The advent of regional science in the 1950s sought to forge a dynamic framework for regional analysis. Unlike its neighbors in geography and economics, regional science explicitly recognizes that all economic processes exist in space as well as in time. An important point of departure is the attempt to link broad-scale, or regional, patterns to underlying social and economic processes. Traditionally, regions have been defined on the basis of some social, economic, or physical characteristic, drawing on the concept of nodality—functional relationships between cities and their hinterlands—or based on administrative or political boundaries. Notwithstanding these apparently clear-cut definitions, the regional concept becomes murky because it has been applied to a variety of spatial scales, from the very local to the international. In addition, regional boundaries are not static; rather, they may depend on the research problem in question and they may change over time. This discussion can be framed on the basis of a recent assessment, by Sergio J. Rey and Luc Anselin, of publication patterns within the discipline, and elaborated by looking at those fields and

subareas within which regional science has most greatly impacted practice and policy.

Economic Methods

Shift-and-Share Analysis

Shift-and-share analysis is a simple analytical framework used to identify patterns of regional economic change over time. Typically, the method makes use of employment data at the state or county level for two time periods to decompose change in economic structure into three components; national shift, industry mix, and regional competitiveness. The national-shift component corresponds to the change in regional employment that may be attributed to macro-level forces beyond the borders of the study area. The industry-mix effect expresses the expected change in employment had each sector of the regional economy followed its corresponding national growth rate; it represents a "proportional shift" due to differences between national and regional economic structures. The regional-competitiveness component comprises a "differential shift" between regional- and national-level sectoral growth rates that is the result of natural resource endowments, comparative advantage, and the effects of regional policy.

The sum of national, industry-mix and regional-competitiveness components equals overall change in employment between two time periods. The basic shift-and-share model may be expressed as follows:

$$E^R_{i(t+1)} = E^R_{i(t)} \cdot \left[(E^N_{t+1}/E^N_t) + (E^N_{i(t+1)}/E^N_{i(t)} - E^N_{t+1}/E^N_t) + (E^R_{i(t+1)}/E^R_{i(t)} - E^N_{i(t+1)}/E^N_{i(t)})\right], \quad (1)$$

where E represents employment, R identifies the region of interest, N refers to the nation, i indicates a given sector of the economy, and t and $t+1$ identify the two time periods. In general, shift-and-share analysis ascribes regional economic change to some combination of national, regional, and sectoral forces. If the national-shift component accounts for most employment change, national trends can be used to make regional forecasts. If the industrial-mix and/or regional-competitiveness components of the model display substantial shifts, the distribution of employment in specific sectors of the economy must be considered. For instance, if a large share of regional employment is found mainly in fast-growing activities, the regional economy has a "favorable" industrial mix and its growth rate will exceed the national average. The competitiveness component may reveal that some regions attract a greater share of employment in a particular industry because they have better access than other regions to important markets or inputs.

Although shift-and-share analysis is a purely descriptive technique, it remains a useful method for decomposing regional change. A recent analysis, for example, has employed a shift-and-share framework to identify the components of urban population change in the United States between 1950 and 2000. Though the shift-and-share technique identifies the relative importance of different components of regional change, it does not attempt to explain the processes that bring about these shifts. Notwithstanding its utility, regional scientists have identified a number of limitations with the technique. In spite of attempts to model industry-mix and regional-competitiveness components as a function of locational characteristics, the method lacks a theoretical foundation. As with many regional economic models, the results of shift-and-share analysis are highly dependent on the level of temporal, geographic, and sectoral aggregation. The technique is of limited utility as forecasting tool and ignores linkages between industries and spatial interaction effects.

In response to these criticisms, several researchers have attempted to extend the basic shift-and-share technique. Because the traditional model confounds some of the regional-competitiveness effects with industrial mix, regional competitiveness was divided, in one study, into a traditional regional shift component and an allocation effect. Another research team developed a "dynamic" shift-and-share method to obtain a more accurate indication of regional economic change in New England. Finally, several scholars have been at the forefront of attempts to reformulate traditional shift-and-share analysis econometrically in order to provide a better understanding of regional dynamics.

Economic-Base Model

The economic-base model is a useful tool for estimating the overall impacts of regional export activity. The debate surrounding the significance of the export base in regional economic growth dates back to the seminal contributions of Douglass North and Charles Tiebout in the 1950s and 1960s. North introduced the export theory of growth, in which regional economic growth is attributed to external demand for a region's goods and services, to describe the process by which regional economic development takes place. In the simple export-base model, local markets are too small to generate scale economies and other positive externalities. As a consequence, only significant external demand can generate the forward and backward linkages and increased division of labor necessary to promote development.

The traditional economic-base model distinguishes between two kinds of economic activity: basic and nonbasic. As indicated in Eq. (2), total regional economic activity is merely the sum of basic and nonbasic components:

$$E_T = E_B + E_{NB}, \quad (2)$$

where E_T refers to total economic activity, E_B indicates basic activity, and E_{NB} represents nonbasic activity. Basic (or export) activities serve demands beyond the boundaries of the region. These activities are derived from a combination of locational factors, comparative advantage, and historical accident. Nonbasic (or local) activity depends on the level of basic activities and serves demands within regional boundaries.

During the past several decades, many regional scientists have addressed the crucial issue of identifying basic economic activity. Due to the lack of reliable economic information at the subnational level, employment data are typically used. In general, three basic techniques exist to estimate the level of basic economic activity at the regional level: (1) the assumption method, in which some portion of regional employment is presumed to comprise the export sector, (2) the minimum-requirements method, in which the share of employment in each sector of the region is compared with the "minimum-required" share in similar locations, and (3) the location quotient, based on the ratio of shares of employment in each sector of the regional economy to employment in each sector of the state or national economy. As mentioned previously, the economic-base model is premised on the fundamental assumption that nonbasic economic activity depends on basic activities. Furthermore, nonbasic activity presumably comprises a constant share (k) of the total economy. Therefore, the model may be reformulated as follows:

$$\begin{aligned} E_T &= (k)E_T + E_B, \\ E_T - (k)E_T &= E_B, \\ E_T &= E_B/(1-k), \\ E_T &= (1-k)^{-1}E_B. \end{aligned} \tag{3}$$

As these equations show, total economic activity is a function of basic employment. The relationship between basic economic activity and total activity is specified by the economic-base multiplier $(1-k)^{-1}$, which reveals the overall impacts within the regional economy of a change in the basic sector.

Because the economic-base model is easy to estimate and makes use of readily available data, it remains an invaluable tool for regional impact analysis. However, the model suffers from several important limitations: it combines all export sectors into one multiplier, does not include linkages between industries, and ignores the role of household consumption. Furthermore, the traditional model is static and appropriate only for short-run analysis and relatively small regions. Like the other methods discussed here, the base model also fails to account for spatial interaction and spatial structure. In response to these shortcomings, regional scientists have attempted to expand and enhance the traditional economic-base model. Improvements include attempts to establish an empirical and theoretical basis for the model econometrically, development of "demo-metric" and other dynamic models, and attempts to incorporate space explicitly into the traditional model.

An econometric approach to the economic base initially proposed in the 1970s stated that basic economic activity at the regional scale is a function of economic activity in the "rest of the world." During the past two decades, econometric methods have been used to account for differences in the magnitude of economic-base multipliers and to confirm that nonbasic employment is driven not only by basic employment, but also by nonbasic employment in all other sectors of the local economy.

Demo-metric models link population changes with regional economic growth; these techniques were developed in response to concerns first voiced by Tiebout that population growth and migration may generate an endogenous growth process over and above the export base. Seminal contributions by others have incorporated population change into the economic-base framework, resulting in more accurate analysis of economic impacts and estimation of multipliers that vary over time. Recently, economic-base and regional-adjustment models have been fused to analyze relationships between population and employment change in the western United States. Other scholars have presented time-series applications in order to rectify the shortcomings of the static traditional model.

Notwithstanding the need to incorporate space explicitly into economic impact analysis, only a handful of scholars have attempted to move from traditional sectoral multipliers to more dynamic geographic multipliers. Recent examples involve using basic spatial econometric techniques to demonstrate that economic activity generates impacts not only locally, but also among neighboring communities.

Input–Output Analysis

Input–output (IO) analysis is a modeling technique that divides the economy into final demand and production and accounts for the direct and indirect interdependencies among different sectors. Several researchers have demonstrated empirically the link between economic-base and input–output models. The technique was introduced by Wassily Leontief in the 1930s and adapted for the purposes of regional analysis by Walter Isard in the 1950s.

Input–output analysis requires regional accounts that capture the transactions among the different sectors of the economy for a given period of time (typically 1 year). Table I offers an example of a regional input–output table. The regional IO table is essentially a double-entry accounting system. Rows of the table correspond to sales from a given sector to all sectors of the regional economy; columns represent purchases of intermediate inputs, labor, etc. made by each sector.

Table I Regional Input–Output Table for Yucatán, Mexico (1993)[a]

	Sector purchases					*Final demand*		
Sector sales	*Agriculture and mining*	*Food and textiles*	*Other manufacturing*	*Commerce, hotels, and restaurants*	*Services*	*Household consumption*	*Other final demand*	*Total output*

The portion of the table with values in boldface type identifies interindustry transactions; these are linkages among firms in the different industries that make up the regional economy. Final demand is composed of household consumption, government spending, investment, and exports. The row sum of interindustry sales and final demand comprises an industry's total output; the column sum of intermediate inputs, salaries, imports, and other value-added components equals total outlays. For the economy as a whole, total output must equal total outlays.

Table I is used for input–output analysis by making three critical assumptions. First, IO analysis assumes that each sector of the economy consumes inputs in fixed proportions (demand for intermediate inputs is a linear function of output). A second assumption is constant returns to scale, which precludes increasing returns in different industries. Finally, the model assumes no substitution between different inputs. Once these assumptions have been made, the fundamental input–output relationship may be expressed mathematically:

$$\sum X_{ij} + f_i = X_i, \tag{4}$$

which states that total output of a given sector (X_i) is equal to interindustry sales to all other sectors ($\sum X_{ij}$) plus sales to final demand (f_i). Subsequently, interindustry transactions and total outlays (X_j) may be used to estimate technical coefficients (a_{ij}) for each sector of the economy:

$$a_{ij} = X_{ij}/X_j. \tag{5}$$

Technical coefficients reveal the total direct input requirements for each industry per unit of output. In regional input–output analysis, these values correspond to inputs purchased within the region exclusively. The technical coefficients corresponding to the IO table for Yucatán are shown in Table II. Once technical coefficients have been estimated, the input–output relationship may be reformulated as follows:

$$\sum a_{ij}X_j + f_i = X_i, \tag{6}$$

which decomposes interindustry transactions into two components: the product of technical coefficients (a_{ij}) and total outlays (X_j). If technical coefficients are thought of as forming a square matrix (A) and final

demand (f) and total output (X) as column vectors, the input–output model may be derived in matrix terms as shown in Eq. (7):

$$\begin{aligned} AX + f &= X, \\ f &= X - AX, \\ f &= (I - A)X, \\ (I - A)^{-1} f &= X. \end{aligned} \tag{7}$$

As these equations indicate, the input–output model ascribes total output in the regional economy to final demand and a multiplier process captured by the "Leontief inverse" $(I - A)^{-1}$. Unlike the economic-base model, IO analysis provides multipliers for each sector of the economy. Three basic input–output multipliers may be identified: output multipliers, which quantify direct and indirect impacts on production of goods and services; income multipliers, which facilitate assessment of effects in terms of returns to labor (wages); and employment multipliers, which quantify job creation effects. The Leontief inverse and output multipliers for Yucatán, Mexico are shown in Table III.

The IO model is typically used by simulating exogenous changes to final demand and using multipliers to estimate resulting impacts. The regional input–output framework can be extended to a multiregional context in order to account for linkages between different locations, as well as different sectors of the economy. A multiregional input–output (MRIO) table partitions transactions into intraregional and interregional economic activity. In addition to the basic data required for regional input–output analysis, some estimate of the interregional distribution of interindustry transactions and final demand must be obtained.

Notwithstanding its utility, the input–output model has some shortcomings. At the regional level, salaries and consumer spending, rather than interindustry linkages, may have the greatest impact on the economy. The basic IO framework, however, fails to incorporate household consumption. In response, an alternative, "Type II" multiplier, which endogenizes consumption effects, has been developed. In addition, the income and consumption portions of the model have been partitioned to estimate interrelational income multipliers that account for the distribution of income among different groups. Social accounting models (discussed later) further decompose economic interdependencies among institutions, factors of production, and activities.

The three previously mentioned assumptions (proportionality, constant returns, and no substitution), are also limitations because they violate basic economic theory. Other assumptions, including perfectly elastic supply and price-inelastic final demands, result in overestimated multiplier effects. During the past decade, several regional scientists have employed econometric methods to address some of these issues. The resulting "integrated" IO/econometric models have been used to forecast changes in technical coefficients, to estimate changes in final demand, to allow for increasing returns, and to incorporate the impact of changes in supply and demand on prices and substitution.

Social Accounting and Computable General Equilibrium Models

Social accounting models (SAMs) are an extension of input–output analysis and provide far greater detail about the relationships between sectors of the economy, social groups, and economic agents. Because they capture information about factors of production and institutions such as households and government, SAMs are especially useful in assessing the social welfare implications of economic policy decisions. The basic social accounting framework, established by Richard Stone in 1961, has since been extended by several other scholars. Whereas IO analysis concentrates primarily on interindustry transactions, social accounting models divide the socioeconomic system into three equally important components: factors of production, institutions, and activities.

The structure of a social accounting matrix facilitates identification of the flows of resources throughout the regional economy. For example, as shown in Fig. 1, production activities transfer "value added" to factors of

SOCIAL ACCOUNTING MATRIX		EXPENDITURES				
		Production activity	*Factors of production*	*Institutions*	*Other (exogenous)*	TOTAL
RECEIPTS	*Production activities*	Interindustry transactions		Consumer expenditures	Exports	
	Factors of production	Value added			Net factor income from abroad	
	Institutions		Wages and profits	Transfers and taxes	Transfers (remittances)	
	Other (exogenous)	Imports		Imported consumer goods		
	TOTAL					

Figure 1 Stylized social accounting matrix.

production (land, labor, and capital). Owners of the factors of production (workers, for example) pass on their income to institutions (such as households). Institutions subsequently devote a portion of their income to the consumption of needed goods and services (provided by production activities and imports). Like their IO counterparts, SAM multipliers are completely demand driven. Policy impacts are typically estimated by simulating a change in exogenous accounts, which propagates impacts throughout endogenous components of the model (institutions, factors of production, activities, and other final demand). Social accounting models have been used in a variety of contexts at a number of spatial scales, particularly in developing countries. Seminal examples include the application to a large-scale development project in Malaysia, the use of social accounts at the village level in Mexico, and development of a multiregion model to estimate the impact of taxes on counties in Iowa. As an extension of the IO framework, SAMs are the fundamental component of computable general equilibrium (CGE) models. CGE models are built on the social accounting framework and use neoclassical economic theory to provide a more realistic representation of behavioral and structural relationships among economic agents. Consequently, these models eliminate many of the restrictive assumptions associated with the traditional input–output model.

The most common "Walrasian" (after Léon Walras, 1834–1910) CGE model is based on assumptions of perfect markets and optimal behavior among producers and consumers; the model simulates economic behavior in which prices and output (supply and demand) adjust to clear markets. Consequently, CGE multipliers tend to be somewhat smaller than their IO counterparts (though they converge to IO multipliers in the long-run). Like IO and social accounting models, CGE models have been used in a wide variety of applications. Examples include the Global Trade Analysis Project, which assesses distributional consequences of trade liberalization for individual nations and regional blocs; a regional CGE model for Scotland (a Macro–Micro Model of Scotland, or AMOS); and the three-region Brazilian Multisectoral and Regional/Interregional Analysis Model (B-MARIA), focusing on regional inequalities and structural change in Brazil.

Although CGE models offer many advantages over the traditional IO and SAM models, they require massive amounts of data and depend greatly on the calibration of parameters that are frequently unknown or unavailable. In addition, they are much more complex than other models are, making it difficult, if not impossible, to trace impacts throughout the economic system. Furthermore, CGE models may not provide significantly better results compared to those obtained from traditional input–output or social accounting models.

Spatial Methods

Space and spatial relationships have always been central to the discipline of regional science, beginning with Isard's seminal work on the space economy. More recently, these ideas have been integrated with more sophisticated mathematical analyses by Masahisa Fujita, Paul Krugman, and Anthony Venables. In a broader perspective, space provides an organizing principle: different processes and actors are linked through their location. A suite of spatial methods commonly used in regional science research is reviewed in the following

discussions. Because regional science has always been concerned with the rigorous quantitative analysis of regional processes, it has provided fertile ground for the development, application, and innovation of spatial social science.

Geographic Information Science

The analysis of space and place in social science has become increasingly important in recent years, and the foundations of spatially integrated social science have been discussed. Interestingly, advances in geographic information science (GIScience) have, in large part, been driven by increasingly available spatial data and by developments in software and hardware that facilitate spatial modeling. Precisely because regional science has been at the forefront of thinking about space and spatial relationships, the integration of GIScience into the discipline has been prolific.

Some researchers have discussed a particularly synergistic aspect of GIScience and its potential contribution to the discipline. Visualization has long played a crucial role in shedding insights about patterns and processes, stimulating new theory and applications. The tools and technologies within GIScience have provided further impetus for new model development and testing. Particular emphasis has been placed on the fruits of quantitative spatial thinking and on geocomputation (quantitative analysis of spatial data in which computing plays a pivotal role). Increases in both computing power and available spatial data have greatly enhanced inferential capabilities of spatial models, in that rigid statistical assumptions (i.e., normality and independence) can be relaxed with permutation or bootstrapping approaches. Spatial modeling techniques have been employed by regional scientists in a host of applications, including urban and regional planning, business location analysis, transportation, studies of epidemiology and crime, community development, and environmental and natural resource management. All of the methods used in the models predate computerized GIS tools, but geographic information systems and GIScience have been pivotal in the expansion and application of these tools.

Spatial Interaction Models

Many relevant social science questions boil down to identifying the driving forces of interaction through spaces. Therefore, techniques have emerged within regional science as a means of measuring and estimating the scope, nature, and volume of flows. The initial application of spatial interaction was borrowed from social physics. These deterministic models were replaced with entropy maximization, which views spatial interaction as a stochastic process. Spatial interaction models were expanded to formulate a theory of movements, in which flows of goods and people over time collectively form the development of a region. Relevant flows shaping regional development can be movements of people (migration), but can also be other varied processes, such as international or interregional trade, shopping trips, or commuting patterns.

Spatial interaction models may be applied to two basic questions. The first type of model would involve the explanation or prediction of spatial choice, i.e., allocation of flows to a particular destination. Many of the techniques for spatial choice modeling have emerged from transportation and demography, wherein flows are explicitly part of any study. The formulation of these models is generally as follows:

$$I_{ij} = \frac{E_i A_j}{d_{ij}^b}, \tag{8}$$

where I represents the interaction between locations i and j, Edescribes the volume of flows originating at point i, A describes the opportunities to be found at point j, d is the distance between them, and b represents the degree of distance decay, or how quickly interaction drops off with increasing distance.

There are also competing destinations models, which look at the choice of a particular destination, given several options. Continuing with the retail example, assume the following conditions:

$$P(I_{ij}) = \frac{(A_j/d_{ij}^b)}{\sum_j (A_j/d_{ij}^b)}, \tag{9}$$

where now there is some probability (P) of interaction between locations i and site j based on the characteristics of j compared to all possible retail locations. This has been further refined into the intervening-opportunities model, asserting that, in an urban area, the consumer will shop at the first service area that meets his/her minimum expectations.

A larger suite of location–allocation models has been developed based on spatial interaction principles. These models were developed to provide recommendations regarding the best locations of public facilities, such as health care services and schools, and to address private sector issues such as location of retail stores, warehouses, or factories. Location–allocation models attempt to optimize aggregate behavior (flows of interaction), satisfying multiple criteria:

$$\min Z = \sum_{i=1}^{n} \sum_{j=1}^{m} w_i d_{ij} a_{ij}, \tag{10}$$

where Z is some objective function to be minimized (such as total travel cost), n is the number of origin

points, m is the number of potential destinations, w is some weight for each origin, and d is distance. The choice of allocation of source i to destination j is flagged by a; if the site is chosen, its value is 1; otherwise it is 0. More advanced models specify hierarchies of centers. The most important implication of this work is the assertion that observable regional patterns emerge as a result of individual decision-making processes, which are subject to a great deal of variation and uncertainty. There have been notable extensions of this basic approach. This approach was linked in one study to an underlying behavioral model (based on cost minimization) that is congruent with economic theory to the larger macro model suggested by gravity or entropy-maximizing approaches. Other researchers have provided a dynamic extension of these models, specifying the mathematical relationships in which the models could more flexibly be used to represent evolving and changing interactions among units.

Location Analysis

Traditional location analysis includes the central place theory of Walter Christaller, the refinements by August Lösch, Ricardian (David Ricardo) ideas of land rent, and Johann von Thünen's insights on market accessibility. At root, these models state that the location of firms and households relates to transportation costs (both in the movement of goods and people) and the accessibility of inputs to production processes, and back to the resulting output markets. The relationship between space or distance and firm profit can be denoted as follows:

$$\pi_i^{m_i} = P_i Q_i - A_C^{m_i} - t_i m Q_i - R^m, \qquad (11)$$

where π represents the profits of firms in industry i at distance m miles from the center of the city, P and Q represent price and output, A_C is the average production cost, t is the per unit output transport cost, and R denotes land rent at location m. Therefore, both per unit costs and average costs are affected directly by transportation costs, leading to discernible spatial patterns in economic activity even at points of equilibrium in a competitive market.

Location theory has been applied to explain urban density, labor migration, and land use patterns. Regional scientists learned long ago that strategic location behavior by firms can lead to industrial agglomeration, economies of scope and of scale, relating very clearly to Marshallian (Alfred Marshall) external economies. Classical location theory assumes that markets are competitive and consumers are homogeneous, but factors of production may be differentially spatially distributed, and firms will choose location strategies to minimize costs. As firms attempt to minimize transportation costs, for example, they may choose to locate in an area where they can exploit economies of scope and scale. Paul Krugman has pointed out, for instance, that firms may choose to locate in an area with a greater pool of highly skilled workers.

The practical applications of location analysis are numerous. First and foremost, location analyses have been employed in applied business questions, such as retail and market area analysis. Second, a major thrust of location analysis within regional science has been on examining and explaining urban–rural disparities and providing guidance to policymakers. These theories relate to long-standing rural underdevelopment, but also serve as a guide to policymakers regarding best-practice policy instruments to stimulate rural economic growth and development.

Spatial Statistics and Spatial Econometrics

Econometric analysis of areal units poses a particular set of problems and challenges for statistical estimation and inference. Isard stressed the importance of thinking about space as continuous phenomenon, but, in practice, data are often assigned to irregular units (such as administrative boundaries) due to data collection techniques, confidentiality requirements, and other logistical concerns. Therefore, the assignment of individual behavior to a possibly arbitrary spatial unit can induce spatial dependence or heterogeneity that may mask or obscure individual decision-making processes. Spatial autocorrelation necessarily induces heteroscedasticity as well as other violations of ideal conditions for econometric analysis, such as normality or independence among observations. The term "spatial econometrics" was coined by Jean Paelinck and Paul Klaassen in 1979, based on five principles: spatial interdependence among units, asymmetry in this dependence, importance of explanatory factors located in other areas, difference between prior and subsequent interaction, and the explicit modeling of spatial relationships.

Interaction effects are expressed in terms of an N by N spatial weighting functions and a spatial parameter. Theoretically, the spatial relationship between two observations in a cross-sectional data set would be given by the covariance matrix; e.g., σ_{ij} represents the covariance between observations i and j. Because estimation of the full covariance matrix is not possible, the researcher must impose a structure on that model. The number of interactions among N observations can be as many as N^2, which cannot be identified (this is referred to as the incidental parameter problem). Instead, the most common way of specifying the structure of spatial dependence when the units of analysis are discrete objects (e.g., plots of land) is by specifying a spatial weighting function such that a matrix W defines a nonzero w_{ij} as

the neighborhood j around observation i. The most commonly used spatial weights can represent connectivity, contiguity, adjacency or association, or the distance decay of a particular process. Weights that define the magnitude of interaction or potential (the so-called spatial economic multiplier) can also be defined. The specification of the interaction effect in a spatial lag model amounts to a weighted average of neighbors' choices, weighted by w_{ij}. Writing out the spatial lag for observation i in scalar terms makes this readily apparent:

$$[Wy]_i = \sum_j w_{ij} y_{ji}. \tag{12}$$

There are two categories of spatial pattern: spatial dependence, or autocorrelation, and spatial heterogeneity. The most widely used statistic to characterize spatial autocorrelation for continuous variables is Moran's I:

$$\frac{\sum_{i=1}^{n}\sum_{j=1}^{n} w_{ij}(x_i - \bar{x})(x_j - \bar{x})}{\sum_{i=1}^{n}(x_i - \bar{x})^2}, \tag{13}$$

where x is the variable in question, and the weights matrix w is the assumed structure of interactions between observation i and j. This statistic is somewhat analogous to a correlation coefficient, except that only the deviations between each observation and its neighbors, defined by the weights matrix, are considered. There are local extensions to this global statistic, such as the local indicator of spatial association:

$$I_i = \frac{(x_i - \bar{x})}{\sum_i (x_i - \bar{x})^2} \sum_j w_{ij}(x_j - \bar{x}), \tag{14}$$

where an I value is assigned to each observation i, which indicates the standardized difference between that observation and the mean relative to a weighted average of its neighbors. In this way, researchers can identify hot spots or spatial outliers within the data set, obtaining a more complete understanding of how individual observations are contributing to overall patterns within the data.

Spatial econometric techniques have been employed in a host of applications. Such approaches have been used in studies of regional growth and convergence in the United States and Europe and in myriad land applications, such as analyzing land use and land value processes, in assessing local interdependencies that arise from land use externalities, and in studying the impact of open space on land values. Other noteworthy applications include studies of public finance and taxation, firm spatial competition for market area, and knowledge spillovers. A current challenge for regional science is the consideration of spatiotemporal patterns and processes. Storage and manipulation of repeated observations on a single object are nontrivial; and developing systems that can separately identify spatial and temporal interactions remains an onerous task, because such systems are analytically intractable due to multiple equilibria and multidimensional interactions.

Planning Applications

Population and Migration Models

Regional scientists are in a unique position to evaluate both the issue of space and the concept of "region," thus adding an important perspective to population and migration studies. Particular examples have included regional population forecasting. There is a need for general equilibrium approaches in studying migration flows and other demographic changes so that the researcher can effectively model the interplay between urban and rural, across different household types, and between local and nonlocal goods.

Regional models of migration flows are often based on assumptions that two types of factors determine an individual's propensity to migrate. The first factor includes characteristics of the individual, such as wealth, education, age, employment history, and ethnicity. The second factor includes characteristics of the points of origin and destination (e.g., relative wages and unemployment rates in each location, so that the migrant makes a decision regarding how the move will change his/her wealth and employment status). The regional element is important both in terms of specifying the migration question and in estimating its impact. Thus, the first objective might be to understand and characterize regional drivers of population change: what are the forces that make some regions more attractive destinations than others, and what is the relative intensity of these driving forces? There are many factors beyond simple wage rates, such as amenities, that influence a potential migrant's utility in a way that often is spatially complex. National and regional economies also change over time, and correspondingly, economic opportunities change. For instance, over the past several decades, much of the population has moved from employment in agriculture, to industry, to service sector activities, and these broad-scale changes have profound impacts on the demographic makeup of regions, as migrants continually seek new opportunities. A second objective is understanding the nontrivial feedback effects of population movements on the regional economy in terms of labor pool, tax base, and related impacts.

Other work in regional science has concerned creating population projections for regions. Understanding of multiregional population trends involves characterizing two aspects of the demographic makeup: the state of the population at a given point of time and the propensity of that state to change, as well as the intensity of the change.

Thus, most techniques for forecasting population changes are based on Markov transition probability matrices. Markov transition probabilities can be specified as follows:

$$p_{ij} = P\left(\frac{X_{n+1}=j}{X_n=i}\right), \tag{15}$$

where X is a random variable representing the state or value of the system at time n, and p_{ij} represents the probability that X will be in state j at time $n+1$, given its value at time n. Thus, any change in population is a function of its value in past periods. Extensions on this basic approach have been to relax the restrictive assumption of stationarity, in that each X state is independent of past values of X. One approach is to include lagged values in the relationship to estimate explicitly the effect of prior periods on the current transition probabilities. Another general set of approaches is to decompose changes in population into various effects such as age, time period, and cohort effects. The shift-and-share model can be adapted to decompose these various components of population change. Maximum-likelihood principles can be used to model origin, destination, and time effects on migration flows via an expectation conditional maximization (ECM) algorithm.

Regional science demographic studies have been concerned with linking changes in urban and regional economies to population trends. Trends in national and regional urban systems related to postindustrialism and the impacts on population flows have been considered. At a national level, there may be overall trends in population movement (e.g., from north to south). At a regional level, population movements may relate much more directly to employment patterns. To identify the extent to which total movement within an area is leading to population change, the demographic efficiency can be defined as follows:

$$E_j = 100\frac{N_j}{T_j}, \tag{16}$$

where T refers to total migration and N refers to net migration. In this manner, the researcher can identify the impact of regular movements among employment centers (such as job turnover, etc.) vs. systemic changes, and where economic functions within regions are changing (e.g., as employment opportunities move from north to south in response to a changing economy). Regional science approaches to population modeling have also responded to the changing nature of regions. The rarely studied but increasingly important phenomenon of "micropolitan" areas, corresponding to changing regional economies, and counterurbanization trends as employment in traditional sectoral activities declines, have been examined.

Multiobjective Decision Making and Operations Research

Because of its inherently interdisciplinary and applied orientation, applied decision-making has long been an important part of regional science techniques. In a decision-support system, a computer or set of computers is used to integrate and manage data for problem solving, planning, and decision making within a particular topic domain. Such a system integrates scientific knowledge with data in an overarching framework of modeling, analysis, or assessment to facilitate planners or decision makers in their plan-making or decision-making efforts. Examples include demography, facility location and allocation, watershed planning and management, air quality assessment, urban growth management, and project impact assessment.

One well-known linear programming technique is the transportation model. In this model, something is "shipped" from a set of discrete sources to a set of discrete destinations. This type of model applies to transportation problems, but it can also be used in any problem when a set of independent sources is supplying some set of independent demands. The amount to be shipped from each source to each of the destinations, while minimizing the total shipping cost and satisfying all supply limits and demand requirements, can be specified as follows:

$$\min z = \sum_i \sum_j c_{ij}x_{ij}, \tag{17}$$

subject to

$$\sum_j x_{ij} = a_i; \tag{18}$$

output from each source equals supply,

$$\sum_i x_{ij} = b_j, \tag{19}$$

input to each destination must equal demand, and $x_{ij} \geq 0$, $\forall i$, $\forall j$. The transshipment model is a variation of the basic transportation problem in which supply locations transport products to centers of demand via intermediate nodes. A variation of the transshipment model, the Beckmann–Marschak problem, includes production/processing activities at each transshipment location. It has been described as a two-commodity spatial allocation process that examines the pattern of production, manufacturing and trade of a single commodity for a system of n suppliers, transportation centers, and m markets.

Regional scientists were among the first scholars to extend traditional linear programming techniques to a multiregional context. Isard applied linear programming to a set of regions given a set of limited resources, production technologies, factor prices, and commodities that were interrelated through trade. However, perhaps due to the limited computing technology available at the time, his model did not consider change over time explicitly.

The first comprehensive source on these methods within regional science can be found in the work of Peter Nijkamp and A. van Delft in 1977. GIScience has provided a new thrust to multicriteria decision support in that it provides a means for linking disparate processes and decision makers through spatial identifiers, and to thus create a shared database of relevant information. Advances in computing power, storage, and processing speed have also facilitated quantum leaps in development and application of these approaches.

Glossary

aggregation Inductive procedures for grouping like individuals on predetermined criteria.
association analysis A technique for dividing a population into groups/classes using presence/absence data.
classification The grouping of individuals into classes (categories) according to predefined criteria.
factorial ecology The classification of areas according to the socioeconomic and other characteristics of their populations.
geodemographics A particular example of factorial ecologies, with the area classifications used for targeted marketing campaigns.
modifiable areal unit problem (MAUP) A major problem for statistical analyses using regionalized data because of the large number of different ways in which the same spatial data set can be classified on predetermined criteria including contiguity constraints.
redistricting A particular example of the regionalization problem, involving the creation of continuous territories to be used in legislative elections, to which the MAUP applies.
regionalization The creation of classes in which the member individuals are spatially contiguous.

This article discusses methods for either dividing a population or grouping a set of individuals into mutually exclusive classes; in regionalization, these classes are identified by their spatial properties.

Introduction

Classification

Classification involves allocating individuals to classes (or types, categories, groups, sets, etc.) on the basis of predefined criteria. It is the foundation for much scientific activity, placing individuals into classes with like individuals about which generalizations can be made. In many cases, the classification is straightforward, based on readily-applicable rules, often associated with binary decision making: a person is either male or female, for example. Many other situations have no such easy rules, however, and there are no a priori clear distinctions between classes either because of the absence of theory/empirical work that would establish their nature and boundaries or because the criteria on which the classification is to be made (e.g., the height and weight of humans) are continuous, not binary. In the latter situation, it is assumed that for the purposes of analysis, and perhaps subsequent action, there are groups of individuals who are similar enough on the relevant criteria to be treated as members of a class. The questions that then arise are how should those classes be determined and what are the class boundaries? These questions have been addressed in several disciplines, although many of the procedures employed derive from work in either psychology or ecology (often termed numerical taxonomy).

Regionalization

Regions are a particular case of this general category of classes. The region is a core concept in geographical scholarship, and it is not infrequently used in other social sciences. It is usually defined as an area possessing a degree of unity on certain organizing principles or criteria, which distinguish it from surrounding areas. Thus, most large areas can be divided into a mosaic of component regions, separate parts that differ from their neighbors in some ways. Each of these regions may be distinct, sharing no characteristics with any of the others, or some may be similar in all (or the majority of) respects but are not contiguous. This leads to the separate identification of

(i) regions, which are contiguous blocks of territory that are homogeneous on predefined criteria, and (ii) regional types, which are two or more separate contiguous blocks of territory that are homogeneous on the predefined criteria but differ on them from neighboring territories. Scale is crucial in the process of defining regions: an homogeneous area defined at one scale may be heterogeneous at another, implying a hierarchy of regions at different scales, with homogeneous regions at one scale nesting into larger regions at another. A river valley may be a region at one scale, for example, but at another it may be divided into the flood plain, the valley slopes, and a watershed plateau dividing it from the next valley.

In its original formulation, the concept of a region was applied to the physical environmental characteristics of areas plus their occupation and manipulation by humans. Thus, the areal differentiation of the earth's surface—the mosaic of regions—was a function of environmental differences and human engagement with them. However, with the emergence of spatial analysis within geography and related disciplines, such as regional science, an alternative definition was introduced in which regional homogeneity resulted from patterns of spatial organization reflecting patterns of movement focused on regional cores (which is the foundation of major texts). This led to a twofold categorization of (i) formal regions, which are areas with a common unity based on local characteristics, and (ii) functional regions, which are areas whose unity was based on them being tributary to the same organizing node, such as a port and its hinterland. The traditional definition covered formal regions; many of the developments in spatial analysis were associated with functional regions. Scale was important in the latter also: the functional region associated with a small town, for example, might nest within the larger tributary area of a large city.

The delineation of both types of regions was long undertaken through map comparison and analysis. Maps showing the distribution of the predetermined criteria were overlain and boundaries identified, usually with some difficulties in deciding exactly where one region ends and another begins. For functional regions, these maps showed flow patterns; again, the goal was to identify areas with common directionality to their flows—almost certainly focused on a central node.

During the past four decades, these "subjective" methods have been superceded by more "objective" procedures using computer algorithms. The pioneer work was done in rural sociology. Berry extended and promoted the approach using a "geographical field theory" that was applied in a variety of contexts. For the definition of regional types (mostly comprising sets of formal regions, although comparable sets of functional regions are feasible—city hinterlands need not be composed of contiguous areas), there is no difference from the general process of classification: regionalization is just a particular case of the larger procedure, in which the observation units to be classified are spatially defined blocks of territory. However, for the definition of regions *sensu stricto* an additional criterion is introduced to the classification procedure—contiguity.

Most regionalizations involve the use of individuals whose nature is predetermined outside the research enterprise. Many formal regionalizations, for example, involve the classification of administrative areas whose boundaries are predefined. In such cases, the characteristics of the populations of these areas are used as the criteria for regionalizing. The areas may be internally heterogeneous, with several separate components that differ among themselves. These separate areas cannot be identified, however, and the regionalization has to use the areal units provided: they are "forced on" the analyst rather than defined "naturally" from the lowest possible scale—in many cases, individual persons or households.

The Approach

Procedures for classification and regionalization were topics of substantial interest two to three decades ago when quantitative procedures for the social sciences were being explored. Today, most of the classifications and regionalizations undertaken in these disciplines employ standard routines in statistical software packages (such as SPSS) and there is little innovation. Thus, the methods set out in the following section are standard procedures. However, workers in cognate disciplines use the massive computing power now available to explore other forms of classification, notably in the analysis of remotely sensed data. Relatively little of this work has infiltrated the social sciences. Such procedures are not readily illustrated using small, simple examples as undertaken here for the established methods. They are introduced here, however, as are methods of regionalizing using point data, techniques that are becoming increasingly popular in the analysis of clusters of events such as disease outbreaks. (There is a much larger literature on various aspects of spatial pattern analysis.)

One of the major findings of research on regionalization during the 1970s was its relationship to an issue in the analysis of much spatial data known as the modifiable areal unit problem. The nature of this problem is set out here as one that has to be faced whenever classifications and regionalizations are undertaken and one that is linked to a larger problem within quantitative social science, the ecological inference problem.

Inductive Classification and Regionalization: Aggregative Procedures

Most of the classification algorithms employed in regionalization exercises do not incorporate the contiguity constraint. Instead, the goal is to define homogeneous regional types, whether formal or functional: where those identified types do not comprise a single block of contiguous territory, they may then be subdivided into separate regions that do meet that criterion. Thus, in discussing methods of regionalization, the focus here is on classification procedures. Particular cases that differ from this are discussed later.

In formal terms, most regionalization–classification algorithms proceed through an analogy with the analysis of variance procedure within the general linear model. The goal is to minimize within-region variance and maximize between-group variance for any given number of regions. This will maximize both the internal homogeneity of the regions and the external heterogeneity among them. It can be achieved in two ways, given data on a number of areas within a larger block of territory (e.g., counties within a state or census tracts within a city):

1. By a process of division, in which the regionalization begins with the single block and then divides it into two or more separate regions on the predefined criteria.
2. By a process of aggregation, whereby the regionalization begins with a large number of small areas, which are grouped together into a smaller number of larger areas according to the agreed criteria.

Most of the classification–regionalization algorithms commonly applied, such as those in the SPSS package, use the latter approach. They take data on the relevant characteristics for a number of areas—the building blocks for the regionalization–classification—and aggregate them into larger, relatively homogeneous, areas using set principles. All such procedures are essentially inductive: they search for the "best" groupings within the population.

Aggregation Algorithms

Most regionalization exercises do not begin with a predetermined number of regions to be defined. Instead, they proceed inductively, generating a range of regionalizations from which analysts have to choose that which best suits their purposes. Thus, whereas most algorithms will proceed directly to a required number of regions if the analyst so specifies, they will also produce a range of regions from $(n - 1)$, where n is the number of building blocks, to 1 or a specified subset within that range.

The algorithms using aggregation strategies are based on square matrices of either similarity or dissimilarity measures, in which the rows and columns are the building blocks and the cell values contain the measure of similarity/ difference between each pair. The procedure operates as follows:

1. The matrix is scanned and the two most similar (least dissimilar) building blocks according to the cell values are joined together to form a region.
2. The matrix is recalculated, with the two building blocks forming the new region removed and replaced by a joint unit. The measures of similarity–difference between this new unit and the others in the matrix are calculated and added to the matrix.
3. The within-region and between-region variation in the variables (or some other measures of internal homogeneity and external heterogeneity) are calculated.
4. The process returns to step 1, and the next grouping is produced, which will involve (i) creating a new region by grouping together two or more of the original building blocks, (ii) extending one of the already created regions by adding one of the original building blocks to one of the regions, or (iii) aggregating two of the already created regions into a larger, single region.

If the goal is to produce regions rather than regional types, a further decision is involved at the first step. If the two units to be combined are contiguous, then the grouping takes place; if they are not, then the grouping is rejected and the matrix is rescanned for the next most similar (least dissimilar) pair, which will then be grouped together if they are contiguous.

The regionalization process is usually summarized in two diagrams. The first shows which units are grouped with which: the building blocks are arranged along the horizontal axis and a measure of the "efficiency" of the grouping forms the vertical axis. The sequence of groups can then be read off the diagram, which is usually referred to as a dendrogram (or linkage tree). The second diagram shows the efficiency measure graphed against the steps in the regionalization sequence.

Preclassification Decision Making

Before any of these aggregation procedures can be applied, several decisions have to be made regarding measurement issues. The first is which measure of similarity–difference to use in the matrix that is scanned to find the most similar pair at each stage of the regionalization. The following are among a range of possibilities:

- If the regionalization is being undertaken on a single variable only measured on an interval or ratio scale, such as average July temperature, then the difference between each pair can readily be measured as the difference (or distance) between its members on that variable.

- If the regionalization is being conducted on three or more interval or ratio variables, then the difference can be measured as the sum of the differences (or distances) between the members of a pair across all variables.
- If these variables employ different metrics, then they can first be standardized to zero mean and unit variance to ensure that each has equal weight in the regionalization (other weightings can be introduced, if desired).
- If there is collinearity among some of the variables, this can be removed by replacing them with a smaller number of composite variables, produced by a principal components analysis, with the component scores forming the individual variables from which the distances in the reduced space can be calculated.
- If the variables are part of a closed number set (such as the percentage of the local workforce employed in a range of industries), then a measure of dissimilarity, such as the Gini coefficient, can be employed.
- If the variables are measured on a nominal scale only, the difference between two units can be measured by the number of variables on which they agree.

All of the these are measures of difference/dissimilarity. In addition, measures of similarity can be employed:

- If the building blocks are being compared across a range of variables, their similarity across that full profile can be assessed using relevant correlation coefficients (e.g., product–moment for ratio/interval data).

The second is how to measure the distances in similarity–dissimilarity matrices when it is not the original building blocks that are being grouped together but rather groups that have already been created (i.e., the second and third types previously outlined). Again, there are several options, including

- The nearest distance method, which represents the distance between a pair of groups (or between an individual and a group) as the shortest distance between any pair of individuals selected one from each of the two groups.
- The furthest distance method, which takes the distance between a pair of groups (or between an individual and a group) as the longest distance between any pair of individuals selected one from each of the two groups.
- The total distance method, which takes the distance between a pair of groups (or between an individual and a group) as the sum of the distances between all pairs of individuals selected from the two groups across all variables.
- The average distance method, which takes the distance between a pair of groups as the distance between their mean (or median) points, often termed the group centroid.

Each of these has problems, as discussed later.

The third issue concerns the measure of the efficiency of each stage in the regionalization process. Again, a number of options is available, including

- The size of the within-group variation, defined as the sum of the squared distances between each individual unit's value on each variable and the mean for its group on that variable: with no groups formed, this is 0.0, and as groups are formed the degree of internal heterogeneity increases.
- The ratio of the within- to between-group variation, with the within-group variation defined as previously discussed and the between-group variation calculated as the sum of the squared differences between the mean for each group on each variable and the overall mean.
- The contribution of the grouping to the error sum of squares (defined by Ward in 1963 as the within-cluster sum of squared distances).

Whichever is used, the value of the efficiency measure can be graphed against the step in the regionalization process; breaks in this graph may identify steps at which the grouping could be stopped.

A commonly employed method, available in statistical packages such as SPSS, is that devised by Ward in 1963 and almost invariably known as Ward's method. Ward argues that the goal of any regionalization should be to produce groups in which the distances between group members and the group's centroid are minimized: the group members should be clustered together as tightly as possible in the m-dimensional space (where m is the number of variables deployed in the regionalization). To achieve this, the formal goal is to minimize the variance of the within-group distances in the next group to be created, what Ward terms the error sum of squares (ESS):

$$\mathrm{ESS} = \sum_{j=1}^{m} \left\{ \frac{\left[\sum_{i=1}^{n} D_{ix}^2\right]}{n} \right\},$$

where D is the distance between building block i and the group centroid x, and n is the number of members of the group, with summation over all m variables. At each step in the regionalization process, all possible groupings are evaluated, and that with the smallest ESS is adopted.

All these decisions are subjective to an extent. Which option is selected depends on the analyst's preferences with regard to the uses planned for the regionalization–classification: There is no best option because there is no agreement on which criteria should prevail.

A Simple Illustration

A simple illustration of the procedure is provided by the following example. Seven glaciers (G_1–G_7) have

advanced at different rates during 1 year (Table I), and we want to aggregate them into groups with similar rates of advance (in meters). The diagram in Fig. 1 shows them arranged along a single axis according to the grouping variable. The first step involves calculating an interglacier dissimilarity matrix, in which the off-diagonal entries are the differences between each pair in their rate of advance. We use the shortest distance method for grouping pairs of individual glaciers and the average distance method for groupings involving already created groups. The shortest distance, 1 m, is between glaciers 4 and 5, and these are grouped together to create a new group, G_A. The within-group variation after this step is 0.5: Both G_4 and G_5 are 0.5 m from the group centroid, and the sum of these squared deviations is $(0.25 + 0.25) = 0.5$.

A new interglacier dissimilarity matrix is now produced in which G_4 and G_5 are replaced by G_A (Fig. 1) and distances between each of the remaining glaciers and the new group are computed as the distance to the centroid of G_A, which is the same as the average distance between the individual glacier and the two glaciers forming that group. There are now two pairs of individual glaciers that are the same distance (2 m) apart, so these form new groups—G_B and G_C, respectively—at the next step, as shown in the bottom of Table I. This adds an additional 2.0 units to the within-group variation, resulting in a total over both steps of 4.5 (the final column in the bottom block of data in Table I).

A further interglacier dissimilarity matrix (not shown) is now created, with G_B replacing G_1 and G_2 and G_C replacing G_6 and G_7 (Fig. 1). The next step of the grouping involves combining G_3 with G_B to form group G_D. After two more steps, all seven glaciers are in a single group—G_F.

The full sequence of steps is shown in a dendrogram (Fig. 2), in which the glaciers are arrayed along the horizontal axis and the extra contribution of each grouping to the within-group variation forms the vertical axis. The formation of the groups is shown in the body of the graph: with every step, the amount of intragroup homogeneity declines as the contribution to the within-group variation increases.

With such an inductive classification procedure, the decision at which step to end the agglomeration and use that number of groups/regions is subjective. The information in Fig. 2 may be used in this regard, along with the data on the within-group variation in the final two columns of the bottom block of Table I. These two columns of data are shown in graphical form in Fig. 3, in which both the extra contribution to the within-group variation at each step and the total variation are shown. These indicate that up to step 4, both the extra contributions and the total variation are relatively small: after this step, the graphs become much steeper. This suggests that the most appropriate stage to stop the process may be after step 4, when there are three groups—G_A–G_C: at the next step, the within-group variation increases substantially.

Table I A Simple Classification: Glacier Advance

The seven glaciers and their rate of advance

G_1	G_2	G_3	G_4	G_5	G_6	G_7
10	12	15	6	7	19	21

The interglacier distance matrix

	G_1	G_2	G_3	G_4	G_5	G_6	G_7
G_1	0	2	5	4	3	9	11
G_2	2	0	3	6	5	7	9
G_3	5	3	0	9	8	4	6
G_4	4	6	9	0	1	13	15
G_5	3	5	8	1	0	12	14
G_6	9	7	4	13	12	0	2
G_7	11	9	6	15	14	2	0

The revised interglacier distance matrix after the first step of the grouping

	G_1	G_2	G_3	G_6	G_7	G_A
G_1	0	2	5	9	11	3.5
G_2	2	0	3	7	9	5.5
G_3	5	3	0	4	6	8.5
G_6	9	7	4	0	2	12.5
G_7	11	9	6	2	0	14.5
G_A	3.5	5.5	8.5	12.5	14.5	0.0

The steps in the grouping of the glaciers

1	G_4	G_5	G_A	0.5	0.5
2 =	G_1	G_2	G_B	2.0	
2 =	G_6	G_7	G_C	2.0	4.5
4	G_B	G_3	G_D	10.67	15.17
5	G_A	G_D	G_E	40.83	56.00
6	G_E	G_C	G_F	153.45	194.28

Suboptimal Groupings and Local Optima

One problem with hierarchical agglomeration procedures is that after a region is formed at one step of the grouping process, it cannot be disaggregated at a later step. This

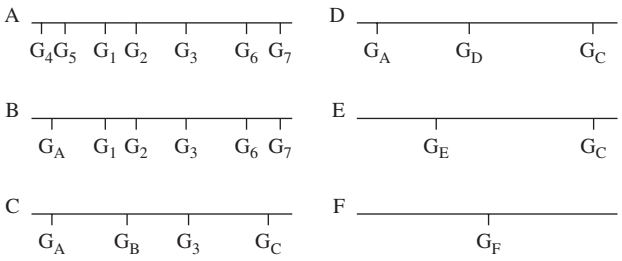

Figure 1 The seven glaciers (G_1–G_7) arranged according to their rate of advance.

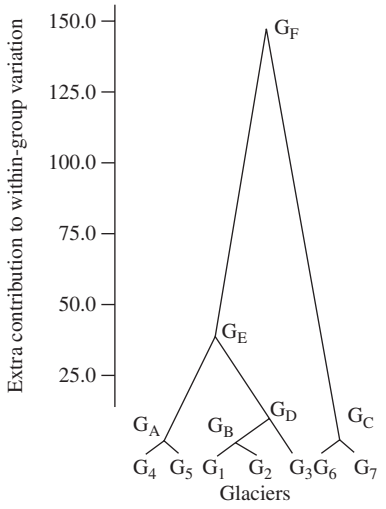

Figure 2 Dendrogram showing the classification of the seven glaciers according to the volume of within-group variation.

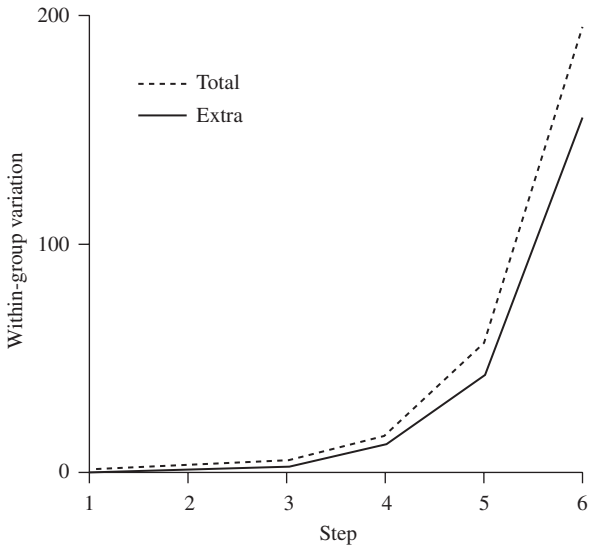

Figure 3 The efficiency of the classification of the seven glaciers showing both the extra contribution to the within-group variation and the total within-group variation at each step.

may mean that whereas the regionalization is optimal at some steps, it is not at others. This is illustrated by the seven-glacier example. At the penultimate step of the classification, there are two groups, G_C and G_E: the former contains glaciers G_6 and G_7 and the latter contains the other five. The within-group variation is 56.00, and the between-group variation is 138.28. Is this the optimal two-group regionalization? Glacier G_3 is a member of group G_E, but it is closest to a member of G_C (G_2). If G_3 were moved from the former to the latter group—making groups with four and three members, respectively—then the within-group variation would be 41.41 and the between-group variation would be 152.87. This grouping is clearly better than that originally produced: the ratio of the two variation components is 0.40 in the first case and 0.27 in the second.

How is such a suboptimal solution produced? G_3 is closest to G_2, as shown on the original dendrogram, but the latter is closest to G_1, with which it is grouped at the second step in the procedure. G_3 is now equidistant between the mean for the new group G_B, comprising glaciers G_1 and G_2, and glacier G_6. However, G_6 has already been grouped with its nearest neighbor G_7, and G_3 is farther from the mean for that group (G_C) than it is from the mean for G_B. So at the next step G_3 is combined with G_B to produce G_D.

The potential problem generated by hierarchical clustering procedures, therefore, is that when grouping previously formed groups, it cannot determine whether the group memberships remain optimal. The optimum at one step in the procedure (or local optimum) is built-in to later stages. In the example, if we had initially opted for just two groups, then glaciers G_3, G_6, and G_7 would have been placed in one group and the other four in the second group. Because we had undertaken an inductive search, however, G_3 was "misclassified" at an early step in the grouping sequence.

This can be corrected in two ways. First, when an inductive, agglomerative search has been undertaken and a desired number of regions determined, a further clustering can be performed specifying that number of regions. Alternatively, Berry suggested subjecting the identified set of regions to a discriminant analysis using the original independent variables from which the dissimilarity matrix was derived to determine if any region members were misclassified.

Ward's Method

As already noted, Ward's method is one of the most commonly used hierarchical grouping procedures because it results in cohesive (or tight) groups with low within-group variation, as measured by the ESS value used to determine the next stage in the grouping. Table II illustrates the steps in grouping the seven glaciers using this procedure.

At the first step, the smallest ESS value is for the grouping of G_4 and G_5: their mean value (centroid) is

$$[(6+7)/2] = 6.5,$$

so the ESS is

$$\left[(6-6.5)^2 + (7-6.5)^2\right]/2 = [(0.25) + (0.25)]/2 = 0.25.$$

Table II Applying Ward's Method to the Grouping of the Glaciers[a]

Step 1	*ESS*	*Step 2*	*ESS*	*Step 3*	*ESS*	*Step 4*	*ESS*	*Step 5*	*ESS*	*Step 6*	*ESS*
G_4, G_5	**0.25**	G_A, G_1	2.89	G_A, G_B	5.69	G_A, G_B	5.69	**G_A, G_B**	**5.69**	G_E, G_F	28.41
G_5, G_1	2.25	**G_1, G_2**	**1.00**	G_B, G_3	4.22	G_B, G_3	4.22	G_B, G_D	17.04		
G_1, G_2	1.00	G_2, G_3	2.25	G_3, G_6	4.00	**G_3, G_C**	**2.38**				
G_2, G_3	2.25	G_3, G_6	4.00	**G_6, G_7**	**1.00**						
G_3, G_6	4.00	G_6, G_7	1.00								
G_6, G_7	1.00										

[a] The pair grouped at each step is shown in bold. ESS, error sum of squares.

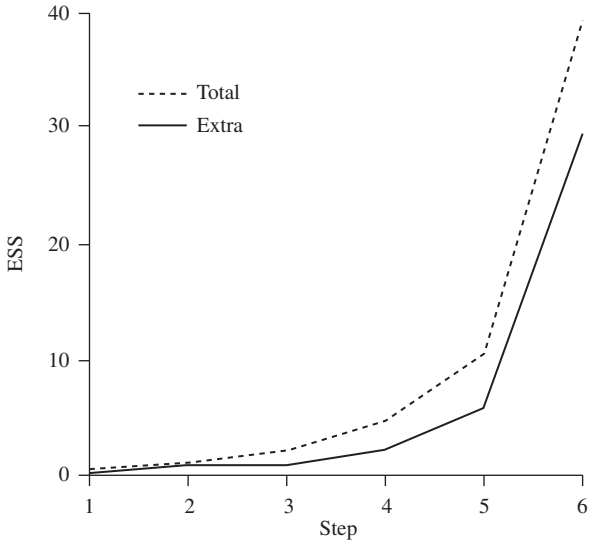

Figure 4 The efficiency of the classification of the seven glaciers using Ward's method showing both the extra contribution to the error sum of squares (ESS) and the total ESS at each step.

These are grouped to form G_A, and at the next step the ESS value is computed for a group involving G_A plus its nearest neighbor, G_1. Their centroid position is

$$[(6 + 7 + 10)/3] = 7.67,$$

so the ESS is

$$\left[(6 - 7.67)^2 + (7 - 7.67)^2 + (10 - 7.67)^2\right]/3 = 2.89.$$

The grouping procedure continues, using the lowest ESS at each step.

Graphing of the ESS and total ESS values at each step (Fig. 4) suggests the same "stopping rule application" as with the previous method (Fig. 3). However, closer inspection of the membership of the groups shows that the problem of suboptimality in step 4 is not repeated: G_3 is grouped with G_C (a combination of G_6 and G_7) rather than with G_B. This illustrates one of the main advantages of Ward's method: because it uses the potential new group centroids in calculating the ESS, rather than the distance between existing group centroids (or between individuals and existing centroids), it is less likely to produce a suboptimal grouping, although this is not invariably the case, and checks should always be made.

Classifications with Closed Number Set Data

One problem with some applications of aggregative classification is that the data form closed number sets—that is, the sum of the values for any building block across all of the variables is a set value (usually 100, if the data are in percentages, or 1.0 for proportions). Use of such data in procedures that employ measures derived from the general linear model, such as correlation coefficients, is invalid, and thus the grouping procedure cannot proceed.

This problem can be avoided, however, by using an alternative procedure that is not constrained by the requirements of the general linear model. It compares the profiles of the various building blocks across the set of variables (which are converted into z scores, with zero mean and unit variance) and groups building blocks with the most similar profiles according to a between-group variation criterion. The groups can then be characterized by their mean profiles.

Factorial Ecology

Widespread use of the variants of these procedures using component or factor analysis as an initial stage for classification and regionalization since the late 1960s led some to give the various applications the collective name of "factorial ecologies." The method was initially deployed by sociologists investigating the residential patterning of cities: it was termed factorial ecology by Sweetser in 1965 and adopted as a general term for multivariate analyses of such patterns. More generally, however, it has been applied as a general descriptive term for classifications of spatial data at a range of scales.

Flow Data and Functional Regionalizations

Classifications with flow data, to create functional regions, involve identifying areas with similar spatial interaction profiles. In the simplest form, these regions can be created by taking a matrix of flows—of the volume of goods moved between two places during a given time period, for example—and for each place identifying the other with which it has the greatest amount of contact. With a square matrix, in which the rows and columns are the places (the building blocks for the regionalization), this simply involves identifying the largest value in each row (excluding the main diagonal). This is illustrated in Table III, which shows the flows among 12 places in a small network, with the rows being the origins and the columns the destinations; their locations are shown in Fig. 5. The largest flows in each row are shown in bold. There are two clear groups of places: the first (B–D) have their main flows to A, whereas the second (F–L) have their main flows to E. This suggests two functional regions based on A and E, respectively. In addition, the main flows for A and E are with each other, suggesting that they are the main nodes in a hierarchy of centers. (Their functional regions are grouped around them in a contiguous formation, although this need not be the case.) More sophisticated examples of such procedures have been devised to produce functional regionalizations of countries used for defining metropolitan regions and reporting census data.

A variant on this approach is the creation of regions as the hinterlands around centers that are the exclusive providers of a certain function, such as education. There may be n different zones with children to be allocated to a school and m schools. The goal might then be to allocate the children to the various schools in order to minimize the total distance that they travel to school, which in effect would mean allocating each n zone to its nearest m school. There may be constraints, however, such as a capacity constraint for each school (in which case the goal would be to minimize the total distance traveled by pupils to school, without any school being allocated an excess capacity), for which linear programming solutions may be sought. Further constraints could include a maximum distance for any child to travel.

Rather than produce a regionalization based simply on the largest flow from each place, an alternative is to compare the profile of flows either to or from a place. This would involve clustering the places in a square matrix (as in Table III) either by the similarity between their rows (which would involve grouping places with similar export patterns) or by the similarity between the columns (grouping places by where their imports come from). This could use one of the agglomerative procedures discussed previously; the outcome would be a regionalization of trade blocks.

Divisive Classification Algorithms

As already noted, most inductive classification procedures employ aggregative algorithms. An alternative procedure

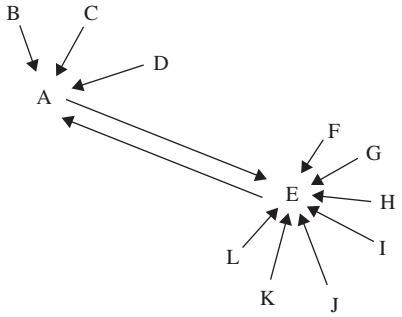

Figure 5 The simple functional regionalization showing the main links among the 12 places.

Table III Example of a Simple Functional Regionalization

From/to	*A*	*B*	*C*	*D*	*E*	*F*	*G*	*H*	*I*	*J*	*K*	*L*
A	—	2	3	1	**8**	3	1	2	1	0	0	1

L	1	0	0	0	**11**	3	1	0	0	1	2	—

is to use divisive methods, which are particularly useful for binary data. One such method is association analysis, developed by plant ecologists.

Take a data set comprising a number of sample sites (m) at each of which the presence or absence of a range of plant species (n) is recorded. One can then calculate the chi-square (χ^2) statistic to evaluate the similarity in the distributions of any pair of species: the greater the dissimilarity (i.e., the probability that where one species is present, the other is absent), the larger the χ^2 value. This produces a matrix of between-species χ^2 values. The species are then divided into two groups using the species that is most dissimilar from all others in its distribution as the discriminator. This is done by summing all the χ^2 values in each column of the matrix and selecting the species with the largest total. The sites are then placed into one of two classes depending on whether the discriminator species is present there or not.

The next step takes the two groups of sites separately and for each computes a matrix of χ^2 values involving the $(n-1)$ species remaining; that is, the species involved in the first step is discarded because it is either present in or absent from all the sites in the relevant group. A further discriminator species is then determined for each of the groups, and a division of each is undertaken. The sequence continues until all the groups contain a single site only: as it does so, the size of the χ^2 value used to determine the next division will decline, indicating that within-group homogeneity is decreasing and between-group heterogeneity is increasing. The divisive process can be halted at any step, and the decision making can be aided by a diagram similar to a dendrogram, with the size of the maximum χ^2 involved in the division on the vertical axis.

This procedure can be applied to the data matrix in two ways. Either it can be deployed to group the sites on the basis of the species that are present/absent there or the original data matrix can be transposed to allow a grouping of the species on the basis of the sites where they are present/absent.

Algorithms Using Artificial (or Computational) Intelligence

Recent developments in computer technology have seen the emergence of computer algorithms for classification employing neural network procedures. Many are widely used in remote sensing, whereby space imagery of environmental and other features is employed for a range of mapping and other activities: classification and regionalization procedures are routinely deployed as means of generalizing large amounts of data. The data relate to small spatial areas called pixels (small squares, as on a TV screen). Each image comprises a value for a large number of such areas in a raster (or checkerboard) format; much of the initial analysis of such data involves their classification into similar types (e.g., for land cover, pixels with mixtures of land use will appear differently from those with a single use).

These inductive procedures begin with a representative sample k of the n building blocks being selected as the "cores" for the regions, and then the genetic algorithm allocates the remaining $(n-k)$ building blocks to those cores through a learning process until homogeneous regions are created. The algorithm is rerun a large number of times with a different sample of k cores, and the best classification is then selected. Such inductive procedures are often termed unsupervised because the cores are randomly selected. An alternative—supervised—procedure involves creating "ideal type" cores as the nodes for the regions; there must therefore be a predetermined number of regions. Such cores have a predetermined population mix, which may be derived either a priori or empirically, from that or another data set. Having created the cores, the building blocks are then regionalized using neural net methods, with the nature of the cores changing during the learning process.

Some of the available procedures employ fuzzy logics (or soft classifications) in which the assumption of mutually exclusive categories deployed in almost all classifications and regionalizations using the procedures discussed previously is relaxed. Individuals can either be placed in several classes, perhaps with some measure of their degree of similarity to each class, or they can be subdivided between two or more classes. In remote sensing, this is especially valuable because the building blocks employed are areas that may have a mixture of land uses (or whatever variables are being used in the classification). As noted previously, many of the units employed in social science classifications and regionalizations are also areas that may be heterogeneous, and such fuzzy logic classification procedures are likely to become more popular in the future. (Fisher argues the value of such approaches because many of the concepts underlying geographical regionalizations, such as the distinction between urban and rural areas, are inherently fuzzy, especially given that they are identified using data that refer to heterogeneous areas.)

Geodemographics

A major application of classification–regionalization procedures during the past two decades has been in an area commonly known as geodemographics. This developed from factorial ecology. The procedures and algorithms involved were adopted by market research firms to identify areas with common socioeconomic and demographic characteristics that could be used for targeting in

various sales campaigns. The procedures were enhanced after the development of geographical information systems allowed the census information to be linked with other data sets (many of them proprietary) based on consumer and other surveys; with these, it is possible to update data sets regularly rather than relying on census data, which may be 10 or more years old. In addition, in many countries the address files associated with the postal and electoral systems are also available for purchase, which can also be used to update address files for targeting.

The types identified using such procedures classify areas according to their residents' lifestyles based on information relating to such characteristics as newspaper readership, types of TV programs watched, and frequency of purchase of various products as well as indicators derived from censuses (such as age and socioeconomic status): they are sometimes called lifestyle databases. these allow firms to target their marketing at certain types of areas, and thus customers, thereby either avoiding areas whose residents are unlikely to purchase their products or identifying areas for potential expansion of sales. In addition, such databases may be used by other bodies, such as political parties seeking to identify target groups of voters for particular policies.

Redistricting as Regionalization

A particular form of regionalization involves the creation of legislative districts for electoral purposes, such as congressional districts in the United States and parliamentary constituencies in the United Kingdom. In such regionalization, the goal is to create a given number of districts, each comprising a contiguous block of territory and within a set margin of error for its total population or electorate. The number of regions required is predetermined. Algorithms have been written to identify groupings of the component areas—the building blocks that are aggregated up to form the districts.

These algorithms operate as follows. Given n building blocks (small areas within the relevant territory being districted) to be aggregated into k districts (where $k < n$), with each district comprising a contiguous block of territory, they begin by selecting k "seeding cores" from among the building blocks using a stratified random selection procedure so that the cores are not clustered together in one portion of the map. Then, they build outward from these by aggregating neighboring areas into each district until they meet the size criterion, and the process continues until all the building blocks are associated with a district and all the districts are within the prescribed size range. Again, this proceeds using random selection procedures. The core district to have the next building block aggregated to it is selected at random, and then one of its contiguous building blocks is selected at random to join the district.

Because of the random elements built in to such procedures, if run many times the computer algorithm will almost certainly identify a number of solutions to the district-building regionalization problem. (The algorithm is also likely to fail many times because one of its identified districts is too small relative to the criterion specified but cannot be expanded because it is surrounded by other districts.) These various solutions can then be evaluated on other criteria, such as their shape, how frequently they cross the boundaries of other administrative areas (such as counties within U.S. states), and how different they are from the existing districts. Decision makers then have to choose which of the options they prefer—a choice that may be made on partisan grounds. For example, in 1973 Morrill found that using the same criteria regarding size, the Republican and Democratic parties derived very different sets of districts for the Washington State legislature. (The Republicans produced a map of districts for the State House in which they would probably win 48 seats compared to the Democrats 38, with 12 marginal; the Democrats' map gave them assured victory for 50 seats, compared to 36 for their opponents, with the remaining 12 too close to call. This, of course, is the long-practiced art of gerrymandering.)

Multicriteria districting is also possible, incorporating additional variables such as conformity with other administrative areas and previous sets of districts. One important criterion applied in areas of the United States in recent years is the racial composition of districts. Under the Voting Rights Act, the voting power of racial minorities should not be diluted by districting schemes, so states have sought to produce a number of districts with black majorities consistent with their proportion of the total population (the so-called minority/majority districts).

Even when the regionalization is a multicriterion exercise, however, a number of feasible solutions will almost certainly be found—and that number could be very large if the ratio of the building blocks (n) to the desired number of regions (k) is also large: the combinatorial possibilities of producing 10 regions using several thousand building blocks are manifold. Thus, the final choice of which regionalization to adopt has to be based on criteria (which may be entirely subjective) that are not incorporated within the algorithm.

Regionalization and the Modifiable Areal Unit Problem

As previously noted, regionalization involves issues of scale, which are crucial to a number of areas of spatial analysis. These combine to form what has become known as the modifiable areal unit problem (MAUP). In certain

types of regionalization, such as the construction of districts for electoral purposes discussed previously, there is a very large number of possible solutions to the problem, only one of which will be optimal (i.e., the best on the selected criterion or criteria), but many others fall within an "optimality range" and are thus acceptable. However, different solutions within this optimality range may produce different outcomes on one or more other criteria.

The MAUP therefore arises when there is a large number of different solutions to the same regionalization problem within predefined constraints. This can pose serious problems both for potential users of a regionalization (such as with a set of congressional districts) and for those who employ the regionalizations as the units for further analyses.

The MAUP and Other Criteria

The first of these problems can be illustrated by the redistricting issues discussed previously. In the Washington State example, the two political parties derived very different regionalizations—with very different potential election results—and the Grand Master employed by the court to produce a "politically nonpartisan" regionalization created yet another, which would have given the Republicans 38 safe seats in the State House and the Democrats 41, with 19 too close to call (recall that the two parties' plans each contained only 12 marginal districts).

In 1982, Johnston and Rossiter developed a computer algorithm that would identify all the possible parliamentary constituencies in a given city, within preset constraints regarding variation in their populations. This was applied to four English cities, and they estimated for each solution to the constituency-building problem how many seats the Labour party would win, given its percentage of the votes in each ward—the building blocks used.

Table IV Redistricting Options in Four English Cities

	City			
	Coventry	*Hull*	*Leicester*	*Sheffield*
No. of building blocks	18	21	16	27
No. of constituencies	4	3	3	6
Labour % of all votes	57	68	59	65
No. of solutions	244	100	214	15,937
No. of constituencies that would be won by Labour				
6	—	—	—	697
5	—	—	—	12,327
4	43	—	—	2913
3	193	100	160	0
2	8	0	54	0
1	0	0	0	0
0	0	0	0	0

The results of this exercise are shown in Table IV. The larger the problem, the greater the number of possible solutions. For example, in the largest city (Sheffield) there were 15,397 different ways in which the 27 wards could be combined into six contiguous constituencies (with a maximum size variation of 12%): of these, Labour (with slightly less than two-thirds of the votes overall) was likely to win five of the six seats in 77% of all the solutions and all six seats in an additional 4%. In none of the cities would Labour win a smaller percentage of the seats than of the votes in any solution, although only in Hull was it bound to win all the seats in every solution (even though it only won two-thirds of the votes). The pattern of votes for Labour across the wards there, and their relative position in the city, meant that it was impossible to create even one constituency in which Labour would not win a majority of the votes.

Cirincione *et al*. used a similar algorithm but a much larger data set. Their example was congressional redistricting in South Carolina in the 1990s, where 3259 census block groups were to be aggregated into six contiguous congressional districts. They ran the algorithm four times using different criteria (size and contiguity only, size and contiguity plus compactness, size and contiguity plus county integrity, and size and contiguity plus compactness and county integrity) and generated 2500 different solutions in each case, giving a total of 10,000 separate sets of six districts. They used these as the equivalent of a sampling distribution to assess whether the actual redistricting plan adopted in the state was likely to have been constructed on racial grounds (i.e., that the racial composition of the districts was a further criterion deployed by the political cartographers). Blacks comprised 30% of the state population in 1990, evenly distributed across the state. Under the requirements of the Voting Rights Act, blacks should have been a majority in at least one, and perhaps two, of the six districts—the so-called minority–majority districts. However, none of the 10,000 plans generated by Cirincione *et al*. contained even a single black-majority district, suggesting (as in the Hull example) that the geography of blacks across the state made it very difficult, if not impossible, to produce a district with a black majority. However, the adopted plan did contain one (a very odd-shaped District 6), and they concluded that this indicated that the redistricting must have been constructed with the production of such a district in mind, thereby violating traditional redistricting criteria in order to comply with the Voting Rights Act.

The MAUP and Statistical Analyses

The second problem relates to the use of the defined regions for statistical analyses. It was first noted by Gehlke

and Biehl in 1934 and further generalized by Yule and Kendall in 1950. Gehlke and Biehl had data on the number of juvenile delinquents and median household incomes in the 252 census tracts in the Cleveland metropolitan area: The correlation between these two variables was −0.502. However, as the tracts were aggregated into larger units (of approximately similar size), the correlation increased: with 175 units it was −0.580, with 125 units it was −0.662, with 100 units it was −0.667, and with 25 units it was −0.763. Using data on wheat and potato yields in English counties, Yule and Kendall found even greater variation according to the number of units. Using all 48 English counties, the correlation was only 0.22; with 24 groups of counties it was 0.30, with 12 groups it was 0.58, with 6 groups it was 0.76, and with 3 groups it was 0.99.

In these studies, only one example of each aggregation (e.g., into six groups of English counties) was employed; however, as shown here, in almost all cases there are many different ways in which n units can be aggregated into k regions, where k is smaller than n. Each of these regionalizations may produce a different correlation coefficient, as demonstrated by Openshaw and Taylor in 1979. They took the 99 counties of the state of Iowa, for which they had data on the percentage of the population older than 60 years of age and the percentage of the votes cast in the 1968 presidential election obtained by the Republican candidate. The correlation between these two at that scale was 0.346. With 30 zones (i.e., aggregations of contiguous counties), the average correlation was 0.33, but with a standard deviation of 0.11; as the number of zones decreased, the standard deviation increased. Even this figure concealed the extent of the variation: with 30 zones, for example, it was possible to get a correlation of 0.98 between the two variables at one extreme and −0.73 at the other. In effect, as Openshaw demonstrated in 1982, it is virtually possible to produce a regionalization of the 99 Iowa counties to produce any desired ordinary least squares relationship between the two variables—both the correlation and the slope coefficient.

One of the major conclusions from these and other findings is that analysts should use the smallest areal unit possible in their analyses in order to avoid the problems just demonstrated. In this regard, the MAUP is a particular case of the ecological inference problem. Another conclusion is that for any specific analysis, one should employ the best possible zoning scheme available. However, as noted previously, much of the data used in spatial analyses—and much other social science research—relate to population aggregates, most frequently for various administrative areas such as those created for censuses (e.g., blocks and tracts). In most analyses of spatial data, therefore, it is necessary to recognize that the patterns and relationships identified are for just one of many alternative realizations of the same aggregation of individual into areal data, and the analysts has only partial control over the aggregation process. As Openshaw (1982) notes, "It is a geographical fact of life that the results of spatial study will *always* depend on the areal units being studied" (p. 37).

The Two Components of the MAUP

There are two components to the MAUP. The aggregation problem occurs because different clusters of building blocks into the same number of regions can result in different geographies, and hence different statistical relationships. The scale problem occurs because the results obtained are also a function of the size of the regions employed—relative, that is, to the original building blocks. In many cases, there is a clear relationship between the scale of the analysis and the results obtained—for example, in the size of the correlation coefficient. However, the interaction of scale and aggregation effects can considerably blur such a general tendency.

Is the MAUP important in many statistical analyses? As Openshaw notes, its impact is fairly trivial if there is agreement on the right geographical object for any particular analysis—the right scale and aggregation. That is extremely unlikely, however, although it may occur in some cases. In the study of the personal vote for House of Representatives members, for example, the obvious unit to employ is the congressional district. Openshaw and Taylor explore three other responses:

1. It is an insoluble problem and thus can only be ignored.
2. It is a problem that can be assumed away, with the results obtained from the particular available data set being accepted as "the real ones."
3. It is a very powerful analytical device for exploring various aspects of geography and spatial variations since alternative regionalizations can be produced. This allows the creation of frequency distributions with which one regionalization can be compared (as with the example from Cirincione *et al*. cited previously) and of optimal regionalizations for particular purposes.

Most geographers and other spatial analysts have at least implicitly adopted the first of these (and perhaps even the second), in part because they lack the available data that would allow the third response to be adopted.

Given the importance of the MAUP, the issue arises as to how it can be incorporated into classification procedures such as regionalizations for census data reporting at small spatial scales. In the UK census from 1951 to 1991, for example, the smallest spatial scale for data reporting was the enumeration districts (EDs)—the small areas used for the administration of the census collection and tabulation procedures. Each ED was a separate unit for data collection. Such EDs were defined for

administrative convenience only and bore no necessary relationship to the underlying geography they were portraying. Many users—private and public sector, plus academic researchers—argued the desirability of these being defined so that they were relatively homogeneous on predetermined characteristics, within prescribed constraints, notably relating to their size (e.g., population or household minima or maxima). Using data for even smaller areas than EDs (postcode sectors), Martin *et al.* used one of Openshaw's classification algorithms (AZP) to produce a set of output areas after the census data had been collected, which met certain criteria—a target population (i.e., average population) with given population minima and homogeneity on specified other variables (such as housing tenure) plus a shape constraint. The result is a geography for publishing data from the 2001 UK census with reporting units that are much more homogeneous than heretofore.

Regionalizing Point Patterns

Most of the agglomerative clustering procedures discussed here involve data sets in which the observation units (or building blocks) are points in an n-dimensional space (such as the orthogonal components derived from a principal components analysis). In many cases, the points in multivariate space refer to the characteristics of areas. The goal is to classify them into groups based on their similarity, as measured by their distance apart in the n-dimensional space.

In these approaches, the goal is to produce the optimal set of regions within certain constraints (or a set of regions within an envelope of constraints). A related approach involves searching for regions that meet other criteria and may indeed overlap. This can be illustrated by some of Openshaw's work on the search for clusters of disease outbreaks. For example, there has been considerable debate in the United Kingdom regarding whether leukemia in children can be associated with proximity to a nuclear power plant or similar installation. Openshaw designed inductive methods, geographical analysis machines (GAMs), to answer this question. The rationale was based on the MAUP: analysis of one particular realization of the geography of a disease may not reveal the clusters, whereas analysis of other realizations (i.e., different regionalizations) may reveal them.

Openshaw's "machines" operated by taking the point pattern of the events whose geography was being investigated, such as leukemia cases. These were integrated in a geographical information system with other data sets (e.g., population data for small areas from censuses) in order to compute rates of occurrence for the disease. The algorithm then selected a random set of points within the relevant map (using grid coordinates) and counted the number of occurrences of the disease within a given distance of that point. The rate of occurrence was then calculated for that region, and its statistical significance was assessed. Repeated a large number of times, perhaps with varying regional sizes (i.e., distances from the randomly selected point), the output was a map of those areas with significant clusters (i.e., unexpectedly high rates). Where there was a large number of significant clusters (i.e., where a number of different random starting points had found such clusters), he argued that this provides a prima facie case that there may well be a localized cause for such outbreaks worthy of investigation.

Openshaw's methods of producing such *ad hoc* regionalizations through inductive, exploratory data analyses have been extended to a range of methods in what geographers call local statistics. Rather than assume that a relationship is constant over an entire map, these methods search for local variations in that relationship, in effect defining regions within regions. Openshaw extended the GAMs to a geographical explanations machine, which identified clusters of rare events and then correlated them with other variables that offered potential explanations for those clusters. Others have extended the methodology to identify regions with similar regression relationships between variables.

Reliability

Duane F. Alwin
Pennsylvania State University, University Park, Pennsylvania, USA

Glossary

congeneric measures Univocal measures whose true scores are perfectly correlated (i.e., linearly related).
internal consistency A general approach to estimating the reliability of a composite score based on a set of univocal measures.
measurement error The difference between an observed variable and the true score it measures.
multitrait–multimethod approach A measurement design intended to partition reliability into two orthogonal parts due to true score trait variance and true score method variance.
parallel measures Univocal measures with tau-equivalent true scores and equal error variances.
propensity distribution A density function of a hypothetical response distribution for a fixed person.
quasi-simplex model A model for the estimation of reliability in longitudinal data.
reliability The proportion of observed score variance due to the latent true score variable.
tau-equivalent measures Univocal measures with tau-equivalent true scores and unequal error variances.
true score The expected value of the hypothetical propensity distribution for a fixed person.
univocity The property of a measure indicating that it measures one and only one underlying variable; measures having this property are said to be univocal.

Reliability of measurement encompasses the design strategies and statistical estimation methods used for assessing the relative consistency of measurement in specified populations using maximally similar efforts to measure the same quantity or attribute.

Introduction

Issues of measurement quality are among the most critical in scientific research because the analysis and interpretation of empirical results depend intimately on the ability to accurately and consistently measure the phenomena of interest. This may be more difficult in social and behavioral sciences, in which the targets of measurement are often not well specified; even when they are, the variables of interest are often impossible to observe directly. For example, concepts such as social status, personality, intelligence, attitudes, values, psychological or emotional states, deviance, or functional status may be difficult to measure precisely because they reflect difficult to define variables and are not directly observable. Even social indicators that are more often thought to directly assess concepts of interest (e.g., education level or race) are not free of conceptual specification errors that lead to imprecision. The inability to define concepts precisely in a conceptually valid way produces errors of measurement, but measurement problems are also critically related to the nature of the communication and cognitive processes involved in gathering data.

Sometimes, the term reliability is used very generally to refer to the overall stability or dependability of research results, including the absence of population specification errors, sampling error, nonresponse bias, as well as various forms of measurement errors. Here, the term is used in its more narrow psychometric meaning, focusing specifically on the absence of measurement errors. Even then, there are at least two different conceptions of error—random and nonrandom (or systematic) errors of measurement—that have consequences for research findings. Within the psychometric tradition, the concept of reliability refers to the absence of random error. This conceptualization of error may be far too narrow for many research purposes, where reliability is better understood as the more general absence of measurement error. However, it is possible to address the question of reliability separately from the more general issue of measurement error, and later the relationship between

random and nonrandom components of error is discussed.

Errors of measurement occur in virtually all measurement, regardless of content, and the factors contributing to differences in unreliability of measurement are worthy of scrutiny. It is well-known that statistical analyses ignoring unreliability of measures generally provide biased estimates of the magnitude and statistical significance of the tests of mean differences and associations among variables. Although the resulting biases tend to underestimate mean differences and the strength of relationships making tests of hypotheses more conservative, they also increase the probability of type II errors and the consequent rejection of correct, scientifically valuable hypotheses about the effects of variables of interest.

This article discusses the major approaches to estimating measurement reliability. There are two traditions for assessing reliability: (i) the classical test theory or psychometric tradition for continuous latent variables and (ii) the recent approach developed for categoric latent variables. From the point of view of either tradition, reliability estimation requires repeated measures across multiple levels of the variable. This article focuses mainly on how repeated measures are used in social research to estimate the reliability of measurement for continuous latent variables.

Key Notation and Symbols

The key notation and symbols used in this article are summarized in Table 1. This article follows the convention of using uppercase symbols to denote random variables and vectors of random variables and uppercase Greek symbols to represent population matrices relating random variables. Lowercase symbols are used to denote person-level scores and within-person parameters of propensity distributions.

Basic Concepts

Reliability for Continuous Variables

On the simplest level, the concept of reliability is founded on the idea of consistency of measurement. Consider a hypothetical thought experiment in which a measure of some quantity of interest (Y) is observed: It could be a child's height, the pressure in a bicycle tire, or a question inquiring about family income in a household survey. Then imagine repeating the experiment, taking a second measure of Y, under the assumption that nothing has changed—that is, neither the measurement device nor the quantity being measured have changed. If across these two replications one obtains consistent results, we say the measure of Y is reliable, and if the results are inconsistent, we say the measure is unreliable. Of course, reliability is not a categoric variable, and ultimately we seek to quantify the degree of consistency or reliability in social measurement.

Classical true score theory (CTST) provides a theoretical model for formalizing the statement of this basic idea and ultimately for the estimation and

Table I Key Symbols Used in Discussion of Reliability

Symbol	*Definition*
Y_{gp}	An *observed score* for variable Y_g on person p
τ_{gp}	The *true score* of person p in measure Y_g defined as $E(y_{gp})$
ε_{pg}	The *error score* for person p in measure Y_g defined as $\varepsilon_{pg} = y_{gp} - \tau_{gp}$
S	A finite population of persons
G	The number of measures in a set of univocal measures
$\mathrm{E}[Y_g]$	The expectation of the observed score random variable Y_g in population S
$\mathrm{E}[T_g]$	The expectation of the true score random variable T_g in population S
$\mathrm{E}[E_g]$	The expectation of the error score random variable E_g in population S
$\mathrm{VAR}[Y_g]$	The variance of the observed score random variable Y_g in population S
$\mathrm{VAR}[T_g]$	The variance of the true score random variable T_g in population S
$\mathrm{VAR}[E_g]$	The variance of the error score random variable E_g in population S
$\mathrm{COV}[T_g, Y_g]$	The covariance of the random variables T_g and Y_g in population S
$\mathrm{COR}[T_g, Y_g]$	The correlation of the random variables T_g and Y_g in population S
K	The number of sets of univocal measures
Σ_{YY}	Covariance matrix for a set of G measures in population S
Λ	The $(G \times K)$ matrix of regression coefficients relating observed measures to true scores in population S
Φ	The $(K \times K)$ matrix of covariances among latent true scores in population S
Θ^2	The $(G \times G)$ matrix of covariances among errors of measurement in population S
M	The number of distinct methods of measurement
P	The number of occasions of measurement

quantification of reliability of measurement. The classical definitions of observed score, true score, and measurement error are reviewed, as well as several results that follow from these definitions, including the definition of reliability. First covered are definitions of these scores for a fixed person, p, a member of the population (S) for which we seek to estimate the reliability of measurement of the random variable Y. Reference to these elements as persons is entirely arbitrary because they may be organizations, work groups, families, counties, or any other any theoretically relevant unit of observation. The reference to "persons" is used because the classical theory of reliability was developed for scores defined for persons and because the application of the theory has been primarily in studies of people. It is important to note that throughout this article the assumption is made that there exists a finite population of persons (S) for whom the CTST model applies and that we wish to draw inferences about the extent of measurement error in that population.

The model assumes that Y is a univocal measure of the continuous latent random variable T, and that there is a set of multiple measures of the random variable $\{Y_1, Y_2, \ldots, Y_g, \ldots, Y_G\}$ that have the univocal property; that is, each measures only one thing, in this case T. An *observed score* y_{gp} for a fixed person p on measure g is defined as a (within-person) random variable for which a range of values for person p can be observed. In the thought experiment performed previously, imagine a hypothetical infinite repetition of measurements creating a propensity distribution for person p relating a probability density function to possible values of Y_g. The true score τ_{gp} for person p on measure g is defined as the expected value of the observed score y_{gp}, where y_{gp} is sampled from the hypothetical propensity distribution of measure Y_g for person p. Figure 1 presents several examples of what such propensity distributions might look like for a Y_g measured on a continuous scale. From this we define measurement error for a given observation as the difference between the true score and the particular score observed for p on Y_g—that is, $\varepsilon_{gp} = y_{gp} - \tau_{gp}$. Note that a different error score would result had we sampled a different y_{gp} from the propensity distribution for person p, and an infinite set of replications will produce a distribution for ε_{gp}.

Several useful results follow from these simple definitions. First, the expected error score is zero—that is, $E(\varepsilon_{gp}) = 0$. Second, the correlation between the true score and the error score for a fixed person is zero—that is, $E(\varepsilon_{gp}, \tau_{gp}) = 0$. These two results follow from the fact that the true score for person p is a fixed constant. Third, the shapes of the probability distributions of ε_{gp} and y_{gp} are identical and the variance of the propensity distribution for y_{gp} is equal to the variance of the

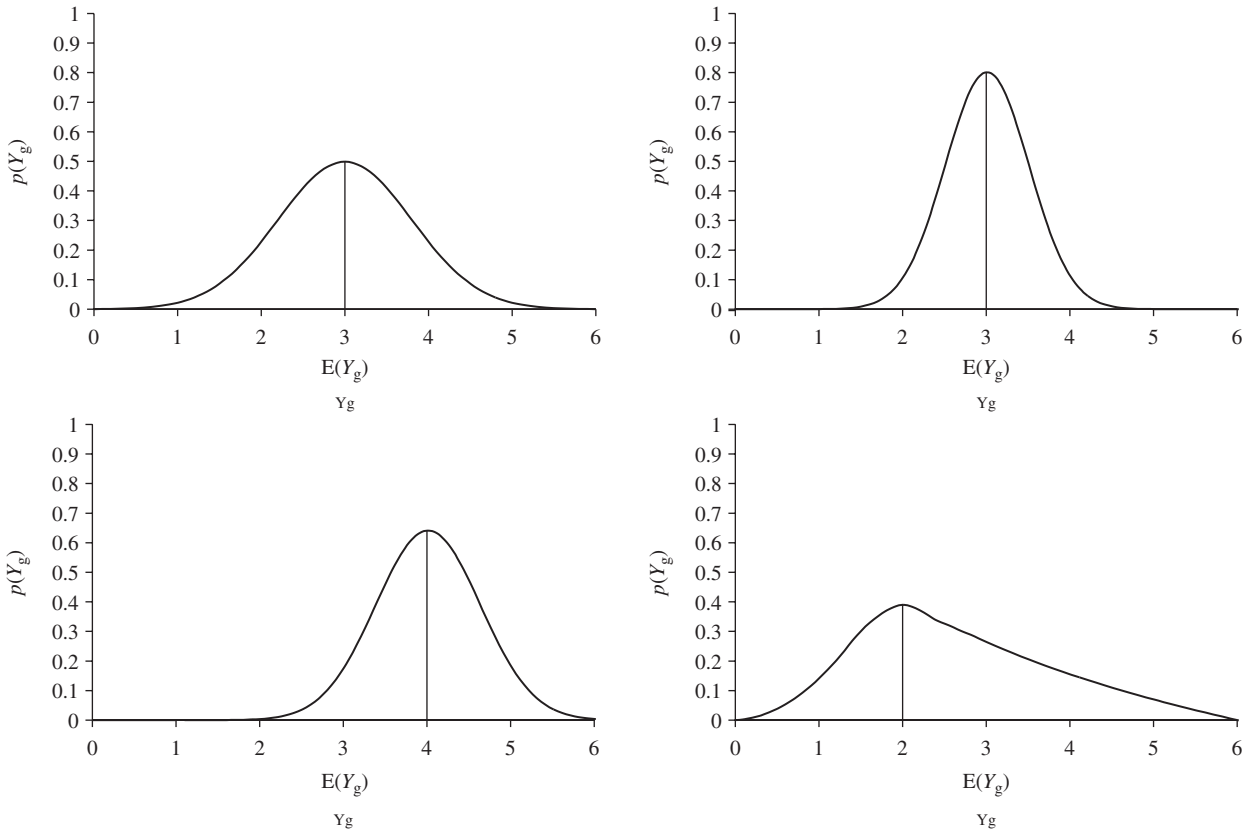

Figure 1 Examples of propensity distribution for a fixed person.

error scores—that is, $\mathrm{VAR}(\varepsilon_{gp}) = \mathrm{VAR}(y_{gp})$. These properties combine to define measurement error under this model as random error.

Given a population of persons for whom the previous model holds, we can write the model $Y_g = T_g + E_g$ for the gth measure of Y, the properties of which are well-known. In this model, the expectation of E_g is zero, from which it follows that $\mathrm{E}[Y_g] = \mathrm{E}[T_g]$. Also under this model, the covariance of the true and error scores is zero, $\mathrm{COV}[T_g, E_g] = 0$, from which it follows that the variance of the observed score equals the sum of the variance of the true score and the variance of the error score, $\mathrm{VAR}[Y_g] = \mathrm{VAR}[T_g] + \mathrm{VAR}[E_g]$. Reliability is defined as a population parameter, namely the proportion of the observed variance that is accounted for by true score variance, which is expressed as the squared correlation between Y_g and T_g: $\mathrm{COR}[Y_g, T_g]^2 = \mathrm{VAR}[T_g]/\mathrm{VAR}[Y_g] = (\mathrm{VAR}[Y_g] - \mathrm{VAR}[E_g])/\mathrm{VAR}[Y_g]$. As a generic concept, then, reliability refers to the relative proportion of random error versus true variance in the measurement of Y_g in a fixed population—that is, variance due to random "noise" versus variance due to "signal," to use a metaphor from telegraphy. As the proportion of error variance in $\mathrm{VAR}[Y_g]$ declines, reliability will approach unity, and as it increases relative to $\mathrm{VAR}[Y_g]$ reliability will approach zero.

Let Y_1 and Y_2 be two measures from the set of measures defined previously, such that $Y_1 = T_1 + E_1$ and $Y_2 = T_2 + E_2$. Assume further that Y_1 and Y_2 are tau equivalent—that is, they have the same true scores, $T = T_1 = T_2$. It follows from this set of definitions that the covariance between Y_1 and Y_2 is equal to the variance of T, $\mathrm{COV}(Y_1, Y_2) = \mathrm{VAR}(T)$. With this result we can define the reliability for the two measures of the random variable of interest, Y_1 and Y_2, in the population of interest as $\mathrm{COV}(Y_1, Y_2)/\mathrm{VAR}[Y_1]$ and $\mathrm{COV}[Y_1, Y_2]/\mathrm{VAR}[Y_2]$, respectively. Such measures are referred to as tau-equivalent measures. If, in addition to tau equivalence, the error variances of the two measures are equal (i.e., $\mathrm{VAR}[E_1] = \mathrm{VAR}[E_2]$), this would imply equal variances, $\mathrm{VAR}[Y_1]$ and $\mathrm{VAR}[Y_2]$, and equal reliabilities for Y_1 and Y_2. In this special case, the reliability of Y_1 and Y_2 can be expressed by their correlation, $\mathrm{COR}[Y_1, Y_2]$, since $\mathrm{COR}[Y_1, Y_2] = \mathrm{COV}[Y_1, Y_2]/(\mathrm{VAR}[Y_1]^{1/2}\ \mathrm{VAR}[Y_2]^{1/2})$. Such measures (with tau equivalence and equal error variances) are said to be parallel measures. Finally, measures are often not tau equivalent, as in the case of different scales or metrics used to measure Y_1 and Y_2, but their true scores are linearly related (i.e., $\mathrm{COR}[T_1, T_2] = 1.0$). When this is the case, the measures are said to be congeneric. Note the nested nature of the relationship between these three models: the tau-equivalent measures model is a special case of the congeneric model, and the parallel measures model is a special case of the tau-equivalence model.

Nonrandom Measurement Error

Usually, we think of measurement error as being more complex than the random error model developed previously. In addition to random errors of measurement, there is also the possibility that Y_{gp} contains systematic (or correlated) errors. The relationship between random and systematic errors can be clarified if we consider the following extension of the classical true score model: $y_{gp} = \tau^*_{gp} + \eta_{gp} + \varepsilon_{gp}$, where η_{gp} is a source of systematic error in the observed score; τ^*_{gp} is the true value, uncontaminated by systematic error; and ε_{gp} is the random error component discussed previously. This model directly relates to the one given previously in that $\tau_{gp} = \tau^*_{gp} + \eta_{gp}$. The idea, then, is that the variable portion of measurement error contains two types of components—a random component, ε_{gp}, and a nonrandom or systematic component, η_{gp}. Within the framework of this model, the goal would be to partition the variance in Y_g into those portions due to τ^*, η, and ε. It is frequently the case that systematic sources of error increase reliability. This is, of course, a major threat to the usefulness of CTST in assessing the quality of measurement. It is important to address the question of systematic measurement errors, but this often requires a more complicated measurement design. This can be implemented using a multitrait–multimethod measurement design along with confirmatory factor analysis, a topic to which we return later.

Common Factor Model Representation of CTST

It is a straightforward exercise to express the basic elements of CTST as a special case of the metric (unstandardized) form of the common factor model and to generalize this model to the specification of K sets of congeneric measures. Consider the following common factor model:

$$\mathbf{Y} = \Lambda\mathbf{T} + \mathbf{E},$$

where $\mathbf{Y}$ is a $(G \times 1)$ vector of observed random variables, $\mathbf{T}$ is a $(K \times 1)$ vector of true score random variables measured by the observed variables, $\mathbf{E}$ is a $(G \times 1)$ vector of error scores, and Λ is a $(G \times K)$ matrix of regression coefficients relating true and observed random variables. The covariance matrix among measures under this model can be represented as follows:

$$\Sigma_{YY} = \Lambda\Phi\Lambda' + \Theta^2,$$

where Σ_{YY}, Φ, and Θ^2 are covariance matrices for the $\mathbf{Y}$, $\mathbf{T}$, and $\mathbf{E}$ vectors defined previously, and Λ is the coefficient matrix as defined previously.

For purposes of this illustration, we consider all variables to be centered about their means. Here, we take the simplest case where $K = 1$; that is, all G variables in Y are measures of T. However, note that the model can

be written for the general case of multiple sets of congeneric measures. In the current case, the model can be represented as follows:

$$\begin{bmatrix} \mathbf{Y}_1 \\ \mathbf{Y}_2 \\ \bullet \\ \bullet \\ \mathbf{Y}_G \end{bmatrix} = \begin{bmatrix} \boldsymbol{\lambda}_{1T} \\ \boldsymbol{\lambda}_{2T} \\ \bullet \\ \bullet \\ \boldsymbol{\lambda}_{GT} \end{bmatrix} \times [\mathbf{T}] + \begin{bmatrix} \boldsymbol{E}_1 \\ \boldsymbol{E}_2 \\ \bullet \\ \bullet \\ \boldsymbol{E}_G \end{bmatrix}.$$

For G congeneric measures of T, there are $2G$ unknown parameters in this model (G λ_{gT} coefficients and G error variances, θ_g^2) with degrees of freedom (df) equal to $0.5G(G+1) - 2G$. In general, this model requires a scale to be fixed for T since it is an unobserved latent random variable. Two options exist for doing this: (i) The diagonal element in Φ can be fixed at some arbitrary value (e.g., 1.0), or (ii) one of the λ_{gT} coefficients can be fixed at some arbitrary value (e.g., 1.0). For G measures of T, the tau-equivalent model has $G+1$ parameters with $\mathrm{df} = 0.5G(G+1) - G + 1$. For a set of G parallel measures there are two parameters to be estimated: VAR[T] and VAR[E], with $\mathrm{df} = 0.5G(G+1) - 2$. Note that both the tau-equivalent measures and parallel measures form of this model invoke the assumption of tau equivalence. This is imposed on the model by fixing all λ_{gT} coefficients to unity. In order to identify the tau-equivalent or parallel measures model, observations on two measures, Y_1 and Y_2, are sufficient to identify the model. For the congeneric model, G must be ≥ 3. It should be clear that the congeneric measures model is the most general and least restrictive of these models, and the tau-equivalent and parallel measures models simply involve restrictions on this model. An internal consistency estimate of the reliability for a set of G measures for which a common factor model holds is developed later, and it is shown that Cronbach's alpha is a special case of the common factor model involving tau-equivalent measures.

What has been stated for the model in the previous discussion can be generalized to any number of G measures of any number of K factors. The only constraint is that the assumptions of the model—univocity and random measurement error—are realistic for the measures and the population from which the data derive. Although there is no way of testing whether the model is correct, when the model is overidentified the fit of the model can be evaluated using standard likelihood ratio approaches to hypothesis testing within the confirmatory factor analysis framework. For example, there is a straightforward test for whether a single factor can account for the covariances among the G measures. Absent such confirming evidence, it is unlikely that a simple true score model is appropriate.

Scaling of Variables

The discussion to this point has assumed interval-level measurement of continuous latent variables and the use of standard Pearson-based covariance approaches to the definition of statistical associations. Observed variables measured on ordinal scales are not continuous (i.e., they do not have origins or units of measurement), and therefore should not be treated as if they are continuous. This does not mean that where the observed variables are categorical the underlying latent variable being measured cannot be assumed to be continuous. Indeed, the tetrachoric and polychoric approaches to ordered dichotomous and ordinal polytomous data assume there is an underlying continuous variable Y^*, corresponding to the observed variable Y, that is normally distributed. The use of these approaches is somewhat cumbersome and labor-intensive because it requires that the estimation of the model be done in two steps. First, one estimates the polychoric or tetrachoric correlations for the observed data, which often takes a substantial amount of time, especially when the number of categories is large. In the second step, one estimates the parameters of the CTST model using maximum likelihood or weighted least squares. There are two basic strategies for estimating polychoric/tetrachoric correlations. One is to estimate the polychoric/tetrachoric correlations and thresholds jointly from all the univariate and bivariate proportions in a multiwave contingency table. This approach is computationally very complex and not generally recommended. The other, which almost always produces identical results, is to estimate the thresholds from the univariate marginals and the polychoric correlations from the bivariate marginals. In 1994, Jöreskog presented a procedure for estimating the asymptotic covariance matrix of polychoric correlations, which requires the thresholds to be equal.

Another approach to examining measurement errors, which also assumes continuous latent variables, appropriate for categoric data, is based on item response theory (IRT). Test psychologists and others have used IRT models to describe item characteristic curves in a battery of items. One specific form of the IRT model, namely Rasch models, has been suggested as one approach to modeling measurement errors. Duncan's work illustrates how the Rasch model can be applied to dichotomous variables measured on the same occasion. These approaches have not explicitly included parameters for describing reliability as defined here.

Designs for Reliability Estimation

Two general design strategies exist for estimating the reliability of measurement using repeated measures: replicate (or similar) measures during the same occasion

of measurement (cross-sectional measurement) or replicate measures in reinterview designs (longitudinal measurement). The application of either design strategy is problematic, and in some cases the estimation procedures require assumptions that are inappropriate given the data gathered in such designs. Estimating reliability from information collected within the same interview is especially difficult, owing to the virtual impossibility of replicating questions exactly. Researchers often employ similar, although not identical, questions and then examine correlation or covariance properties of the data collected. In other words, rather than multiple or repeated measures, investigators often use multiple indicators as a substitute. However, it is risky to use covariance information from multiple indicators to estimate item reliability because items that are different contain specific components of variance, orthogonal to the quantity measured in common, and because difficulties in separating reliable components of specific variance from random error variance present significant obstacles to this estimation approach. Because of potentially biasing effects of memory and other cognitive processes, it is virtually impossible to obtain unbiased estimates of reliability from cross-sectional surveys.

A second approach to estimating reliability in survey data uses the multiple-wave reinterview (i.e., test–retest) or panel design. Such longitudinal designs also have problems for the purpose of estimating reliability. For example, the test–retest approach using a single reinterview must assume that there is no change in the underlying quantity being measured. With two waves of a panel study, the assumption of no change, or even perfect correlational stability, is unrealistic, and without this assumption little purchase can be made on the question of reliability in designs involving two waves. The analysis of panel data must be able to cope with the fact that people change over time so that models for estimating reliability must take the potential for individual-level change into account. Given these requirements, techniques have been developed for estimating measurement reliability in panel designs where $p \geq 3$ in which change in the latent true score is incorporated into the model. With this approach, there is no need to rely on multiple measures within a particular wave or cross section in order to estimate the measurement reliability. This approach is possible using modern structural equation models for longitudinal data.

Reliability Models for Composite Scores

The most common approach to assessing reliability in cross-sectional data is through the use of multiple indicators of a given concept and the estimation of the reliability of a linear composite score made up of those measures. Let Y symbolize such a linear composite defined as the sum $Y_1 + Y_2 + \cdots + Y_g + \cdots + Y_G$; that is, $\sum_g (Yg)$, where g is an index that runs from 1 to G. Such estimates of reliability are referred to as internal consistency estimates of reliability (ICR). In this case, we can formulate a reliability model for the composite as $Y = T + E$, where T is a composite of true scores for the G measures, and E is a composite of error scores. This assumes that for each measure the random error model holds, that is, $Y_g = T_g + E_g$, and thus $T = \sum_g (Tg)$ and $E = \sum_g (Eg)$. The goal of the internal consistency approach is to obtain an estimate of $\mathrm{VAR}(T)/\mathrm{VAR}(Y) = [\mathrm{VAR}(Y) - \mathrm{VAR}(E)]/\mathrm{VAR}(Y)$. This can be defined as a straightforward extension of the common factor model of CTST given previously. The following identities result from the previous development:

$$\mathrm{VAR}(Y) = \sum_j \sum_i \Sigma_{YY}$$
$$\mathrm{VAR}(T) = \sum_j \sum_i [\Lambda \Phi \Lambda']$$
$$\mathrm{VAR}(E) = \sum_j \sum_i \Theta^2.$$

(Note that i and j represent indexes that run over the rows and columns of these matrices, where $i = 1$ to G and $j = 1$ to G.) In other words, the common factor representation of the CTST model given previously for the population basically partitions the composite observed score variance into true score and error variance. These quantities can be manipulated to form an internal consistency measure of composite reliability as follows:

$$\mathrm{ICR} = \frac{\sum_j \sum_i \Sigma_{YY} - \sum_j \sum_i \Theta^2}{\sum_j \sum_i \Sigma_{YY}}.$$

The most common estimate of internal consistency reliability is Cronbach's α, computed as follows:

$$\boldsymbol{\alpha} = \frac{\boldsymbol{G}}{\boldsymbol{G} - \mathbf{1}} \left[\mathbf{1} - \frac{\sum_g \mathbf{VAR}(\boldsymbol{Y}_g)}{\mathbf{VAR}(\boldsymbol{Y})} \right].$$

This formula is derived from the assumption of G unit-weighted (or equally weighted) tau-equivalent measures. The logic of the formula can be seen as follows. First, rewrite $\sum_j \sum_i \Theta^2$ in the previous expression for ICR as equal to $\sum_j \sum_i \Sigma_Y - \sum_j \sum_i \Sigma_T$, where Σ_Y is a diagonal matrix formed from the diagonal elements of Σ_{YY}, and Σ_T is a diagonal matrix formed from the diagonal of $\Lambda \Phi \Lambda'$. Note further that under tau-equivalence $\Lambda = 1$ (a vector of 1s), so this reduces to φI, where φ is the variance of T_g, and I is

a $(G \times G)$ identity matrix. Note that in the population model for tau-equivalent measures, all the elements in Σ_{YY} are identical and equal to φ, the variance of the true score of T_g. From these definitions, we can rewrite ICR as follows:

$$\text{ICR} = \frac{\sum_j \sum_i \Sigma_{YY} - \sum_j \sum_i \Sigma_Y + \sum_j \sum_i \varphi I}{\sum_j \sum_i \Sigma_{YY}}.$$

Note further that $\sum_j \sum_i \Sigma_{YY} - \sum_j \sum_i \Sigma_Y = G(G-1)\varphi$, and $\sum_j \sum_i \varphi I = G\varphi$, and thus Cronbach's α can be derived from the following identities:

$$\begin{aligned}
\text{ICR} &= [G(G-1)\varphi + G\varphi] / \sum_j \sum_i \Sigma_{YY} \\
&= [G/G-1][G(G-1)]\varphi / \sum_j \sum_i \Sigma_{YY} \\
&= [G/G-1]\left[\sum_j \sum_i \Sigma_{YY} - \sum_j \sum_i \Sigma_Y\right] \Big/ \sum_j \sum_i \Sigma_{YY} \\
&= [G/G-1]\left[1 - \left[\sum_j \sum_i \Sigma_Y / \sum_j \sum_i \Sigma_{YY}\right]\right].
\end{aligned}$$

The final identity is equivalent to the formula for Cronbach's α given previously. The point of this derivation is that the ICR approach actually has a more general formulation (the congeneric measures model) for which Cronbach's α is but a special case (i.e., ICR $= \alpha$ when the G measures are tau equivalent).

These methods can be generalized to the case of weighted composites, where Yw is the composite formed from the application of a set of weights to the G variables in Y. However, we will not consider this case here, except to note that when the vector of weights, w, is chosen to be proportional to $\Theta^{-2}\Lambda$, such a set of weights will be optimal for maximizing ICR.

There have been other variations to formulating ICR. Heise and Bohrnstedt, for example, defined an ICR coefficient, named Ω, based on the use of U^2 in place of Θ^2 in the previous formulation for ICR, where U^2 is a diagonal matrix of unique variances from an orthogonal common factor analysis of a set of G variables without the CTST assumptions of univocity (e.g., $K > 1$). They proposed partitioning Ω into its contributions from the common factors of the model, arbitrarily labeling the first factor common variance as "valid" variance and successive factor common variance as "invalid" variance.

Although it is a very popular approach, ICR coefficients have several major shortcomings. First, ICR is an unbiased estimate of composite reliability only when the true score model assumptions hold. To the extent the model assumptions are violated, it is generally believed that ICR approaches provide a lower bound estimate of reliability. However, at the same time, there is every possibility that ICR is inflated due to correlated errors (e.g., common method variance among the items), and that some reliable variance is really invalid in the sense that it represents something about responses other than true score variation, such as nonrandom sources of measurement error. ICR therefore captures systematic sources of measurement error in addition to true score variation and in this sense cannot be unambiguously interpreted as a measure of data quality.

Reliability Models for Single Measures

There are two questionable assumptions of the CTST approach. The first is that the measures are univocal measures of a single underlying variable. The second is that the errors of the measures are independent of one another. These assumptions rule out, for example, the operation of memory in the organization of responses to items in a series of questions. Obviously, respondents are fully cognizant of the answers they have given to previous questions, so there is the possibility that memory operates to distort the degree of consistency in responses. These assumptions for reliability estimation in cross-sectional studies also rule out the operation of other types of correlated errors, such as the operation of systematic method factors. Thus, in cross-sectional data it may be impossible to assume that measurement errors are independent, since similar questions are often given in sequence or at least included in the same battery. Given the shortcomings of the ICR approaches, attention has turned to more closely examining the sources of variation at the item level. Two variants on the basic CTST model have been developed for this purpose: the multitrait–multimethod measurement design and the quasi-simplex approach for longitudinal data.

Multitrait–Multimethod Models

There is an increasing amount of support for the view that shared method variance inflates ICR estimates. One approach to dealing with this is to reformulate the CTST along the lines of a multiple-factor approach and to include sources of systematic variation from both true variables and method factors. With multiple measures of the same concept, as well as different concepts measured by the same method, it is possible to formulate a multitrait–multimethod model. In general, the measurement of K traits measured by each of Q methods (generating $G = KQ$ observed variables) allows the specification of such a model.

Following from the discussion of nonrandom measurement errors, we can formulate an extension of the common factor representation of the CTST given previously as follows:

$$\mathbf{Y} = \Lambda_{T^*}\mathbf{T}^* + \Lambda_M\mathbf{M} + \mathbf{E},$$

where $\mathbf{Y}$ is a $(G \times 1)$ vector of observed random variables, $\mathbf{T}^*$ is a $(K \times 1)$ vector of "trait" true score random variables, $\mathbf{M}$ is a $(Q \times 1)$ vector of "method" true score random variables, and $\mathbf{E}$ is a $(G \times 1)$ vector of error scores. The matrices Λ_{T^*} and Λ_M are $(G \times K)$ and $(G \times Q)$ coefficient matrices containing the regression relationships between the G observed variables and the K and Q latent trait and method latent variables. Note that with respect to the CTST model given previously, $\Lambda T = \Lambda_{T^*}\mathbf{T}^* + \Lambda_M\mathbf{M}$. The covariance structure for the model can be stated as

$$\Sigma_{YY} = [\Lambda_{T^*} \mid \Lambda_M]\, \Phi_T[\Lambda_{T^*}|\Lambda_M]' + \Theta^2,$$

where Φ_T has the following structure:

$$\Phi_T = \left[\begin{array}{c|c} \Phi_{T^*} & 0 \\ \hline 0 & \Phi_M \end{array}\right].$$

Note that the specification of the model places the constraint that the trait and method factors are uncorrelated. The estimation of this model permits the decomposition of reliable variance in each of the observed measures into valid and invalid parts.

Quasi-Simplex Models

A second approach to estimating reliability of single items uses the reinterview approach within a longitudinal design, or what are often called "panel" designs. The limitation of the test–retest approach using a single reinterview is that it must assume there is no change in the underlying quantity being measured. To address the issue of taking individual-level change into account, both Coleman and Heise developed a technique based on three-wave quasi-simplex models within the framework of a model that permits change in the underlying variable being measured. This approach can be generalized to multiwave panels. This class of autoregressive or quasi-Markov simplex model specifies two structural equations for a set of P over-time measures of a given variable Y_t (where $t = 1, 2, \ldots, P$) as follows:

$$Y_t = T_t + E_t$$
$$T_t = \beta_{t,t-1}T_{t-1} + Z_t.$$

The first equation represents a set of measurement assumptions indicating that over-time measures are assumed to be tau equivalent, except for true score change, and that measurement error is random. The second equation specifies the causal processes involved in change of the latent variable over time. Here, it is assumed that Z_t is a random disturbance representing true score change over time. This model assumes a lag-1 or Markovian process in which the distribution of the true variables at time t is dependent only on the distribution at time $t-1$ and not directly dependent on distributions of the variable at earlier times. If these assumptions do not hold, then this type of simplex model may not be appropriate. In order to estimate such models, it is necessary to make some assumptions regarding the measurement error structures and the nature of the true change processes underlying the measures. All estimation strategies available for such three-wave data require a lag-1 assumption regarding the nature of the true change. This assumption in general seems a reasonable one, but erroneous results can be obtained if it is violated. The various approaches differ in their assumptions about measurement error. One approach assumes equal reliabilities over occasions of measurement. This is often a realistic and useful assumption, especially when the process is not in dynamic equilibrium (i.e., when the observed variances vary with time). Another approach to estimating the parameters of the previous model is to assume constant measurement error variances rather than constant reliabilities. Where $P = 3$, either model is just-identified, and where $P > 3$ the model is overidentified with degrees of freedom equal to $0.5[P\ (P+1)] - 2P$. The four-wave model has two degrees of freedom, which can be used to perform likelihood ratio tests of the fit of the model.

One of the main advantages of the reinterview design, then, is that in appropriate circumstances it is possible to eliminate the confounding of the systematic error component discussed earlier, if systematic components of error are not stable over time. In order to address the question of stable components of error, the panel survey must deal with the problem of memory because in the panel design, by definition, measurement is repeated. Therefore, although this overcomes one limitation of cross-sectional surveys, it presents problems if respondents can remember what they say and are motivated to provide consistent responses. If reinterviews are spread over months or years, this can help rule out sources of bias that occur in cross-sectional studies. Given the difficulty of estimating memory functions, estimation of reliability from reinterview designs makes sense only if one can rule out memory as a factor in the covariance of measures over time, and thus the occasions of measurement must be separated by sufficient periods of time to rule out the operation of memory.

Reliability Models for Categorical Latent Variables

The approaches previously discussed rely on models in which the latent variable is assumed to be continuous

and in which the data can be assumed to vary according to an interval scale or an approximation (e.g., one that is at least ordinal in character). These assumptions, however, are clearly problematic for categorical latent variables. Latent-class models can be used to assess the extent of measurement error in measures of categorical variables. Several investigators have explored discrete-time Markov chain models, where the Markovian property is posited to hold at the level of the latent classes measured repeatedly. These models provide an analog to the conception of reliability involved in the structural equation modeling approaches for panel data discussed previously.

Conclusions

The foregoing discussion has concentrated on the theoretical background for strategies aimed at quantifying the reliability of measurement in social research. All definitions, relationships, and results were given for a hypothetical finite population (S), and nothing has been stated up to this point about sampling. In order to estimate reliability parameters for a given population of interest, one will need to sample the specific population using probability methods. In so doing, all the usual corrections for sample design effects and for sampling error must be taken into account in drawing inferences about reliability of measurement. This set of considerations is stressed in order to reinforce the fact that not only is the level of reliability influenced by the properties of the measuring device and the conditions of measurement but also, as a population parameter expressed by the ratio of true score to observed score variance, it is obviously influenced by the characteristics of the population to which the measures are applied.

Reliability Assessment

Edward G. Carmines
Indiana University, Bloomington, Indiana, USA

James A. Woods
West Virginia University, Morgantown, West Virginia, USA

Glossary

measurement The process of linking abstract concepts to empirical indicators of those concepts.
random measurement error All of the chance factors that confound the measurement of any phenomenon.
reliability The extent to which an experiment, test, or any measuring procedure yields the same results on repeated trials.
validity The extent to which an indicator of some abstract concept measures what it purports to measure.

Reliability focuses on the extent to which an empirical measurement yields consistent results in repeated trials. The more consistent a measure is, the more reliable it is. If a bathroom scale repeatedly registers a person's weight at 5 pounds less than the true weight, that scale is consistent on repeated trials—it is reliable. However, that scale is not a valid indicator of weight, because it is never correct. That is the difference between these two basic properties of empirical measurement. Validity is the extent to which the indicator measures what it purports to measure. Reliability is the extent to which the indicator is consistent across attempts.

Measurement

Measurement is crucial to science. From the perspective of the social sciences, measurement may be thought of as the process of linking abstract concepts to empirical indicators of those concepts. It focuses on the relationship between the empirically grounded indicator, the observable response, and the underlying unobservable concept. Thus, measurement allows the social scientist to move from abstract, indirectly observable concepts and theories to empirical, directly observable indicators of those theoretical concepts. Many studies in the social sciences represent abstract concepts by a single empirical indicator. For example, social status is sometimes measured by occupational prestige. Or the state of the economy is measured by per capita income. From a measurement perspective, this reliance on single indicators is undesirable for two reasons. First, when using a single indicator, it is almost always impossible to estimate reliability. To do this, there must be some *a priori* information available, and this is usually not the case. Second, even if the reliability of a single indicator can be estimated, it is more affected by random error, as compared to a composite measure made up of two or more indicators.

Random and Nonrandom Measurement Error

Two basic types of errors affect empirical measurements: random error and nonrandom error. Random error consists of all of the chance factors that confound the measurement of any phenomenon. If an indicator is a reliable indicator of a theoretical concept, it will produce consistent results on repeated observations because random error does not cause systematic fluctuation from one observation to the next. That is, to take a very simple example, if a scale records an individual's weight as 5 pounds less than the true weight on the first attempt,

5 pounds more than the true weight on the second attempt, 8 pounds more than the true weight on the third attempt, and 10 pounds less than the true weight on the fourth attempt, that scale is not very reliable as a measure for weight. The more random the error, the more unreliable is the measure.

Classical Test Theory

Classical test theory is used to assess random measurement error. By determining the amount of random error, reliability can be estimated.

Reliability

Random error is present in any measure. Reliability focuses on the assessment of random error and estimating its consequences. Although it is always desirable to eliminate as much random error from the measurement process as possible, it is even more important to be able to detect the existence and impact of random error. Because random error is always present to at least a minimum extent, the basic formulation in classical test theory is that the observed score is equal to the true score that would be obtained if there were no measurement error plus a random error component, or $X = t + e$, where X is the observed score, t is the true score, and e is the random disturbance. The true score is an unobservable quantity that cannot be directly measured. Theoretically, it is the average that would be obtained if a particular phenomenon was measured an infinite number of times. The random error component, or random disturbance, indicates the differences between observations.

Classical test theory makes the following assumptions about measurement error:

Assumption 1: The expected random error is zero,

$$E(e) = 0.$$

Assumption 2: The correlation between the true score and random error is zero,

$$\rho_{(t,e)} = 0.$$

Assumption 3: The correlation between the random error of one variable and the true score of another variable is zero,

$$\rho_{(e_1,t_2)} = 0.$$

Assumption 4: The correlation between errors on distinct measurements is zero,

$$\rho_{(e_1,e_2)} = 0.$$

From these assumptions, we see that the expected value of the observed score is equal to the expected value of the true score plus the expected value of the error:

$$E(X) = E(t) + E(e).$$

However, because, by assumption 1, the expected value of e is zero, $E(e) = 0$, then,

$$E(X) = E(t).$$

This formula applies to repeated measurements of a single variable for a single person. However, reliability refers to the consistency of repeated measurements across persons and not within a single person. The equation for the observed score may be rewritten so that it applies to the variances of the single observed score, true score, and random error:

$$\mathrm{Var}(X) = \mathrm{Var}(t + e) = \mathrm{Var}(t) + 2\mathrm{Cov}(t, e) + \mathrm{Var}(e).$$

Assumption 2 stated that the correlation (and covariance) between the true score and random error is zero, so $2\ \mathrm{Cov}(t, e) = 0$. Consequently,

$$\mathrm{Var}(X) = \mathrm{Var}(t) + \mathrm{Var}(e).$$

So the observed score variance equals the sum of the true score variance and the random error variance. Reliability can be expressed as the ratio of the true score variance to the observed score variance:

$$\rho_x = \frac{\mathrm{Var}(t)}{\mathrm{Var}(X)}.$$

That is, ρ_x is the reliability of X as a measure of t. Alternatively, reliability can be expressed in terms of the error variance as a proportion of the observed variance:

$$\rho_x = 1 - \left[\frac{\mathrm{Var}(e)}{\mathrm{Var}(X)}\right].$$

This equation makes it clear that reliability varies between 0 and 1. If all observed variance consists of error, then reliability will be 0, because $1 - (1/1) = 0$. At the other extreme, if there was no random error in the measurement of some phenomenon, then reliability will be 1, because $1 - (0/1) = 1$.

Parallel Measurements

One estimate of a measure's reliability can be obtained by correlating parallel measurements. Two measurements are defined as parallel if they have identical true scores and equal error variances. Thus, X and X' are parallel if $X = t + e$ and $X' = t + e'$, where $\mathrm{Var}(e) = \mathrm{Var}(e')$ and $t = t$. Thus, parallel measures are functions of the same true score, and the differences between them are the result of purely random error.

Assessing Reliability

There are four basic methods for estimating the reliability of empirical measurements. These are the retest method, the alternative-form method, the split-halves method, and the internal consistency method.

Retest Method

The most straightforward and intuitive method of assessing reliability is to correlate the same measures administered at different points in time. Figure 1 shows a representation of the retest method. The equations for the tests at times 1 and 2 can be written as follows:

$$X_1 = X_t + e_1$$

and

$$X_2 = X_t + e_2.$$

Because in parallel measures $t = t$ and $\mathrm{Var}(e_1) = \mathrm{Var}(e_2)$, and by assumption $\rho_{(e_1,t_2)} = 0$ and $\rho_{(e_1,e_2)} = 0$, it follows that $\rho_x = \rho_{x_1x_2}$. That is, reliability is the correlation between the scores on the same test obtained at two points in time. If the retest reliability coefficient is exactly 1.0, the results on the two administrations of the test are the same. However, because there is almost always random measurement error, the correlations across time will not be perfect.

Although test–retest correlations are a simple and intuitively appealing way to assess reliability, they have some serious problems and limitations. First, often researchers can obtain a measure only at a single point in time. It may be too expensive or impractical to measure the phenomenon at different times. Moreover, if the test–retest correlations are low, it may not indicate unreliability but rather the possibility that, in the interim, the theoretical concept of interest has undergone a change. For example, if the measure of support for a candidate at the beginning of a campaign differs from that at the end of a campaign, the suspicion would probably be that there was real change in the candidate's popularity during the course of the campaign—not that the measurement of popularity was necessarily unreliable.

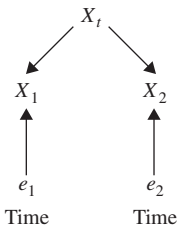

Figure 1 A representation of the retest method for estimating reliability.

Another problem that affects test–retest correlations and lowers reliability estimates is reactivity. Sometimes the very act of measuring a phenomenon can induce change in the phenomenon. A person may become sensitized to the concept of being measured and thus change his/her answer based only on the earlier measurement. Lowered reliability estimates are not the only effects. If the period between time 1 and time 2 is short enough, the subject may remember his/her answer at time 1 and thus appear more consistent than is actually the case. These memory effects can inflate reliability estimates.

Alternative-Form Method

The alternative-form method of assessing reliability is similar to the retest method in that it requires administering a test to the same people at different points in time. The difference between this method and the retest method is that an alternative form of the same test is given on the second testing. Because the two forms of the same test are intended to measure the same theoretical concept, they should not differ systematically from each other. Using random procedures to select items for the different forms of the test can ensure that the tests do not differ systematically. In this case, the reliability is the correlation between the alternative forms of the test. The two forms should be administered about 2 weeks apart, to allow for day-to-day fluctuations in the individual.

This method for assessing reliability is superior to the retest method because it reduces the extent to which an individual's memory can inflate the reliability estimate. However, this method, like the retest method, does not allow the researcher to distinguish true change from the unreliability of the measure if the measurement takes place only on two occasions. Therefore, the results of alternative-form reliability studies are easier to interpret if the phenomenon being measured is relatively enduring and not subject to rapid and radical alteration. A limitation of this method is the difficulty of designing alternative forms that are truly parallel.

Split-Halves Method

Reliability estimated by using the split-halves method, unlike the retest or alternative-form methods, can be conducted on only one occasion. In the split-halves method, the total set of parallel items is divided into halves and the scores on the halves are correlated to yield an estimate of reliability. The halves can be considered approximations to alternative forms. The correlations between the two halves would be the reliability for each half of the test and not for the total test. To estimate the reliability of the entire test, a statistical correction, called the Spearman–Brown prophecy formula, must be estimated.

Because the total test is twice as long as each half, the Spearman–Brown prophecy formula is expressed as

$$\rho_{xx''} = \frac{2\rho_{xx'}}{1 + \rho_{xx'}}, \quad (1)$$

where $\rho_{xx''}$ is the reliability coefficient for the whole test and $\rho_{xx'}$ is the split-half correlation. For example, if the correlation between the halves is 0.75, the reliability for the whole test would be $[(2)(0.75)]/(1 + 0.75) = 0.857$. The reliability coefficient varies between 0 and 1, taking on these extreme values if the correlation between the halves is 0.00 or 1.00.

The more general version of the Spearman–Brown prophecy formula is

$$\rho_{x_n x_n''} = \frac{N\rho_{xx'}}{1 + (N-1)\rho_{xx'}}. \quad (2)$$

This formula estimates the reliability of a scale that is N times longer than the original scale. A researcher can also use the Spearman–Brown prophecy formula to determine the number of items that would be needed to attain a given reliability. To estimate the number of items required to obtain a particular reliability, the following formula is used:

$$N = \frac{\rho_{xx''}(1 - \rho_{xx'})}{\rho_{xx'}(1 - \rho_{xx''})}, \quad (3)$$

where $\rho_{xx''}$ is the desired reliability, $\rho_{xx'}$ is the reliability of the existing test, and N is the number of times the test would be lengthened to obtain reliability of $\rho_{xx''}$. For example, if a 10-item test has a reliability of 0.60, then the estimated lengthening required to obtain a reliability of 0.80 would be $N = 0.8(1 - 0.6)/0.6(1 - 0.8) = 2.7$. In other words, 27 parallel items would be required to attain a reliability of 0.80.

There is an element of indeterminateness in using the split-halves technique to estimate reliability, due to the different ways that the items can be grouped into halves. The most typical way to divide the items is to place the even-numbered items in one group and the odd-numbered items in the other group. But other ways of partitioning the total item set are also used, including separately scoring the first and second halves of the items and randomly dividing the items into two groups. For a 10-item scale, there are 126 different splits, and each will probably result in a slightly different correlation between the two halves, which will lead to a different reliability estimate. It is therefore possible to obtain different reliability estimates even if the same items are administered to the same individuals.

Internal Consistency Methods

Because of the indeterminateness of the split-halves technique, other methods that do not require either splitting or repeating items have been developed to estimate reliability. These techniques go under the general rubric of "measures of internal consistency." The most popular of these measures is Cronbach's alpha. Cronbach's alpha is equal to the average of all possible split-half correlations for a composite scale $2N$ items long, and is calculated from the variance–covariance matrix as follows:

$$\alpha = \frac{N}{N-1}\left[1 - \frac{\sum \mathrm{Var}(Y_i)}{\mathrm{Var}_x}\right], \quad (4)$$

where N is the number of items, $\sum \mathrm{Var}(Y_i)$ is the sum of the item variances, and Var_x is the variance of the total composite. If the correlation matrix rather than the variance–covariance matrix is being used, the formula becomes

$$\alpha = \frac{a}{a-1}\left[1 - \frac{a}{a+2b}\right], \quad (5)$$

where a is the number of items in the composite and b is the sum of the correlations among the items. Alpha is a lower bound to the reliability of an unweighted scale of N items, i.e., the reliability is always equal to or greater than alpha. It is equal to the reliability if the items are parallel. The reliability of a scale can never be lower than alpha, even if the items depart substantially from being parallel measurements. Thus, alpha is a conservative estimate of reliability.

Cronbach's alpha is a generalization of Kuder and Richardson's procedure, which was designed to estimate the reliability of scales composed of dichotomously scored items. These items are scored either 0 or 1, depending on whether the individual possesses the particular characteristic of interest. Because Cronbach's alpha can handle dichotomously scored items or items that can take on three or more values, because it encompasses the Spearman–Brown prophecy formula, because it makes use of all of the information contained in the items, and because it is easy to compute, it is a very popular estimate of reliability.

Correction for Attenuation

No matter which specific method is used for obtaining an estimate of reliability, one of the estimate's most important uses is to "correct" correlations for unreliability due to random measurement error. If the reliability of each variable can be estimated, these estimates can be used to determine what the correlation between the two variables would be if they were made perfectly reliable. This process is called correction for attenuation. The formula for the correction for attenuation is

$$\rho_{x_t y_t} = \frac{\rho_{x_t y_t'}}{\sqrt{\rho_{xx'}\rho_{yy'}}}, \quad (6)$$

where $\rho_{x_t y_t}$ is the correlation corrected for attenuation, $\rho_{xx'}$ is the reliability of X, $\rho_{yy'}$ is the reliability of Y, and $\rho_{x_t y_t'}$ is the observed correlation between x and y. By correcting correlations between measures for attenuation due to unreliability, the researcher gains a more accurate estimate of the correlation between the underlying theoretical concepts.

Religious Affiliation and Commitment, Measurement of

David E. Campbell
University of Notre Dame, Notre Dame, Indiana, USA

Glossary

black Protestants/Black Church A religious tradition composed of denominations historically governed by and in service of African Americans. Although these denominations share many beliefs and organizational characteristics with white evangelical churches, they are nonetheless distinct owing to their doctrinal emphases on social justice and civil rights and to their social role as one of the few kinds of organizations free from white control throughout African American history.

denomination The specific religious organization to which someone belongs, often affiliated with a national or international organization (e.g.. Southern Baptists).

evangelical Protestants A religious tradition characterized by a conservative theology. Evangelical Protestants generally believe that an individual must be personally converted to a belief in Jesus Christ. They also emphasize the importance of the Bible and stress the need for missions in order to convert others.

mainline Protestants A religious tradition characterized by a more modernist (some would say liberal) theology and interpretation of scripture, with less emphasis on personal piety.

religious tradition A general grouping of denominations, united by a common history and common beliefs (e.g., evangelical Protestants).

The religious diversity within the United States makes religion simultaneously important and difficult to understand. Survey researchers must distinguish between an individual's religious affiliation (church membership) and level of religious commitment. This entry offers practical guidance for researchers relying on existing data sets, such as the General Social Survey and American National Election Studies, as well as scholars designing their own data collection.

Introduction

The last decade or so has seen a revival of the study of religion within the social sciences. This has been especially true in the United States, where religiously themed issues regularly ignite controversy in the public square and a large majority of Americans profess adherence to religion (the predictions of secularization theorists to the contrary notwithstanding). Along with this increasing scholarly interest in religion has come increasing sophistication regarding the best methods to measure individuals' religious involvement. Even scholars whose primary interest is not religion can benefit from these advances in the measurement of religious variables because accurate measures are necessary to avoid biasing the interpretation of other statistical relationships in models that control for religious engagement.

Scholars of religion have come to recognize that the measurement of religious engagement requires information about both religious affiliation and commitment, or what the literature on the subject often calls belonging and behaving (a third dimension, believing, is not relevant to this particular discussion). Belonging refers to religious identity, one's denomination and/or religious tradition. Behaving entails religious activities, whether public (such as attending worship services) or private (such as praying). These two dimensions of religious involvement are not orthogonal, but religious researchers have nonetheless found them to be empirically and

theoretically distinctive enough to warrant separate consideration.

Belonging: Religious Affiliation

The sheer number of religious denominations within the United States can be overwhelming to any researcher trying to make sense of the religious groups to which Americans belong. The codebook for the 2000 American National Election Study (ANES), for example, lists over 130 possible denominations, a list that grows with each extension of the ANES time series. In contrast, in the 1950s the sole religiously relevant item in the ANES was simply whether the respondent identified as Catholic, Protestant, or Jewish. This expanding list of denominations is partly a function of the growing religious diversity within the United States, but also reflects social scientists' increasingly nuanced measurement of religious affiliation over the last 50 years.

The first step in measuring denominational affiliation in survey research, therefore, is ensuring that the design of the survey enables respondents to identify their denomination. Experience suggests that neither confronting respondents with a massive list of denominations nor asking them to recall the specific affiliation of their church without a prompt is likely to be very successful. A better method is to follow the model of the ANES, which uses a branching questionnaire to determine religious affiliation (see Table I). Respondents are first asked if they ever attend religious services. If they do, the follow-up inquires whether their place of worship is Protestant, Roman Catholic, Jewish, or something else. Those who do not attend services are asked, "Regardless of whether you now attend religious services, do you ever think of yourself as part of a particular church or denomination?" If the answer is yes, they too are asked to identify themselves as Protestant, Catholic, Jewish, or another faith. Protestants are then asked about their specific affiliation (Baptist, Methodist, etc.), with precise follow-up questions to distinguish among subgroups within each denomination (e.g. Evangelical Lutheran Church in America vs. Missouri Synod Lutherans). Similarly, Jews are asked whether they consider themselves Orthodox, Conservative, or Reform. In parallel fashion, respondents choosing the "Other" category also have the opportunity to specify their denomination. Although the branching format of this item is best suited to a telephone or Internet survey, it can be adapted for self-administered surveys. Whenever possible, any survey should also collect the verbatim name of the church a respondent attends. This can provide invaluable information when classifying ambiguous responses.

Table 1 Questions to Determine Religious Affiliation[a]

(If respondent attends religious services): Do you mostly attend a place that is Protestant, Roman Catholic or what?
If respondent does not attend religious services: Regardless of whether you now attend any religious services do you ever think of yourself as part of a particular church or denomination? (If yes): Do you consider yourself Protestant, Roman Catholic, Jewish, or what?
Protestants:
(If Baptist): With which Baptist group is your church associated? Is it the Southern Baptist Convention, the American Baptist Churches in the USA, the American Baptist Association, the National Baptist Convention, USA, an independent Baptist church or some other Baptist group? (If independent Baptist): Are you affiliated with any larger Baptist group or is this strictly a local church?
(If Lutheran): Is this church part of the Evangelical Lutheran Church in America, the Missouri Synod, or some other Lutheran group?
(If Methodist): Is your church part of the United Methodist Church, African Methodist Episcopal, or some other Methodist group?
(If Presbyterian): Is this the Presbyterian Church in the USA or some other Presbyterian group?
(If Reformed): Is this the Christian Reformed Church, the Reformed Church in America, or some other Reformed group?
(If Brethren): Is this the Church of the Brethren, the Plymouth Brethren, or what?
(If Christian or "just Christian"): When you say "Christian" does that mean the denomination called the "Christian Church"
(Disciples of Christ) or some other Christian denomination, or do you mean to say "I am just a Christian?"
(If Church or Churches of Christ): Is this the Church of Christ or United Church of Christ?
(If Church of God): Is this the Church of God of Anderson, Indiana, the Church of God of Cleveland, Tennessee, the Church of God in Christ, or some other Church of God?
(If Holiness or Pentecostal): What kind of church is that? What is it called exactly? Is that part of a larger church or denomination? What is that church called?
(If other): What is it called exactly? Is that church part of a denomination? Is that group Christian?
(If Jewish): (If respondent attends religious services): Do you usually attend a synagogue or temple that is Orthodox, Conservative, Reform, or what? (If respondent does not attend religious services but considers self Jewish): Do you consider yourself Orthodox, Conservative, Reform, or what?

[a] From the American National Election Studies.

Although providing an array of denominational options allows the analyst to make subtle distinctions among the churches to which respondents belong, when analyzing the data the scope of denominational choices may seem to be as much a curse as a blessing. The generally accepted strategy for dealing with the complexities of religious affiliation is to collapse the denominations into a smaller set of religious traditions. As defined in 1996 by Kellstedt *et al*., a religious tradition is "a group of religious communities that share a set of beliefs that generates a distinctive worldview"—a family of denominations with a common history and trajectory.

Moving from an array of denominations to a set of religious traditions requires an appreciation for the subtleties of America's religious landscape. The Evangelical Lutheran Church in America (ELCA) is a good example of why sensitivity to the wrinkles of denominationalism is important. Notwithstanding the denomination's name, members of the ELCA are not classified as members of the evangelical tradition. This is because "evangelical" is generally applied to theologically conservative Protestants, and the ELCA is more accurately classified as a mainline (i.e., liberal) denomination.

To assist analysts in finding their way through the thickets of America's many denominations, Steensland *et al*. developed in 2000 a classification system that groups denominations into a manageable number of religious traditions, based on their historical commonalities. Building on the work of Kellstedt and his colleagues, Steensland *et al*. emphasized that traditions should be treated as nominal, not ordinal, categories. This contrasts with the approach of Smith in 1990, who classified denominations by where they fell along a continuum defined by the terms fundamentalist, moderate, and liberal. Smith's approach has become quasi-institutionalized; a variable in the public General Social Survey (GSS) data file places each respondent who identifies with a denomination along this continuum. Steensland and his colleagues, however, argued that this system is not conceptually clear and offers limited analytical leverage for understanding the impact religion has on Americans' social and political attitudes. Instead they recommended that individuals be grouped into a relatively small number of denominational categories, assuming no ordinal relationship among them.

Within Protestantism, Steensland and his colleagues recommended that the analyst divide respondents into three mutually exclusive religious traditions. The first is the black Protestant tradition. Because the Black Church has historically been the central institution in the African American community, its doctrinal emphases and religious practices differ from white Protestant denominations. Although there is widespread consensus regarding the need to classify black Protestants as a distinct tradition, researchers have employed two slightly different methods of classifying members of the Black Church. One is to limit the category to African Americans who attend a church that is affiliated with a historically black denomination; the other is to include all African Americans with any Protestant affiliation, regardless of the specific denomination. The decision of which method to use depends on the theoretically grounded assumptions of the analyst. In the first method, the analyst is assuming that the distinctiveness of black Protestants is dependent on their attending a specific type of church. In the second, the implicit assumption is that the most important criterion is the respondents' race and not denominational affiliation. Empirically, differences between the two methods are minor because almost all blacks who affiliate with a church belong to one of seven predominantly black denominations: African Methodist Episcopal (A.M.E.) church; African Methodist Episcopal Zion (A.M.E.Z.) church; Christian Methodist Episcopal (C.M.E.) church; National Baptist Convention, U.S.A, Incorporated (NBC); National Baptist Convention of America, Unincorporated (NBCA); Progressive National Baptist Convention (PNBC), and Church of God in Christ (COGIC).

In addition to a division along racial lines, among white Protestants a distinction should be made between members of mainline and evangelical denominations. Mainline Protestant churches are characterized as having a theology that seeks accommodation with modernity, with more emphasis on social justice than personal piety. They typically do not hold to a literal interpretation of scripture. Evangelical denominations, on the other hand, generally have a strict interpretation of the Bible, stress personal piety as paramount, and emphasize the need for their members to remain separate from the wider cultural milieu. These differences are due to the fact that evangelical churches are generally associated with sect movements, which emphasize separation from more established denominations, whereas mainline churches are more attuned to ecumenism.

Table II contains a list of denominations classified as belonging to the mainline or evangelical traditions. Although this and similar lists include a large number of denominations covering most of the Protestant universe, the sheer number of churches makes it impossible for them to be totally comprehensive. Upon encountering a denomination that is not classified, researchers will find the *Encyclopedia of American Religions* invaluable. As the most comprehensive source of information about individual denominations in the United States, this encyclopedia generally provides enough information about a particular church to classify it as evangelical or mainline.

Another significant religious tradition in the United States is Roman Catholicism, a category with little ambiguity. Similarly, self-identified Jews are easily classified. Given the widespread use of the terms, researchers

will profit from asking Jewish respondents to identify themselves as belonging to a specific tradition with Judaism, such as Orthodox, Reform, and so on, as in the ANES.

In spite of their relatively small numbers, most studies treat Jews as being distinct from other religious groups. This is not the case for a group of other denominations that do not easily fit within the aforementioned religious traditions, some of which are similar in size, and (arguably at least) equally distinctive. In spite of their heterogeneity, these nontraditional churches are typically grouped together in a catch-all "Other" category. Typical examples include the Latter-day Saints (LDS) and Christian Scientists, as well as non-Judeo-Christian religions (such as Islam) and Eastern Orthodox churches. Some analysts further subdivide some members of this catch-all group and distinguish between conservative nontraditional and liberal nontraditional denominations. LDS is an example of the former, and Unitarian-Universalist is an example of the latter.

For most surveys of the general population, particularly those with a national scope, the small number of respondents in these categories make any further distinctions statistically meaningless. However, some sampling frames could produce sizable numbers of respondents within the groups normally relegated to the "Other" or "Nontraditional" categories. For example, because of the

LDS' geographic concentration, a survey within western states will probably have a large number of LDS respondents. Owing to their distinctive theology and social cohesion, whenever their numbers warrant it they should be classified as a separate group. The same applies to other distinctive groups such as Muslims and members of Eastern Orthodox denominations, populations that are also geographically concentrated in some areas of the United States.

Thus far, the discussion has centered only on respondents who identify with a specific religious denomination. Between 2 and 5% of respondents to surveys such as the GSS, however, are classified as Protestants without a denomination. The ambiguity of nondenominationalism leaves the analyst with the challenge of determining whether nonaffiliation is a reflection of a person's secularism or of membership in an explicitly nondenominational church. This is hardly a trivial question because nondenominationalism is a growing trend in American Protestantism. Most notably, mega-churches, which are capturing an ever-increasing share of the religious market, are usually nondenominational. Steensland and his colleagues addressed this issue by dividing respondents identified as nondenominational Protestants between those who report attending church once a month or more and those who report attending less frequently. They classify nonaffiliated respondents who attend church at least monthly as evangelical Protestants, on the grounds that the nondenominational movement is restricted to evangelical churches. In 1996, Kellstedt and his colleagues, who proposed a classification system that is otherwise similar to the Steensland *et al*. scheme, labeled nonaffiliated Protestants with a minimal level of religious commitment as secularists, a category that also includes respondents who report that they are atheists or agnostics. Although this is not a self-identified tradition in the same sense as, say, evangelicalism, Kellstedt *et al*. nonetheless argued persuasively that secularists constitute a distinct group in contemporary American society, an argument bolstered by Layman's 2001 evidence of secularists' impact on the political landscape of the United States.

Behaving: Religious Commitment

The introduction of secularists as a religious tradition underscores that measuring denominational affiliation without also gauging religious commitment paints an incomplete picture of religion's role in American society. There are numerous measures of religious behavior as a form of commitment, but by far the most common is attendance at religious services. Being common, however, does not mean that the measure of church attendance is without controversy. On the contrary, the accuracy of the church attendance measures in surveys such as the GSS is a matter of considerable dispute.

For decades, numerous sources of data have estimated a strikingly similar rate of church attendance in the United States—around 40% of Americans report attending worship services each week. This reported rate of church attendance is remarkably robust to alternative survey questions. Gallup asks respondents if they attended church "last week"; other surveys, notably the GSS, typically ask respondents how frequently they attend church. Both methods produce essentially the same estimated levels of church attendance. In spite of this consistency, however, some scholars have questioned whether surveys accurately gauge the rate of attendance at religious services. The standard questions probably facilitate telescoping, which occurs when a respondent reports having been in church over a wider time span than specified by the interviewer (e.g., someone who attended church 2 weeks prior reporting that she had attended the previous week). They also do little to minimize social desirability bias, the tendency for people to report that they attend church frequently because of the normative value attached to religious commitment in the United States.

These suspicions were articulated most forcefully by Hadaway, Marler, and Chaves in 1993; their research casts doubt on the conventional wisdom that 40% of Americans attend church every week. They collected data on the attendance at religious services in Protestant churches in a single county and a selection of Catholic dioceses nationally and concluded that survey-based estimates are roughly twice the observed rate of church attendance. The research of Hadaway, Marler, and Chaves has proven to be controversial, provoking a plethora of studies revisiting the question of how frequently Americans attend religious services and how church attendance should be measured. In a follow-up to their seminal 1993 article, Marler and Hadaway in 1999 answered many of their critics' objections by testing the accuracy of self-reported church attendance within a single church's congregation. Marler and Hadaway counted the attendance at a particular church by telephone and then surveyed that congregation by telephone over the next week, asking respondents whether they had attended church within the previous 7 days. As with the earlier study, they found substantial overreporting of church attendance, in the range of 59 to 83% (depending on various assumptions).

At this writing, no consensus has developed in the wake of the claims made by scholars who question the validity of survey-based estimates of how many Americans regularly darken the doors of their churches. One camp is adamant that surveys produce hopelessly inaccurate estimates of church attendance, whereas researchers on the other side of the debate are quick to point to the problems endemic

to head counts in the pews. This is not the place to attempt to resolve this debate; instead, the discussion here centers on what can been learned about measuring church attendance from the literature on the subject.

In response to Hadaway and his colleagues, Woodberry pointed out that an extremely important but typically ignored factor affecting the validity of any survey-based measure of religious behavior is simply the quality of the survey's sample. Woodberry noted that surveys with a high refusal rate oversample church-goers because "highly religious respondents are generally . . . more cooperative and thus presumably are less likely to refuse an interview." Whereas a high response rate is always desirable to minimize sampling bias, for a valid measure of church attendance it is essential. Woodberry also stressed that atheoretical weighting schemes designed to correct for sampling bias can accentuate the inaccuracy of survey-based church attendance measures. For example, weighting by gender undersamples women who work full-time, who attend church less frequently than do homemakers. Woodberry also pointed out that telephone surveys oversample churchgoers because the 5–8% of the U.S. population without a phone is less likely to be regular church attenders than those who do have a phone.

In addition to ensuring that the quality of the sample is as high as possible, researchers should pay careful attention to the wording and context of the survey item gauging church attendance. Based on an experiment conducted in the 1996 GSS, Smith recommended in 1998 that telescoping be minimized by repeatedly reminding respondents that their responses to the church attendance question are only to cover the previous 7 days. Desirability bias can be avoided by including church attendance in a list of other activities, such as visiting a doctor (see Table III). Using this method rather than the standard GSS question significantly lowered the percentage of respondents who reported attending church in the previous week, from the usual 40% to just over 30%, which Smith interpreted as weeding out a substantial portion of inaccuracies.

Smith also reported evidence regarding what people mean when they indicate they have attended "religious services" because this term could mean anything from a worship service to Bible study group to watching a religious program on television. Again, data from the 1996 GSS speak to this question. Respondents who answered affirmatively when asked about attending religious services were asked to indicate whether in the previous 7 days they had attended a weekly worship service, participated in another type of religious meeting, or tuned into a religious program on television or radio (see Table III).

Of those who indicated that they attended religious services in the first question, 4.6% have an inconsistent response in the follow-up question, and another 6.5% were uncertain. Because space on a survey questionnaire is always at a premium, theoretical concerns should determine whether or not this follow-up question is included when measuring church attendance. For some purposes, it may be enough to know the frequency with which the respondent has a communal religious experience without greater specificity; for other purposes, specifying attendance at a worship service is necessary.

Of course, these suggestions for measuring church attendance apply only to analysts designing their own survey instruments. When using secondary sources of data, researchers are limited by the measure employed. In this case, researchers should at least be aware that the marginal frequencies of church attendance are likely to be biased, although the precise extent of that bias remains in dispute.

Attendance at religious services is not the only measure of religious behavior frequently employed by survey researchers. Other behavioral indicators of religious commitment include questions regarding private devotionalism, such as praying or scripture reading.

Table III Questions to Measure Attendance at Religious Services[a]

Now I'm going to ask you about things you did during the last seven days. I'm only interested in what you did during the last seven days. From (last day of week) to today did you . . .

a. Go to see a doctor or receive medical treatment at a clinic or hospital?
b. Have a meal (breakfast, lunch, or dinner) at a restaurant (including fast food places and take-out)?
c. Go to a movie theater to see a film?
d. Attend religious services?

On what day or days did you attend religious services during the last seven days? (Probe: Did you attend religious services on any other days during the last seven days? (Ask until respondent says, "No").

During the last seven days did you do the following:

a. Attend a regular, weekly worship service at a church/synagogue (e.g., mass or Sunday morning services). Don't include watching a service on TV or listening to one on the radio.
b. Watch a religious program on television or listen to a religious program on the radio
c. Attend some other type of religious event or meeting (e.g., prayer breakfast, Bible study group, choir practices, church sponsored lectures, adult fellowship meetings)?

[a] From 1996 General Social Survey; see also Smith (1998).

Scholars of religion generally also treat questions that determine the extent to which a respondent's life is guided by religion as a measure of commitment.

The difficulty in employing questions such as these is that the normative significance attached to such activities differs across religious traditions. In 1996, Leege stressed that the standard measures of religious commitment in surveys such as the ANES have a Protestant bias. For example, many Protestant denominations, especially within the evangelical tradition, place great emphasis on reading the Bible frequently. This is not the case among Roman Catholics. Therefore, whether a Catholic reads the Bible frequently is not as good an indication of commitment to the precepts of Catholicism because it is an indication of commitment to the norms of the evangelical tradition. Perhaps the point can be made most clearly by thinking about an obviously inappropriate question, such as asking Christians whether they adhere to kosher dietary restrictions.

The solution, it would seem, requires measures of religious commitment that are specific to each religious tradition—a difficult task given America's denominational diversity. A clever way around this problem was proposed in 2001 by Mockabee, Monson, and Grant. They detailed a method to weight individuals' participation in a religious activity by its normative significance within that individual's tradition. This is done by weighting the behavior by the proportion of each respondent's coreligionists who report participating in that activity. More specifically:

$$C_i = (\Sigma\delta_{kt})^{-1}(\Sigma\delta_{kt}B_k),$$

where C_i is the commitment score for each individual I, B_k measures how frequently the individual participates in each of k activities, and δ_{kt} is the proportion of people in the same religious tradition who report participating in that activity. Upon employing these weights, Mockabee, Monson, and Grant found that, as expected, the average level of religious commitment rises among Catholics. However, they also concluded that the weights have a limited substantive impact in models predicting political behavior, such as the 1996 presidential vote. They did not test the difference their weighting scheme has when modeling other types of dependent variables, but it seems likely that the weights would result in moderate corrections for bias.

The bottom line, therefore, is that although tradition-specific measures of religious commitment are probably best, weighting the standard behavioral measures by the norms of each tradition appears to be a workable solution. And depending on the dependent variable being modeled, the weights themselves may not even have all that much of an impact, providing reassurance that the bias in these measures is within reasonable bounds. As the United States becomes more and more religiously diverse, we should expect the bias in standard behavioral measures of religious commitment to increase and a weighting system such as that proposed by Mockabee, Monson, and Grant to have increasing analytical utility. However, weights are only a post hoc correction for invalid measures. We hope that scholars of religion will continue to develop better measures of religious commitment that apply to diverse religious traditions.

Conclusion

For many researchers, particularly those intending to use religious affiliation and commitment as control variables only, the examples discussed here will provide a starting place for constructing valid measures of religious affiliation and commitment. Some studies, however, will explore new angles on religion and thus will require adapting these methods of measurement or even the development of new methods. Such efforts can also be guided by principles distilled from the research cited here.

Whether the researcher is developing new methods of measurement or not, the study of religion's impact on social behavior should be guided by one paramount principle: the specifics of religious affiliation and commitment aside, the most important thing to learn from the literature on religion is the need for understanding the nuances of the American religious environment. All scholars studying religion should be prepared to learn to navigate through America's religious labyrinth. Given the myriad ways in which religion affects social attitudes and behavior, this is an investment that has the potential to pay a big dividend.

Remote Sensing

John A. Kupfer
University of Arizona, Tucson, Arizona, USA

Charles W. Emerson
Western Michigan University, Kalamazoo, Michigan, USA

Glossary

electromagnetic radiation (EMR) A combination of oscillating electric and magnetic fields propagating through space and carrying energy from one place to another; electromagentic radiation is generally classified by its wavelength (e.g., visible light, 0.4–0.7 μm).
multispectral Imagery consisting of multiple bands, each of which was recorded simultaneously at different wavelengths.
pixel A picture element in a digitized image that represents the area corresponding to a given measurement of electromagnetic radiation.
platform The vehicle or unit from which a remote sensing system collects data (e.g., a satellite or airplane).
reflectance Ratio of the amount of energy incident on an object to the amount reflected.
sensor A device that converts electromagnetic radiation into an electrical signal that can be recorded, displayed, and analyzed.

Remote sensing has been defined by the American Society for Photogrammetry and Remote Sensing as "the measurement or acquisition of information of some property of an object or phenomenon by a recording device that is not in physical ... contact with the object or phenomenon under study." In most cases, the information being measured is electromagnetic radiation (EMR), with the sun serving as the energy source in passive measurements of reflected radiation, the earth as the source in measurements of emitted thermal radiation, and an energy-emitting device as the source in the case of active remote sensing systems such as radar. Measurements of the interactions of EMR with the earth's surface are recorded by a sensor that is typically mounted on an airplane or satellite platform. Data received by the sensor are recorded and written to a digital data file composed of a two-dimensional grid of spatial objects called pixels, each of which represents a specified area on the earth's surface. Additional dimensions of information are provided by measuring radiation in a range of spectral bands (e.g., energy reflected from objects in different subsets of wavelength) and by examining characteristics of the same location at various times.

The Remote Sensing Process

Physical Principles

The amount of energy that passes onto, off, or through a surface per unit time is called *radiant flux*, and the characteristics of the radiant flux and what happens to it as it interacts with the earth's surface are a fundamental focus of remote sensing research. Because different objects have different spectral properties (e.g., the amount of energy reflected in various wavelengths), it is possible to infer characteristics of surface features by monitoring the nature of radiant flux. A sensor's ability to detect surface properties and, consequently, a scientist's ability to extract meaningful information from remotely sensed imagery are a function of (i) the number and dimension of specific wavelength intervals to which a given remote sensing instrument is sensitive (spectral resolution), (ii) the amount of area on the earth's surface that is represented by a pixel (spatial resolution), (iii) the frequency with which a sensor records imagery for a given

area (temporal resolution), and (iv) the ability of an imaging system to discriminate differences in radiant flux—that is, the range of digital values that is recorded (radiometric resolution).

Sensor Technology

When a sensor element is exposed to electromagnetic radiation (EMR), an electrical charge or change in resistance is produced and converted to a digital number ranging from 64 steps for early satellites to 4096 steps for some modern sensors. Some passive digital remote sensors are panchromatic in that they cover a relatively wide range of EMR wavelengths in a single band of grayscale values. The result is comparable to a black-and-white photograph. Multispectral sensors, on the other hand, divide the electromagnetic spectrum into a range of individual wavelength bands. The Landsat Multispectral Scanner (MSS), for example, records EMR in four wavelength bands: 0.5–0.6 μm (green), 0.6–0.7 μm (red), 0.7–0.8 μm (near infrared), and 0.8–1.1 μm (near infrared). Hyperspectral scanners go one step further, utilizing dozens or even hundreds of narrow, contiguous bands, thus approaching a continuous spectral response curve.

A trade-off that must be made when going from a single panchromatic band to a larger set of narrower multispectral or hyperspectral bands is the reduction in the amount of reflected radiation recorded per band. When the range of wavelengths reaching the sensing elements used in satellite and aerial scanners is restricted, they have to view a relatively larger patch of the earth's surface in order to yield a measurable electrical response. The newer earth resources satellites therefore generally include a finer spatial resolution panchromatic "sharpening" band in addition to multispectral bands having coarser spatial resolutions. The increased radiometric depth of some sensors, along with the need for higher spatial or spectral resolution, has led to huge increases in file sizes that continue to push the performance envelope of modern computer workstations.

Clear skies are a basic condition for passive remote sensing of the earth's surface. However, in many areas of the world, such as the tropics, this requirement is rarely met, limiting the utility of optical and thermal sensors in these areas. Active radar sensors overcome this problem by providing their own source of microwave EMR, which is not significantly absorbed or reflected by light rain or snow, clouds, or smoke particles. Side-looking radar or side-looking airborne radar systems have fixed antennas that send out pulses of radiation as the platform moves along. The interval between the time a pulse is sent and received is converted to a distance from the platform's path, and the intensity of the received pulse is converted to a grayscale value. Radar images appear very different from optical images since microwave radiation interacts differently with Earth surface materials. Having the source of radiation at the sensor also changes the geometry of radar images compared to optical images. Synthetic aperture radar systems electronically simulate a series of antennas as the sensor moves along track. Mathematical combination of larger numbers of these simulated antennas at increasing distances leads to a constant spatial resolution in the across-track direction.

LIDAR (light detection and ranging) systems use pulses of laser light directed toward the ground to measure the platform–ground distance. This technology, when combined with accurate measurements of the sensor location and attitude (using the global positioning system and inertial navigation systems in the case of aircraft-borne sensors), facilitates the creation of detailed digital elevation models, digital representations of the earth's surface composed of regularly spaced point locations with an elevation attribute. Small-footprint LIDAR systems use a highly focused beam that is approximately 0.1 m in diameter, depending on the aircraft altitude. Multiple pulses are collected for the same area on the ground to distinguish the height of the vegetation canopy from the ground surface. Large footprint systems that survey ground patches with a diameter of 5–15 m are currently under development. These systems use the waveform of the reflected light to derive a vertical profile of the vegetation canopy.

Image Processing

After digital data are recorded by a sensor and stored, they typically undergo digital image processing, including a preprocessing phase and a postprocessing phase. Preprocessing of the data involves (i) radiometric corrections, which correct the data to avoid error or distortions due to internal sensor errors, sun angle, topography, and various atmospheric effects, and (ii) geometric corrections, which include correcting for geometric distortions due to sensor–Earth geometry variations and converting the data to real-world coordinates (Table I). Postprocessing involves (i) image enhancement, which may be used to improve the appearance of the imagery to assist in interpretation and analysis of the data, and (ii) image transformations, which can be used to combine or transform the original bands into new images that better display or highlight certain features in the image.

Postprocessing may also include image classification, which entails grouping pixels into nominal classes using combinations of the digital numbers that represent reflectance in each band. The result is a classified image (e.g., of land use or vegetation type). Unsupervised classification methods are inductive approaches that statistically cluster pixels into a predefined number of classes based on their spectral properties. The meaning of the classes is subsequently established by relating the pixels in

Table I Summary of Selected Image Enhancement and Transformation Techniques

Technique	*Example*	*Purpose*
Geometric correction	Deskewing	Remove systematic distortions inherent in sensor
	Registration	Convert image to ground coordinates
Radiometric enhancement	Sun elevation correction	Normalize multidate images for illumination differences
	Contrast stretch	Expand range of grayscale or color values to enhance viewing
Spectral enhancement	Band ratioing	Reduce effects of shadows
	Principal components analysis	Reduce dimensionality (No. of bands)
Spatial enhancement	Low-pass filter	Smooth image to enhance broad trends in brightness
	High-pass filter	Emphasize details
Change detection	Image differencing	Highlight differences between two images obtained on different dates

each class to corresponding features on the earth's surface (e.g., "forest" pixels). Supervised classification methods, in contrast, utilize validated training sites that represent the desired output classes. The spectral signatures of the training sites are then used by the classification algorithm to classify other pixels that have similar spectral responses.

Remote Sensing History and Prominent Satellite Platforms

Photography and Satellite Imagery

In 1824, Joseph Nicéphore Niépce obtained the first fixed image of a landscape. The first known aerial photograph was taken from a balloon by Gaspard Felix Tournachon (a.k.a. "Nadar"), a magician who photographed Bievre, France, in 1858. The practical benefits of aerial photography were realized early on, with balloons, kites, and even homing pigeons serving as the camera platform until the invention of the airplane in 1903. More than 1 million aerial reconnaissance photographs were taken during World War I, and after the war civilian development of aerial photography interpretation continued, particularly in the area of resource assessment and management.

In the 1930s, panchromatic color film was developed, which approximated the human eye's response to visible light. The spectral range was extended with the development of color infrared film in World War II, which was sensitive to EMR in the near-infrared range. Radar, another World War II invention, was turned toward the ground after the war, resulting in the first side-looking airborne radar images. This technology has benefited from the rapid advances in electronics so that modern synthetic aperture radar systems can provide high-resolution imagery from space or aircraft platforms. The Cold War led to the development of a number of space-based military reconnaissance programs, such as CORONA, ARGON, and LANYARD. More than 800,000 of these high-resolution satellite images taken between 1959 and 1972 were recently declassified and offered for sale by the U.S. Geological Survey.

Civilian spin-offs of space technology included meteorological satellites such as TIROS (Television Infrared Observation Satellite), which became operational in 1960. The use of satellites for meteorological and related applications continues today with the GOES (Geostationary Operational Environmental Satellite) satellites, which are the data source for the satellite loops seen on daily weather reports. These satellites, which have one visible and four thermal bands with resolutions from 1 to 8 km, occupy an orbit that has a 24-hour period matching the earth's rotation: They are thus geostationary and continuously remain above the same location on the equator. The polar-orbiting National Oceanic and Atmospheric Administration series of satellites carrying the Advanced Very High Resolution Radiometer sensor have a relatively coarse 1.1-km resolution but provide twice-daily information that is used for a range of applications. ORBIMAGE also operates OrbView-1, which provides 10-km resolution imagery of severe weather and lightning, and OrbView-2, which provides 1.1-km imagery of the entire globe for ocean monitoring and agricultural applications.

The success of space-based military and meteorological imaging in the 1960s led to a joint NASA/U.S. Department of the Interior feasibility study on Earth Resources Technology Satellites (ERTS). Six satellites were planned, with ERTS-1 being launched in July 1972. The program name was changed to Landsat with the launch of the second satellite in 1975. Landsats 1–3 had a Return Beam Vidicon sensor in addition to a four-band Multispectral Scanner (MSS), with the latter becoming the primary sensor. Landsat-4 (1982) and -5 (1984) carried a new, higher resolution sensor called the Thematic Mapper (TM), in addition to a slightly modified MSS, which was included to provide continuity with earlier satellites. In comparison to the four-band, 80-m nominal spatial resolution (pixel size) of MSS imagery, TM images had six bands with 30-m nominal spatial

resolution in the visible, near-, and mid-infrared wavelengths and a 120-m thermal infrared band that detected emitted terrestrial radiation. Landsat-6 failed to achieve orbit in 1993, and Landsat-7 was launched in 1999, carrying the Enhanced Thematic Mapper Plus (ETM+) sensor. This sensor provides continuity with Landsat-4 and -5 because it has the same six reflective bands as the TM sensor plus a higher resolution (60-m) thermal infrared band and a 15-m panchromatic band. In May 2003, a scan line corrector in the ETM+ sensor failed, and the system has been operating in a reduced capacity mode since July 2003.

A number of other countries and organizations, including India, the Soviet Union/Russia, Japan, China, Brazil, Canada, and the European Space Agency, have had imaging satellites in the past or are planning future launches. The French government, with the participation of Belgium and Sweden, developed the Système Pour l'Observation de la Terre (SPOT) program in 1978. SPOT-1, launched in 1986, employed a linear array of high-resolution visible (HRV) sensors (not unlike a desktop flatbed scanner) with pointable optics that allowed stereoscopic viewing of areas imaged from adjacent tracks. The HRV sensor operated in a 10-m resolution panchromatic mode and a 20-m resolution multispectral mode with three bands in the green, red, and near-infrared ranges of the electromagnetic spectrum. The later HRVIR (high-resolution visible and infrared) sensor carried on SPOT-4 added a 20-m mid-infrared band to aid in vegetation monitoring and soil moisture mapping and a "vegetation" instrument, which provided 1-km resolution imaging of the whole globe daily. The vegetation instrument is also carried aboard SPOT-5 (launched in May 2002), along with twin high-resolution geometric scanners with a 2.5- or 5-m panchromatic resolution and a 10-m multispectral resolution (20-m mid-infrared). The high-resolution stereographic sensor collects panchromatic imagery in a fore-and-aft fashion to allow preparation of digital elevation models at 10 m resolution.

In 1999, Space Imaging Corporation launched IKONOS, a high-resolution (1-m panchromatic, 4-m multispectral) satellite, as a purely commercial venture. This was followed by the launch of EROS-A in 2000, DigitalGlobe's Quickbird satellite in 2001, and ORBIMAGE's OrbView-3 in June 2003. All of these satellites fill a niche for high-resolution space imagery that is not met by the fleet of governmental satellites (with the possible exception of SPOT-5). In some sense, they can replace mid- to high-altitude aerial photography, with the added benefit of regular repeat cycles.

Sources of Imagery

Current and historical remotely sensed images are available from a number of private and governmental sources. The Earth Observing System (EOS), the primary component of NASA's Earth Science Enterprise, seeks to provide data, modeling capabilities and eventually an understanding of human impacts on the environment. As of late 2003, two satellites, Terra and Aqua, had been launched as part of this program, with the latter carrying five sensors: ASTER (Advanced Spaceborne Thermal Emission and Reflection Radiometer), MODIS (Moderate-Resolution Imaging Spectroradiometer), CERES (Clouds and the Earth's Radiant Energy System), MISR (Multiangle Imaging Spectro-Radiometer), and MOPPITT (Measurements of Pollution in the Troposphere). The EROS (Earth Resources Observation Systems) Data Center, a unit of the U.S. Geological Survey, is a major source of aerial photographs, satellite imagery, and other mapping products. Local and state governments often make satellite images, photographs, and other products of aerial survey firms available at low or no cost via the Internet. Private firms, such as Space Imaging, Digital Globe, and ORBIMAGE, also distribute their own products.

Remote Sensing Applications

Remote Sensing of Terrestrial Features

Many natural and anthropogenic features on the earth's surface can be identified, mapped, and studied on the basis of their spectral properties, the proportion or amount of energy reflected, absorbed, transmitted, or emitted by an object at various wavelengths. An object's spectral properties depend on its composition and condition, so the effective utilization of remote sensing data requires an understanding of the properties of the features under investigation and the factors that influence these characteristics. Although different features may be indistinguishable in one spectral band, they may be very different in others, underscoring the value of examining properties in a range of wavelengths. A graph of the spectral reflectance of an object as a function of wavelength is called a spectral reflectance curve (Fig. 1), and the configuration of the curve provides insights into the nature and characteristics of an object and influences the choice of wavelengths in which remote sensing data are acquired for a particular application.

Spectrally, vegetation can be distinguished from inorganic materials by its high absorption of red and blue light, moderate reflectance of green light, and high reflectance of near-infrared energy. Pigments in a typical green plant, including chlorophyll *a* (maximum absorption, 0.44 and 0.67 μm), chlorophyll *b* (maximum absorption, 0.49 and 0.65 μm), and β-carotene (maximum absorption, 0.45 μm), are responsible for high absorption in the red and blue portions of the visible light spectrum. Near infrared reflectance (0.7−1.2 μm) tends to be high for

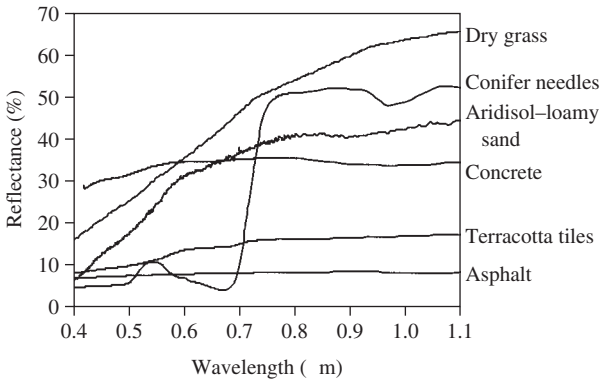

Figure 1 Spectral reflectance curves in the visible and near infrared wavelengths for dry grass, green conifer needles, a light yellowish brown loamy sand—aridisol soil, concrete, terracotta roofing tiles, and asphalt. Data reproduced from the ASTER Spectral Library through the courtesy of the Jet Propulsion Laboratory, California Institute of Technology, Pasadena, California.

healthy green vegetation due to internal scattering of EMR at the cell wall–air interfaces within the leaf. At longer wavelengths, water within the leaves (especially in the spongy mesophyll) is a strong absorber of middle-infrared wavelengths; thus, as the water content of leaves increases, reflection in these bands (especially between 1.5–1.8 and 2.1–2.3 μm) decreases.

Different vegetation types (e.g., grassland, deciduous forest, and desert scrub) can often be distinguished in images due to differences in leaf size and shape, plant morphology, water content, and vegetation density, enabling the creation of vegetation maps that are useful in fields such as natural resource management, forestry, and ecology. When coupled with faunal surveys, vegetation maps can be used in applications such as endangered species habitat mapping and timber harvest planning. Information on temporal dynamics of vegetation can be gained by utilizing multiple image dates, taken either at different times over a growing season or over multiple years. Examples of research using multitemporal analyses include the documentation of changes in land use and land cover related to human activities (e.g., agricultural conversion and urban growth) and the delineation of spatial patterns and effects of disturbances (e.g., clear-cutting, wildfires, and insect outbreaks). Because many plant species undergo relatively unique seasonal (phenological) changes, multitemporal remote sensing can also play a role in monitoring crop development and health and in projecting agricultural yields.

Further insight into vegetation characteristics can be gained by applying vegetation indices derived from the original data (e.g., the Normalized Difference Vegetation Index). Such indices are dimensionless, radiometric measures that function as indicators of relative abundance or activity of green vegetation, including leaf area index, percentage green cover, chlorophyll content, green biomass, or photosynthetically active radiation. For instance, there is a well-known inverse relationship between spectral response in the visible spectrum and plant biomass, allowing scientists to make regional and global estimates of biomass and productivity that are central in the study of global change effects.

In addition to providing a means for examining vegetation characteristics, remote sensing can be used to identify, categorize, and map anthropogenic features. Maps designed to show both natural and human-created features, known as land use and land cover maps, may be of tremendous value to groups as diverse as urban planners, economists, transportation managers, real estate developers, demographers, natural resource managers, and conservationists. The premise of land use and land cover mapping is the same as that for vegetation studies: different urban materials, such as concrete, blacktop asphalt, and asphalt shingles, have unique spectral properties that distinguish them from other such materials and vegetation. Two other similarities to remote sensing of vegetation are that different portions of the electromagnetic spectrum are better suited for extracting different types of information (e.g., estimating building perimeter and area vs identifying different land use types), and there is a tradeoff between the detail of the information needed and the spatial resolution of the data needed to capture such features. In general, because of the fine scale of many objects of interest in urban and suburban landscapes, it is frequently important to have data with extremely high spatial resolution (typically <5 m and often <1–2 m), limiting the utility of some of the primary sensor platforms more commonly used in Earth resource applications.

Remote sensing can also play an important role in the study of soils, minerals, geomorphology, and topography, especially when vegetation is sparse or absent. Several factors influence soil reflectance in remotely sensed images, including mineral composition (e.g., iron oxide content), organic matter content, soil texture, moisture content, and surface roughness. When the effects of these factors on the spectral properties of soils are understood, remote sensing can be used in the identification, inventory, and mapping of soil types and properties that can be used to inform decisions about crop nutrition and herbicide usage, short-term stresses (e.g., drought), and susceptibility of soil to erosion. Observed differences in soil texture or moisture can also be used in archeological applications, for instance, to detect the impact of humans on the soil that may be related to past land use practices.

Similarly, general geologic information, such as chemical composition of rocks and minerals on the earth's

surface, lithology, geologic structure, drainage patterns, and landform characteristics, can be extracted from remotely sensed data. This information can be valuable in the production of geologic maps that, when coupled with information collected in the field, can provide surficial clues to the locations of subsurface deposits of ore minerals, oil and gas, and groundwater. Geological information developed from imagery is also valuable in hazards planning and civil engineering applications.

Remote Sensing of Aquatic and Atmospheric Phenomena

When measuring the spectral properties of water bodies, total radiance recorded by a sensor is a function of EMR received from four sources: (i) radiation that never reaches the water surface (atmospheric noise or path radiance); (ii) radiation that reaches the water surface but is reflected in the top few millimeters; (iii) radiation that penetrates the air–water interface, interacts with the water and organic/inorganic constituents, and then exits the water column without contacting the bottom (subsurface volumetric radiance); and (iv) radiation that penetrates the water, reaches the bottom of the water body, and is propagated back through and exits the water column (bottom reflectance). The goal of most aquatic remote sensing is to extract or isolate the radiance of interest from all of the other components.

Remote sensing has been used to examine and map a wide range of hydrologic variables. Because water bodies absorb much more of the incident radiant flux in the near- and mid-infrared wavelengths than do land surface features, remote sensing can be used to delineate the land–water interface and monitor the surface extent of water bodies. Multitemporal measurements can be used to document flood timing and extent, fluctuations in lake size at a variety of timescales (seasonal, annual, and decadal), drought effects, and changes in wetland area. Recent research has similarly focused on ways by which remote sensing can be used to measure the extent, cover, and volume of snowpack, glaciers, and ice shelves, providing information relevant to water management issues and global environmental change studies. Data from thermal infrared wavelengths is pivotal in monitoring ocean-wide trends in sea surface temperatures that are indicators of El Niño/Southern Oscillation and La Niña events that greatly affect regional climate patterns and thus bear on water management issues.

Spectral properties of pure water differ from those of water with suspended sediment and minerals as a function of both the quantity and characteristics (e.g., particle size and absorption) of the material. By collecting *in situ* measurements of suspended material concentrations and relating these measures to remotely sensed data, it is possible to derive estimates of the type, amount, and spatial distribution of suspended materials in inland and near-shore waters. This allows scientists to examine soil erosion, reservoir and harbor sedimentation, and water quality. Estimates of suspended sediments are also valuable because such material can impede the transmission of solar radiation into the water column and influence photosynthesis of submerged aquatic vegetation and phytoplankton.

In addition to providing information on inorganic constituents of water bodies, remote sensing can be used to examine organic components of aquatic ecosystems. Of particular interest has been the ability of remote sensing systems to detect and estimate concentrations of phytoplankton, small single-celled plants that contain chlorophyll and other photosynthetically active pigments. Because different types of phytoplankton contain varying concentrations of chlorophyll, it is possible to estimate the amount and general type of phytoplankton, which can provide information on the health and chemistry of the water body. For reasons similar to those discussed previously for terrestrial vegetation, numerous studies have documented a relationship between selected spectral bands and the concentration of aquatic chlorophyll. Near-surface estimates of chlorophyll concentration can thus be derived to estimate biomass and productivity, which in turn can be used to better understand the dynamics of ocean and coastal currents, assess the ocean's role in the global carbon cycle, and clarify marine influences on global climate change. In recent years, remote sensing has also been used to monitor declines in coral reef health related to water pollution or environmental variability.

Finally, remote sensing is increasingly used to examine a range of atmospheric phenomena. Various aspects of precipitation (location, intensity, and amount) can be measured or estimated directly, through the use of active microwave sensors such as the Nexrad radar systems operated by the National Weather Service in the United States, or indirectly, through measures of cloud reflectance, cloud-top temperatures, and the presence of frozen precipitation aloft. Although ground-based radar provides real-time information on precipitation with high spatial resolution, the spatial coverage of such systems is localized. Conversely, meteorological satellites have global coverage, but the information provided is at a coarser timescale and provides only an estimate of local conditions such as actual rainfall amounts. Nonetheless, the latter have proved valuable in estimating global rainfall patterns and monitoring drought development. Lastly, satellite imagery is used to examine cloud cover and atmospheric moisture in the mid- and upper level of the troposphere and, recently, to gather information on a broader range of atmospheric conditions, including atmospheric chemistry (e.g., aerosol concentrations)

and temperatures in the troposphere and lower stratosphere.

Conclusions

Although remote sensing techniques have primarily been viewed as a means for gathering data that are then interpreted by the user, they are increasingly serving other roles in scientific and applied research. Remotely sensed data on natural and anthropogenic features such as vegetation cover, land use, topography, and hydrography now serve as input to a range of simulation models, including hydrologic, climatic, ecological, and economic models. Classified images of land use and land cover are combined with surveys of demographic and socioeconomic variables to develop models that allow scientists to better understand processes such as deforestation and land use conversion. Remotely sensed imagery and the products derived from analysis of imagery are also important sources of data for geographic information systems (GIS). In fact, most comprehensive image analysis software packages now include GIS functions for change detection overlays, local spatial analysis techniques, conversions between raster (i.e., pixel-based grids) and vector (i.e., points, lines, and polygons defined and displayed on the basis of two-dimensional Cartesian coordinate pairs) data structures, and other not strictly image-related processes. GIS software packages by necessity work with raster data and images in a number of formats, and they increasingly include analysis functions that were previously only found in specialized image analysis packages.

Compared to field-based sampling, remote sensing cannot provide measures of human and environmental phenomena, such as water quality, vegetation composition, soil properties, or plant health, with the same amount of detail. However, when coupled with field surveying, remote sensing offers the ability to view and map large areas of the earth's surface at multiple times and to obtain information for areas that would otherwise be difficult or impossible to sample due to physical or financial constraints. Remote sensing has thus become a valuable tool in research and applications in a wide range of disciplines, such as engineering, geology, geography, urban planning, forestry, and agriculture. Furthermore, the Internet has increased the availability and dissemination of remote sensing products, and decreasing costs coupled with continuous improvements in spatial, spectral, radiometric, and temporal resolutions are making remote sensed data accessible to a broader range of end users and expanding the role of remote sensing in society.

Glossary

case study A study in which one unit is analyzed, typically in an intensive manner that is attentive to time and process. Although, strictly speaking, in a case study the $N = 1$, frequently the effective number of observations is considerably higher.

cross-sectional design A study in which observations on a variable or multiple variables are collected across units at the same point in time.

experimental design A study in which the treatment is consciously manipulated by the researcher and in which units are randomly assigned to treatment and control groups. To distinguish experimental from quasi-experimental designs, the former are sometimes called randomized experiments.

external validity Concept originally introduced by Donald T. Campbell to refer to the generalizability of the finding of a causal relationship between variables beyond the domain of the actual units, spatial and temporal setting, and specific treatments that are examined.

internal validity Concept originally introduced by Donald T. Campbell to refer to a causal relationship between variables in the actual units, spatial and temporal setting, and specific treatments that are examined.

large *N* study A study in which observations are made across a large number of units. Such studies, however, vary significantly in terms of their *N*, with typical cross-national studies in the field of comparative politics and international relations oscillating between 30 and 100 and those using opinion surveys reaching into the thousands.

longitudinal design A study in which multiple observations on variables are collected across time for the same unit. Also known as time series design.

observational studies Nonexperimental studies, also called correlational studies, in which the treatment is not consciously manipulated by the researcher. Rather, researchers simply record the values of variables as they naturally occur. These studies include natural experiments in which particularly sharp and obvious changes in the value of a variable are held to offer an analogy to the introduction of a treatment.

pooled time series, cross-sectional design A design that combines a cross-sectional design and a longitudinal design; includes panel studies and repeated measures design.

quasi-experimental design Design in which the treatment is consciously manipulated by the researcher, as in an experiment, but in which, unlike in experiments, units are not randomly assigned to treatment and control groups.

research design A key aspect of the research process that revolves around the direct impact on the prospects of causal inference of four core questions: How is the value of the independent variable(s) assigned? How are units selected? How many units are selected? and How are comparisons organized (i.e., whether temporally and/or spatially)? In addition, research designs can be evaluated in terms of their indirect impact on causal inference in light of their requirements and contributions vis-à-vis theory and data.

small *N* study A study in which observations are made across a small number of units. Typically, each unit is treated as a case study so that multiple observations on each unit are made.

The methodology of research design hinges on the choices made with regard to four core questions: How is the value of the independent variable(s) assigned? How are units

selected? How many units are selected? and How are comparisons organized (i.e., whether temporally and/or spatially)? These choices can be assessed in terms of their direct impact but also their indirect impact—due their requirements and contributions vis-à-vis theory and data—on the prospects of making causal inferences. Three research traditions—experimental and quasi-experimental, quantitative, and qualitative—represent distinct responses to these methodological choices and each has important strengths but also significant weaknesses. Thus, the need for choices about research design to be explicitly addressed and justified, and the need to actively construct bridges across research traditions, is emphasized.

Introduction: Goals, Problems, and Options

The pioneering work on research design by Donald T. Campbell and associates has made such a major contribution that it is difficult to think about research design without, in one way or another, drawing on their insightful discussions. They provide a valuable template for thinking about research design, helpfully framing the discussion in terms of the basic goal of validity, a range of problems or threats to validity, and a set of options or design choices that can be pursued as a way to guard against these threats. At the same time, their work displays some limitations and biases and ultimately fails to offer a clear, encompassing, and balanced understanding of the challenges involved in research design. This assessment and comparison of research designs thus adopts Campbell *et al.*'s basic template and some of their key ideas about the goals, problems, and options of research design but also parts company with them in some significant ways.

First, Campbell *et al.*'s discussion of the goals of research design in terms of the concept of validity is both somewhat confusing and biased. Initially, Campbell introduced the concepts of internal and external validity, which disaggregated the ultimate goal of research design—to increase the prospects of making causal inferences—and aptly distinguished different problems of causal inference that are affected and potentially solved by different design choices. Over time, however, these two concepts have been awkwardly relabeled and, more important, defined in different ways in different texts. In addition, two other types of validity—statistical conclusion validity and construct validity—that pertain in part to research design but spill over into questions of data analysis and measurement, respectively, have been introduced into the discussion, further complicating matters. Another problem with this typology of validity is that it is somewhat biased. Thus, Lee Cronbach has argued that Campbell *et al.* gave undue primacy to internal over external validity and did not recognize the importance of generalizability. This is a critique that they have acknowledged and sought to address in their latest statement. However, they still do not fully incorporate the difficulties of generalizing on the basis of experimental and quasi-experimental designs in their overall assessment of the strengths and weaknesses of design options.

To avoid these problems, we only consider internal and external validity to be the core goals directly relevant to a discussion of research design, and both retain the classic labels of internal and external validity and follow the original definitions offered by Campbell and Julian Stanley in 1966. As they argue, the establishment of the internal validity of a causal proposition involves showing that a factor is the cause of an effect or, more modestly, probing alternative hypotheses and opting for those that stand up best to attempts at disconfirmation. In contrast, the verification of the external validity of a causal proposition entails demonstrating that a causal proposition can be generalized beyond the domain of the actual units, spatial and temporal setting, and specific treatments that are actually studied. In turn, both internal and external validity can be viewed as distinct and equally essential goals of research design.

Second, Campbell *et al.*'s discussion of the problems of causal inference is organized around a fairly *ad hoc* and cumbersome list of threats to validity. To be sure, the listed threats to validity are all important, and their analysis of the way different designs get around or fail to get around these threats to validity is exemplary. Indeed, they offer many specific recommendations that creatively respond to thorny and complex problems routinely encountered in the conduct of substantive research. However, they do little to present their list of threats in a logically explicit manner, to distinguish threats that are relevant to experimental designs from those that pertain to nonexperimental designs, and to offer a sense of the extent to which the threats to validity they discuss constitute a complete list. In place of their list, we propose a scheme whereby research design choices are evaluated in light of a set of problems of causal inference that are directly and indirectly affected by design choices.

Figures 1 and 2 provide a graphic representation of the assumptions and potential problems of causal inference that design options impact in a direct manner. With regard to the analysis of single units, the core concerns are the need to ascertain that the posited direction of causality is correctly described and that the proposed model of the link among causal variables is fully and correctly specified. With regard to the analysis of multiple units, the key issues are the need to validate the assumptions of unit independence and unit homogeneity. In turn, Fig. 3 draws attention to the need to place the discussion of research design in the broader context of the research

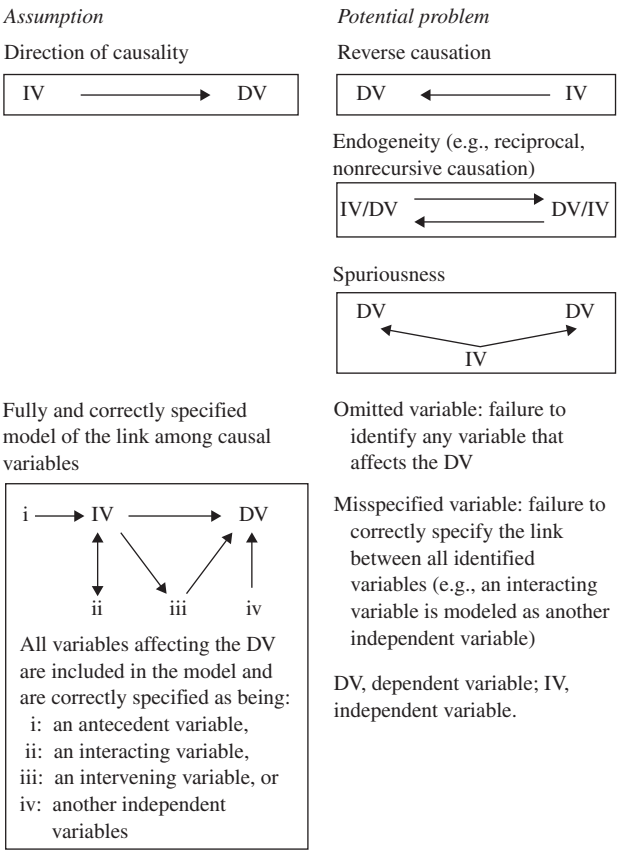

Figure 1 Problems of causal inference: Issues in the analysis of single units.

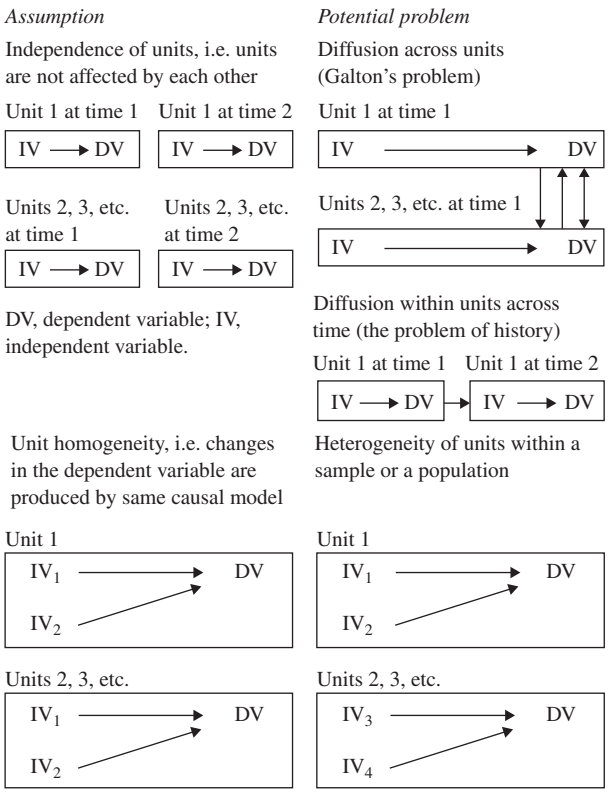

Figure 2 Problems of causal inference: Issues in the analysis of multiple units and singular units across time.

process and to consider how design options have an indirect but important impact on causal inference as a result of their requirements and contributions vis-à-vis theory and data.

Third, Campbell *et al*.'s discussion of design options is fairly limited and their assessment biased toward experimental designs. Indeed, they place such strong emphasis on certain design options—the ability of researcher to consciously manipulate independent variables and randomly assign units to treatment and control groups—that they offer a narrow and unbalanced optic on questions of research design. They do highlight the difficulties of conducting experiments and emphasize the ways in which experiments are likely to never guarantee that all threats to validity are eliminated. Moreover, occasionally they offer an exemplary display of pluralism. However, they tend to overlook some significant shortcomings associated with experimental data and downplay the significant potential virtues of nonexperimental data, and they ignore both the role played by design choices other than those that are defining elements of experiments and the way in which design choices have an indirect impact on causal inference. Thus, to assess the

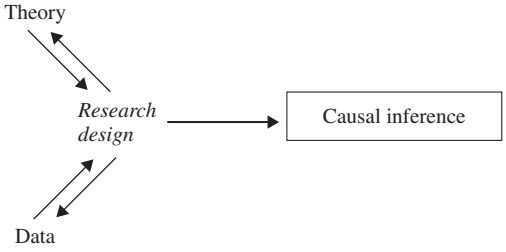

Figure 3 Research design in context.
Although research is frequently portrayed as proceeding in a linear fashion from theory to data collection and causal inference, as a matter of practice research is an interactive and iterative process. Thus, it is important to recognize that design options are (i) affected by the state of available theory and can also affect theory building and (ii) limited by the availability of data and also have an impact on the quality of data that are generated.

strengths and weaknesses of different research designs in a systematic and balanced manner, it is important to recognize that design options revolve around at least four core questions: How is the value of the independent variable(s) assigned? How are units selected? How

Table I Research Designs: Classification Criteria and Options

Classification criteria	*Main options*	*Disaggregate designs*
How is the value of the independent variable(s) assigned?	Manipulation, random assignation of cases to treatment and control groups	Experimental (randomized experiment)
	Manipulation, nonrandom assignation of cases to treatment and control groups	Quasi-experimental
	Nature	Observational
How are units selected?	Random sample	Representative
	Purposive (deliberate or intentional) sample	Typical (mode, mean, or median)
		Heterogeneous (extreme and typical)
	Entire population	Census
How many units are selected?	Many	Large-*N*
	Few	Small-*N*
	One	Case study
How are comparisons organized?	Across units	Cross-sectional
	Across time	Longitudinal

many units are selected? and How are comparisons organized (i.e., whether temporally and/or spatially) (Table I)? Moreover, it is necessary to address the manner in which design choices have both a direct and an indirect impact on causal inference.

Recognizing the seminal nature of the work by Campbell *et al.* but also seeking to overcome its limitations, this article provides an overview of the current state of knowledge on research design. The number of alternative research designs is, in principle, very large. Indeed, focusing only on the main options related to the four criteria presented in Table I, it is clear that the range of possible designs is much greater than usually believed, although not all will be sensible. However, the following discussion is organized in terms of research traditions, given that this is how much research and discussion about design options is carried out, focusing on experimental and quasi-experimental designs first, turning next to large *N* or quantitative designs, and completing the discussion with case study and small *N* or qualitative designs. In each case, the focus is on the prototypical designs associated with each tradition and an assessment and comparison of the strengths and weaknesses of these designs. The need for choices about research design to be explicitly addressed and justified, and the need to actively construct bridges across research traditions, is emphasized.

Experimental and Quasi-Experimental Designs

Experimental designs, also called randomized experiments, are characterized by two distinguishing features: (i) the conscious manipulation by the researcher of a treatment or, more generically, an independent variable of interest, and (ii) the random assignment of units to treatment and control groups (Fig. 4). Experiments also draw upon other design elements, and thus it is possible to distinguish a variety of experimental designs. However, these two features are the defining features of the prototypical experimental design.

The strengths of this design are undeniable. Given that the treatment is administered before a posttest measure on the dependent variable is registered, the direction of causality is clearly established. In addition, the random assignment of units to treatment and control groups ensures that these groups are equivalent; that is, they do not vary systematically on any variable except the manipulated variable. In this manner, multiple unexamined variables are held to not vary in any patterned manner and, hence, control over these alternative hypotheses is ensured by turning other variation into noise. Thus, the beauty of experimental designs is that the data generated lend themselves to a particularly simple form of analysis, in which the differences in posttest measures of the treatment and control groups can be interpreted as a measure of the causal effect of the treatment. Indeed, experiments are the most powerful means of gaining control and establishing the internal validity of a causal claim (Table II).

A quasi-experimental design differs from an experimental design in that in the former the treatment is consciously manipulated by the researcher but the units are not randomly assigned to treatment and control groups. Thus, this design offers less of a basis for assuming the initial equivalence of treatment and control groups and requires researchers to consider how third extraneous variables might confound efforts at ascertaining causal effects and to be explicit about alternative hypotheses. The difficulties this difference between experiments and quasi-experiments introduces are central to the work of Campbell *et al*. Indeed, their work can be understood essentially as an effort to alert researchers to

The units are randomly divided into two groups—the treatment group and the control group—and a treatment is applied to the treatment group and not to the control group.

Measures are taken of the values of the dependent or outcome variable for the treatment and control groups. The generated data are organized as follows:

	Treatment group Units 1, 2, 3, . . . , n	Control group Units 1, 2, 3, . . . , n
Independent variable	Yes (treatment)	No
Dependent variable	*Value*	*Value*

Alternatively, after the units have been randomly divided into two groups, a pretest measure of the value of the dependent variable for both the treatment group and the control group is made. The generated data are organized as follows:

	Treatment group Units 1, 2, 3, . . . , n		Control group Units 1, 2, 3, . . . , n	
	T_1	T_2	T_1	T_2
Independent variable	No	Yes (treatment)	No	No
Dependent variable	Value	*Value*	Value	*Value*

In both instances, the analysis of the data focuses on the difference in values on the dependent variable between treatment and control groups (the italicized values), a difference that can be interpreted as a measure of the causal effect of the treatment.

When a pretest measure on the dependent variable is obtained in addition to a posttest measure, a comparison of the values of units of the treatment and control groups at T_1 (the underlined values) serves to double-check that all units are "equivalent," given that this goal is already ensured by the random assignment of units.

Figure 4 Experimental designs: Defining features.

Table II Experimental Designs: An Assessment

Design elements	*Strengths*	*Weaknesses*
Conscious manipulation of independent variables	Establishes causal direction (internal validity)	Lack of viability, due to practical and/or ethical reasons, to study many important questions
		Unsuitable for the study of action and lack of attention to causal mechanisms (internal validity)
		Unsuitable for an assessment of complex causes
		Requires *a priori* knowledge of plausible independent variables and well-specified causal model; not useful in theory generation
		Tends to generate obtrusive, reactive measurements
Random assignment of units to treatment and control groups	Establishes equivalence of units, helps guard against third, extraneous variables (internal validity)	Lack of viability, due to practical and/or ethical reasons, to study many important questions
Nonrandom selection of units, setting, and treatment		Difficult to generalize from sample to population (external validity)

the various ways in which factors other than the treatment may be responsible for the observed posttest variance between treatment and control groups. Thus, in large part due to the significant effort by Campbell *et al.* to anticipate potential threats to the validity of quasi-experiments—and to offer a range of designs that minimize and help guard against such threats—researchers have a sophisticated road map for consciously taking into consideration how third extraneous variables may exercise a confounding effect. In summary, even though quasi-experiments are more complicated than experiments, both designs offer a powerful basis for making claims

about causality, and it is thus hardly surprising that these designs have been used often in psychology and economics and are increasingly being adopted by political scientists.

The considerable strengths of experimental and quasi-experimental designs notwithstanding, it is important to recognize the serious weaknesses associated with these designs. One standard limitation concerns the viability of conducting experiments, whether for practical and/or ethical reasons, to study the sort of questions that are of interest to many social scientists. The fact that we cannot or would not want to manipulate some variables and/or randomly assign subjects to control and treatment groups has vast implications. Indeed, as Hubert Blalock (1991) argues, "If we were to confine our analyses to experimental and quasi-experimental designs, virtually all of sociology and political science would have to go to the wayside." (p. 332) However, the problem is deeper than the standard concern with viability would indicate and actually derives from the very substance of the subject matter of the social sciences.

The core difference between the social and natural sciences is that the former are first and foremost about agents and actions. However, a basic feature of experimental and quasi-experimental designs—the conscious manipulation of the treatment—is founded on a notable asymmetry, which places the experimenter in an active role and relegates the experimentee to a passive, reactive role. In effect, experiments and quasi-experiments treat subjects as objects and embody an implicit behaviorist perspective that renders them ineffectual instruments for the study of the causal significance of action and, relatedly, forces them to be silent on the critical question of causal mechanisms. Indeed, as William Shadish *et al.* recognize, although experimental and quasi-experimental designs can be used to predict what the effect of a factor is, they are less useful for explaining why and how such effects are generated. This is a significant limitation. Indeed, it is not far-fetched to argue that the internal validity of a causal argument is not fully established until the causal mechanisms that generate the causal effect are properly identified and tested.

Experiments are also of limited use with regard to the study of complex causal relationships. This failure is in part due to the inability to deal squarely with agency through experiments and quasi-experiments. Consequently, these designs are not suitable means for getting at a core theoretical concern in social theory: the interaction between structures and agents, or macro and micro causal factors. In addition, because experiments and quasi-experiments are in essence instruments geared to the study of short-term effects, they are not useful for studying causes that work themselves out over an extended period of time or for assessing the interaction between long- and short-term causal factors. Moreover, because experimenters, as a way to manipulate the treatment, must rigidly assign variables to the status of independent and dependent variables, they do not constitute a means of assessing feedback effects or reciprocal and nonrecursive causation. In short, a range of theories simply cannot be tested through experimental and quasi-experimental designs.

Another significant limitation concerns the generalizability of results derived from experiments. The reason for this is that although a defining feature of experiments is that units are randomly assigned to treatment and control groups; the units, settings, and treatments are usually not randomly selected. Indeed, inasmuch as control is gained through the manipulation of the treatment and the random assignment of units to treatment and control groups, it is practically inevitable that the ability to randomly select these units will decline. The purposive or intentional selection of units that researchers have to use is not without merits, and it can certainly be carried out with an eye to the relationship between the studied sample and the universe. However, even when carefully practiced, purposive selection tends to lead to biased results. Indeed, in many instances the gap between the conditions of experimental research (whether in the laboratory or in field settings) and the phenomenon being studied can be substantial; hence, the ability to generalize beyond the domain of the actual units, spatial and temporal setting, and specific treatments that are examined is compromised. Thus, it is important to recognize that both internal and external validity are critical aspects of knowledge, and that there are good reasons for the standard view that the gains made by experiments in terms of internal validity tend to come at the cost of a loss in external validity.

Finally, two other limitations are indirect consequences of the manipulation of treatments that characterizes experimental and quasi-experimental designs. First, because of this design element, experiments and quasi-experiments approach the two-sided issue of causal theorizing from one side: They focus on the effect of causes rather than on the causes of effects. Thus, they require *a priori* knowledge about plausible independent variables and presume that all that needs to be determined is the effect of preselected causes. Hence, experiments and quasi-experiments are of less use during the early, exploratory stage in the research process, when a typical challenge is to uncover potential independent variables by working backward from a dependent variable. Furthermore, experiments and quasi-experiments assume a well-specified causal model and thus require that the state of theory building already be fairly advanced. Second, the manipulation of treatments makes experiments and quasi-experiments a particularly obtrusive and reactive form of generating data. The gain made by manipulating treatments comes at the cost of the

quality of the data generated for analysis. In summary, as shown in Table II, although experiments especially, but also quasi-experiments, have some important strengths, they are also associated with a number of significant weaknesses.

Observational Designs

The distinction between experimental and observational studies is a fundamental and deep one. The key difference is that in observational studies, control of possible third variables is not attained "automatically" through random assignment. Rather, in observational studies third variables have to be formulated and measured explicitly, and control is sought through the analysis of the data. However, the distinction between large *N* studies, on the one hand, and case and small *N* studies, on the other hand, is equally profound and probably more pervasive. This second distinction is not unique to observational studies. Indeed, the quantitative vs qualitative distinction runs through both the experimental and the observational research communities. However, the discussion of this distinction is developed only in the context of observational studies and focuses primarily on the prototypical quantitative and qualitative studies: the large *N*, cross-sectional study and the small *N* study based on the longitudinal case study, respectively.

Large *N* Studies

A large *N* study has some considerable strengths that make it, in some regards, superior to an experimental study. First, because it uses data generated through the natural course of events, it is a viable design for studying important questions that involve nonmanipulable variables that cannot be addressed with an experimental method. Second, because a large *N* study is not constrained by the requirement to randomly assign units to treatment and control groups, it is more likely to entail a randomly selected sample. This is a major benefit that gives large *N* researchers the ability to generalize beyond the domain of the actual units, spatial and temporal setting, and specific treatments that are actually studied and to establish the generalizability of their findings (external validity), a core weakness of experimental methods. However, much as is the case with regard to random assignment in the context of experimental designs, the beauty of random selection is tarnished by the difficulty of applying this design element to many units, settings, and variables (Table III).

Another important strength of large *N* studies, due to their tendency to study quite large samples, is their ability to use statistical analysis to establish patterns of association with a high degree of precision and confidence. Such results, however, differ significantly from those that can be obtained using experimental data. Indeed, although experimental data offer strong grounds for making claims about causality, because large *N* studies are observational it is crucial to remember the simple but profound point that "association is not causation" and, moreover, that even "a lack of correlation does not disprove causation" (Bollen, 1989: p. 52). This does not mean that claims about causality cannot be made on the basis of large *N* studies. Indeed, such claims can be made legitimately if researchers verify the causal assumptions of their statistical models, including nonspuriousness, the lack of omitted variables, independence of cases, and unit homogeneity. However, it is extremely difficult to substantiate that patterns of association establish causality (internal validity).

Table III Observational Designs: Large-*N* Studies

Design elements	*Strengths*	*Weaknesses*
Assignment of value of the independent variable(s) by nature	Viability of studying important questions that involve nonmanipulable variables	
Random selection of units or selection of an entire population	Establishes generalizability (external validity)	Lack of viability for many units, settings, and variables
Selection of many units that are compared cross-sectionally and/or longitudinally	Establishes patterns of association with a high degree of precision and confidence	Association does not establish causation (internal validity) and it is difficult to verify the causal assumptions in statistical models
	Constitutes a tool for theory generation	Associations are more interpretable when guided by a strong theory, i.e., a theory with few variables and detailed predictions
		Measurement validity is harder to establish the larger the *N* and the larger the number of variables
		Lack of attention to causal mechanisms (internal validity)

In short, claims about causality derived from large *N* studies should be treated with great caution.

Regarding the indirect consequences of design choices, it bears emphasizing that large *N* studies are quite useful for exploratory work. In an experiment, treatments need to be planned in advance and need to be relatively few in number, a particularly difficult and restrictive requirement for many areas of the social science. In contrast, at least with regard to the kinds of questions that are common to macro-oriented inquiries in sociology, political science, and economics, it is possible to obtain more data after examining some relationships. This practice runs the risk of capitalizing on chance if not rigorously tested on new data, but it is potentially an important part of any study.

This benefit notwithstanding, a core problem regarding the demands that large *N* research puts on theory and data should be highlighted. On the one hand, associations are more interpretable when guided by a strong theory—that is, one with few variables and detailed predictions. In other words, good large *N* research not only requires a causal model specified prior to testing but also puts a heavy burden on the ability of theory builders to reduce the number of potential explanatory factors. On the other hand, to ensure that the causal model is fully specified, it is important that potential independent variables are not omitted. This fact complicates the interpretation of results. Moreover, it makes a heavy, sometimes practically impossible, demand concerning data. Indeed, because potentially confounding factors are not controlled "automatically" through random assignment in large *N* studies but rather must be modeled and measured explicitly, the need to collect data on numerous variables across a large number of cases and/or time entails some serious costs. This demand opens the door to well-founded charges concerning the validity of the data. In addition, the data requirements of large *N* designs make it extremely difficult to offer a quantitative study of causal mechanisms, a crucial shortcoming that further weakens the claims about causality (internal validity) that can be made on the basis of a large *N* study. Gains in terms of generalizability and findings about patterns of association are heavily dependent on good theory and good data—valuable resources that are not always available.

Some advances that go beyond the cross-sectional design typically used in large *N* studies help get around some of these limitations. Especially noteworthy are time series and panel studies, event history analysis, and hierarchical modeling. These methods offer fruitful ways of addressing the problems associated with the assumptions of unit independence and unit homogeneity. However, these potential gains tend to make even more imposing demands in the area of data collection than cross-sectional designs and thus are achieved at a cost. In summary, as Table III highlights, much as in the case of experimental and quasi-experimental designs, it is only fair to note the strengths of quantitative or large *N* designs but also to recognize their weaknesses.

Case and Small *N* Studies

The status of the case and small *N* studies tradition in the social sciences has been marked by a notable disjuncture between the high number of its practitioners and its low standing in the broader methodological community. This odd situation, however, has been changing over time. After famously stating that "one-shot case studies [are] of almost no scientific value," Campbell retracted this harsh critique of a staple of qualitative research. In turn, statistician David Freedman has argued that case studies, when well designed, can establish causality in a more powerful manner than is standard in most quantitative research. Finally, a flourishing debate on case and small *N* research in recent years has increasingly made explicit the rationale for choosing a qualitative research design and the methodological foundations of rigorous qualitative research. As a result, the reconstructed logic of qualitative methods is catching up with the logic of qualitative research, and a clear sense of the strengths and weaknesses of this tradition is emerging.

One well-established and important strength of case and small *N* studies is that they represent a viable design to address important questions that involve nonmanipulable variables. This is a virtue shared by small and large *N* studies, but in this regard small *N* researchers have an advantage, particularly in light of their ability to gain access to various types of data and form a complex picture of their cases, including a keen sense of developments over time. For this reason, much of the analysis in the social sciences on a range of critical questions, especially during the initial stages in the research process, is done by qualitative researchers (Table IV).

A feature of case and small *N* studies setting them apart from both large *N* and experimental studies and accounting for a key comparative advantage is the manner in which these studies can be used to analyze the role of agency and hence to establish causal mechanisms. This is a critical point. Indeed, as philosophers of science and methodologists have increasingly insisted, it is not enough to focus on causal effects. Rather, it is necessary to go beyond statements about what the effect of a factor is and to consider how and why the effect operates. This calls for the specification of causal mechanisms, which requires, in most areas of the social sciences, considering agency. In this regard, it is probably not an overstatement to suggest that a qualitative design is the method *par excellence* to study agency and hence to empirically ground the analysis of causal mechanisms.

A related strength of case and small *N* studies is that they offer a basis for assessing causality (internal validity).

Table IV Observational Designs: Case and Small-*N* Studies

Design elements	*Strengths*	*Weaknesses*
Assignment of value of the independent variable(s) by nature	Viability of studying important questions that involve nonmanipulable variables	
Selection of one or a few units that are compared longitudinally and/or cross-sectionally	Addresses agency and establishes causal mechanisms	In the absence of strong theory, it is difficult to establish control and eliminate potential variables (internal validity)
	The study of causal mechanisms, and within- and cross-case analysis, offers a basis for assessing causality (internal validity)	
	Constitutes a powerful tool for theory generation	
	Measurement validity is easier to establish the smaller the *N*	
Purposive selection of a few units		Difficult to generalize from sample to population (external validity)

This is done, most fundamentally, through a within-case form of analysis that uses empirical evidence about causal mechanisms as a way to check expectations concerning the direction of causal processes, to eliminate potential third variables, and to verify the assumption of unit independence and unit homogeneity. Moreover, this goal is also frequently advanced by combining the prototypical longitudinal within-case design with a cross-sectional design, such as a traditional cross-case study or a cross-sectional within-case study either focused on different implications of a theory or cast at a different level of aggregation. Through these means, which capitalize on knowledge about process and the ways in which case studies lend themselves to more observations than are suggested by the strict definition of a case study as an $N = 1$ study, small *N* researchers can make valuable contributions that are important to highlight.

However, the weaknesses of qualitative methods as a tool for establishing causality should also be duly recognized. To use case studies to assess causality, it is necessary to be explicit about the posited causal model—including all its variables, the relationship among the variables, and the form of the effect of each variable or combination of variables—as well as about the causal mechanisms that are considered to be in play. This is a demanding task, but failing to specify these things in advance makes it easy for researchers to simply focus on confirming evidence and to disregard alternative interpretations. Indeed, a drawback of most analyses of causal mechanisms is that they fail to specify formally what mechanisms are posited and what plausible alternative mechanisms should be considered and also to set up the study of mechanisms as a standard test among competing hypotheses.

Moreover, even if such steps are taken, it is necessary to recognize the limits of small *N* analysis, in light of the number of observations they entail, as a tool for causal assessment. Some important exceptions to this general principle exist. First, occasionally qualitative researchers may be able to design their research in a way that resembles a natural experiment, in which the hypothesized causal factor changes markedly while other factors remain the same. Second, it is possible to establish patterns of association with precision even with a relatively small sample using techniques of analysis such as exact tests, permutation tests, resampling, or Bayesian methods that do not rely on asymptotics.

Third, presuming a powerful theory is being tested, a few observations could very well serve as the basis for clear results. However, frequently qualitative researchers seek to assess complex causal relationships and, when this is the case, small *N* designs tend to constitute weak means of controlling for alternative hypotheses and for ruling out chance. Indeed, claims to test complex causes using small *N* designs rely on the quite unreasonable assumptions that (i) the world operates in a deterministic fashion, (ii) the proposed causal model is complete, and (iii) there is no measurement error. In short, the use of case studies and small *N* studies to assess causality tends to rely on some very stringent assumptions concerning the state of theory and data.

Another significant limitation concerns the difficulty of using case studies to make generalizations. When studying a small number of cases, random selection is not advisable. Indeed, random selection offers a basis for generalization only when a large number of cases are selected and hence the law of large numbers takes force. Thus, qualitative researchers have to resort to the purposive selection of their cases. When this is done, it is important to avoid drawing a sample of convenience that bears an unclear relationship to the broader population. Moreover, it is important that researchers be aware of how their choice of cases might introduce bias.

Such efforts to select cases in a conscious and careful manner, however, should not be mistaken as steps providing a sufficient basis for making claims about generalizations (external validity).

Finally, with regard to the indirect consequences of design choices, two strengths of case and small *N* studies deserve mention. One is that this type of design constitutes a powerful tool for theory generation. Indeed, one of the clear benefits of qualitative research is its fruitfulness at a tool for generating ideas about causal variables and mechanisms and for theorizing that is closely informed by knowledge of the substantive problem of interest. Another related benefit is that the detailed knowledge of context that is associated with case studies plays a critical role in helping researchers establish measurement validity. In summary, as is the case with the experimental and quantitative traditions, the qualitative tradition is characterized by a mix of strengths and weaknesses (Table IV) that must be considered in any balanced assessment of the potentials of different research designs.

Conclusion: Choices and Bridges

The broad message concerning research design we have sought to convey is that making causal inferences about the complex realities of interest to social scientists is probably more difficult than is generally believed and that questions of research design play a key role in determining whether researchers have a solid basis for making claims about causal relationships. Technical fixes cannot, in general, get around design problems, but more attention goes to the former than the latter. Indeed, given the centrality of research design to the research process as a whole, it is probably fair to say that research design is a relatively unappreciated aspect of methodology and that it deserves more attention from methodologists and practicing researchers alike. Beyond this generic admonition, two further points that build on but go beyond the previous discussion offer material for further consideration.

One point is the need for choices about research design to be explicitly addressed and justified. There is a tendency for researchers to work within distinct research traditions and to simply opt for certain designs as a matter of default. Such a tendency is understandable in that different designs require different skills and training, and in a practical sense researchers are thus not free to choose among research designs. Nonetheless, short of justifying their design choices in light of the range of possible options, at the very least researchers should address the impact of their choices on the certainty of their conclusions. As this article shows, this entails a consideration of the direct impact on the prospects of causal inference of the four core choices involved in research design and of the indirect impact, due to their requirements and contributions vis-à-vis theory and data, of these choices.

A second point is the need to creatively construct bridges across research traditions. Although it is common for certain traditions to be presented as inherently superior to others and the standard against which other traditions should be measured, this article has shown that all traditions are characterized by certain strengths and weaknesses and that it is thus more accurate and useful to think in terms of the tradeoffs involved in working within different traditions. An implication of this assessment, then, is that greater effort should be made to capitalize on what are clearly the complementary strengths of different traditions (compare Tables II–IV).

Efforts at bridging, whether carried out through multiple studies on the same question or mixed designs that combine multiple designs within a single study, are very demanding. Thus, although it is common to point out that multiple studies in the context of a shared research program offer a way of combining different designs, such combinations are only effective inasmuch as research programs are organized around clearly specified concepts and questions and are advanced, at least to a certain extent, through explicitly coordinated teamwork. In turn, the effective use of mixed designs requires a level of methodological sophistication, as well as theoretical and substantive knowledge, that is rare. Nonetheless, the high payoffs associated with the use of mixed methods make these options strongly recommendable.

Research Ethics Committees in the Social Sciences

Søren Holm
Cardiff University, Cardiff, United Kingdom

Louise Irving
University of Manchester, Manchester, United Kingdom

Glossary

funder(s) Organization(s) providing funding for the study through contracts, grants, or donations to an authorized member of the employing and/or care organization.
institutional review board U.S. term for research ethics committee.
research ethics committee An official or semiofficial body that has as its main task the assessment of the ethical and/or legal probity of research projects involving human research subjects before these research projects are initiated.
Strategic Health Authority—UK A body established by the National Health Service to oversee health matters for the population of a defined area.
subjects Persons agreeing to take part in the study. In some legal and regulatory documents the term "participants" is used instead. The term participants implies a more equal relationship between researcher and those being researched. This may not always reflect the true state of affairs.

Social science research projects involving human research subjects in some circumstances have to be reviewed by a research ethics committee (REC). A REC is any official or semiofficial body that has as its main task the assessment of the ethical and/or legal probity of research projects involving human research subjects before these research projects are initiated. Such bodies exist in many jurisdictions and in many research organizations, although their name varies from context to context (e.g., institutional review boards in the United States). They should be distinguished from bodies dealing with questions of scientific fraud and misconduct and from bodies whose main involvement in research ethics is the writing of guidelines for researchers or for RECs.

History and Current Structure of Research Ethics Committees

History

The current system of research ethics committees (RECs) has its origin in two separate historical developments, one internal and one external to the academic world. The closest institutional precursors to RECs are the formal and informal systems that most academic departments and research organizations have traditionally had for the evaluation of the research projects of doctoral students and junior members of staff. Senior members of staff have traditionally assessed the projects of junior staff before they could be initiated. This assessment has often concentrated on methodological issues, but it has also included assessment of the objective of the research and of any ethical or legal problems. In some settings, this assessment was formalized through, for instance, a dissertation committee that had to approve all doctoral projects.

The other major historical root of current RECs is the public and political response to "research scandals" in which instances of unethical research conduct have been exposed. Such scandals have occurred regularly, perhaps most prominently in biomedicine but also in the social sciences and psychology. Examples include Stanley Milgram's obedience studies in psychology and Laud Humphrey's "tearoom trade" study in the social

sciences. Stable features of these scandals have been harm to research subjects, violation of the rights of research subjects, deception of research subjects, exploitation of vulnerable or marginalized groups, and in general a lack of attention to the interests of research subjects.

Such scandals have, over time, led both to the tightening of legal rules and guidelines for the ethical conduct of research and to the establishment of RECs in order to ensure the following of rules and guidelines. It is impossible to give a complete account of this succession of scandals here, so those that have been most important for the formation of RECs are discussed.

The Nuremberg (Nürnberg) code from 1948 was developed as part of the judgment against the doctors involved in the horrific medical and biological research conducted on concentration camp prisoners in Nazi camps during World War II. This declaration was the first to require consent from research subjects as a necessary part of any research project.

In the 1960s, a number of publications surveyed research practice and found many examples of research conducted without any consent of research subjects or involving deception. This led the World Medical Association to put forward the Helsinki Declaration in 1964, regulating medical research and introducing the general requirement of informed consent for research. In 1966, the U.S. Surgeon General issued instruction to all research institutions receiving federal grants that they had to have institutional review boards assess all federally funded research. At approximately the same time, a number of professional associations in the social sciences put forward explicit research ethics guidelines (the American Sociological Association in 1969 and the American Anthropological Association in 1967). Despite the regulatory developments in the late 1960s introducing RECs or REC-like bodies, there has been a continuing stream of new research scandals, leading to tighter control and more explicit guidelines.

Current Structure and Formal Role of RECs in Major Jurisdictions

In the United States, RECs are called institutional review boards (IRBs). Each institution that is supported by a department or agency subject to federal policy, and that conducts research involving human subjects, must have an IRB to review and approve research. All projects in such institutions have to be reviewed, whether or not the individual project receives federal funding. If an institution does not comply, all federal funding may be removed. It is possible for institutions to use the IRBs of other institutions or an outside commercial IRB provider. Federal policy requires that IRBs have at least five members with varying backgrounds to promote complete and adequate review of research activities conducted by the institution. The membership of the IRB must include one scientist, one nonscientist, and one person not affiliated in any way with the institution. The nonaffiliated member should have knowledge of the local community, and if there is a large minority population, he or she should be representative of that particular minority. An IRB should not be composed entirely of men or of women. Experts may be called in as nonvoting advisers. IRBs, which regularly review research involving vulnerable subjects such as children or those incapacitated, must consider inclusion of a member with the appropriate expertise.

In the United Kingdom, social science research can fall under the remit of a REC in two different ways. It can be conducted in the National Health Service (NHS) or on a population derived in some way from the NHS (e.g., former patients identified through NHS files), or it can be conducted at a university or other institution of higher education having a REC.

All research into health and social care that involve the NHS is subject to independent review by NHS RECs. These committees are established by the geographically defined Strategic Health Authorities or directly by the Department of Health. Their remit is to evaluate all research involving human subjects in the NHS whatever the methodology or profession of the researcher. Their legal basis is binding guidance from the Department of Health. The appointment of REC members is by a publicly advertised, open process and members are appointed for a fixed term, usually 5 years. There must be at least 7 members and no more than 18 members. The members should have a sufficiently broad range of experience and expertise to assess the scientific, clinical, and methodological aspects of research proposals. At least 3 members must be independent of any organization in which research under ethical review is likely to take place. The lay members must constitute at least one-third of the membership, and they must be independent of the NHS. At least half the lay members must never have been either health or social care professionals and must never have carried out research involving human participants, their tissue or data. For both lay and expert members, there should be a balanced age and gender distribution, and effort should be made to recruit black, ethnic minority, and disabled members.

Most UK universities have established institutional RECs to evaluate research with human subjects. These RECs have no clear legal basis, but submission of all projects involving human subjects is usually compulsory for all staff and students as part of their employment or study conditions. Because these RECs are established by the individual universities, there are no common rules

concerning membership, but most have some kind of lay representation.

The Council of Europe has agreed to a human rights convention covering a range of areas in biomedical ethics, including research ethics. The Convention for the Protection of Human Rights and Dignity of the Human Being with Regard to the Application of Biology and Medicine has been ratified by most European countries, and its provisions on research are thus binding in these countries. These provisions cover all research in the health care field, including social science research. The main provision is article 16, which states that

> *Research on a person may only be undertaken if all the following conditions are met:*
>
> *i. There is no alternative of comparable effectiveness to research on humans;*
>
> *ii. The risks which may be incurred by that person are not disproportionate to the potential benefits of the research;*
>
> *iii. The research project has been approved by the competent body after independent examination of its scientific merit, including assessment of the importance of the aim of the research, and multidisciplinary review of its ethical acceptability,*
>
> *iv. The persons undergoing research have been informed of their rights and the safeguards prescribed by law for their protection;*
>
> *v. The necessary consent as provided for under Article 5 has been given expressly, specifically and is documented. Such consent may be freely withdrawn at any time.*

A more comprehensive additional protocol to the convention, explicating and extending the provisions on research, is being prepared.

In their work, RECs will often look beyond the formal legal rules and take account of research ethics guidelines promulgated by different professional organizations. Such guidelines exist both at the international level and at the national level.

At the international level, the relevant guidelines include the Helsinki Declaration of the World Medical Association covering research in the health care setting and the Council for International Organizations of Medical Sciences (CIOMS) guidelines covering medical research in developing countries. No generally recognized international ethics guidelines exist for social science research.

At the national level, influential guidelines have been prepared by the Social Research Association and the British Sociological Association in the United Kingdom and by the American Sociological Association, the American Anthropological Association, and the American Psychological Association in the United States. All the professional codes give guidance on access to subjects, the acquisition of informed consent, the right of subjects to privacy and confidentiality, the reputation of the profession, and obligations to sponsors and colleagues.

Purpose and Function of RECs

RECs have three major purposes. They are intended to protect research subjects/participants from harm and from violations of their rights, to ensure that the quality of research projects is sufficient to warrant the "use" of human subjects, and to add public legitimation to research projects.

Protection of Research Subjects

In most cases, there is a fundamental inequality in the (social) power, status, and knowledge possessed by researchers and their research subjects. This enables researchers to exploit research subjects in various ways. Researchers may harm research subjects directly during the research process or indirectly through the way the results of the research are presented. This possibility of harm exists in all kinds of research involving human subjects. There are no research methods in which the possibility of harm to the subjects is completely removed.

In their evaluation of harm, RECs will seek to ensure that the risk and magnitude of harm are not so great that they make the project ethically problematic, and that the risk and magnitude of harm are appropriately balanced by the benefits the project can generate. There is thus both an absolute threshold for allowable harm and a relative balancing against potential benefits. The benefits in question can be benefits to the research subjects, but they may also be benefits to the research population or to society.

Researchers may also violate the ethical and legal rights of subjects, even in cases in which they do not directly harm the subjects. These rights include rights to privacy, self-determination, physical integrity, and control of personal data.

If the researchers have the permission from the research subjects to perform the research in the form of a fully informed and voluntary consent, and the research is conducted according to the permission given, then there is no rights violation involved since all the rights mentioned previously are waivable. A REC will therefore seek to ensure that the description of the research project given to potential research participants is comprehensive and truthful in order to make any consent given fully valid.

Scientific Evaluation of Projects

As part of the approval process, RECs evaluate the scientific quality of the research projects submitted. This function of RECs is more controversial than the

function of protection of research subjects. It is sometimes claimed by disgruntled researchers that RECs should not assess scientific quality and/or are not qualified to assess scientific quality.

However, it is important to note that the assessment of scientific quality can be seen as a necessary component in the overall evaluation of the ethical status of a project. The major ethical justification for "using" human subjects in research (e.g., for using their time) is that the research project in question can generate valuable knowledge. If a research project is badly designed and is therefore unlikely to generate any kind of addition to knowledge, it is *prima facie* unethical. Scientific review is therefore part of a comprehensive ethical review.

How can the scientific quality of a wide range of projects be reviewed in RECs that typically have a limited number of members and therefore a limited range of expertise concerning research methodologies? First, it is important to note that the task of the REC is not to decide whether a given project has the best possible methodology and research design but only to decide whether the methodology is good enough. This is still not an uncontentious evaluation, but it is clearly less contentious than trying to decide on the best methodology. RECs can generally solve this task either by using external experts for projects for which no members are expert or by inviting the researchers to explain their methodology and its strengths and weaknesses.

RECs as Public Bodies Legitimating Research

Although researchers often view RECs only as an obstacle to be overcome, it is important to acknowledge that RECs also legitimate and thereby facilitate research. The right to academic freedom and to free choice of research topic (where it exists) is only a negative right protecting the researcher from interference from outside bodies; it is not a positive right giving the researcher permission to involve other persons as research subjects. RECs are a way of giving ethically legitimate research a form of quality approval, and being able to point to REC approval can help researchers in situations in which potential research subjects have an a priori negative attitude toward research.

Research involving human subjects is a social practice that relies on social acceptance for it to continue and flourish. This social acceptance has to encompass both the goals of the activity and the way the activity is conducted. Research and development is always an optional goal. It is not incoherent or irrational to think that no more research should be performed, as long as one is willing to also accept that no more progress will be made. The RECs probably have only a minor role to play in explaining the general goals of research to the public, but they do have potentially very important roles to play with regard to the social acceptance of the goals and conduct of specific projects.

If we view RECs as institutions within a democratic framework that at the same time regulates and legitimizes research, we can become clearer about the roles of the RECs. When an REC approves a project, it is not a neutral administrative act—it is also an implicit endorsement of the project and its qualities.

RECs and the Evaluation of Research in Other Countries

Developed countries often sponsor research in developing countries, either research directed at the research needs of the developing country in question or research directed at general research questions not specifically of interest to the developing country in question. Many research funding agencies require REC approval from two RECs, one in the funding country and one in the country in which the research is to take place. This creates possibilities for conflict and raises two important questions. Why require REC approval in the funding country? and What standard should be applied?

Often, agencies require dual approval because they want to ensure that they cannot be accused of performing research in developing countries that could not be performed in the home country for ethical or legal reasons. This is obviously a laudable aim, even if it contains a large element of self-interest, but it does not fully answer the second question of what standards to apply.

Standards of consent, confidentiality, anonymity, data protection, and reporting that may be suitable in the context of a developed country may not fit another cultural context. Such a standard may be ill fitting in many ways. It may not take into account different ideas about the proper limits of self-determination or privacy, and it may in certain areas be too confining and in others too permissive. How is the REC to know this? In many cases, fairly detailed knowledge is needed of the culture in question to be able to assess the ethical appropriateness of a specific research project, and it can be very difficult for a REC to get this information.

A number of national and international bodies have tried to analyze these problems and develop more precise guidelines. This activity has been particularly intense in the biomedical field, in which some AIDS research in poor countries has been seen as exploitative. A U.S. report and a UK report have reached similar conclusions that are also echoed in the latest revision of the World Medical Association's Helsinki Declaration. The main principle is that although the precise way in which informed consent is obtained and documented may vary from setting to

setting, research that is performed in developing countries has to adhere to the same ethical standards as research in the sponsoring country, and it has to be of some benefit to the country in which it is performed.

Common Problems in the Evaluation of Social Science Research by RECs

A number of problems commonly occur in the evaluation of social science research by RECs. In RECs that mostly deal with biomedical research there is often a lack of knowledge about social science research methods, and the professional members of such RECs (often doctors and other health care professionals) may believe that the biomedical research paradigm, with its emphasis on quantitative research, is the only valid paradigm. This can lead to problems for qualitative researchers.

Other problems occur regularly even in RECs that are used to assessing social science projects. The three most common problems concern research in sensitive areas, research involving deception, and observational research in spaces on the border of private and public space.

Research in sensitive areas can be difficult to evaluate either because it is controversial or because it raises questions about the role of the researcher when he or she is gaining knowledge about illegal actions performed by research participants or is indirectly participating in these illegal activities. RECs should never disallow valid research projects simply because they are controversial, but this has occurred in many instances. This problem is especially likely to occur if the REC in question is institutional and therefore has a potential conflict of interest between the unbiased evaluation of the research project and the interests of the institution in maintaining its reputation.

Research involving deception in inherently problematic because it is impossible for the research subjects to give true informed consent if they are deceived about the purpose or procedures of the research. In some jurisdictions deceptive research is prohibited, but in those in which it is allowed RECs have a difficult task in deciding how to balance the interests of the research subjects against the knowledge likely to be produced by the research. Classic examples of deceptive research for which the ethics of the research is still being discussed are Stanley Milgram's obedience studies and Laud Humphrey's "tearoom trade" study.

Observational research can raise problems for RECs in cases in which it is performed without the consent or knowledge of some of the persons being observed, especially if they are observed in spaces that are on the border between public and private space. It is generally accepted that by performing actions in a public space a person has relinquished his or her right to privacy concerning these acts, and that any observation of persons in a public space for research purposes is therefore *prima facie* justified. However, the demarcation between public and private space varies between cultures (and between age cohorts of individual cultures) as well as between different agents in specific social settings. A hospital ward, for instance, may be conceptualized as a public space with regard to the nurses and other health care professionals working there but as a private (or at least semiprivate) space with regard to the individual patients. A REC asked to assess a project involving observation of nurses washing patients would therefore have to make a number of difficult decisions concerning consent from nurses and patients and the proper limits of observation in this setting.

Future Trends in REC Function

Like all mechanisms for public control, RECs have to develop as societies and research practices develop. A number of current trends in societal development are likely to influence the future configuration and function of RECs: the reconfiguration of autonomy in postmodern societies, the recognition of the full implications of multiculturalism, the increasing commercialization of research, and the perceived need to control compliance with REC decisions.

There is no doubt that the current system of research ethics regulation, including the REC system, is built on modern ideas of the ideal, rational decision maker weighing harms and benefits according to a rationally construed ordering of preferences. In postmodern society, this ideal is being increasingly undermined. Although additional weight is being given to the rights of individuals to organize their lives as they choose, it is also recognized that they may do so in ways that do not conform to ideals of rational decision making. RECs will therefore have to struggle to develop ways of protecting this new kind of postmodern decision maker, with his or her own constructed set of values and preferences.

Most RECs function in multicultural societies, but until now they have mostly functioned based on the values of the majority culture. As the full implications of multiculturalism are developed and absorbed into public life, RECs will also have to change their composition and function. A major discussion for the future will be whether REC membership should be representative of the different cultures involved in projects evaluated by the REC or whether the values and ideas of these cultures should be incorporated into the function of the REC in some other way. Representative membership is an attractive idea but may be practically impossible to achieve in areas where the number of relevant cultural groups is large.

Research is being increasingly commercialized. This happens both directly when research is initiated, directed, and funded by commercial organizations and indirectly when academic institutions become more focused on commercial exploitation of the intellectual property generated by their employees. RECs will have to respond to this trend. The response is likely to include much closer scrutiny of the relationship between the researcher and the funder, with particular focus on the researcher's independence and on whether the funder can bar publication of the research if the results are not favorable. More focus is also likely to be placed on how research subjects are treated in regard to the distribution of the economic and other benefits flowing from the intellectual property generated through the research.

A final trend that is already evident in RECs dealing with biomedical research is a move to giving RECs a role not only in the initial ethical assessment of projects but also in the control of whether the projects are carried out in an ethical manner. This is likely also to happen for other kinds of RECs. When research "scandals" are unveiled, a standard response is "We must have stricter regulation," but it is doubtful whether this is a correct and useful response. Many of the scandals concern projects that have either never been approved by a REC or are conducted in breach of the approved protocol. It is unclear why and how stricter regulation can help in such cases. The more reasonable response seems to be to punish the transgressors and to ensure better control in the future so that no unapproved research can be conducted and breaches of the approved protocols can be detected and rectified.

Glossary

checkerboard problem Geographic units are related to one another in space but tabular segregation indices assume independence of parcels that can be problematic.
composition independence Invariance to the group fractions in the overall region.
decomposability A property of a segregation index in which aggregation across geographic units or population groups is possible.
parcel A unit of geography such as a census tract or block group.
residential segregation The differential distribution of social groups across geography.

Residential segregation is the differential distribution of social groups across geographic space. Social groups can be demarcated by a variety of traits including, but not limited to, racial and ethnic classifications, religion, language or nativity, gender, and family structure. However, residential segregation is most commonly measured for racial and ethnic groups across urban neighborhoods. Most broadly, segregation may be seen as the differential distribution of social traits across a set of units such as census tracts, occupational categories or schools.

Introduction

Population distribution in terms of residential patterns provides a window on the social organization of groups. The extent of concentration and segregation reveals the structure of group relations in society and frames social interaction. It also provides a snapshot of a number of social processes at work such that at a given point in time, segregation indices summarize the outcome of discrimination, self-selection, governmental intervention, and differential residential patterns incidental to compositional processes. Segregation indices have become so well established that they are now cited regularly in policy documents and news media.

History and Development of Segregation Measurement

Residential segregation has been one phenomenon measured extensively by social scientists and discussions of the importance of residential segregation permeate 20th century writing in urban sociology. Efforts to develop a summary statistic for urban residential patterns extend back over the past half-century and have overlapped with efforts to measure population distribution and population diversity more generally.

For residential segregation methodology, a watershed was reached in 1955 with the publication of a methodological analysis by Duncan and Duncan. This well-traveled article reviewed six major indices, pointing out their mathematical properties, their strengths and weaknesses, and their relation to the segregation (Lorenz) curve. Presumably as a result of that article and the Duncans' own empirical research, the dissimilarity index (D) became the workhorse of segregation analysis. In the 1970's, a methodological debate broke D's hegemony, particularly as it was noted that D failed several key

statistical and substantive criteria and did not necessarily capture all of the information that would be present in a map shaded according to demographic composition.

New measures of segregation were developed, sometimes without awareness of traditional measures. For instance, alternative measures were developed to capture racial segregation across schools. The geography literature also independently spawned indices and a literature of spatial autocorrelation. In other studies of social group segregation, parallel methodological debates arose. These can be most commonly found in occupational differentiation and income segregation. Multiple indices of income and industrial inequality have been developed to measure the distribution of resources in the population of workers, households, and firms.

Although the methodology of segregation is employed most often in ethnic residential settings, it also appears in other applications. Residential segregation has been studied for socioeconomic status, nativity, language, and less often for life cycle and family structure traits. In some applications, investigators have examined an added dimension within the residential pattern, such as racial residential segregation within broad socioeconomic groupings.

For residential segregation, many researchers have adopted a strategy of reporting multiple indices of residential segregation in the aftermath of challenges to the dissimilarity index. Recently, the U.S. Census Bureau and other researchers have reported as many as 19 segregation indices of metropolitan areas for decennial censuses from 1980 to 2000.

Common Properties

All residential segregation measures try to capture the pattern of neighboring in some way, most commonly providing a normed summary statistic describing the degree of residential differentiation. Typically, indices make use of data cross-classified by social category and census geography, such as the census tract.

Perhaps the easiest starting point for the concept of segregation is the two-dimensional tabulation (see Fig. 1). From this sort of two-dimensional tabulation we can generate most of the residential segregation indices in widespread use. Such arrays arise directly in census tabulations. For instance, in the 2000 U.S. census public release data, e.g. SF1 and SF3, the "groups" above appear for race, Spanish Origin and ancestry categories. The "parcels" available are units of geography, such as census tracts or block groups. In general, any data that can be arrayed in this form—most specifically but not exclusively that for which the "group" is a socioeconomic trait and the "parcel" is a geographic unit—lend itself to segregation measurement of the type described below. In principle

	Group A	Group B	Group C
Parcel 1			
Parcel 2			
Parcel 3			
Parcel 4			
Parcel 5			

Figure 1 Two-dimensional tabulation for segregation measurement.

then, the very techniques used for summarizing two-dimensional tabulations could be carried over to residential segregation measurement. This simple fact is often underappreciated in the segregation literature, which seems to have grown up independently of the general literature in social statistics. Explicit spatial measures (below), which take into account the absolute or relative location of the parcels, require a somewhat different approach.

A good index is meaningful statistically and from the social scientific standpoint, if it can handle three or more groups simultaneously, reflects map validity, and allows comparisons over time and space. Various criteria have been nominated to evaluate any index of residential segregation. Although this list is not exhaustive, it includes:

1. A measure of association. The interpretation is a proportion of variance explained measure.
2. Normed. For example, bounded between zero and unity, where 0 indicates no segregation (no relationship between parcel and group membership; and 1 indicates complete segregation (complete predictability) of group from parcel).
3. Decomposability. A preferred measure would have a property of being able to be aggregated across geographic units or population groups.
4. Composition Independence. Some investigators argue that a preferred segregation would be invariant to the fraction minority in the overall region. Others have a preference for composition-dependent measures.
5. Social welfare criteria. Scale invariance, the principle of transfers, system size invariance and the Lorenz criterion have evolved in the income inequality literature and have been brought into the segregation literature (see James and Taeuber; Reardon and Firebaugh; Schwartz and Winship).

Few measures meet all of the desiderata and some analysts would forgo a property for theoretical reasons.

At this point we turn to a selective review, concentrating on measures that have appeared most often in the

literature. First we treat nonspatial indices, measures that can be calculated directly from a parcel-by-group tabulation. Second, we treat explicitly spatial measures. These may arise from either (a) tabulated data augmented by some coordinate or other spatial information identifying each parcel or (b) individual data with point coordinates (x–y or longitude–latitude) and associated attributes of the person or household at that location. Of course, geographic aggregation of spatial point data into parcels can generate (a) from (b).

Conventional Tabular Measures

In this section, we describe five of the more preferred and commonly implemented indices, their features, and their applications. This can be calculated from the standard parcel-by-trait calculation above. We begin with the most widely used and historically important index.

Index of Dissimilarity (*D*)

$$D = \frac{1}{2}\sum_{i=1}^{I}\left|\frac{n_{ij}}{N_j} - \frac{n_{ik}}{N_k}\right|, \tag{1}$$

where j, k are distinct groups; n_{ij} is the population of group j in the ith parcel; n_{ik} is the population of group k in the ith parcel; N_j is the total population of group j; and N_k is the total population of group k.

The workhorse of residential segregation indices, the index of dissimilarity, is the most widely used measure to compare the levels of residential segregation of racial and ethnic groups within urban areas and across them. It is calculated by taking half the sum of the absolute difference between the proportions of each group in each parcel.

Strengths and weaknesses of the dissimilarity index are well known. Strengths are several. First it has longevity; it has been in use since the early 20th century, and it formed the basic index for many early studies of residential segregation. As a consequence, there exists a long time series of dissimilarity, measures: racial residential segregation for cities, some occupational segregation indices and the like. Second, it meets several key desirable properties. It is normed with 0 indicating a proportionate distribution of each group in each parcel and 1 indicating that no groups share a parcel. It is not sensitive to group size (composition invariant); that is, doubling the number of persons of one group in each parcel (and thus increasing the fraction in the city) leaves the index unchanged. The dissimilarity index also benefits from an intuitive verbal interpretation: the fraction of one group that would have to relocate to produce an "even" (unsegregated) distribution.

The index also suffers from several key weaknesses, which have been described at length. The dissimilarity index also does not satisfy all of the welfare approach criteria, perhaps most seriously failing in the principle of transfers. Redistribution of persons across parcels that both exceed (or fall below) the mean does not change the index value. This is an undesirable payoff criterion in the eyes of many, in that redistribution away from the most extreme parcels may not change D's value. The dissimilarity index also fails for decomposition. Perhaps the most disadvantageous aspect of the dissimilarity index for contemporary segregation studies is its limitation to dichotomies. The two-group limitation was of little consequence when cities were literally seen in black and white. While efforts have been made to adjust D for three or more groups (see the work of Sakoda and of Reardon and Firebaugh), these are not widely used and have been generally superceded by other measures.

Still, ease of calculation, a high level of correlation with other indices and ease of interpretation have given the dissimilarity index considerable staying power. Finally, some authors have identified dissimilarity to be the key indicator of one dimension of segregation, namely evenness, which we discuss below.

Entropy Index (*H*)

$$H = \frac{(E^* - \bar{E})}{E^*}, \tag{2a}$$

$$E^* = (-1)\sum_{k=1}^{K} P_k(\ln(P_k)), \tag{2b}$$

$$\bar{E} = (-1)\sum_{i=1}^{I}\frac{n_i}{N}\sum_{k=1}^{K} P_{ik}(\ln(P_{ik})), \tag{2c}$$

where P_k is the proportion of group k in the population; P_{ik} is the proportion of group k in parcel i; n_i is the total population in parcel i; N is the total population (note, we define $P_{ik}(\ln(P_{ik})) = 0$ for $P_{ik} = 0$).

Introduced to the segregation literature by Theil and Finizza to measure the extent of racial segregation across schools, it is also known as the information theory index. The entropy statistic (E) gives the demographic diversity of each parcel. Thus, using the interior summation of formula (2c) above, it is possible to calculate the diversity of each individual neighborhood with respect to race or ethnic groups. Diversity is maximized (to the value of $\ln(K)$) when all groups are present in equal proportions ($p_i = p_j$). In contrast, units with only one group present would have a value of zero. This feature demonstrates the connection between neighborhood diversity and metropolitan segregation.

The entropy index (H) is bounded from 0 to 1. Values closer to zero reveal the average diversity of categories to

be similar to the total diversity level (E^*), indicating less segregation. The maximum value of unity for complete segregation is attained when every parcel contains only one subgroup. The entropy index is the weighted average deviation of each category's diversity from the total diversity, standardized by the total diversity.

The entropy index offers several positive attributes. Most notably it is readily decomposed across both geography and groups. Theil and Finizza's original work made use of this property to describe racial segregation within and between school districts. Because K is not limited to 2, the entropy index has been increasingly used to handle multiple group situations. For instance, metropolitan areas might be compared on the degree to which they are generally segregated with respect to Anglos (non-Hispanic Whites), Blacks, Latinos, Asians, and others simultaneously. Current applications of this sort are found in the work of Fischer, who looks at multiple ethnic groups and income segregation simultaneously for 60 U.S. metropolitan areas, and in the work of Reardon, Yun, and Eitle in their examination of school segregation in over 200 U.S. metropolitan areas.

One weakness of this index is that it does not strictly adhere to composition invariance (i.e., doubling the number of one group will change the index value), although this seems not to be a major issue in practical applications. Also, it does not offer quite as intuitive an interpretation as dissimilarity, but the entropy index can be seen as a proportional reduction of error measure for nominal variables.

Exposure Indices (*P*)

Isolation Index (within group)

$$P_{jj} = \sum_{i=1}^{I} \left(\frac{n_{ij}}{N_j}\right)\left(\frac{n_{ij}}{n_i}\right) \tag{3a}$$

Interaction index (across group)

$$P_{kk} = \sum_{i=1}^{I} \left(\frac{n_{ij}}{N_j}\right)\left(\frac{n_{ik}}{n_i}\right) \tag{3b}$$

where n_{ij} is the population of group j in parcel i; n_i is the population in parcel i; N_j is the total population of group j; and n_{ik} is the population of group k in parcel i.

The first of the two expressions describes the hypothetical probability that a member in subgroup j will meet another member of his/her subgroup. Hence, it has been labeled the isolation index, where greater values suggest higher levels of isolation and segregation. The second expression, P_{jk}, assesses the probability of exposure of one group to a second and greater values on this index reflect higher levels of exposure between members of two different groups or less segregation. The isolation and interaction indices for a subgroup will sum to one if there are exactly two groups in the area or if interaction indices are estimated for all additional groups.

Exposure indices (sometimes denoted P^*) have gained a considerable following in the residential segregation literature. This may be for several reasons. First, the indices are readily calculated from available census tabular data. Second, these indices have an intuitive interpretation as "exposure," and equivalently, the probability of encountering a member of one's own or another group in one's neighborhood. Perhaps the most debatable trait of the exposure family of indices is that of its sensitivity to composition. Exposure indices fail the composition-independence criterion mentioned above. It can be shown that these indices are bounded by the overall composition of the wider unit, e.g., metropolitan area, of which they are a part. Thus $P_j \leq P_{jj} \leq 1$ and $0 \leq P_{jk} \leq 1$. The composition-dependent nature of the exposure index can be seen by some as a singular deficiency. (One can norm the index for composition, as has been discussed in the literature, at which point it becomes equivalent to the correlation ratio.) Alternatively, some argue that the sensitivity to composition is sociologically meaningful. Metropolitan ethnic exposure indices do exhibit a higher correlation with overall ethnic composition than dissimilarity or entropy.

Spatial Measures

Spatial Proximity (*SP*)

$$P = \sum_{k=1}^{K} \frac{\left(N_k^2\right)\left(P_{kk}\right)}{\left(N^2\right)\left(P_{00}\right)}$$

$$P_{kk} = \left(\frac{1}{N_k}\right)^2 \sum_{i=1}^{I}\sum_{j=1}^{J} \left(n_{ik}\right)\left(n_{jk}\right) f\left(d_{ij}\right) \tag{4}$$

$$P_{00} = \left(\frac{1}{N}\right)^2 \sum_{i=1}^{I}\sum_{j=1}^{J} \left(n_i\right)\left(n_j\right) f\left(d_{ij}\right)$$

where n_{ik} is the population of group k in parcel i; n_{ij} is the population of group k in parcel j; $f(d_{ij})$ is a function of distance between parcels i and j; n_i is the population in parcel i; n_j is the population in parcel j; N_k is the total population of group k; and N is the total population.

The spatial proximity index was presented by White to address the "checkerboard" or map validity problem of other measures of residential segregation. In a slight revision of it, White norms the measure in [0, 1] and it is presented above. Despite their reference to the distribution of subgroups across geographic areas, these other indices (dissimilarity, exposure, entropy) do not account for any of the relative spatial position of the parcels.

If $f(d_{ij}) = d_{ij}$ then P equals the proportion of spatial variance explained, and the measure has a parallel to

those used in the geography literature. If $f(d)$ takes on another function, then P can represent the proportion of variation in that aspect of neighboring captured by the function. While this discussion is in terms of explicit geographic distance, in any tabulation for which the cells could be connected by some (social) distance measure, this calculation could be applied. Other spatial approaches have been devised, and as we discuss below, there is opportunity for further development along these lines.

Other Measures

The number of other potential segregation measures (and the associated literature on inequality generally) is too large to enumerate in detail. We mention only a few and their links to this literature. Several of these—often termed concentration or centralization indices—describe the relative location of (ethnic) groups among tracts within an (metropolitan) area, but these have not seen wide application in the literature. The measurement of income inequality can be shown to be related to residential segregation, especially through the segregation or Lorenz curve and associated inequality indices, such as the Gini index or the family of Atkinson measures. The interested reader is referred to other methodological summaries for discussion of properties of these measures. (Formulas are given in the work of Iceland, Weinberg, and Steinmetz, of White, and of Massey and Denton among others.)

Selecting a Measure: Dimensions of Segregation Measurement

Taken together, the literature has grown to identify 20 or more indices. The expansion of the number of competing indices has spawned a related series of investigations to analyze the "dimensions" of segregation, with an eye toward choosing an index representative of each dimension. Massey and Denton, for instance, used factor analysis to identify five dimensions of segregation. Massey, White, and Phua confirmed this for segregation statistics about a decade later. The dimensions generally identified (and the indices classified within them) include (following Iceland, Weinberg, and Steinmetz):

Evenness: *Dissimilarity, Entropy* (*or Information Theory*), Gini, Atkinson
Exposure: *Isolation, Interaction*, Correlation Ratio
Concentration: Delta, Absolute Concentration, Relative Concentration
Centralization: Absolute Centralization; Relative Centralization
Clustering: *Spatial Proximity*, Absolute Clustering, Relative Clustering, Distance Decay Interaction, Distance Decay Isolation

Several of these indices (in italics) have been described above. Although space does not permit a full discussion of these measures, some attention to their objectives and interpretation is useful.

Evenness measures generally adjust for composition. That is, dissimilarity, Gini, and entropy are calculated in such a way that the ethnic composition of the city overall does not directly influence the value of the index. This would be preferred in most measures of association, thus freeing the summary statistic of the influence of the marginal distribution. Note that this dimension contains the companion measures used to assess income inequality. The Gini index has long been the normed [0, 1] standard for an index of income inequality. It can also be used in the residential segregation case, which can be seen by plotting the associated segregation curve as the cumulative fraction of one group against the cumulative fraction of another. (Duncan and Duncan give a full exposition of this.) The Atkinson family of indices does much the same, but allows one to weight different segments of the segregation curve, and in so doing, makes explicit the value of reducing inequality in certain portions of the distribution.

Exposure indices have grown in popularity, at least in sociological circles. As discussed above, the isolation and interaction indices are influenced by population composition, and some investigators see this as preferable, since the hypothetical probability of encountering someone is the behavioral concept pursued by these indices. The correlation ratio (sometimes called eta-squared) can be interpreted as the interaction index adjusted for composition. Once adjusted in this way, it is very highly correlated with evenness measures, further indicating the differing assumptions in each group played by overall city composition. The correlation ratio can also be interpreted as a measure of association for a binomial variable. Each of these exposure indices is defined in such a way that only a pairwise comparison can be made at one time.

The several concentration indices generally calculate the distribution of a group with respect to the population densities that apply for the units of residence. Thus, a minority group would be maximally concentrated if its members resided in highest density neighborhoods. As described by Iceland and others, there are three variants of the calculation, but all three require information on the geographic extent of residential units. Somewhat parallel to this, measures of centralization capture the degree to which the group of interest resides in the neighborhoods located most closely to the center of the city. For example, a level of relative centralization approaching unity indicates that minority group members

are almost all located closer to the center of the city than majority group members. Again, this pair of measures requires explicit geographic information. Iceland, Weinberg, and Steinmetz argue that the current urban pattern (multiple nucleation) makes measures of centralization increasingly outmoded.

Clustering measures explicitly incorporate some aspect of relative spatial location, although it need not be oriented to the central business district or residential density (as above). Again, several indices exist within this group and the spatial proximity measure is one of these. As expressed above, it offers the interpretation as a normed measure. Other measures—absolute clustering, relative clustering—have parallel interpretations, although their specifications differ. The distance decay interaction and distance decay isolation indices operate similarly to the exposure indices, save that the value of the contribution across parcels is weighted by a function of distance presumed to capture the social importance of space.

Avenues for Segregation Measurement in the 21st Century

The changing demography of urban areas immediately translates into significant conceptual and methodological challenges for new research on residential segregation. The lively index debate of past years often focused on basic mathematical properties and related substantive criteria, such as the principle of transfers. The compromise has often been to calculate many indices and identify where they agree or just let the user choose. We can identify a few factors that are likely to provide pressure for deeper thinking about index choice and revisiting some of these methodological issues. Currently, technology of data dissemination and analysis all favor work with more complex demographic structure and virtually any index specification. Whereas once the choice of an index may have been guided by practical concerns about the burden of calculation, new work will not be so hampered.

The most consequential development for segregation methods is the increasing ethnic diversity of urban settings. Fueled by international migration, cities in high-income societies have come to accommodate a wider array of ethnic groups, and even in moderate income societies, ethnic diversity (fueled by both internal and international migration) leads to much the same outcome. Furthermore, the salience of residential segregation for other traits (family composition, occupation) also argues for the development and use of measures that can handle three or more groups simultaneously. Measures developed for segregation between 2 groups have been further developed to incorporate more groups (see the work of Reardon and Firebaugh and of Sakoda) but they remain more commonly applied to pairwise computations. Others, such as entropy and spatial proximity, can better manage polytomies, and it is likely the desire to analyze multigroup segregation—seen in the emerging literature on multiethnic cities—will generate more use of these particular indices.

Second, and a somewhat related development is the issue of the value of a "reference" group. If one argues that there is a clear comparison group, the dichotomous calculations of segregation from that group make sense. Thus, in the conventional analysis of ethnic segregation one might examine segregation from Canadian charter groups (English and French origin) or in the United States from the Anglo (non-Hispanic white) population. Once that reference group orientation is abandoned, then the analyst needs a way to summarize the relative position of groups to one another and/or a summary measure of segregation across all groups. Some data reduction techniques, such as multidimensional scaling or cluster analysis, could prove helpful in showing the relative segregation of groups from one another. Lest it be seen as an issue limited to ethnic diversity, the same problem would arise for the analyst interested in summarizing the segregation pattern across any nominal variable.

A third exciting challenge for segregation analysts is the incorporation of more geographic detail into the calculations and indices. Several of the indices already mentioned above travel somewhat down this road, but to be sure, most have a rather crude operationalization of urban geography. The desire to develop more geographically sophisticated measures would suggest that indices should incorporate more socially meaningful functions of space. Dating back to the 1980s, several analysts have made progress in involving geography. Measures that involve more work with neighborhood contiguity, functions of distance, and topographic irregularities might find increasing numbers of adherents in years to come.

A fourth challenge is seen in the need to "control" for other traits in segregation analysis. For instance, the analyst would like to calculate the amount of segregation between a pair of (or larger set of) ethnic groups after adjusting for the effect of income. While some work on this has been done (confirming a high level of racial segregation within income classes), a full multivariate set of controls is harder to introduce. Multilevel and microlevel datasets present some opportunities here.

A fifth challenge is that of making comparisons across space and time. Although still less well established than the unemployment rate or the Gini index of income equality, segregation measures have become a key social indicator. The challenge, then, is to begin reworking segregation analyses, exploiting improved indices and data management. Comparable work can be conducted for other settings, including developing countries, thus improving scholars' ability to make international

comparisons. With respect to time, the assessment of segregation trends is complicated by changing social identities, particularly in race and ethnic origins. This complication is further compounded by modifications of geographic boundaries. Population change within geographic units from one point in time to another results in changes in the classification and boundaries of larger urban regions such as metropolitan areas as well as of parcels such as census tracts. From one census to another, new metropolitan areas emerge while others surrender this status, new areas become contained within existing metropolises and census tracts are amalgamated or further divided.

Finally, the technology of data analysis, data management, and calculation will help analysts surmount these challenges. Large data tabulations for multiple levels of geography and time periods are being placed readily in the public domain by statistical agencies. The painstaking "hand" calculation of indices of two generations ago, or the arduous computer manipulation of data files, have been replaced by a circumstance in which most any index can quickly be calculated across multiple geographies for a wide array of social traits. Given the social importance of residential segregation by race, ethnic group, or other socioeconomic trait, it is likely that the future will see more sophisticated indices calculated for a wider array of social groups.

Response Bias

Timothy R. Graeff
Middle Tennessee State University, Murfreesboro, Tennessee, USA

Glossary

apathy bias Bias that results from respondents not caring about the survey or deciding to respond quickly or randomly simply to finish the survey.
counter biasing statement A statement that is given at the beginning of a question and assures respondents that all responses are acceptable and appropriate.
interviewer bias Bias that results from the characteristics of an interviewer causing respondents to censor or alter their answers, or from an interviewer's reactions to a respondent's answers encouraging certain types of answers and inhibiting others.
leading questions Questions that contain words or phrases that suggest or imply a certain answer.
random sampling error A type of survey error that is the result of taking a random sample that includes only a subset of the population.
randomized response questions A series of two questions in which the answer to the first question (known only to the respondent) determines which of two subsequent questions the respondent answers: either an innocuous question or a potentially sensitive question.
reverse-scored items Survey questions that are purposely phrased negatively (reverse phrasing of the majority of other items on the survey).
social desirability bias Bias that occurs when respondents answer based on what is perceived as being socially acceptable, and not the respondent's true state.
uninformed response bias Bias associated with respondents answering questions about which they have no knowledge or experience simply because they feel obligated to respond.

Response bias is a type of survey error that results from respondents intentionally or unintentionally biasing, changing, censoring, or otherwise misrepresenting their true opinions, thoughts, and beliefs when answering survey questions. As a result, respondents' answers to survey questions do not accurately represent their true state. Response bias can result from the topic of the question, the data collection procedures and the characteristics of interviewers, the order of questions on a survey, the phrasing or wording of survey questions, and even from people simply forgetting, wanting to be nice, wanting to appear informed and not ignorant, or wanting to please the interviewer. Because there are no statistical measures of the amount of response bias for a survey, and increasing the sample size generally has no effect on reducing response bias, it is incumbent upon the researcher to identify and anticipate response bias so that the sources of the bias can be eliminated or changed prior to conducting the study and collecting the data. To identify sources of response bias, researchers should consider the reasons why a respondent would lie or report answers to survey questions that do not accurately reflect their true state.

Surveys and Error

The purpose of conducting a survey research project is to measure a characteristic (parameter) of a population of interest. Unfortunately, researchers cannot be 100% confident that the calculated sample statistic (e.g., average age of people in the sample) is exactly the same as the true population parameter (the true average age of people in the population). The difference between the calculated sample statistic and the true population parameter is called survey error, of which there are many sources. Response bias is a type of survey error that results from respondents intentionally or unintentionally biasing, censoring, or otherwise misrepresenting their true opinions, thoughts, beliefs, and responses to survey

questions. For example, many people lie about their age, income, weight, daily activities, and even the types of products they buy. As a result, survey results very often do not accurately estimate true population parameters.

Comparing Response Bias to Random Sampling Error

To understand response bias it is helpful to first understand what response bias is not. Response bias is not random. In fact, many of the issues associated with response bias and strategies for dealing with response bias differ greatly from those associated with random sampling error. Random sampling error is the result of taking a random sample that includes only a subset of a population. Every time a different sample of people from a population is taken the calculated sample statistic will be a different value because different people are being included in the sample each time. Because of random sampling error, sample statistics are just as likely to underestimate the population parameter as they are to overestimate the population parameter. Even though it can never be eliminated (short of taking a complete census of every member of the population), there are statistical measures for estimating and accounting for the amount of random sampling error (plus or minus) that is associated with a sample statistic. The standard error of the mean is used to estimate the amount of random error associated with an average, and the standard error of the proportion is used to estimate the amount of random error associated with a proportion.

$$SE_{\text{mean}} = S/\sqrt{n} \qquad SE_{\text{proportion}} = \sqrt{p(1-p)/n},$$

where S is the sample standard deviation, p is the sample proportion, and n is the sample size. Notice that random sampling error can be reduced by increasing the sample size (the denominator in each equation).

In contrast, response bias is a source of error that usually affects all respondents in a similar manner, resulting in error that is consistently in one direction or the other. With response bias, the difference between the population parameter and the sample statistic can result from the topic of the survey questions; respondents' desire to fit in, appear prestigious, or please the interviewer; and can even result from problems with the data collection methodology, techniques, or procedures. Data collection procedures and the topic of survey questions systematically affect respondents in a manner that causes them to lie or misrepresent their true state. For example, if male university students are interviewed by an attractive female interviewer, they will most likely overestimate how often they exercise to impress the interviewer. Unfortunately, there are no statistical measures of response bias that are comparable to standard error measures of random sampling error. Further, increasing the sample size will generally have no effect on reducing this response bias. Unless the data collection procedures are changed, a larger sample will only result in a greater number of males lying about how often they exercise. The important differences between response bias and random sampling error are summarized in Table I.

Response bias can be reduced by changing the data collection procedures and methodologies. For example, anonymous mail surveys might be best for measuring how often male students exercise. Unless the biasing effect of the attractive female interviewer is removed, males will tend to overestimate how often they exercise. Because there are no statistical measures of the amount of response bias, and increasing the sample size has no effect on reducing response bias, it is imperative that researchers identify and anticipate response bias to eliminate the sources of such bias prior to conducting the study and collecting the data.

Types of Response Bias

Response bias occurs when respondents do not answer truthfully or their answers are not representative of how they really behave, think, or feel. They intentionally or unintentionally misrepresent their true state. To identify potential response bias, ask, "Why would someone lie, misrepresent, bias, or censor their answers?" There are many potential answers to this question. Sometimes response bias is simply due to the topic of the question. Other times response bias occurs because of the data collection procedures and the characteristics of interviewers. Response bias is also caused by the order of questions on a survey and the phrasing of survey questions. And yes, response bias can also result from people simply forgetting, wanting to be nice, wanting to appear informed and not ignorant, and even wanting to please the interviewer.

Social Desirability Bias

People naturally want others to view them favorably with respect to socially acceptable values, behaviors, beliefs, and opinions. Thus, answers to survey questions are often guided by what is perceived as being socially acceptable. For example, even if a person does not donate money to charity, they might report that they have donated. Donating money to charity is the socially acceptable behavior. Social desirability bias can affect responses to questions about whether or not people spank their children, whether or not they recently purchased any fur coats, or even whether or not they voted in recent elections. Research on topics about which there are socially

Table I Comparing Response Bias to Random Sampling Error

	Response bias	*Random sampling error*
What causes the error?	Problems with data collection procedures, question wording, the nature of the survey procedures, characteristics of the interviewer, respondents wanting to please the interviewer, etc.	Randomly selecting members from the population. Each time a sample is taken different people will be included in the sample, and thus, a different sample statistic will be calculated.
What is the effect of the error on sample statistics?	Systematic. Because of response bias, the sample statistic tends to either overestimate or underestimate the true population parameter consistently and systematically across all respondents.	Random. The sample statistic is just as likely to overestimate the population parameter as it is to underestimate the population parameter.
Can the error be estimated statistically?	No. The amount of response bias cannot be estimated statistically.	Yes. The amount of random sampling error can be estimated as the standard error of the mean (when calculating an average) and the standard error of the proportion (when calculating a percentage). $SE_{\text{mean}} = S/\sqrt{n}$ $SE_{\text{prop.}} = \sqrt{p(1-q)/n}$
How can the error be reduced?	Changing the data collection procedures and methodology to reduce or eliminate the source of the response bias. Increasing the sample size has no effect on reducing the amount of response bias.	Increasing the sample size (the denominator in the standard error equations) will reduce the amount of random sampling error in the estimates.

acceptable behaviors, views, and opinions is very susceptible to social desirability bias.

Social desirability bias is by far the most studied form of response bias. Social desirability bias can result from (1) the nature of the data collection or experimental procedures or settings, (2) the degree to which a respondent seeks to present themselves in a favorable light, (3) the degree to which the topic of the survey and the survey questions refer to socially value-laden topics, (4) the degree to which respondents answers will be viewed publicly versus privately (anonymously), (5) respondents' expectations regarding the use of the research and their individual answers, and (6) the extent to which respondents can guess what types of responses will please the interviewer or sponsor of the researcher.

Social desirability bias is often viewed as consisting of two factors, self-deception and impression management. Self-deception refers to the natural tendency to view oneself favorably. Self-deception has been linked to other personality factors such as anxiety, achievement, motivation, and self-esteem. Impression management refers to the situational dependent desire to present oneself in a positive light. This can manifest itself in the form of false reports and deliberately biased answers to survey questions.

There is no standard statistical procedure for measuring the amount of social desirability bias across varying situations, contexts, and survey topics. Nonetheless, researchers have developed scales, such as the Marlowe–Crowne 33-item Social Desirability Scale, and shorter versions of the scale, to identify and measure the presence of social desirability bias in survey results. When a social desirability scale is added to a survey, significant correlations between the social desirability scale and other survey questions indicate the presence of social desirability bias due to respondents' desire to answer in socially desirable ways. Low correlations between the social desirability scale and other survey questions suggest the lack of social desirability bias.

Unfortunately, such social desirability scales cannot be used as standardized measures of social desirability bias across varying situations, settings, data collection procedures, and research topics. Along with the obvious disadvantage of making the survey longer, such social desirability scales often contain questions that respondents might perceive as inappropriate and unrelated to the fundamental purpose of the survey.

Other attempts to measure and reduce social desirability bias include the use of a pseudo lie detector called the bogus pipeline. With a bogus pipeline, researchers tell respondents that the data collection procedures and/or measurement apparatus are capable of identifying when someone is lying. Thus, respondents are more motivated to respond truthfully. Of course, such procedures would be inappropriate for many social research procedures, techniques and data collection methodologies.

The amount of social desirability bias in a survey can vary by (1) mode of contact (anonymous versus

face-to-face interviews or signed surveys), (2) differences in a respondent's home country and culture (respondents from lesser developed countries have been found to be more likely to respond to personality surveys in a manner consistent with existing cultural stereotypes), and (3) the amount of monetary incentive provided to the respondent (respondents receiving larger monetary incentives have been found to exert greater effort in completing a survey and were more likely to respond in a manner that was favorable toward the survey sponsor).

Acquiescence/Yea-Saying Bias

With acquiescence bias a response is based on respondents' perceptions of how they think the researcher wants them to respond, leading to potential demand effects. Respondents might acquiesce and respond favorably toward the idea of a new product because they think that is what a market researcher wants to hear. The manner in which interviewers react to respondents' answers can also give respondents cues regarding what the interviewer wants to hear. The way interviewers provide encouragement to respondents can affect their sense of what they are supposed to do and how they are to respond. Some respondents can also be biased by a natural tendency toward positive responses. Many people exhibit a tendency to agree with statements presented to them rather than disagree. Such tendencies toward positive responses can even vary across cultures.

Prestige Bias

Many people will bias their responses to make themselves appear more prestigious in the eyes of others. Males might overestimate their income if the interviewer is an attractive female. People naturally overestimate social status and occupation, and underestimate their weight, age, and extent to which they suffer from certain medical problems.

Threat Bias

With threat bias, a response is influenced by the extent to which respondents feel threatened by negative consequences associated with certain answers. People might lie about whether or not they have ever shoplifted because of the potential legal ramifications of admitting to shoplifting.

Hostility Bias

With hostility bias, a response is biased due to feelings of anger on the part of the respondent. If respondents feel forced to complete a long survey, or if the interviewer or data collection procedures cause them to get mad, they might deliberately fabricate answers in a retaliatory effort to get even with the researcher. Any affective responses to the research or the data collection procedure itself can introduce confounding variables and additional sources of bias into the research results.

Sponsorship Bias

With sponsorship bias, a response is influenced by respondents' perceptions of the person or organization sponsoring the research. If respondents know who is sponsoring the research, they can often figure out how the research sponsor wants them to respond, leading to demand effects. People might underestimate the amount of red meat they eat on a survey conducted by the American Heart Association. Alternatively, people might overestimate the amount of red meat they eat on a survey conducted by the National Cattlemen's Beef Association. This is similar to acquiescence bias in that people often answer survey questions based on how they think the researcher wants them to respond. This is likely for research measuring low involvement situations or behaviors.

Question Order Bias

Beliefs, feelings, or attitudes that are made salient because of questions asked early in a survey can influence responses to subsequent questions. Questions about teenage delinquency and other social problems associated with young people asked early in a survey can influence responses to subsequent questions about spanking, child discipline, and corporal punishment. Also, the order in which a series of questions are asked on a survey can affect responses to the items. Extreme evaluations (e.g., strongly positive or strongly negative) of the first few items in a list might influence evaluations about subsequent items in the list. Responses to early questions can be used as an anchoring point against which responses to subsequent questions are compared.

Extremity Bias

Many people do not like using the extreme ends of scales and do not like feeling that they are at the extreme, compared to others. For example, if income categories are set up as: less than $20,000; $20,000–$30,000; $30,001–$40,000, etc., a person who earns $19,000 might bias their response by choosing the second category so that they are not in the bottom income category. When asked about the amount of time spent on personal matters while at work, people will naturally not want to be in the top category. One solution to this problem is to include additional response categories that are at the extreme ends of the scale—even if you do not expect anyone to use them. For example, make the income categories: less

than $10,000; $10,000–$15,000; $15,001–$20,000; $20,001–$25,000; and so on. This way someone earning $19,000 is more likely to honestly report their income (check the third income category) without having to be in the bottom income category.

Interviewer Bias

Characteristics of an interviewer can cause people to bias their responses. An attractive interviewer might cause males to bias their responses related to income, weight, or frequency of exercising. However, the effects of interviewer characteristics are minimized in telephone interviews compared to in-person interviews simply because the respondent cannot observe the interviewer. An interviewer's reactions to a respondent's answers can actually encourage certain types of responses and inhibit others. Based on an interviewer's smile, frown, or even the raise of an eyebrow, people can determine what the interviewer wants to hear (what would please them), and then give them those answers. If a person gives their opinion on a controversial topic and the interviewer responds with, "*Hmmm . . . , that's interesting*," the respondent can quickly determine that their answer was not expected or somehow out of line with normal responses. The respondent might censor or bias subsequent answers. Interviewer training can reduce this problem.

Memory Bias

People forget things over long periods of time, and evaluations and opinions can easily change over time. Memory for events can be biased by telescoping errors. Backward telescoping occurs when respondents report that recent events occurred further back in time. Forward telescoping occurs when respondents report that distant events occurred more recently than they really did. Further, evaluations can also change over time. A person might not feel as strongly about the quality of a restaurant meal (either positively or negatively) the more time that lapses between when they ate the meal and when they are asked about it. Evaluations (both positive and negative) can become more moderate as more and more time lapses. What is *terrific* today might be evaluated as only *pretty good* a week from now. Similarly, what is *terrible* today might be evaluated as *not that bad* a week from now. If asking for evaluations, beliefs, perceptions, or attitudes toward events, minimize the amount of time between the person's experience of the event and when they are asked questions about it.

Apathy Bias

This results from respondents who do not care about the survey or who decide to respond quickly or randomly simply to finish the survey. This can happen with very long surveys and those for which respondents have not developed a commitment to complete the survey.

Uninformed Response Bias

Respondents often answer questions about which they have no knowledge or experience simply because they feel obligated to respond. They do this because they do not want to appear uninformed or ignorant. Offering, and making sure that respondents are aware of, a *Don't Know* or *No Opinion* option on the survey tends to reduce this bias. However, many people will still answer questions about which they are uninformed even when they are told it is acceptable to respond with *Don't Know.*

Uninformed responses are especially troublesome in that efforts to increase response rates can have inadvertent negative effects on the validity of research results. Stimulus factors designed to increase item response rates can lead to higher uninformed response rates. Uninformed respondents can be pressured to provide meaningless answers to survey questions. Further, if the purpose of the research is to measure beliefs, attitudes or perceptions, respondents' familiarity with similar sounding attitude objects can also guide their responses. Thus, respondents often unintentionally give uninformed responses simply because they are mistaken about the object being evaluated.

Reducing Response Bias

As listed above, there are many sources of response bias. By being aware of these, researchers can plan their survey procedures to minimize the likelihood that these sources of response bias will have significant effects on their survey results. Strategies for reducing these types of response bias include:

1. Assure respondents of anonymity of responses and privacy with respect to data related to their individual responses (to reduce social desirability bias and threat bias).
2. Whenever possible, use anonymous survey data collection procedures and consider procedures that do not require an interviewer (to reduce social desirability bias, prestige bias, and interviewer bias).
3. Avoid revealing the purpose of the research, the sponsor of the research, or the source of the survey (to reduce acquiescence bias and year-saying bias).
4. Make the survey short, interesting, and easy to complete. Try to get respondents committed to completing the entire survey. Use prompters to help respondents work their way through the survey, such as *the next section will be easier; thank you for your help with*

those questions, please answer a few more questions; or *there are only a few more questions remaining to answer* (to reduce hostility bias and apathy bias).

5. Carefully consider the order of the survey questions and the possible response categories. Try to ask more general questions earlier in the survey, and ask questions about more specific issues, people, events, places, or ideas later in the survey (to reduce question order bias and extremity bias).

6. Reduce the amount of time between a respondent's experience of an event and their responses to questions about that event (to reduce memory bias).

7. Consider using reverse scored items on the survey. Most survey questions are phrased positively. However, some researchers purposely reverse the phrasing of some items so that they are phrased negatively to increase the chance that respondents will read all of the questions, decreasing the likelihood of acquiescence bias, apathy bias, and straight line (column) responding (e.g., apathetically circling a column of Strongly Answer answers). For example, questions one, two, and four below are phrased positively, and question three is phrased negatively. If respondents answer strongly agree (SA) to all four questions, this indicates that they did not carefully read all four questions. They might have assumed that all four questions were phrased positively—leading to a straight line (column) of Strongly Agree answers (see Table II).

A respondent's answer to a reverse scored question must be converted by subtracting the answer's scale value (*X*) from the total number of scale values plus one. In this example, if SD were coded as 1, and SA were coded as 5, a respondent's answer to question 3 would be converted as (6 – X) to place all four scales in the same direction.

However, using reverse scored (reverse worded) items is not without its own limitations. Recent research has demonstrated that the mixture of positive and negative phrased items can lessen a scale's internal consistency. Negative worded items often show lower reliability and weaker item-to-total correlations than positive worded items. When a scale is subjected to factor analysis, reverse scored items often load on a separate factor, thus eliminating the unidimensionality of a scale designed to measure a single construct. Research has also demonstrated that such problems often arise when researching respondents from subcultures, such as ethnic and racial minorities. Differences in cultures and traditions can lead to varying patterns of responses to negatively worded questions, especially when survey questions are translated into languages that employ different methods of representing negatives and contradictions. Thus, including reverse scored items can be particularly problematic for cross-cultural research and surveys conducted in foreign cultures.

Table II Adding a Reverse Scored Item to a Survey

1. I am very articulate.	SD	D	N	A	SA
2. I am very comfortable talking with people I have recently met.	SD	D	N	A	SA
3. I often have difficulty striking up a conversation with people I have just met.	SD	D	N	A	SA
4. I have very good verbal communication skills.	SD	D	N	A	SA

8. Make respondents aware that they can answer any question with *Don't Know* or *No Opinion*. Include questions that measure respondents' level of knowledge about a topic in addition to their attitudes and opinions about a topic (to identify and reduce uninformed response bias).

Response Bias and Question Wording

The wording of survey questions themselves can also lead to response bias. Leading questions are those that contain words or phrases that suggest or imply a certain answer. They lead people to respond in a biased manner. Such response bias is not due to respondents purposely biasing their answers, but rather to the particular way in which a survey question is worded. Consider the following question: "*More and more people are coming to accept cell phone usage in public as socially acceptable behavior. Do you feel that using cell phones in public is socially acceptable behavior?*" Many respondents will respond with *yes* because the question implies that many other people feel it is acceptable behavior. To avoid response bias due to question wording:

1. Avoid suggestions and implications in the question. Asking, "*How pleased are you with the efficient manner in which the Governor dealt with the State's financial problems?*" will lead to biased responses because the question implies that the Governor dealt with the problems efficiently.

2. Avoid emotionally charged words. Asking about possible solutions to the terrorism *crisis* will result in different responses than asking about solutions to the terrorism *problem*, which in turn will lead to different responses than asking about solutions to the terrorism *situation*. Compared to a situation, a crisis usually demands quicker and greater attention.

3. Do not provide reasons or justifications for responses in the question. Let respondents come up with their own reasons for how they answer. Asking, "*Do you support an increase in the state income tax to raise money to help fund education so that the children in our state will be better*

prepared to succeed in life?" encourages positive responses because of the justification given in the question—to help children be better prepared to succeed in life.

4. Use a counter biasing statement. A counter biasing statement is given at the beginning of a question and assures respondents that all responses are acceptable and appropriate. Students might naturally overestimate the amount of time they spend studying. However, including a counter biasing statement such as, "*Some students spend very little time studying, others spend a great deal of time studying, how many hours do you study in a typical week*?" lets them know that all answers are acceptable, even those that indicate very little studying.

Randomized Response Questions

Another strategy to avoid response bias is to use randomized response questions. Randomized response questions consist of two questions in which the answer to the first question (known only to the respondent) determines which of two subsequent questions the respondent answers—either an innocuous question or a potentially sensitive question. Randomized response questions are used when asking about potentially embarrassing, threatening, or otherwise sensitive issues. They reduce response bias by allowing the respondent to answer potentially sensitive questions honestly, because the researcher does not know which of two questions the respondent answered. For example, all respondents are asked an initial question. Respondents do not reveal their answer to the initial question. *Is the last digit in your social security number even or odd?* If it is an even number, they are to answer question A. Alternatively, if it is an odd number, they are to answer question B.

A: *Is the last digit in your home phone number between 5 and 9?*

B: *Do you spank your children?*

___Yes___ No

Respondents are assured anonymity and are more likely to answer truthfully because only they know which second question (A or B) they have answered. Based on simple probability theory, the percentage of respondents who spank their children can be determined as follows: $P(\text{yes}) = [P(\text{question A}) \times P(\text{yes to A})] + [P(\text{question B}) \times P(\text{yes to B})]$.

To illustrate, 35% of the respondents answered *yes* to the second question. Since the probability of answering question A (the last digit in their SSN is even) and the probability of answering question B (the last digit in their SSN is odd) are both 50%, and the probability of having a phone number that ends in a digit between 5 and 9 is also 50%, the percentage of respondents who spank their children (X) is calculated as:

$$0.35 = [0.5(0.5)] + [0.5(X)]$$
$$0.35 = 0.25 + 0.5(X)$$
$$0.10 = 0.5(X)$$
$$0.20 = X$$

Thus, 20% of the respondents spank their children.

Response Bias and Research Conclusions

All that researchers ever really know is what they measure—a person's response to a survey question, the box a person checks on a survey, or the numbers and words they write on a survey. The question that must be asked is, "Why did we observe this particular measurement or these particular differences in measurement across groups or time periods?" There are two possible answers to this question, which refer to two possible explanations for observed measurements.

1. The observed measurement is a real effect. The observed measurement is an accurate estimate of the population parameter. The observed measurements reflect accurate differences in population parameters across groups or time periods.

2. The observed measurement is the result of error. The observed measurement is not an accurate estimate of the population parameter. The observed measurements do not reflect accurate differences in population parameters across groups or time periods.

To illustrate, consider the case of a survey designed to measure the amount of time that parents of elementary school children spend reading to their children and working with their children on school work. The results revealed that parents spend an average of two hours every night reading to their children and working with them on school work. One explanation for this result is that it is an accurate estimate of the population parameter. That is, parents really do spend an average of two hours every night reading to their children and working with them on school work. However, an alternative explanation is that the survey result is due to error. In addition to random sampling error (where the survey result is just as likely to either overestimate or underestimate the true parameter), a significant amount of response bias is likely in this situation. Parents will naturally want to overestimate the amount of time they spend reading to their children and working with them on school work if the survey is administered by the school district (social desirability bias, prestige bias, acquiescence bias, sponsorship bias).

Statistical tests allow for the possibility that observed measurements are due to either real effects or error. The p-value of a statistical test indicates the probability

that an observed measurement is due to error, and not a real effect. But, such p-values indicate only the probability that the observed measurements are due to random sampling error. Even if a statistical test reveals a very low p-value (e.g., $p < 0.01$) indicating that there is less than 1% chance that the observed results are due to random sampling error, the observed measurements could still be the result of systematic response bias that cannot be estimated statistically. Further, the margin of error for a survey (e.g., $\pm 3\%$ for a sample size of approximately 1000) represents the amount of random sampling error that is associated with an estimate. It does not include any error that might be present in the results due to systematic response bias. Increasing the sample size will reduce the amount of random sampling error, but will have no effect on reducing response bias. A larger sample size will not reduce the natural tendency for all parents to overestimate the amount of time they spend reading to their children and working with them on school work.

Conclusions from the results of social research must always be evaluated by recognizing the potential for response bias in the results. Unfortunately, no statistical procedures are available for measuring the amount of response bias in a survey. Researchers must examine the entirety of the data collection procedures and methods to identify potential sources of response bias being introduced into the results.

Risk and Needs Assessments

Christopher Baird
National Council on Crime and Delinquency, Oakland, California, USA

Glossary

base rate The rate at which an event occurs for the entire population studied.
equity The quality of being just, fair, and impartial.
interrater reliability The extent to which different raters or decision makers come to the same conclusion.
needs assessment A formal process ensuring that specific areas of potential needs are assessed periodically for every case referred for services or supervision.
risk assessment A formalized process used to classify individuals into different groups based on observed rates of a specific behavior or outcome experienced by cases with similar profiles.
validity The degree of accuracy attained in measuring what the system is designed to measure; the extent to which a system or premise produces the desired results.

Introduction

In every human service field, there is a critical need to determine the proper level of intervention required to ensure the safety and well-being of the individual served and/or the safety of society in general. Risk assessment, by definition, attempts to identify those cases in which a subsequent negative event (crime, child maltreatment, or disease) is most likely to occur. Social services also recognize that there is an ethical mandate to ensure that decisions that have substantial impact on children, families, and the community are just, consistent, and based on appropriate criteria. Formal risk and needs assessments are designed to accomplish these objectives.

Beginning in the mid-1970s, the use of formal risk and needs assessment instruments in social service agencies expanded rapidly in the United States. Today, these instruments are commonly found in the fields of adult corrections, juvenile justice, and child welfare. In addition, recent efforts to create similar indices for domestic violence initiatives and programs designed to prevent other social problems have shown considerable promise. The increase in the use of risk and needs assessments was driven largely by recognition for the need for more efficient, consistent, and valid decision making in human service agencies.

Frontline workers in social services are asked to make extremely difficult decisions, but there is often significant variance in the skill levels, education, and experience of staff that make these decisions. Consequently, decisions regarding case openings and closings and the level of care, supervision, or custody to be provided have long been criticized as inappropriate, inconsistent, or both. Research has clearly demonstrated that decisions in social service agencies vary significantly from worker to worker, even among those considered to be experts in a particular field. As pressure to make critical decisions in a timely fashion increases, so does the potential for error. Inappropriate decisions can be costly or even tragic, resulting in serious injury or death when agencies fail to properly assess risk.

Risk assessment systems used in social services are formalized methods that provide structure and criteria with the expectation that these assessments will increase the reliability and accuracy of decision making. A variety of systems for estimating risk have been developed over the years. Some experts have expressed concern that the theoretical and empirical support for these systems is inadequate. Because different methods of risk assessment development have been employed over the past two decades, risk assessment procedures vary on a number of dimensions, and the task of comparing one to another is quite complex. Generally, however, there are two basic

types of risk assessment systems. In consensus-based or expert systems, workers assess specific client characteristics identified by the consensus judgment of experts and then exercise their own clinical judgment about future risk. Actuarial systems are based on an empirical study of the relationship between case characteristics and outcomes. The study identifies items/factors with a strong association to observed behaviors and constructs an actuarial instrument that workers score to identify low-, medium-, or high-risk cases.

A substantial number of "head-to-head" tests have been conducted in a number of disciplines during the past five decades. In 1993, Dawes eloquently summarized the results of this research as follows:

> *In the last 50 years or so, the question of whether a statistical or clinical approach is superior has been the subject of extensive empirical investigation; statistical vs clinical methods of predicting important human outcomes have been compared with each other, in what might be described as a "contest." The results have been uniform. Even fairly simple statistical methods outperform clinical judgment. The superiority of statistical prediction holds in diverse areas, ranging from diagnosing heart attacks and predicting who will survive them to forecasting who will succeed in careers, stay out of jail on parole, or be dismissed from police forces.* (p. A40)

In 1996, Grove and Meehl presented an exhaustive review of the literature citing 136 studies ranging from the 1928 Illinois Parole Board Study to the present, concluding that a "great preponderance of studies favor the actuarial approach." They did, however, find a few (8) studies in which clinical judgment outperformed actuarial models.

It is now generally recognized that actuarial or research-based risk assessments are superior to "expert systems." In addressing the efficacy of actuarial systems, three issues are of critical importance: validity, reliability, and equity.

Measuring Validity: Classification versus Prediction

Human services have long struggled with how the validity of risk instruments is best determined. Validity of decision-making systems has traditionally been measured by the degree to which "predictions" about case outcomes are realized. Ruscio (1998) defines validity of child welfare risk instruments in the following manner:

> *The efficacy of your decision policy can be examined through the use of a simple fourfold classification table crossing the optimal outcome for each child (kept at home vs placed into care) with the decision that is reached. There are two types of correct decisions, or "hits," that are possible: True positives are decisions that place children into care when appropriate, and true negatives are decisions that keep children at home when appropriate. There are also two types of incorrect decisions, or "misses," that are possible: False positives are decisions that unnecessarily place children into care, and false negatives are decisions that fail to place children into care when placement is necessary. Based on this classification table, the effectiveness of a decision policy may be evaluated in several ways. For instance, one could determine how many of the decisions to place a child into foster care were correct (true positives divided by the sum of true and false positives); how many children who optimally should have been kept in the home actually were (true negatives divided by the sum of true negatives and false positives); or how many placement decisions, overall, were correct (the sum of true positives and true negatives divided by the total number of cases).* (p. 148)

Although calculation of false positives, false negatives, and the overall percentage of correct predictions is useful in many settings, it may not be the best method for gauging the efficacy of a risk assessment system when the probability of success/failure is substantially different than 50–50. When events are relatively rare, they are inherently difficult to predict. In such instances, simply assuming an event will not occur may produce more predictive accuracy than any attempt to determine where or when occurrence is likely. For example, if recidivism is reported in only 20% of cases released from juvenile correctional agencies, then simply predicting no case opened to services will have subsequent maltreatment reported produces an 80% "hit rate." Obviously, such a prediction, although highly accurate, is of little value. (In essence, the "sensitivity" of the prediction is 0.8, but the specificity—correct identification of those who do fail—is zero.) A valid and reliable risk assessment system may improve the hit rate marginally, but it is possible such a system could result in a higher percentage of false positives and false negatives and still provide the agency with quality information about the relative probability of subsequent maltreatment. Consider the scenario in which a child welfare population ($N = 100$) has a subsequent maltreatment rate of 15%. A risk assessment identifies 25% of the population as "high risk," which, for this example, is equated with a prediction of subsequent maltreatment. Actual versus predicted outcomes are presented in Table I.

In the previous example, an overall hit rate of 82% is attained (3% lower than that attained when all cases are predicted to succeed) with a rate of false positives (subsequent maltreatment) of 56% and false negatives of 5.3%. Despite the high proportion of false positives, cases that were rated high risk experienced maltreatment at a 44% rate, whereas only 5.3% of those rated at lower risk levels had subsequent maltreatment reported. The

Table I Actual vs Predicted Outcomes

	Predicted outcomes	
Actual outcomes	*No subsequent maltreatment*	*Subsequent maltreatment*
No subsequent maltreatment	71	14
Subsequent maltreatment	4	11

ratio of "failures" in the high-risk group to failures in the low-risk group is more than 8:1. Such results help agencies identify which families are more likely to abuse or neglect their children. In addition, 11 of the 15 cases (73.3%) in which subsequent maltreatment occurred were correctly identified (a relatively high rate of specificity).

Many fields, such as juvenile justice, medicine, and adult corrections, have largely abandoned the idea that risk assessment is an exercise in prediction. Instead, terms such as base expectancy rates have replaced discussions of false positives and false negatives. In corrections, for example, high risk does not equal a prediction of failure: In fact, in most correctional systems, more high-risk cases succeed than fail. Instead, high risk simply denotes inclusion in a group of offenders with significantly higher historical rates of recidivism than other groups.

The field of medicine offers similar examples. In cancer research, it is common practice to identify characteristics of malignancies and surrounding tissue and to classify patients as high, moderate, or low risk based on the observed rates of recurrence within a specified time period. A designation of high risk of recurrence does not equate with a "prediction" that the cancer will recur. In fact, most medical professionals carefully avoid making such predictions. As treatment options expand and improve, recurrence-free survival rates have increased to the point where, if false positives and negatives were to be minimized, the best "prediction" for high-risk cases would be "no recurrence." Still, knowing that cases with similar characteristics have experienced a recurrence rate of 10, 25, or 45% helps the doctor and patient select the most appropriate treatment plan.

Conceptually, the use of false positives and false negatives to evaluate risk assessment systems creates another dilemma. Although outcomes are often dichotomous (an event will either occur or not occur), most risk assessment models assign cases to at least three different risk levels (low, moderate, and high). If efficacy is based on predicting an outcome, it must be asked what prediction is being made for cases at intermediate risk levels: Is the designation "moderate risk" a prediction that subsequent maltreatment will or will not occur? We submit that it is neither, but simply the recognition that these cases "recidivate" at higher rates than some and at lower rates than others. Knowing this allows workers to establish appropriate service plans, just as similar information permits doctors and patients to decide on a particular course of action.

Therefore, in evaluating the relative efficacy of risk assessment systems, it is imperative to be very clear about expectations. The terms prediction and classification are often used interchangeably but really connote different expectations. Prediction is more precise than classification. According to "Merriam Webster's" definition, prediction "declares in advance on the basis of observation, experience, or scientific reason." To predict accurately in any field is difficult; to accurately predict human behavior is especially complex because many factors contribute to determining how individuals will act. Classification, on the other hand, is simply "a systematic arrangement in groups or categories according to established criteria." Although accurate prediction would greatly benefit human services and society, it has not proven feasible. The goals of risk assessment are much more modest; it is simply meant to assign cases to different categories based on observed rates of behavior.

New definitions of purposes of risk assessment have emerged in recent years. Silver and Banks (1998) state that "traditional measures of 'predictive accuracy' which carry with them the assumption that dichotomous decisions will be made, have little utility for assessing the potency of a risk classification model" and that "the primary utility of a risk classification model is in providing a continuum of risk estimates associated with a variety of conditions which can be used to guide a range of decision making responses." *(p. 8)*

Two factors are important in measuring the potency of risk assessment instruments: the relative differences in outcomes between risk groups and the actual distribution of cases across risk classifications. In essence, the validity of risk assessment instruments should be measured by the degree to which subgroupings of a meaningful size are identified and the degree to which different rates of "failure" are found for each subgroup.

Actuarial or research-based risk assessment instruments have demonstrated the ability to accurately classify cases to different risk levels in several different fields. Figures 1 and 2 represent results obtained in child welfare and adult corrections, respectively.

As the figures illustrate, well-designed risk instruments can effectively identify groups with very different rates of failure (as defined by each field). In Fig. 2, for example (a risk assessment system used in Nevada), high-risk cases are 6.5 times more likely than low-risk cases to have a new conviction or revocation while on community supervision. This information helps agencies define the level of supervision required to protect the community and help ensure a higher success rate for inmates transitioning to living in the community.

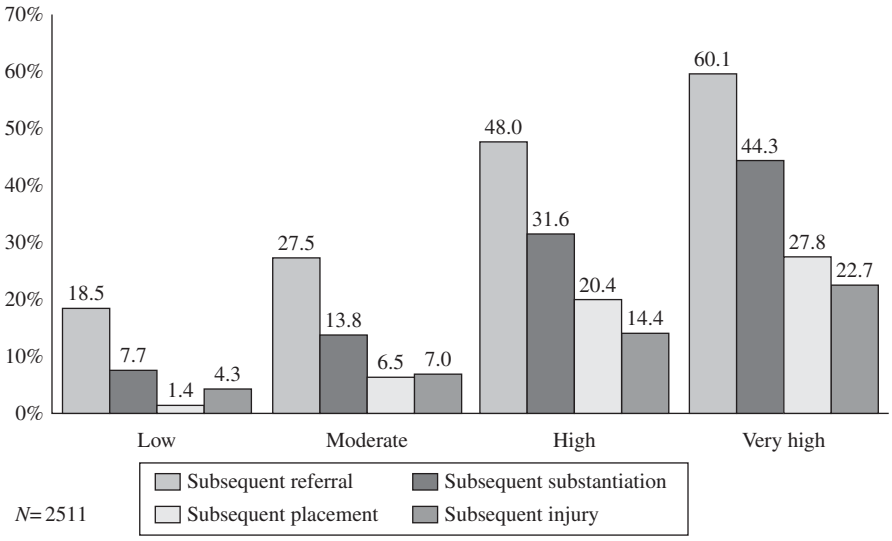

Figure 1 California risk assessment outcomes by risk level.

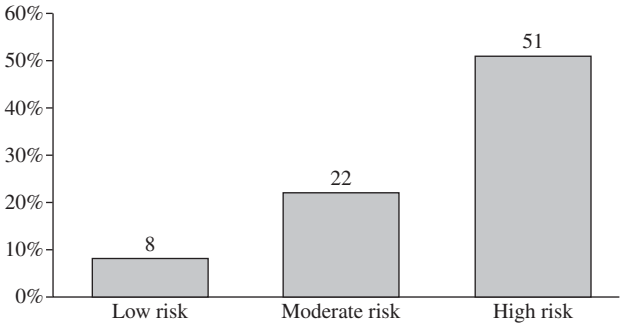

Figure 2 Nevada probation and parole: Subsequent revocation or new felony conviction by risk level.

Reliability and Equity

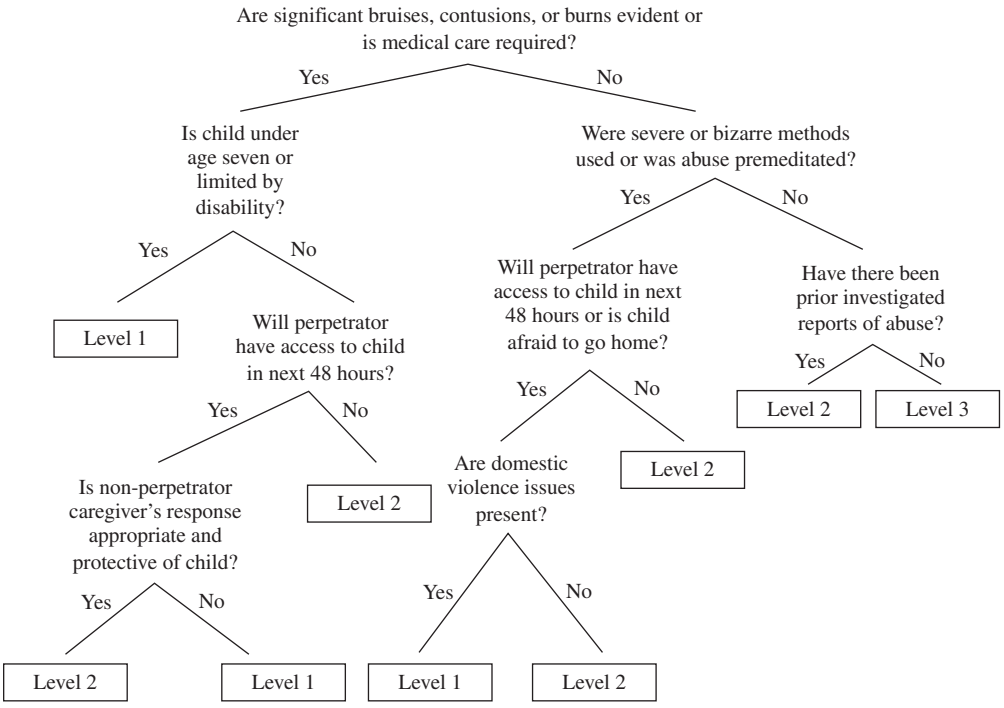
Obtaining valid estimates of the risk represented by each case is obviously critical to social services. To be valid, risk instruments must also be reliable and equitable. As noted earlier, decision making in social service agencies is often related more to who makes the decision than to the characteristics of the case. To enhance consistency, or interrater reliability, a variety of mechanisms, most of which include risk assessment, have been introduced into the decision-making process. In some instances, different measures are combined to guide decisions. For example, sentencing guidelines sometimes consider both risk of reoffending and the severity of the current offense; supervision or service requirements are sometimes established by combining risk and needs assessments in a "service matrix."

In risk assessment, it has been firmly established that a high level of reliability can be attained when risk factors are simple, objective, and well defined. It is also evident that reliability will suffer unless individual risk factors are combined in some fashion to derive a specific risk designation. Two methods for arriving at such a designation are common: a decision tree format (Fig. 3) and an additive index (Table II).

An early study demonstrating why ratings of risk factors must be systematically combined to arrive at a risk classification was conducted by Margaret Blenkner in 1954. Three expert clinical social workers were asked to perform several clinical assessments of 47 clients using information recorded at intake to a private social service agency. After reading each file, making the assessments, and recording them on a data-collection form, each clinician was asked to make a prognosis for future casework success (the cases were closed and outcomes had been established previously by other clinical judges).

In subsequent analysis, five of the assessment measures these clinicians had recorded demonstrated a strong relationship with case outcome, and Blenkner added them together to create a summary score. Although the summary scores demonstrated a very high correlation with case outcomes, the prognoses of the three clinical judges proved unrelated to outcomes and to one another. Meehl observed that

> *Apparently these skilled case readers can rate relatively more specific but still fairly complex factors reliably enough so that an inefficient mathematical formula combining them can predict the criterion; whereas the same judges cannot combine the same data "impressionistically" to yield results above chance.* (p. 108)



Level 1 requires a face-to-face response within 24 hours.
Level 2 requires a face-to-face response within three working days.

Figure 3 Minnesota response priority: physical abuse.

The Blenkner study illustrates why many observers believe clinical judges do poorly in a predictive setting; they differentially select and weigh information about the subject. Despite the fact that the variables in Blenkner's formula had been developed by clinicians and required clinical skill to observe, clinical judges performed very poorly when asked to predict case outcome.

The best measures of interrater reliability are quite simple. First, it is important to determine the rate at which independent raters agree on a risk designation. Next, it is important to adjust "percent agreement" to account for "chance agreement." This is done by applying a statistical measure (usually Cohen's kappa). Although there is no definitive threshold that designates an acceptable level of reliability, kappas <0.3 generally indicate very weak reliability. Although researchers vary on what is considered an adequate kappa (depending on the types of questions posed, the number of potential responses, etc.), a kappa of 0.6 is generally deemed acceptable.

The third measurement issue critical to risk assessment is equity. Equity is a major issue in societies in which minorities are often treated differently by the justice and social service systems. In the United States, for example, there is substantial minority overrepresentation in the juvenile justice, adult corrections, and foster care systems. Inequities in these systems reverberate throughout society, resulting in serious social ills at nearly every level of the social structure. Hence, it is essential that risk assessment systems demonstrate that all groups in a society are treated equitably. To ensure equal treatment, risk assessments must be tested independently on cases of each race/ethnicity. The number of cases assigned to each risk level, as well as observed "failure rates," should be essentially equal for all groups, or it must be clearly evident that differences are due to factors other than race/ethnicity.

Well-designed risk instruments in many social service settings can help control bias and sharply reduce minority overrepresentation. Table III presents child welfare data from Michigan. Essentially, equal proportions of African Americans and Whites are classified to each risk level. The results from Michigan are similar to those from several other jurisdictions in the United States that use actuarial risk instruments. What is clear from data presented here is that proper use of validated risk assessment instruments can result in more equitable decision making and substantially reduce disparity in case disposition.

High	45.1	46.0
Very high	13.7	12.7

Needs Assessment

In addition to determining the level of risk represented by cases entering the social service system, it is equally important to ensure that case needs are appropriately assessed and corresponding service plans are developed and implemented. Needs assessment is often a companion piece to risk assessment that is used to systematically identify critical issues and help workers plan effective

Table IV Family Strengths and Needs Assessment

Case Name: _____ Date: ___/___/_____

Case Number: _____ Referral Date: _____/_____/_____ Initial Reassess #: 1 2 3 4 5

	Score	Scored
1. Substance abuse		
a. No evidence of problem	0	
b. Abuse creates some problems in family OR caregiver in treatment	3

The primary needs of the family are:	Needs level
1. _____	_____ Low (0–10)
2. _____	_____ Medium (11–20)
3. _____	_____ High (21–54)

service interventions. In essence, needs assessment serves the following purposes:

- It ensures that all workers consistently consider each case's strengths and weaknesses in an objective format when assessing need for services.
- It provides an important case planning reference for workers and first-line supervisors that eliminates long, disorganized case narratives and reduces paperwork.
- It provides a basis for monitoring whether appropriate service referrals are made.
- The initial needs assessment, when followed by periodic reassessments, permits case workers and supervisors to easily assess change in case functioning and thus monitor the impact of services on the case.
- It provides management with aggregated information on the issues clients face. These profiles can then be used to develop resources to meet client needs.

Needs assessments can be used at either the individual or the family level, depending on the mission and goals of each social service agency. An example of a family-based needs assessment used in a child welfare agency is presented in Table IV.

Summary

Formalized risk and needs assessments can significantly improve decision making in social services and help agencies target resources to cases that need them most. These assessments increase consistency among workers and help control bias that is evident in systems in which decisions are made by individuals with varying levels of education and experience. They offer a proactive and efficient means for improving service delivery and outcomes.

Sample Design

W. Penn Handwerker
University of Connecticut, Storrs, Connecticut, USA

Glossary

autocorrelation Correlation of case residuals, ordinarily among cases adjacent in time or space.
case A member of a population, the primary sampling unit on which one makes measurements.
confidence interval (limits) Interval identified by specific upper and lower bounds, or limits, that contains the population parameter a specific proportion of the time (e.g., 95%) for the same variable measured for all possible samples of a specific size drawn from a specific population at a specific time.
enumeration (listing) unit Spatially discrete sampling unit that contains sets of cases.
ethnography, ethnographic analysis Identification and description of cultures based on analysis of behavioral and cognitive similarities among cases.
parameter The value of a variable that characterizes a population.
point estimate One's single best guess about a parameter of interest.
population The set of cases to which one generalizes sample findings.
sampling distribution The frequency distribution of all possible statistics of a given kind (e.g., means) calculated from measurements of a specific variable made on all possible samples of a specific size drawn from a specific population at a specific time, the average variability in which is summarized by a number called a standard error rather than a standard deviation.
sampling frame A list of all cases (members of the population) either individually or by enumeration unit.
statistic The value of a variable calculated from sample data that constitutes a point estimate of a parameter.

Sample design refers to the means by which one selects the primary units for data collection and analysis appropriate for a specific research question. These units may consist of states, cities, census enumeration districts, court records, cohorts, or individuals. Irrespective of the kind of unit, data are always collected at specific times and places about a specific set of cases (a sample) that comprises a selected subset of a larger set of cases, times, and places (a population). Answers to research questions thus take the form of inferences from samples to populations. A useful sample design warrants the conclusion that one's inferences are both accurate and appropriately precise.

Research Questions Can Target Variables or Cultures

Decisions about sample design depend on the research question. Some research questions call for answers that come from the analysis of variables:

- What is the percentage of students at Humboldt State University in fall 1987 who believe that we need to preserve wilderness areas?
- Has the degree to which Barbadian couples share child care and household responsibilities changed between 1950 and 1980?
- Does traumatic stress experienced in childhood increase the risk of depression in adulthood?

Other questions call for answers that come from the analysis of cases, or ethnographic analysis:

- Is there a pattern of behavior that constitutes a culture of drug use or a cultural model of what constitutes sexual behavior?

Sampling and Inference for Variables

The set of cases, times, and places from which we sample is a population (or universe). Populations are characterized

by values called parameters. Each question posed earlier identifies a specific parameter and the pertinent population. For example, the population in the first question consists of all students enrolled in Humboldt State University in the school year 1987–1988; the parameter is the percentage who believe we need to preserve wilderness areas. Instead of the number of students enrolled in a university, the population might consist of the people who live in St. Johns, Antigua, or a cohort of women living in Brazil. Instead of a percentage, the parameter might be an incidence rate (e.g., the incidence of child abuse), an average (e.g., the average number of children born to women by age 50), or another univariate statistic. Answers to questions such as these ordinarily come from synchronic observational studies that employ a cross-sectional design. Accurate and precise answers depend on samples of sufficient size that employ random selection criteria.

The population in the second question consists of all the couples living in Barbados between 1950 and 1990; the parameter is a measure of historical differences in the variable "the degree to which Barbadian couples share child care and household responsibilities." Instead of the couples who live in a specific geographical region during a specific historical period, the population might consist of all countries in the world from 1960 to 1990 or court records for the past 12 months. A measure of historical differences remains the parameter of interest, but the variable that may or may not change may be infant mortality or the proportion of drug use charges made against people from ethnic minorities. Answers to questions such as these come from diachronic studies that employ a retrospective or prospective panel or time series design. Accurate and precise answers depend on samples of sufficient size that employ random selection criteria.

The population in the third question consists, potentially, of all people at all times and places; the parameter is a function that maps "traumatic stress experienced in childhood" onto "depression in adulthood." Answers to questions such as these come from a variety of both synchronic and diachronic research designs applied to specific sets of people at specific times and places. Accurate and precise answers depend on samples of sufficient size that employ random selection criteria.

Sampling and Inference for Ethnographic Analysis

The population in the fourth question, like the third, consists potentially of all people at all times and places; the parameter, however, is a construct that summarizes behavioral and cognitive similarities among a set of people. This shift in the meaning of the parameter means that answers to ethnographic questions come from the analysis of autocorrelation among cases.

Cultures consist of recurrent patterns of behavior rationalized by shared domain-specific schemes. They exert effects because the sensory inputs they generate constitute an environment to which people must respond. The effects of cultures come from how people respond to ecological contingencies that influence the consequences of behavior. In short, people construct the cultures in which they participate, and make them evolve, through social interaction. The socially constructed properties of cultures means that any one person who knows about a particular culture participates with other experts in its construction and evolution. Cultures thus inescapably embody spatial and temporal autocorrelation. What one cultural participant does or tells you will correspond closely to what another cultural participant does or tells you. The errors you make in predicting what one cultural participant will do or say will correspond closely to the errors you make predicting what another cultural participant will do or say.

This means that a random sample of people does not constitute a random sample of culture. The culture of an individual consists of configurations of cognition, emotion, and behavior that intersect in multiple ways the cultures of other individuals. Hence, random samples of individuals will yield a random sample of the intersecting configurations of cognition, emotion, and behavior (i.e., the cultures) in a population. However, random samples (defined by case independence) of cultural phenomena (which necessarily contain case dependence) cannot exist: they constitute mutually exclusive alternatives. To identify and describe cultures, ethnographic analysis aims to accurately characterize spatial and temporal autocorrelation. Like answers to the third question, answers to ethnographic questions come from a variety of both synchronic and diachronic research designs applied to specific sets of people at specific times and places. Accurate and precise answers depend on samples designed to actively search for cultural variation that comes from specific forms of variation in life experiences. Sample size depends on the degree of similarity among cases.

Selection Criteria Provide the Ingredients for Sample Designs

Cases can be selected on the basis of one or more of six criteria:

1. Availability
2. Fulfilling a size quota
3. Random (or known probability) selection
4. Case characteristics
5. Presence in specific enumeration units
6. Presence along transects or at specific map coordinates

All samples that utilize random (or known probability) selection are called probability samples. If one does not employ random selection, one produces one of four different forms of nonprobability samples.

Nonprobability Samples

If you select a predetermined number or proportion of cases with specific case characteristics, or from specific enumeration units, transects, or sets of map coordinates, you produce a quota sample. If you select cases on the basis of case characteristics to acquire specific forms of information, you produce a purposive (judgment) sample. If you select cases simply because they will participate in your study, you produce an availability (convenience) sample. If cases become available because one case puts you in contact with another, or other cases, you produce a snowball sample.

Probability Samples

Probability samples are distinguished from nonprobability samples because the former exhibit known sampling distributions that warrant parameter estimation with classical statistical tests (e.g., chi-squared, *t* test, and *F* ratio). By convention, we identify parameters with Greek letters, such as β (beta), α (alpha), ε (epsilon), ρ (rho), and σ (sigma). Samples, in contrast, yield statistics. By convention, we identify statistics with Latin letters and words (e.g., *b*, median, percentage, and mean). Each statistic constitutes a point estimate of a parameter, which is one's single best guess about the value of the parameter.

Statistics constitute point estimates of parameters because samples of populations cannot perfectly replicate the properties of the populations from which they derive. Every sample yields different findings, and every statistic contains three sources of error (construct, measurement, and sampling). Construct error derives from trying to measure a construct that imperfectly fits the culture or cultures found in the population studied. Measurement error derives from imperfections in the means by which a value is assigned to an observation from a set of possible outcomes. To the extent to which significant construct and measurement errors can be ruled out, the difference between a specific statistic and the population parameter constitutes sampling error in that specific sample. Measurements of the same variable made on a large number of samples of the same size drawn from the same population exhibit a characteristic sampling distribution of errors around the parameter. Some statistics underestimate the parameter, whereas others overestimate the parameter.

Sampling errors may reflect chance or bias. Sampling errors that derive from chance exhibit characteristic distributions. Many such sampling distributions (the family of *t* distributions and the normal distribution) are symmetrical and are summarized by a mean of 0 and a standard deviation of 1. The average amount of error in a sampling distribution is called the standard error rather than standard deviation to distinguish sampling distributions from the frequency distributions of the variables studied in social science research.

Although some statistics underestimate the parameter and others overestimate it, when cases are selected independently and have the same probability of inclusion in any one sample, sampling errors come solely from chance. When this condition applies, the sampling distribution of all possible statistics reveals that most statistics come very close to the parameter, and the average amount of sampling error is 0. With statistics that exhibit a normal sampling distribution, for example, 68% of all sample statistics fall within ± 1.00 standard errors of the parameter, and 95% of all sample statistics fall within ± 1.96 standard errors of the parameter.

Small samples contain large amounts of sampling error because randomly selected extreme values exert great effects. Large samples contain small amounts of sampling error and thus estimate parameters very precisely. Sample precision is measured by the size of confidence intervals. Accurate samples yield confidence intervals that contain the parameter a given proportion (usually 95%) of the time. Statistical test findings apply to samples of all sizes because they incorporate into their results the degree of sampling error contained in samples of different sizes. Confidence intervals for small samples are wider than confidence intervals for large samples, but statistics from both large and small samples estimate parameters equally accurately.

This generalization holds only for statistics from samples that are reasonably unbiased. Unbiased samples are those in which all members of the population have an equal chance of selection. The only way to reliably obtain a reasonably unbiased sample is to employ the random selection criterion.

Simple Random Samples

Simple random samples (SRSs) constitute the reference standard against which all other samples are judged. The procedure for selecting a random sample requires two steps. First, make a list of all members of the population. Second, randomly select a specific number of cases from the total list. Random selection may rely on tables of pseudo-random numbers or the algorithms that generate uniform pseudo-random number distributions in statistical analysis software such as SYSTAT. One may sample with or without replacing cases selected for the sample back into the population. Sampling without replacement produces unequal probabilities of case selection, but these are inconsequential except with very small populations. More important, even SRSs overestimate the true

standard error by the factor, $\sqrt{N/(N-n)}$. Application of the finite population multiplier, $\sqrt{(N-n)/N}$, will produce correct standard errors. The importance of this correction increases as the ratio of sample size (n) to population size (N) increases.

Random Systematic Samples

Random systematic samples (RSSs) constitute a variation on SRSs in which random selection of a starting point is substituted for random selection of all cases. For example, to select an RSS of 20% of a population, randomly select a number between 1 and 5, make your first case the one with the randomly selected number, and select every fifth case thereafter. To select an RSS of 5% of a population, randomly select a number between 1 and 20, make your first case the one with the randomly selected number, and select every 20th case thereafter.

Periodicity in a list of population members introduces significant bias into RSSs. In the absence of periodicity, and with a known population size, to determine a sampling interval (k), divide the size of the population (N) by a desired sample size (n). RSSs produce unbiased samples when k is an integer. The bias introduced when k is not an integer is inconsequential with large populations. However, if you know the size of the population, the following procedure always yields unbiased estimates:

1. Randomly select a number (j) between 1 and N.
2. Express the ratio (j/k) as an integer and a remainder (m).
3. When m equals 0, select the case numbered k as your first sample element; when m does not equal 0, select the case numbered m as your first sample element.

Stratified, Cluster, Transect, and Case-Control Samples

All other probability samples incorporate SRSs or RSSs into the selection process. Stratified samples, for example, consist of a series of simple random or random systematic samples of population sectors identified by case characteristics (e.g., age, class, gender, and ethnicity) or combinations of characteristics (e.g., old and young women, and old and young men). Disproportionally stratified samples employ a quota criterion to oversample population sectors that might otherwise be insufficiently represented in the final sample. Cluster samples consist of samples in which cases are selected from SRSs or RSSs of enumeration units that contain sets of cases, such as households, hospitals, city blocks, buildings, files, file drawers, or census enumeration districts. Probability proportional to size samples are cluster samples in which the number of cases selected from specific enumeration units matches a quota proportional to the size of unit relative to the entire population. Transect samples consist of samples in which cases or enumeration units are selected from SRSs or RSSs of units that lie along randomly drawn transects or randomly selected map coordinates. Case-control samples consist of a set of purposefully (judgmentally) identified cases, a small set of which may be selected randomly, plus a set of randomly selected controls. This sampling procedure originated in epidemiology, in which cases are characterized by specific health conditions not experienced by controls. However, the procedure is readily generalizable by defining cases and controls by reference to a binary variable that distinguishes cases with a specific experience from controls without that experience.

How to Create Practical and Useful Sampling Designs

Practical sampling designs balance feasibility, cost, and power. What constitutes a useful sampling design varies with the properties of the parameter to be inferred and the data collection context.

Inferences about Variables

When one's research question calls for an inference about a variable's parameter, differences between parameters, or the parametric relationship between variables, accurate and precise answers depend on samples of sufficient size that employ random selection criteria. However, the primary types of such samples (SRS, RSS, stratified, cluster, transect, and case–control) vary dramatically in their feasibility, cost, and power for the issue at hand. For example, SRSs cannot be drawn in the absence of a complete list of primary sampling units. Such lists commonly do not exist; it may not be possible or cost-efficient to create one. If cases with a specific experience can be distinguished from controls without that experience, a case-control sample may be selected by SRS. Even when SRSs can be drawn, however, it may not be cost-efficient to search out and contact independently selected primary sampling units.

Primary sampling units almost always can be identified either within a spatially bounded region or by enumeration units. When the population occupies a spatially bounded region, samples based on transects or sets of map coordinates are efficient choices. When a comprehensive list of enumeration units can be assembled efficiently, cluster samples of one kind or another become both feasible and relatively cheap. However, both cluster samples and SRSs exhibit large standard errors compared to stratified samples. Stratification thus makes it possible to achieve the same power with smaller sample sizes.

Power refers to one's ability to precisely identify a parameter, to detect differences in a parameter over time or space, or identify the parametric influence of one variable on another, if the effect is real rather than due to chance. Sample design determines the population to which one can validly generalize, but you will waste your time if you don't put in the effort to select a sample large enough to estimate parameters with requisite precisions.

Power varies with the risk of a type I or α error that one is willing to accept, sample size, and the size of the effect that one wants to be able to detect. The probability of making a type II or β error—of not detecting a real relationship between variables—is 1-power. For a fixed sample and effect size, when α is lowered, β simultaneously rises. When one wants to rigorously avoid concluding, for example, that traumatic stress in childhood influences the risk of depression in adulthood when, in fact, it does not, one might set α at 0.01. But, how power goes up and β goes down varies dramatically with the size of the effect.

Figure 1 illustrates the interdependencies between sample size, power, and effect size, when α is 0.01 (assuming the standard errors of SRSs). Figure 2 illustrates the interdependencies between sample size, β, and effect size, when α is 0.01 (assuming the standard errors of SRSs). As sample size increases, the ability to detect a real relationship (power) increases, and the possibility that it will not be detected (β) decreases. However, the way in which power increases and β decreases varies dramatically with the size of the effect. If the real shared variance between variables is approximately 0.06 (a Pearson's r of 0.25), it would be missed approximately half the time even with a sample of 100 cases. If the real shared variance between variables is approximately 0.25 (a Pearson's r of 0.50), it would be missed only approximately 9% of the time with a sample of only 50 cases and 1% of the time with a sample of 75 cases. In contrast, if the real shared variance between variables is approximately 0.76 (a Pearson's r of 0.873), one could expect to miss it only approximately 3% of the time even with a sample of 10 cases and not at all with 15 cases. Decisions about sample size ordinarily seek to be able to detect the smallest important effect 80% of the time or better. Power analyses may be conducted by specialty software or by power routines that come with the major statistical software packages.

A useful balance of feasibility, cost, and power usually comes in the form of a multistage sample design. Table I shows a multistage design appropriate for a study of drug- and sex-related HIV risk behaviors among recent Latino migrants to the United States from Mexico and Central America. The context for such a study illustrates many of the difficulties that sample designs must resolve.

First, the size of the population is unknown, which eliminates the choice of an SRS. Second, it is unknown who among the population engages in drug- or sex-related

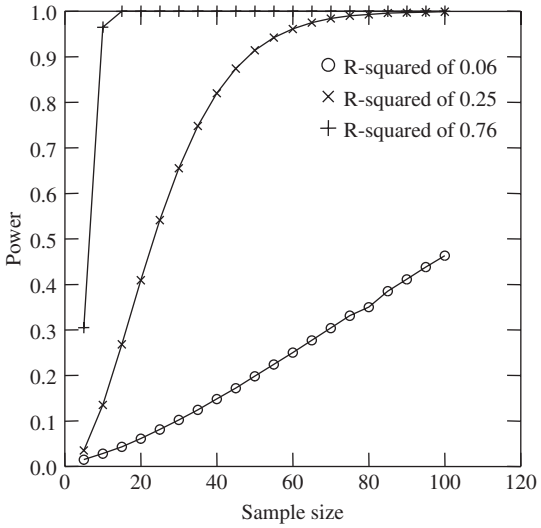

Figure 1 Relationship between power and sample size for effects of different sizes.

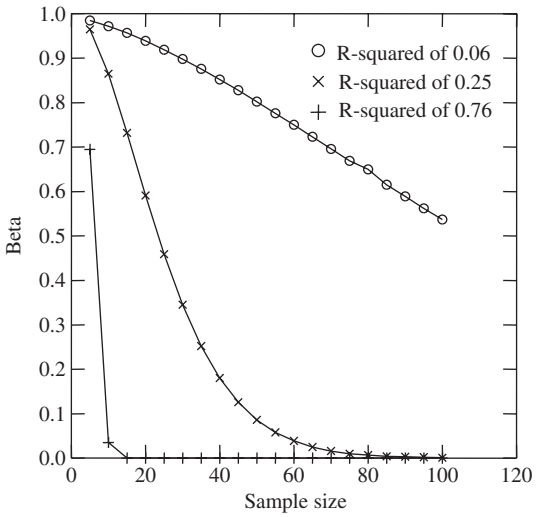

Figure 2 Relationship between beta and sample size for effects of different sizes.

HIV risk behavior, which eliminates the choice of a case-control sample. Third, the region in which migrants live is clearly delimited, but the target population of migrants may comprise a tiny proportion of the total number of people living within the region. Migrants frequently live in locations highly dispersed among the vast majority of the region's population; many may be effectively hidden from conventional enumeration units (e.g., households) because they change residence frequently. When these conditions apply, transect or map coordinate samples would constitute costly sample design choices. Conventional ways of thinking about cluster sampling do not apply.

Table I Multistage Sampling Design for a Cross-Sectional Observational Study of Drug- and Sex-related Risk Behaviors among New Latino Migrants

Stage I: Comprehensive list of enumeration units				
Stage Ib: Stratification of enumeration units				
Stage II: Random systematic sample of each kind of enumeration unit				
Stage IIb: Stratification by ethnicity and gender				
Ethnicity	*Mexican*		*Central American*	
Gender	*Men*	*Women*	*Men*	*Women*
No. of interviews	Contingent on power analysis	Contingent on power analysis	Contingent on power analysis	Contingent on power analysis
Stage III: Random systematic sample of primary sampling units				

Fourth, it remains possible to assemble without undue cost a list of the unconventional enumeration units that would include even those migrants who otherwise remain hidden. These units might include street locations, farms, bars, community agencies, churches, and significant time differences for each. If different types of locations and times attract cases with different characteristics, the comprehensive list of enumeration units may be usefully stratified into different kinds of units based on those characteristics.

Fifth, RSS is easy to apply and does not require a comprehensive list of primary sampling units (cases). When cases are distributed randomly, RSSs exhibit the same standard errors as SRSs. Stratification of enumeration units by case characteristics orders the cases with regard to the variables studied. With ordered cases, RSSs exhibit lower standard errors (greater power) than SRSs. Further stratification on the basis of ethnicity and gender may or may not be cost-efficient relative to the gain in power it would yield. In the absence of stratification, explicit measurement of internal validity confounds implements a posttest-only control group research design that substitutes for random assignment the explicit measurement of internal validity confounds. RSSs from each kind of enumeration unit and RSSs of cases from each randomly selected enumeration unit complete the multistage design.

An appropriate power analysis focuses on the objective of the proposed study to test hypotheses about circumstances that increase or decrease the likelihood of engaging in specific HIV risk behaviors. Given an alpha level of 0.05, a two-tailed test, and the assumptions of SRS, the analysis would indicate the sample size necessary to detect effects of specific independent variables 80% of the time, or the power of tests based on different sample sizes. Table II shows how power would vary for the study in question with variation in sample size, the ratio of the reference and response groups, and varying effect sizes using binary independent variables. A sample size of up to 1204 cases would be required to detect a 50% increase in the likelihood of a given risk behavior (or a 33% reduction in the likelihood of a given risk behavior) if the ratio of reference and response groups was 20/80. However, a 500-case sample would have good to excellent power to detect an odds ratio ≥ 1.76 (or ≤ 0.57) whether the ratio of reference and response groups approximates 60/40 or 80/20. A 600-case sample does not appreciably improve the power of these analyses. An argument that we could both anticipate effects of this size and that smaller effects would not be of clinical or substantive significance at the current time—or not worth the expense of doubling the sample size—warrants a total sample size of approximately 500 cases.

Table II Power for Logistic Regression Tests with Varying Sample Size, Ratio of Reference to Response Group, and Size of Effect (Odds Ratio) with a Binary Independent Variable

Sample split	*Odds ratio*	*Power, N = 400(%)*	*Power, N = 500(%)*	*Power, N = 600(%)*
80/20	2.07 or 0.48	82	89	94
	1.76 or 0.57	62	71	78
	1.50 or 0.67[a]	37	44	50
60/40	2.07 or 0.48	94	97	99
	1.76 or 0.57	78	86	92
	1.50 or 0.67[b]	50	59	67

[a] Sample size necessary to detect an odds ratio of 1.50 or 0.67 at a power of 80% is 204.
[b] Sample size necessary to detect an odds ratio of 1.50 or 0.67 at a power of 80% is 809.

By employing random selection criteria and sample sizes determined by a power analysis, the sample design in Table I allows accurate and reasonably precise estimates of parameters bearing on drug- and sex-related HIV risk behavior for a specific population of Mexican and Central American migrants to the United States. That the total population of cases came to be explicitly known only during the course of case selection and data collection does not bear on the validity of inferences from the sample to the population.

Inferences about Cultures

When a research question calls for an answer in the form of a construct that summarizes behavioral and cognitive similarities among a set of people, accurate and precise answers depend on samples designed to actively search for cultural variation that comes from specific forms of variation in life experiences. When generalizing about cases rather than variables, the meaning of power changes, and sample size depends on the degree of similarity among cases.

For example, in ethnographic analyses, power refers to the reliability and validity of inferences about the content of the behavioral and cognitive similarities among cases (the culture or cultures they share). Important work by Susan Weller has shown that estimates of both the reliability and the validity of those inferences come from the application of the Spearman-Brown prophesy formula to the average level of similarity among cases. If the average level of similarity is 0.50, 9 cases will yield a reliability coefficient of 0.90 and a validity coefficient of 0.95. Only 18 cases will yield a reliability coefficient of 0.95 and a validity coefficient of 0.97. If the average level of agreement is 0.60, only 12 cases are needed for the same level of reliability and validity. As the level of similarity increases to 0.70, 0.80, and 0.90, the number of cases (sample size) declines to 8, 6, and 3 cases, respectively. At an average level of agreement of 0.90, 3 cases yield a reliability coefficient of 0.96 and a validity coefficient of 0.99.

Sample designs for ethnographic analysis thus differ in important respects from sample designs for variable analyses. They do not require large sample sizes, and they do not depend on random selection. Useful sample designs for the study of cultures stratify the population by contrasting life experiences that may produce cultural differences; employ judgmental selection of key informants and critical cases; and select other cases based on their availability, either out of convenience or through a snowball procedure. Sample size for specific strata is set by quota, depending on the average level of agreement. Efficient sample designs track levels of agreement and expand sample sizes and change stratification criteria consistent with levels of agreement and identified cultural boundaries.

The multistage sample design in Table I may be usefully employed for an ethnographic study of the same population and the same topic, with the following important changes in procedure:

1. The list of enumeration units (stage I) may be assembled in the process of conducting informal and semistructured interviews or observations. Indeed, an ethnographic component to a research design allows one to assemble such lists for a later survey with which to make inferences about variable parameters, to assess the importance of stratifying such a list, and to assess and avoid construct errors that might otherwise find their way into a study's measuring instruments.
2. Purposive (judgmental) selection should substitute for RSS selection in stage II.
3. Selection of cases from specific enumeration units in stage III should employ a combination of purpose (judgment), availability (convenience), and snowball criteria, rather than RSS criteria.
4. Selection of cases must include selection of the social relations of those cases.
5. Data collection (i) begins with the purposeful or convenient identification of cases (and their social relations) and (ii) initiates an iterative process that results in the construction of the multiple stages shown in Table I.

Informal and semistructured interviews and observations are designed to actively search for sources of cultural difference. They elicit information on the adequacy of the initial stratification criteria. Identification of people who think and act differently leads to interviews with cases selected on the basis of new stratification criteria. Because people construct cultures and make them evolve, valid, reliable generalization is restricted to the population that exhibits those specific life experiences and to the immediate future. This makes it particularly important for ethnographic studies to explicitly measure potentially pertinent life experience variables.

Different research goals require different stratification criteria. Demeaning remarks directed at and restricted opportunities provided for members of ethnic minorities (e.g., Native Americans) by members of a dominant ethnic majority constitute two forms of traumatic stress experienced in childhood that may exhibit dramatic effects on later behavior. Table III shows a stratified sampling design for a retrospective study of continuity and change in

Table III Stratified Sampling Design for a Retrospective Study

	Age 20 in historical period X											
	1960s				*1980s*				*2000s*			
Gender	Women		Men		Women		Men		Women		Men	
Native (N)–nonnative (nN)	N	nN	N	nN	N	nN	N	nN	N	nN	N	nN
No. of interviews contingent on average level of similarity	4–18	4–18	4–18	4–18	4–18	4–18	4–18	4–18	4–18	4–18	4–18	4–18

Table IV Stratified Sampling Design for a Case–Control Study

	Cases				*Controls*			
Gender	Women		Men		Women		Men	
Age	<20	>20	<20	>20	<20	>20	<20	>20
No. of interviews contingent on average level of similarity	4–18	4–18	4–18	4–18	4–18	4–18	4–18	4–18

the meaning of social interaction between members of majority and minority ethnic groups. People in their 60s in 2000 can tell what they remember about native–nonnative interaction in the 1960s, when they were in their 20s. People in their 40s in 2000 can tell what they remember about native–nonnative interaction in the 1980s, when they were in their 20s. People in their 20s in 2000 can tell what they remember about native–nonnative interaction during that historical period.

Table IV shows a stratified sampling design for a case-control study, a design widely applicable to outcomes evaluation research. Evaluation outcomes research tests the efficacy of interventions designed to induce specific forms of cultural change. Judgments about the efficacy of interventions require information on whether or not and the degree to which people who started with one culture ended with another. Cultural differences between participants (cases) and nonparticipants (controls) that cannot be explained by other potential internal validity confounds, such as gender and age, constitute evidence of a successful intervention.

How to Use Sample Design to Avoid Selection Bias

Selection bias alters the population to which one may validly generalize. It may make it impossible to answer one's research question. Unlike other aspects of sample design, the effects of selection bias do not vary with whether one's research question calls for an analysis of variables or cases (ethnographic analysis).

Nonresponse cases and missing data constitute important and, perhaps, the most common sources of selection bias. The severity of these sources increases as the level of nonresponse and missing data increases. However, solutions to these problems come from how a survey is implemented (including recruitment, training, and oversight of interviewers or observers), and from the design of data collection instruments. Solutions do not come from sample designs.

Sample design contributions to selection bias come from the inclusion or exclusion of important components of the population sampled. For example, health studies that draw on clinic samples miss all the cases who do not attend the clinic in question or, more generally, do not seek care during the study. Studies of entrepreneurship that exclude failed entrepreneurs can validly generalize only to successful examples. A study that seeks to evaluate trends will require a sample design that allows at least three data points, not just "before" and "after."

Final choices on a sample design must be based on careful examination of the possibility that a specific design might exclude an important subset of cases and how that exclusion may affect the findings, one's ability to generalize to one's target population, and even one's ability to answer the original research question.

Sample Size

Chirayath M. Suchindran
University of North Carolina, Chapel Hill, North Carolina, USA

Glossary

censoring When individuals who are followed for a fixed duration of time do not experience the outcome of interest by the time the observation period ends. Such observations are called censored observations. For a right-censored observation, all that is known is that the time to the event occurrence exceeds the period of observation.

effect size The difference detected in the end point in a study; depending on the end point, the effect size may be means, regression coefficients, odds ratios, or hazards ratios.

intraclass correlation Used as a measure of homogeneity among elements of a cluster; can be viewed as the correlation among pairs of observations within a cluster.

Type I error An error that occurs when the experimental situation declares that the specified difference is real, when, in fact, this is not true. The probability of a Type I error is known as the level of significance.

Type II error In experimental studies, failure to detect the specified difference (the second kind of error). The power of a statistical test is then the conditional probability that the null hypothesis is correctly rejected when it is false (complement of the second kind of error).

A well-designed scientific study must determine, at the outset, the sample size; the sample must be large enough to provide an adequate number of observations such that the quantities of interest can be estimated with sufficient precision and that any difference of importance is likely to be detected. These determinations are based on sound statistical principles. The methods for determining the sample size depend on the goals of the study, the types of outcome measures, the planned mechanism of data gathering, and the tolerance in certain error levels. For example, the planned study may be observational or experimental. The planned data gathering may be through a simple random sample of individuals or through other complex sample design. Often, information is collected through complex sample surveys that involve stratification and several stages of clustering, and the quantities of interest may involve ratio and regression estimates. When the sampling scheme involves several levels, the sample size depends on the magnitude of variations at all levels. Intervention studies may involve many baseline measures before intervention starts and several postintervention measurements to determine the effect of intervention. In follow-up studies, it may also be important to adjust the sampling size for missing data, dropouts, and censoring.

Basic Principles

Sampling techniques are used either to estimate statistical quantities with desired precision or to test statistical hypotheses. The first step in the determination of the sample size is to specify the design of the study (simple random samples of the population, stratified samples, cluster sampling, longitudinal measurement, etc.). If the goal is statistical estimation, the endpoint to be estimated and the desired precision would be specified. The desired precision can be stated in terms of standard error or a specified confidence interval. If the goal is to conduct statistical testing, the determination of sample size will involve specifying (1) the statistical test employed in testing the differences in end point, (2) the difference in the end point to be detected, (3) the anticipated level of variability in the end point (either from previous studies or from theoretical models), and (4) the desired error levels (Type I and Type II errors). The value of increased information in the sample is taken into consideration in the context of the cost of obtaining it. Guidelines are often needed for specifications of effect size and associated

variability. One strategy is to take into account as much available prior information as possible. Alternatively, a sample size is selected in advance and the information (say, power or effect size) that is likely to be obtained with that sample size is examined. Large-scale surveys often aim to gather many items of information. If a desired degree of precision is prescribed for each item, calculations may lead to a number of different estimates for the sample size. These are usually compromised within the cost constraint. Sample size determinations under several sampling designs or experimental situations are presented in the following sections.

Simple Random Sampling

A simple random sample (SRS) is the simplest form of probability sample. As stated earlier, the goal of the study may be to estimate a quantity with a desired precision (defined as the variance or the deviance from the population mean) or to test a hypothesis about the mean. Each of the situations can be formally examined under the SRS scheme as follows. Assume that there is population of finite size N from which it is desired to draw a sample of size n. In the first scenario, the goal is to estimate the mean of a quantity with a desired variance V^2. An appropriate value of n can be determined by examining the theoretical value of the variance of the sample mean with the desired variance. From sampling theory, it is known that the sample mean $\bar{y}$, under simple random sampling without replacement has a variance $[(1-n/N)/n]S^2$, where S^2 is the element variance in the population. Equating the desired variance V^2 to the theoretical value, the desired sample size can be obtained as $n = n'/(1+n'/N)$, where $n' = S^2/V^2$. If the finite population correction can be ignored, the sample size will be exactly the ratio of the element variance to the desired variance. In another scenario, the precision is expressed differently in terms of margin of errors. The margin of error specification states the closeness of the sample mean to the population mean. Let μ denote the population mean; the aim is to estimate μ with a sample mean within a specified deviance. The specification is made as $P(|\bar{y}-\mu| \leq \varepsilon) = 1-\alpha$. In this specification, ε is the margin of error and α is the level of significance. Using the results on confidence intervals for sample means obtains an equation connecting the margin of error and sample size as follows:

$$\varepsilon = Z_{\alpha/2}\sqrt{1-n/N}\left(S/\sqrt{n}\right), \tag{1}$$

where $Z_{\alpha/2}$ represents the $(1-\alpha/2)$th percentile of the standard normal distribution. Writing $n' = Z^2_{\alpha/2}(S^2/\varepsilon^2)$, it can be seen from Eq. (1) that, in the case of sampling with replacement, the required sampling size will be n'. When sampling is done without replacement, the solution of Eq. (1) gives the required sampling size as $n = n'/(1+n'/N)$. In these examples, sample size calculations are specified as an estimation of the mean of the population with a specified error. In a third scenario, it is possible to specify the estimation of sampling size as a formulation of one sample test of a mean for which the null hypothesis is $\mu+\mu_0$ and the alternative hypothesis is $\mu+\mu_1$. With an assumed level of significance of α and power $1-\beta$, the required sample size can be obtained under the assumption of normality as follows:

$$n = \frac{(Z_{\alpha/2}+Z_{\beta})^2}{(\mu_1-\mu_0)^2}S^2. \tag{2}$$

The various formulations of sample size calculations show the need to have some prior knowledge of the effect size $(\mu_1-\mu_0)$ and variability S^2 in carrying out the calculations. A number of suggestions have been made in the literature as to how to make reasonable guesses of these values. These include searching past studies that include similar variables or conducting pilot studies. Pilot studies that are too small are less dependable than expert guesses. A reasonable guess can be made concerning the variability in terms of the coefficient of variation. The formulas for sample size calculations can then be expressed in terms of coefficients of variation to obtain the required sample sizes. When the quantity to be estimated is a proportion (P), variance based on a binomial model can be utilized. The term $P(1-P)$ is not sensitive to changes in the middle range of P $(0.2-0.8)$, and generally, a reasonable guess of the value of P can be made.

Stratified Sampling

Stratification (or blocking) of the study population is often performed prior to sampling in order to increase the precision of the estimate of the quantity of interest. A procedure similar to the simple random sampling case requires knowledge of the variability within each stratum. Such information is seldom available. The concept of "design effect" has been introduced to simplify the calculations. The design effect (denoted as deff) is defined as the ratio of the variance of an estimate under a sampling plan to the variance of the same estimate from a simple random sample with same number of observation units. The sampling plan could be a stratified sampling or other complex sample designs. The design effect is a measure of the precision gained or lost by use of the more complex design instead of a simple random sample. If the design effect can be guessed, it is necessary to estimate the sample size using a simple random sample, as shown in the previous section, and multiply this sample

size by deff to obtain the sample size needed under the complex design. Thus, in order to estimate the population mean of a continuous variable with margin of error specified and use of stratified sampling, the required sample size n is obtained using a modification of Eq. (1) (ignoring finite population correction):

$$n = Z^2_{\alpha/2}\left(\frac{S^2}{\varepsilon^2}\right) \times \text{deff}. \quad (3)$$

The value of the design effect can be obtained from previous surveys or through pilot studies. Once the overall sampling size is determined, the allocation of the samples to strata must be considered. Two methods are generally proposed in the literature. In proportional allocation, the sampling units are allocated in proportion to the size of the stratum. When the variances of observations within strata are more or less equal across strata, proportional allocation is the best allocation for increasing precision. When the variances vary greatly across strata, an optimum allocation procedure is suggested. When the costs of sampling in each stratum are the same, the sample allocation in a stratum h is proportional to the product $N_h S_h$, where N_h is the size of the strata and S_h is the standard deviation of observations within the strata (Neyman allocation). One difficulty with the optimal allocation is that the correct information on the variability within the strata is rarely obtained.

In experimental situations in which the goal is to compare a treatment group with a control group, the allocation of the samples in each group can be simplified. Denote the mean and the variance of the first (treatment group) as μ_1 and σ_1^2 and the mean and the variance of the second group as μ_2 and σ_2^2. Also assume that the allocation sample to each group is made in a way such that $n_2/n_1 = r$. Note that in this case, the allocation to two groups is predetermined. Then the required sample size can be calculated as follows:

$$n_1 = \frac{(\sigma_1^2 + \sigma_2^2/r)(Z_{\alpha/2} + Z_\beta)^2}{(\mu_1 - \mu_2)^2} \quad \text{and} \quad n_2 = rn_1, \quad (4)$$

where α is the desired level of significance and $1 - \beta$ is the power.

Cluster Sampling

Many surveys often employ cluster sampling, whereby sampling units are clusters of elements. In a one-stage cluster sampling, every element within a sampled cluster is included in the sample. In two-stage cluster sampling, a subsampling is done to select elements from the chosen clusters. Elements within a cluster may be very similar. A measure of similarity (or homogeneity) of elements within the cluster is provided by the intraclass correlation coefficient (ICC), which is defined to be the Pearson correlation coefficient of all pairs of observations within the cluster taken over all clusters. The ICC plays an important role in the calculation of sample size. For example, in a single-stage cluster sampling, when all clusters are of equal size, the design effect can be approximated as $1 + (M - 1) \times \text{ICC}$, where M is the size of the cluster. In this case, the number of clusters to be selected is calculated in two stages. First, determine the sample size as if the sampling is done under simple random sampling. Then multiply that sample size by the design effect. Once again, the ICC must be known to complete the calculations, but ICC is seldom known and has to be estimated through pilot studies or derived from the values obtained in similar surveys.

Many intervention studies use group-randomized design to examine the effect of an intervention. For example, school-based studies are often used in drug-use prevention studies. In these studies, schools are randomized to treatment and control groups. The question then arises as to how many schools must be selected for each group. In these trials, a school is considered as a cluster and the intraclass correlation is used as a measure of dependence among students within the school. If the goal is to test the difference in the means of a continuous outcome at a significance level α with a desired power $1 - \beta$, the number of schools (n) to be allocated for each group will be

$$n = \frac{(Z_{\alpha/2} + Z_\beta)^2 2S^2[1 + (M - 1) \times \text{ICC}]}{M\Delta^2}, \quad (5)$$

where M is the size of the school, Δ is the hypothesized difference in mean of the treatment and control schools, and S^2 is the total element variance (which includes both within- and between-persons components of variance). In most situations, the cluster (school) size will not be equal. In such situations, the size M is replaced by an average of cluster sizes (usually a harmonic mean of the cluster sizes).

Repeated Measures Design

Experimental studies often involve repeated measurements of outcome measures. For example, for comparison of an intervention group with a control group, intervention studies make baseline measurements of outcome before the intervention and then repeat the measurements one or more times after implementation of the intervention. The sample size requirements depend on the type of hypothesis to be tested, the number of pre- and postintervention measurements, and the level of correlations among observations from the same individual. Under this scenario, sample size formulas

have been developed for three possible methods of analysis—namely, (1) a simple analysis using the mean of each individual's postintervention measures as the summary measure, (2) a simple analysis of each individual's difference between means of postintervention and preintervention measurements, and (3) using the preintervention measurements as a covariate in a linear model for comparing the intervention comparison of postintervention means.

Repeated measures data are considered as correlated observations and the generalized estimating equation (GEE) method is employed in analyzing such data. Several authors have discussed estimation of sample size when the GEE method is involved as a tool of analysis; one study provides an approach to estimate sample size for two-group repeated measures when the correlation structure among the repeated measures is unknown.

Follow-up Studies

Follow-up studies usually begin with assigning individuals to an intervention or control group; the individuals are then followed for a fixed period or until the event of interest occurs. The objective of this study design is to detect a change in the rate of occurrence of the event (hazard) in the intervention group in relation to that of the control group. In this study situation, it is possible that some individual observations will be censored; this means that some individuals may not experience the outcome of interest by the time the study is terminated. For censored observations, all that is known is that the time to the event exceeds the duration of observation. The desired sampling size is the minimum number of individuals required to detect a specified change in the hazards ratio. A simple formula has been developed to calculate the required sample size. Let P_I and P_C denote the proportion of individuals assigned, respectively, to the intervention and control group. Let the ratio of the hazard function of individuals in the intervention group to that of the control group be a constant denoted by Δ. Then the total number of individuals required for the study can be expressed as follows:

$$n = \frac{1}{d}\,\frac{(Z_\beta + Z_{1-\alpha})^2}{P_I P_C \log^2 \Delta},$$

where d is the proportion of individuals expected to experience the event of interest. As before, $Z_{1-\alpha}$ and Z_β denote $1-\alpha$ and β percentiles of the normal distribution. The determination of d requires some additional information. Let f denote the planned follow-up time. Often, there is some prior information available about the rate of event occurrence in the control group. Suppose that $S_C(f)$ denotes the probability that an individual in the control group does not experience the event by time f. Then the proportion of individuals in control group experiencing the event by the follow-up time f is $d_C = 1 - S_C(f)$. Thus, under the postulated hazards ratio Δ, the proportion of individuals expected to experience the event in the intervention group is $d_I = 1 - (1 - d_C)^{1/\Delta}$. Then $d = P_C d_C + P_I d_I$.

Epidemiologic Study Designs

Epidemiological studies often use study designs that require special formulas for sample size determinations. For example, in a case-control study, a sample of people with an end point of interest (cases) is compared to a sample without and end point of interest (controls). In this case, the sampling is performed with stratification according to the end point, which is different from the usual stratified sampling. A case-control design will lead to the calculation of an odds ratio as an approximate relative risk, and the sample sizes are determined using an odds ratio as the index of interest. To prevent confounding effects, matched case-control studies (in which the cases and controls are matched at a level of a potentially confounding factor) are sometimes used. Sample size calculations for such designs have been described. Other epidemiologic designs that require special formulas for sample size calculations include nested case-control studies and case-cohort designs.

Covariate Adjustments

Frequently, studies will have end points with regression adjustments for one or more covariates. Many of the sample size calculation formulas can be easily modified to take this situation into account. For example, consider a simple logistic regression situation for which the goal is to examine the relationships of a covariate with a binary response. The model setup is $\log[p/(1-p)] = \beta_0 + \beta_1 x$, where x is a covariate. The sample size determination is made to test the null hypothesis $\beta_1 = 0$. When x is a continuous covariate, the required sample size can be obtained as follows:

$$n = \frac{(Z_{\alpha/2} + Z_\beta)^2}{P^*(1-P^*)\beta^{*2}},$$

where P^* is the event rate at the mean of the covariate x and β^* is the effect size to be tested. Simple modifications are needed when the covariate is binary or when additional covariates are included.

Conclusion

Sample size determination is an integral part of any well-designed scientific study. The procedure to determine sample size depends on the proposed design characteristics including the nature of the outcome of interest in the study. There exists a vast amount of literature on the topic, including several books. The modern computer environment also facilitates determination of sample size; software designed exclusively for this purpose is available. Many of the procedures depend on the normality assumption of the statistic. Modern computer-intensive statistical methods give some alternative procedures that do not depend on the normality assumption. For example, many people working in this field of study now prefer to use bootstrap procedures to derive the sample size. Uncertainty in specifying prior information of effect size has led to Bayesian approaches to sample size determination. These computer-intensive procedures seem to have several advantages over many of the conventional procedures of estimating sampling size.

Glossary

anchoring When a respondent forms a frame of reference around some division point in a scale or index because of some strong opinion or perception of research purpose.
calibration The process of achieving precision and accuracy by breaking a complex phenomena down into coherent parts for measurement purposes.
cross-validation A test or series of pretests run on a scale or index to account for validity shrinkage and more accurate accounts of validity and reliability.
dimension (or domain) The important part of personality, behavior, feeling, opinion, attitude, or judgment that concerns the researcher and stands alone as a unitary portion of the whole. The standardization of the characteristic must be established to allow for the measurement of the value of the characteristic to be measured. For example, for numerical values it is units of measurement used for expressing this particular numerical value. For texts, it is the language of the text.
index A numerical scale used to compare variables with one another or with some reference number.
norming The reporting of expected scores among population subgroups by standardizing raw scores to reflect fairly normal distributions.
scale A cluster of items that taps into measurements developed on face validity and/or professional judgment of measuring what one intends to measure. The intent is to measure the relative degree, amount, or differences between variables.
triangulation Combining research methods to give a range of perspectives. It is often beneficial when designing an evaluation to incorporate aspects of both qualitative and quantitative research designs.

Scales and indexes (indices) are used by researchers when the objects of study are complex, usually social, phenomena, such as love or prejudice, or income, education, crime, or attendance. However, there is no reason to restrict the use of scales and indexes to feelings since personality traits, behavior, opinion, attitude, judgment, and many other concepts or variables in science lend themselves to measurement by scales and indexes. Many, if not most, researchers prefer not to make major distinctions between scales and indexes and to use the terms interchangeably. This article, however, emphasizes distinctions that can be made by reviewing the role of calibration in measurement, what scales and indexes look like, their usage and purposes, and current trends in social measurement.

Calibration in Measurement

Scales and indexes (indices), in addition to most kinds of summary measures or assessment instruments in the research process, are basically types of tests that consist of items in question format or those calling for a subjective judgment. Like all tests, they are intended to be scored, but there is a major difference between scaling and scoring a test. When a test is scored, the result is usually a number, such as 94 out of 100, and it is used primarily for ranking those who scored a 94 with those who scored lower or higher. When a test is scaled, the result is also usually a number, such as 5.562, but the scale score indicates how consistent or coherent the underlying

phenomenon of interest is measured for the person taking the test. The same is true for indexes, which often involve a collection of scale scores, because the related items in indexes, like scales, are designed to report on the unidimensional characteristics of an abstract, multidimensional concept. For example, a scale may be used to measure all the extroversion characteristics of personality, and an index may be used to measure crime by asking about involvement in property crime, violent crime, and vice crime, where these types of crime make up three unidimensional characteristics of the composite, multidimensional concept called crime.

Therefore, scales and indexes not only play a key role in the measurement part of the research process but also reflect on the conceptualization and operationalization stages. For measurement purposes, scales and indexes provide the benefit of calibration, a relatively easy way to achieve precision and accuracy, since complex aspects of a phenomenon are broken down into fairly discrete units. However, not all social phenomena lend themselves easily to calibration, and the researcher is often bound by how variables have been conceptualized (defined) and operationalized (to be measured). Some slack is always present between the construct (the way something is imagined or theorized to happen) and the concept (the way other researchers suggest something happens), and it is possible for unknown error, known error, and researcher bias to enter into the measurement process. Calibration in measurement provides an excellent way of safeguarding against these risks, but it must be done intelligently and thoughtfully, especially for the dependent variable, outcome, or effect since it is the complexity of social behavior that is to be explained. Because the construction of scales and indexes often relies on the intelligence and thoughtfulness of the researcher, they are frequently criticized, but it is up to the researcher to be rigorous and consistent in coding and scoring.

As part of a theory-driven research process, scales and indexes as methods of calibration provide an excellent way for researchers to bind the horizontal logic (the presumed flow of cause and effect) of their research design with the vertical logic (how accurately theory is reflected) of their research design. This is accomplished by the researcher thinking about the dimensionality of variables, and it involves establishing the level of data involved or testing for validity and reliability. Scales and indexes, like calibration in general, frequently capture the dimensionality of variables, reduce the complexity of phenomena, summarize scores in meaningful ways, and simplify data analysis. Hence, a danger or disadvantage to the use of scales and indexes is that they may oversimplify or overquantify phenomena, particularly complex human or social phenomena that a critic might argue does not lend itself well to measurement on a 5- or 7-point scale.

Overview of Scales and Indexes

The appearance of scales and indexes ranges from very simple graphic representations (e.g., of a thermometer) to designed questionnaire formats and fairly complicated grids of lines, circles, or objects for which responses are called for by making marks on those lines, circles, or objects. All scales have in common the measurement of a variable in such a way that it can be expressed on a continuum. Indexes are similarly constructed, except that multiple indicators of a variable or various aspects of a concept are combined into a single measure. Although both scales and indexes are composite measures, it may be useful to make further distinctions between scales and indexes for overview purposes.

A scale is an attempt to increase the complexity of the level of measurement of variables from nominal to at least ordinal, and possibly interval or ratio. Scales can be utilized to provide a more complex composite and/or indicator of phenomena (variables) to be compared. Aptitude, attitude, interest, performance, and personality tests are all measuring instruments based on scales. A scale is always unidimensional, which means that it usually has construct and content validity. A scale is always at the ordinal or interval level. Scales are predictive of outcomes (e.g., behavior, attitudes, or feelings) because they measure underlying traits (e.g., introversion, patience, or verbal ability). Scaling is the branch of measurement that involves the construction of an instrument that associates qualitative constructs with quantitative metric units. Scaling evolved out of efforts in psychology and education to measure "unmeasurable" constructs such as authoritarianism and self-esteem. Scaling attempts to do one of the most difficult of research tasks—measure abstract concepts. Scales are primarily used to predict effects, as Table I illustrates.

A great many scales can be found in the literature or in handbooks, and new researchers are well advised to borrow or use an established scale before attempting to create one of their own. However, a few researchers who develop scales are interested in improving current scales and utilizing technology to refine current variable measurements. Scales allow the level of measurement that permits an intensity, potency, or "pulling together" of a measurement of variables through the utilization of

Table I Example of Scale Items Measuring Introversion

I prefer small gatherings to large gatherings.
When the phone rings, I usually let it ring at least a couple of times.

numerous responses or indicators to measure what researchers purport to "measure." It is this intensity, potency, or coming together of behavior, attitudes, and feelings that the researcher calls a "trait," something inside the person that, it is hoped, is captured in scale construction. Clearly, scaling is about quantifying the mysterious mental world of subjective experience (the immeasurable) as it impacts on empirically observed phenomena (the measurable).

An index is a statistical indicator (data or variable that provides information or allows predictions) that provides a representative value of a dimension or domain of sets such as behavior, attitudes, or feelings by measuring or "indexing" these into a single indicator or score. Indices often serve as barometers for a given variable or interest and benchmarks (standards or comparisons) against which performance (attitude, aptitudes, interests, personality, etc.) is measured.

It is possible to use statistical techniques (e.g., factor analysis) to give a more robust construct validity (or factor weights), but it is difficult to employ indexes as multidimensional measures with the theory that statistics can help determine all the unidimensional characteristics of a multidimensional phenomenon.

Indexes are usually at the ordinal level of measurement; that is, they are rank ordered and directional. An index collecting data at the nominal level of measurement is called a typology (i.e., a simple classification of traits). Indexes can be predictive of outcomes (again, using statistical techniques such as regression), but they are designed mainly for exploring the relevant causes or underlying and measurable symptoms of traits (e.g., criminality, psychopathy, or alcoholism). Indexes primarily identify causes or symptoms, as Table II illustrates.

In sociological and criminological research, indexes are usually administered in the form of surveys or questionnaires and are typically found in the appendixes of published research articles. They also comprise a significant proportion of theses and dissertations. It is sometimes the case that a researcher does not know that he or she has developed an index until after publication of his or her research and subsequent adoption of portions of his or her questionnaire or survey as a commonly used index by other researchers, who often refer to it as a scale because they use the terms scale and index interchangeably.

Table II Example of Index Items Measuring Delinquency

I have defied a teacher's authority to his/her face.
I have purposely damaged or destroyed public property.
I often skip school without a legitimate excuse.
I have stolen things worth less than $50.
I have stolen things worth more than $50.
I use tobacco.
I like to fight.
I like to gamble.
I drink beer, wine, or other alcohol.
I use illicit drugs.

However, an index is quite different from a scale. An index typically involves the measurement of many more dimensions than a scale, and sometimes an index summarizes the combined scores for more than one phenomenon. Unlike scales, an index is not concerned with the intensity or "coming together" of attributes that make up a concept or variable. Rather, an index produces a more reliable indicator of a concept or variable by accumulating a number of responses or scores on attributes that, when taken together, conveniently grasp all the known possibilities in a cause-and-effect relationship. Consider Table II, in which there are items measuring defiance to authority, disrespect toward property, a dislike of rules, an inclination toward minor stealing, and an inclination toward major stealing, among other possibilities. Each of these could have separate motives or causes, and it is certainly possible for a delinquent to engage in defiance and disrespect without engaging in stealing, but it is the job of an index to exhaust the relevant possibilities. Scales can be more discriminating because one can easily devise a scale for defiance, another scale for disrespect, and so forth. As a general rule, if one has combined three or more (implicit or explicit) scales to measure different dimensions of the same concept, then one has constructed an index, if it appears that all the relevant possibilities are exhausted. Most researchers, however, prefer to say they are using scales since scales are regarded as superior to indexes because they convey more precise information about an individual concept or variable than do index scores.

Testing for Validity and Reliability

Scales and indexes are attractive to researchers because they usually have published calculations of validity and reliability. Whenever one uses a previously published scale or index, it is common to report these original calculations along with any current calculations in the present study. Part of the attraction may be due to the fact that almost all scales and indexes are checked or validated in a pretest situation. These procedures basically involve item analysis, and they are followed by further checks for validity and reliability of the whole instrument. A researcher should begin by applying some of the best practices of good questionnaire design toward the item and response patterns on pretest results. Do the items (questions) fit together in the most productive way, or do they overlap? Do the response patterns (answers) hint at ways to improve the measuring instrument? Table III presents a sample questionnaire item to demonstrate

Table III Sample Complex Questionnaire Item

12. On October 31, 1998, Sam robbed a bank while wearing a Halloween mask and carrying a gun. While speeding from the crime scene, Sam lost control of his Jeep Cherokee and ran into a telephone pole. When the police, who had previously received a bulletin about the bank robbery, arrived at the accident scene and saw the Halloween mask and bag of money in Sam's car, they immediately placed him under arrest for bank robbery, frisked him, and then asked him; "Where's the gun?" Sam replied that the gun was in his glove compartment. As police took him to police headquarters, Sam asked; "How many years am I going to have to do for the bank robbery?" Sam's lawyer has moved to suppress both statements because Miranda warnings were not given. Assuming that Sam's statements are suppressed, but would ordinarily have guaranteed him 15 years in prison with the statements included, what do you think his sentence should be?
    A. 0–2 years
    B. 3–6 years
    C. 7–10 years
    D. 11–14 years

Table IV Formula for Item Analysis

Difficulty index

$$\frac{\text{No. of people in best group who got item right} + \text{No. of people in worst group who got item right}}{\text{Total number of people in both groups}}$$

Discrimination index

$$\frac{\text{No. of people in best group who got item right} - \text{No. of people in worst group who got item right}}{(0.5)\ \text{Total number of people in both groups}}$$

how item analysis would be conducted on a single question.

First, the principles of good questionnaire design do not seem to have been followed with this example because the sentence stem in the question was not short, clearly stated, or well written. However, it is the kind of question one would find on an achievement test or exam in an academic environment, and this is the kind of question for which item analysis was designed. Note that there is an attempt to make all the responses equidistant from one another. It does not matter if the responses are A, B, C, D, 1, 2, 3, 4, or 0–2, 3–6, 7–10, 11–14, as long as the response choices are fairly equidistant and mutually exclusive. On an academic achievement test, care would be taken to ensure that there is only one correct answer and that distracters are kept to a minimum so that no more than 2% of respondents in the pretest situation are confused by any distracter. This 2% rule applies to responses for any one question and to all the questions that make up the scale or index. In other words, if more than 2% of respondents are thrown off from the pattern that most respondents follow, then one would question the content validity of the scale or index. Content validity, like face validity, is severely affected by researcher bias, and unless the test is being used in an academic achievement environment in which the instructor is certain about correct answers, the researcher investigating more complex social phenomena should be prepared to consider the item response patterns of respondents for validity purposes.

Coefficients of Difficulty and Discrimination

Item analysis of distracter patterns is usually followed by calculation of the difficulty level and the discrimination index. To calculate these, one must sort all the completed pretests in some rank order, such as from best to worse responses, in the judgment of the researcher. Then, one takes the top 27% of the best and the bottom 27% of the worst and works out the formulas shown in Table IV. The procedure is very similar to the Kuder–Richardson, or KR-20, coefficient, which is a type of split-half reliability.

The difficulty index will derive a number from 0.00 to 0.99; ideally, one hopes to obtain a number in the moderately difficult range (0.50–0.70). The discrimination index will derive a number from −1.00 to 1.00; ideally, one hopes to obtain a number in the twenties (0.20–0.29). Anything higher means that the researcher may be favoring what he or she regards as the best respondents. A zero, near-zero, or below zero score means that the researcher is rewarding chance, or guessing, since four responses equate to a 25% equal probability of getting an answer correct; the 27% best–worst dichotomy with this formula controls for this. There are tradeoffs between difficulty and discrimination, and the general rule is that as difficulty increases, discrimination approaches zero.

Calculating the difficulty and discrimination indexes provides some assurance that the researcher is not being arbitrary or biased. This is especially important if

and when the researcher decides to attach meaning or significance to the scale items in some sort of coding scheme, such as stating that those who chose longer punishments are more punishment oriented than those who chose shorter punishments. Otherwise, the researcher is left with a fairly empty claim that face validity depends solely on his or her arbitrary judgment.

Statistical Tests for Validity and Reliability

Establishing more advanced types of validity, such as construct, concurrent, and convergent validity, requires the researcher to take additional steps, often statistical. Construct validity refers to the degree to which inferences can be made from the operationalizations in the study to the theoretical constructs on which those operationalizations were based (what the researcher thinks can actually be measured). Concurrent validity is a method of determining validity as the correlation of the test with known valid measures. Validity may be assessed by the extent to which a test yields the same results as those of other measures of the same phenomenon. Construct validity is the extent to which the scores of an assessment instrument relate to other performances of the subjects according to some theory or hypothesis—that is, the extent to which a test measures "only" what it is intended to measure. The standard approach for construct validity is to examine the different subgroups of respondents and determine if there are any chi-square differences in the response patterns that might suggest that, externally, there are other indicators not included in the scale or index. Alternatively, researchers could argue that their multiple measures tap into all known domains or a dimension(s) of a concept by using discriminant function, factor, or cluster analysis, but these advanced statistical techniques are usually reserved for attempts to establish the predictive properties of the scale or index, which is the purpose of concurrent and convergent validity. The ability to forecast future events or behavior from a scale or index is certainly not guaranteed by statistical methods of calculating validity, and researchers would be well advised to supplement, or triangulate, their research design by including interviews, case record checks, or observational follow-ups on at least a subsample of respondents.

Reliability is typically calculated by manipulating the measuring instrument. Three primary techniques to demonstrate reliability are test–retest (administering the instrument again to the same group), multiple forms (disguising administration of the instrument to the same group), and the split-half technique (administering only half the instrument to a group at any one time). In using these methods, the researcher is not searching for the exact same pattern of responses but ones that are similar, stable, and consistent. Statistical methods such as the Kuder–Richardson coefficient and Cronbach's alpha calculate reliability; again, however, researchers would be well advised to not rely on statistics but to consider such threats to reliability as setting, history, interaction, and reactivity. Setting and history threats to reliability may occur because the scale or index was developed at a time when people were acutely conscious or aware of some social problem, and interaction and reactivity effects may cloud the stability and consistency of respondents' choices simply because they believe they are being studied. Some of the latter threats can be thwarted by incorporating lie scales or social desirability scales into the instrument, but it is more important for researchers to remember that it is not so much a matter of proving validity and reliability as it is a matter of reducing threats to validity and reliability.

Usage of the Most Common Types of Scales

Scales are typically either comparative or noncomparative. Comparative scales include the following techniques: paired comparisons, rank-order comparisons, constant sum scaling, Bogardus social distance scales, the Q-sort, and Guttman scales. Noncomparative scales include the techniques of continuous rating, Likert scales, the semantic differential, Stapel scaling, Thurstone scales, and multidimensional scaling. Other types of scales exist that defy categorization and rely on graphic representations, such as rulers, clocks, thermometers, or grids. It is probably best to begin with a discussion of comparative scales since it is most likely the case that no matter whether respondents are explicitly asked to compare something or not, they will undoubtedly do so because they are bound by their cognitive frames of reference, which often include comparisons between objects.

Comparative Scales

A paired comparison scale presents the respondent with two choices and calls for a preference. For example, the respondent is asked which color he or she likes better, red or blue, and a similar process is repeated throughout the scale items. Note that there are no scale properties within each item; that is, respondents are not provided with any scale other than the extreme choices they must make (e.g., red or blue) on each item. All the questions on such an instrument make up the scale. Scoring is accomplished by following the researcher's coding key for what each choice means. Although this technique appears to collect

nominal-level data, the scale score is considered to be at the ordinal level of measurement.

A second type of comparison scale involves rank-order comparison, which presents the respondent with a number of items, cues, or objects and asks him or her to rank them in order from first to last, from 1 to 10, or along some other rating category. For example, respondents may be asked to rate excerpts from political speeches and assign them a rank order from most conservative to most liberal. Each respondent's rankings are then tabulated to assign scale scores to different patterns of variation, which are normally treated as ordinal-level data.

A third type of comparison scale involves giving the respondents an imaginary constant sum or fixed amount of something, such as $100,000 to start a business, and then asks them to allocate this fixed amount among budget items such as salaries, benefits, equipment, and raw materials. To this might be added an item asking them what they would spend an additional several hundred thousand dollars on from a fixed list of items to purchase. The idea is to scale the respondent's choices each time, producing a number of subscales and, overall, producing a composite scale, in reference to a constant sum that may or may not be exactly the same for each question. This technique is generally considered to involve an ordinal level of measurement.

Bogardus social distance scales are named after Emory Stephen Bogardus (1882–1973), a sociologist who made contributions to the study of prejudice. A social distance scale measures degrees of tolerance or prejudice between social groups. For example, respondents would be asked if they want to allow certain foreigners to have citizenship, if they would want to live next door to certain foreigners, if they would want to be coworkers with certain foreigners, if they would want to be close friends with certain foreigners, and if they would want to be related by kinship in marriage to certain foreigners. Social distance scales are assumed to be cumulative (i.e., to have certain Guttman scale properties) and have the longest usage of any scales in sociology.

Q-sort scales are generally used for measuring the dimensions of complex attitudes, and there is a presumption that the technique measures true feelings. In addition, it is normally a fun instrument that rarely produces negative reactions in respondents. Q-sort is a comparative technique that requires respondents to sort various cues or items written on cards into a predetermined number of piles. The piles represent categories that range, for example, from most like their own attitude to least like their own attitude, and they comprise the scale. The cue cards typically contain short descriptors or adjectives, such as outgoing, happy, or sad, and it is customary not to exceed 140 items for respondents to sort. Q-sort scales can have as few as three piles, reflecting perceptions, for example, of the lower, middle, and upper class, or they can be complicated grids with a large number of rows and columns. Respondents are generally allowed to move the cards freely until they are satisfied with final placement.

Guttman scales are named after Louis Guttman (1916–1987), a statistician who made enormous contributions to social science measurement. Usage of a Guttman scale is sometimes called scalogram analysis. A Guttman scale is composed of a series of items for which the respondent cumulatively indicates agreement or disagreement. For example, a Guttman scale might ask if a person would tell a little lie (yes or no), then ask if he or she would tell a bigger lie (yes or no), then ask if he or she would lie for no reason at all (yes or no), and then ask if he or she would lie so much that he or she could not tell the difference (yes or no). It can be readily seen that Guttman scales are strictly unidimensional, and they are easily scored with the scale defined as the total number of questions or items passed or agreed with. Researchers should take care to ensure that the cumulative pattern is logical. Unpredictable response patterns, or random error, are controlled for by calculating a coefficient of reproducibility, which is the integer 1 minus the number of errors or unlikely responses divided by the number of responses. Items that produce greater than 80% agreement among all respondents should be discarded from the final scale, and items that reach a 90% coefficient of reproducibility indicate accuracy or scalability. Guttman scale scores have the advantage of being highly informative about where a respondent stands on each item since a scale score of 2 means that he or she agreed only to the first two items and not the ones that followed. They have the disadvantage of usually requiring the passage of time for a respondent to have done all the things asked about.

Almost all comparative scales are designed for use with fairly sophisticated, experienced, or opinionated respondents since it is the comparison process built into these scales that provides some safeguard against systematic error in the form of halo effects, generosity effects, extreme response effects, and contrast effects. To control for nonsystematic error, such as that driven by respondent fatigue or inattention, researchers are well advised to calculate the coefficient of reproducibility and conduct other checks for reliability, such as using multiple raters to generate composite ratings that can then be compared to individual ratings in a pretest environment.

Noncomparative Scales

Noncomparative scales are more likely to resemble a questionnaire presentation, and they expose the respondent to only two things to think about at a given time: the object of the sentence stem in the question or item and the translation of his or her subjective impression about that item into the number of rating divisions

provided. The respondents' frame of reference is not therefore unimportant, and they probably construct a frame of reference on the spot based on their assessment of the whole questionnaire. A number of books on questionnaire design as well as empirical literature indicate that respondents anchor their frame of reference on a neutral point or something they have a strong opinion about when they complete a questionnaire. Hence, researchers often take great care in thinking about the division points they provide raters in their noncomparative scales and indexes. Whether 5-, 7-, or 10-point divisions are used depends in large part on how successfully the researcher is able to thwart respondent anchoring as much as it involves providing reasonable divisions that represent a veridical map of subjective reality.

A continuous rating scale is a type of noncomparative scale that presents the respondent with a continuum, or line, on which to place slash marks in response to a question or item. The idea is to let respondents imagine for themselves what are the division points. Sometimes, the lines are labeled at each end, for example, by strongly disagree and strongly agree. Sometimes, the researcher provides hash marks along to line to help orient the respondent. Scoring is done by the researcher using a ruler, usually measured in millimeters, to record numerical, presumably interval-level, responses for each question or item. This technique has some appeal to those who use the confidence interval approach to statistical interpretation since the method of data collection and the method of data analysis are similar.

Likert scales are named after Renis Likert (1903–1981), an attitudinal researcher, and are the most widely used scales in social science. They provide ordinal data measurement. Generally, they consist of 10–15 questions, but they often begin with a pool as large as 100 questions. Normally, they have an even number of division points, such as strongly disagree, disagree, agree, and strongly agree, with no middle or neutral point representing no opinion. However, Likert scales with 4- to 9-point scales are frequently found in various fields of research, and 5-point divisions are perhaps most commonly used. Any even number of division points will eliminate neutral ground, and any odd number of division points will provide a neutral response option. Because Likert scales have such widespread use, an example of one is provided in Table V.

Because the example in Table V deals with self-esteem, it could obviously be extended to a longer series of items. In fact, researchers often brainstorm all the potential items that could comprise such a scale, as long as the items tap into a unidimensional concept of interest. To reduce the question pool, raters or judges can be used in a pretest environment to rank the items as more or less relevant to the concept of interest, the rankings of these judges can be correlated, and weak items with intercorrelations lower than 0.60 can be thrown out. A t test difference of means analysis can also be done between groups of judges to improve the discrimination value of a Likert scale. It is not infrequently the case that some questions or items are negatively worded, so reverse coding or scoring is needed for these items, with the idea being that such reversals downplay the risk of respondents faking or distorting their answers. The researcher typically uses a Likert scale to test for significant differences between the medians of comparable groups, in the two-sample case using the Mann–Whitney test, in the paired sample case using the Wilcoxon test, and with three or more samples using the Kruskal–Willis test. Well-constructed Likert scales have a tendency to produce rather high reliability coefficients, and the only problem researchers are likely to encounter is what to do with missing data when a respondent skips a question or item. When missing items occur, it is customary for the researcher to assign the average score calculated from whatever items have been answered, although this should not be done when there are too many missing items.

The semantic differential is a technique used to measure the meaning of an object to a respondent. Any concept, person, place, or thing can be presented, and respondents are asked to rate their subjective impressions on a series of bipolar, 7-point scales. Respondents would, for example, indicate their position among the dividing points between such bipolar endpoints as fair–unfair, good–bad, valuable–worthless, active–passive,

Table V Example of a Likert Scale

Strongly disagree	Disagree	Somewhat agree	Strongly agree	1. I feel good about myself.
Strongly disagree	Somewhat disagree	Somewhat agree	Strongly agree	2. Most people think I'm a nice person.
Strongly disagree	Somewhat disagree	Somewhat agree	Strongly agree	3. I always try to be who I am.
Strongly disagree	Somewhat disagree	Somewhat agree	Strongly agree	4. I have a strong personality.
Strongly disagree	Somewhat disagree	Somewhat agree	Strongly agree	5. I present myself well.
Strongly disagree	Somewhat disagree	Somewhat agree	Strongly agree	6. I watch out for my self-interests.
Strongly disagree	Somewhat disagree	Somewhat agree	Strongly agree	7. I am usually self-confident.
Strongly disagree	Somewhat disagree	Somewhat agree	Strongly agree	8. I am proud of who I am.

and strong–weak. Researchers generally choose bipolar endpoints that are reasonably relevant to the object presented. For example, a good–bad bipolar endpoint might be useful when asking respondents to measure their impression of politicians, but a strong–weak bipolar endpoint might be appropriate for an impression of athletes. In other words, the bipolar endpoints are usually customized for the object under consideration. Numerical scoring with the semantic differential produces scale scores that usually require the researcher to assign some meaning to the bipolar directions, where the respondent chooses more favorable words or less favorable words. This ordinarily requires examination of the variation, or standard deviation, among the responses. If respondents are not using all available 7 points across the scale, researchers sometimes collapse the scale to 6 points or less to make the meanings more significant. Such collapsing of a scale should be reported in the research write-up, and it is normally considered an instrumentation threat to validity and reliability. Semantic differential scales have been found useful in cross-cultural research and where broad differences in vocabulary exist among a population sample. Semantic differential and Stapel scales are also widely used in the fields of market research and business.

A Stapel scale is a measure of attitude or impression that consists of a single adjective presented in the middle of an even-numbered range of responses, from −5 to 5. It is usually used when the researcher cannot think of any bipolar adjectives when constructing a semantic differential scale. For this reason, it is sometimes referred to as a unipolar version of the semantic differential. Respondents are sometimes, although infrequently, asked to report any words they think of that explain their numbered ratings. For example, if the unipolar adjective is "challenging" in relation to a university's reputation and the respondent choose −2, then the respondent might write down a word such as "boring" to better reflect what he or she meant by −2. This additional information captured by a Stapel scale can then be analyzed, become the basis for a semantic differential scale, or be used to refine future measurement.

Thurstone scales are named after Louis Thurstone (1887–1955), a psychologist who practically invented scaling at the interval level of measurement. Basically, a Thurstone scale is constructed so that different positions on the scale represent known attitudinal positions with meaningful distances between them. This is accomplished by using raters or judges in an extensive pretest environment. Working independently, the judges are asked to create as many statements about an object as possible. This produces a pool of statements. To get the judges started, the researcher often issues a fill-in-the-blank command, such as "criminals are _____." Sometimes, more than 100 statements are collected. Then, the judges are asked to rank each statement in the pool as either being unfavorably inclined toward the object or favorably inclined toward the object. These rankings are done on a scale of 1 to 11, with 11 being favorably inclined. Note that the judges are not allowed to express their own opinions but instead are objectively rating statements as more or less charitable toward the object. The median and interquartile range (75th percentile minus the 25th percentile) are then calculated from rankings for each statement. Items are selected for the final scale from statements that have equidistant medians and the smallest interquartile ranges within each median's category. This process produces a scale consisting of statements with known equidistant intervals between them, and it also includes statements that have the least amount of variability among judges. Weights can be assigned to some statements to adjust mathematically for a lack of perfect equidistance. Hence, a Thurstone scale discriminates around the intensity or potency of certain attitudinal positions that make up all the known high and low attitudinal positions toward an object. To administer a developed Thurstone scale, the researcher simply has to ask respondents to agree or disagree with the final set of statements, and the mean response is the scale score. Rarely are Thurstone scales encountered in the contemporary literature because the construction technique is considered cumbersome. Also, many researchers today are in the habit of considering ordinal as interval, especially with regard to the rather high reliabilities obtained with simpler methods, such as Guttman and Likert scaling.

Multidimensional scaling (MDS) is an extension of computerized factor analysis that reveals the underlying dimensions of a correlation matrix consisting of responses to a scale. For example, a scale is pretested, and the results are factor analyzed. However, instead of the researcher rotating the axes in an orientation that produces dimensions that can be easily explained (e.g., orthogonal and varimax rotation generally minimize to one or two dimensions), the researcher uses a function minimization algorithm that allows him or her to preset the number of dimensions (usually three) and let the computer program rotate in all sorts of orientations. A screen test is normally used to justify the number of dimensions to plot, and the scatterplot of distances between observed and expected similarities is called a Shepard diagram; Both are precursors to a graphical mapped output of the three dimensions. The researcher then examines this graphic for clusters of points, or configurations, that represent the similarities among scale items that uncover the underlying dimensions of the respondents' subjective impressions. MDS techniques work well with semantic differential-type measures and have proven useful with other scale refinements. They have the advantage of being compatible with multiple regression as a tool for regressing certain meaningful variables onto the coordinates for different dimensions.

Usage of the Most Common Types of Indexes

Indexes are different from scales in that two or more variables or the multiple yet related aspects of a dimension or domain are measured in an index. However, a more basic difference is that with an index, there is no assumption about measuring intensity, as would be done with a scale. For illustration purposes, Table VI shows this basic difference with regard to the way in which scoring is done.

Note in Table VI how the response to each item in the index can earn only one point. Also note how an increasing level of intensity is captured by the way scale items are presented, and that as many as seven points can be earned for each item in the scale. The inability of an index to capture information about the intensity of subjective impressions along unidimensional lines toward an object means that indexes would be more useful when research is on exploratory ground, particularly when multidimensional concepts or overlapping domains are involved. When the researcher cannot delineate all the known dimensions or domains of a construct, an index is appropriate because, in essence, the researcher is using proxies or indicators to guess at the fullness of the object. Thus, it is sometimes stated that an index collects causes and a scale predicts effects because an index taps into uncharted territory and a scale taps into known territory. It is the case, however, that common thinking about indexes is just the opposite. People have become accustomed to only seeing the indicator use of indexes, as with crime indexes and consumer price indexes that measure observable outcomes, behaviors, or events.

Truly useful indexes can be constructed for theory testing, elaboration, specification, or integration of theoretical variables. Some researchers continue to prefer calling them scales because they appear to be getting at elusive concepts, but this is only convergent validity, not predictive validity. An index can be validated or made reliable in most of the same ways as can scales, and it is even possible to construct indexes at the interval level with weighting schemes. Researchers constructing indexes are usually concerned with representativeness and generalizability, purposes that go beyond the quest for calibration in measurement, and these purposes are typically accomplished by standardizing and cross-validating a test. These procedures can also be followed for scales.

Table VI Comparison of Index versus Scale Measurement

Index:	Successful business plan + adequate venture capital + good corporate organization + successful public stock + satisfactory merger
Scoring:	1 point for each action
Scale:	(1) Successful business plan, (2) adequate venture capital, (3) good corporate organization, (4) successful public stock, (5) satisfactory merger
Scoring:	1–7 points for each action

Norming, Standardization, and Cross-Validation

A fully developed index is typically normed, standardized, and cross-validated. Norming involves examining the distribution of raw scores from the pretest respondents and doing within-group comparisons by age, race, and gender, for example, to search for signs of any adverse impact or gaps in what should theoretically be normal distributions. The number of cases selected for within-group analysis should reflect the proportions of those groups in the larger population. The raw scores are then converted to standard scores (z scores) or percentile points, and smoothing operations are performed on the actual scores across and within subgroups until normal distributions are approximated. Index items can also be deleted or revised at this point. The resulting index scores can then be said to have been normed on various population groups, and it is customary for researchers to report what the average score should be for these groups.

Standardization is the process of administering a revised index to a second sample of pretest respondents. Indexes are usually revised by rewording an item slightly, rather than by deleting items, because some aspects of a domain may be particularly difficult to write items for and it is better to try to tap that domain than to forget about it. The standardization sample generally involves respondents from a forensic population for which the researcher suspects attributes of the domain are common. For example, an offender population might be used to standardize a criminological index, but only to compare the distribution of scores between this offender population and the normed scores. Standardization here means the researcher has essentially used an experimental group to verify that the index is constructed so that approximately normal distributions can still be obtained, and it is customary for researchers to also report these respondents as a group upon which the instrument has been normed.

Cross-validation is the process of administering yet another pretest, this time to a sample other than a population for which the researcher suspects attributes of the domain are common—in other words, an ordinary sample of ordinary people. This sample should be used to calculate validity and reliability coefficients, and it should represent the reported properties of the index. Cross-validation is an important step because with only a standardization sample, a researcher will get artificially inflated coefficients, primarily because of criterion validity. It is more honest to let chance and validity shrinkage run

its course and report lower, if not average, coefficients from cross-validation testing.

The Dimensionality of Indexes

The least complicated indexes are unweighted; that is, each item counts for one point, or the items represent raw counts that occur naturally. An example of an unweighted index is the Uniform Crime Report (UCR Crime Index), which has been calculated by the Federal Bureau of Investigation since 1930 and uses raw counts of murder, rape, robbery, aggravated assault, burglary, larceny, auto theft, and arson. The UCR was designed to be a sort of moral barometer of the nation's mental health, at least insofar as counts of the most serious crimes in society are concerned. One way to improve the UCR is to create a weighted index that assigns extra points to some crimes and not to others based on surveying people's perceptions of seriousness. Another way would be to norm the index by accounting for offense rates or perceptions of seriousness by age, race, and gender. In any event, both unweighted and weighted indexes have the ultimate purpose of indicating, imaging, modeling, or profiling the potential for something based on the accumulation of point values that represent possible determinants, causes, or symptoms. Indexes usually contain many items that represent the behavioral domain because past behavior is a good predictor of future behavior, but indexes also cross domains and can include items that measure other dimensions, such as thinking and feeling, as Table VII illustrates.

Table VII presents portions of an inequity index derived from theories in criminology and social psychology about perceptions of effort-based injustice or unbalanced exchange relationships. This construct has played a role in many theories as a precipitating factor for the readiness to offend or the potential to engage in antisocial behavior. The inequity index consists of a series of three bundled items: The first item asks about the respondent's behaviors, or how much effort he or she put into something; the second item asks about the respondent's cognitions, or how much the respondent observed a reflection of his or her effort from others; and the third item asks about the respondent's feelings, or how much the respondent felt let down for his or her effort. For each bundle in the index, scoring proceeds by adding respondent values for the first item, subtracting values for the second item, and adding values for the third item. The domains of behavior, cognition, and feeling tapped by this instrument could just as easily have been measured by scales, but three separate scales would be required, the instrument would be unwieldy, and it would be doubtful whether the researcher was tapping into the inequity construct. The example should illustrate how particularly useful indexes can be for the measurement of theoretical constructs when the researcher is not interested in exhausting the dimensionality of any one domain but, rather, in exhausting all the overlapping dimensionality between domains.

Table VII Inequity Index Tapping the Behavioral, Cognitive, and Emotional Domains

Instructions: Think about the relationships you have with those closest to you, and place a number on the line in front of each item for how many times in the past year you have behaved, thought, or felt that way.
_____1. Made efforts to impress others with your intelligence
_____2. Were recognized for your intelligence
_____3. Felt unappreciated for your intelligence
_____4. Put a lot of effort into some project
_____5. Felt satisfied from working on some project
_____6. Felt unmotivated from working on some project
_____7. Tried to be sociable
_____8. Received comments on how sociable you were
_____9. Felt like others were not being sociable with you
_____10. Showed consideration for others
_____11. Received consideration from others
_____12. Felt like others were inconsiderate toward you

Trends in Scales and Indexes

The two most common trends in the field of measurement by scales and indexes are the habits of researchers to treat scales and indexes synonymously and to treat ordinal-level data collected by scales with high reliability as interval-level data for all practical purposes. These are unfortunate trends because there is a rich, unexplored usefulness for measurement by indexes, and although Thurstone-type procedures and weighting schemes are cumbersome, interval-level scales and indexes can be constructed.

Factor analysis also seems to be used frequently by researchers to identify the multiple dimensions of a concept. The logic of factor analysis is that sometimes there is utility in assessing the correlations between several related indicators in such a way so as to uncover the latent, abstract concept that those indicators measure. Factor analysis involves confirmation of whether or not those indicators are indeed measuring a single concept, and if they are, the group scores for those "factors" are called eigenvalues and treated by researchers as proxies for the dimensions.

Mathematical scaling or MDS is a fairly recent trend, and it seems to have found a place among data analysts steeped in the multiple regression tradition. MDS is a set of data analysis techniques that display the structure of distance-like data as a geometrical picture. It represents one way in which researchers are constantly working to revise and improve their scales and indexes. As previously stated, researchers are well advised to seek out existing

scales and indexes from a handbook, manual, or, in some cases, the researchers, at varying costs. At times, using a published scale or index will prevent reinvention of the wheel, and at other times there is no substitute for constructing, validating, standardizing, and cross-validating one's own scale or index. This area of measurement will likely remain vibrant for many years.

Secondary Data

Marc Riedel
Southeastern Louisiana University, Hammond, Louisiana, USA

Glossary

aggregation Secondary data can be made available at various levels, for example, traffic accidents can be reported at the level of events with detailed information on participants. However, it can be aggregated so that the only information available is the number of traffic accidents per month or year.
imputation Statistical procedure that uses existing data to estimate the most likely values for data that are missing.
listwise deletion When cases are deleted from a data set if any variable for the case has missing values. For example, if a case had, in addition to three other completely reported variables, a variable of race and was missing the respondent's race or ethnicity, the entire case would be deleted from analysis.
objective indicators Data or information generated by an organization that is believed to represent the valid and reliable output of the organization.
pairwise deletion When cases are deleted from a data set only if information is missing for the variables being analyzed. For example, in comparing race to income, only those cases that had missing values on race and income would be deleted. Other variables with missing values would be retained.
rare events Events that are statistically uncommon when compared to a population at risk.
units Cases collected for the ultimate purpose of describing patterns; can be individuals, groups, or social artifacts.
values Characteristics describing objects and variables. For example, in a survey in which the variable was "gender," the values would be "male" or "female."

Secondary data is information that was gathered for another purpose. In his classic 1972 study of secondary analysis, Herbert Hyman stated that purpose is expressed when a secondary analyst "by an act of *abstraction* uses questions originally employed to indicate one entity to illuminate other aspects that a former analyst did not have in mind at all." [italics in the original] (p. 37). This article focuses primarily on quantitative secondary data.

Types of Secondary Data

There are three types of quantitative secondary data: surveys, official statistics, and official records. Depending on how the data are stored, each may be referred to as archival data. Surveys are characterized by data acquired through questionnaires or interviews and, generally, probability sampling. The research issues raised by secondary use of surveys are very different from issues surrounding official statistics and records. Many of the problems in the use of surveys focus on questions of analyses, whereas for official statistics and records, the major problems are with the characteristics of the data set itself.

Official statistics and records are collections of information maintained and made available in permanent form by organizations. Official records are collections of statistical data that are generated as an organizational by-product of another mission or goal. They are "official" in the sense that they are the records of a bureaucratic office; official statistics, on the other hand, are designed for public consumption. For example, police departments keep extensive data on criminal complaints, investigations, arrests, and characteristics of victims and offenders. Official statistics in the form of annual reports from the FBI on crime in the United States provide information that is accessible to anyone. Official records, on the other hand, are more difficult to access than official statistics because they are constructed primarily for internal use. Compared to official statistics, agencies that generate official records retain a proprietary interest in their use.

The proprietary issues range from legally protected information about individuals to a concern that research using official records may throw an unfavorable light on agencies.

Official records typically contain a greater amount of detail than official statistics. Official statistics are collected from many agencies and are meant to be disseminated widely. Hence, the data collected focus on a few elements that will be reported consistently and accurately. For example, the data that is reported in national mortality statistics is taken from death certificates that contain much less information than is available in the files of coroners or medical examiners.

For official records, the unit of analysis is usually based on the target of service delivery. Thus, welfare agencies collect information on individuals who apply for food stamps, employment agencies collect information on people looking for work, etc. Official statistics, on the other hand, make information available at higher levels of aggregation, such as the monthly or annual number of people applying for welfare or employment.

Finally, one advantage of official records is that the persons who originally completed the forms may be present in the agency and available to the researcher. In the absence of adequate documentation, the researcher is given the opportunity to learn how the information was gathered. By contrast, official statistics may be gathered from many different agencies or presented in a form that makes it difficult or impossible to discern the procedures.

The distinction between official statistics and official records is not meant to be a distinction between national and local data. Local and state agencies provide annual reports that qualify as official statistics and are not found in archives. Official records may be archived locally, but may not be generally available. The distinction is between types of secondary data that raise different issues for researchers wanting to use the data.

Uses of Secondary Data

Accessible and Inexpensive

Secondary data is both accessible and inexpensive. Several of the largest archives in the world are located in the United States. The largest is the Inter-University Consortium for Political and Social Research (ICPSR) located at the University of Michigan. The ICPSR archives hold more than 1700 studies divided into 26,000 files covering approximately 130 counties. While membership in ICPSR gives universities and other organizations access to services and data, a very large number of data files can be downloaded without cost from their Web site.

While archives provide access to a large number of data sets generated and maintained by federal and other agencies, many researchers contribute their data sets to the archives upon completion of their research. In addition, for researchers interested in records not found in archives, most agencies use computer systems to store data that can be used for research, providing access is given.

Secondary data archives have contributed greatly to the efficiency of individual researchers. In his book on secondary data, Riedel mentions how secondary data archives have "reduced the *schlepping* factor." Research a bare 25 years ago involved a great deal of "schlepping," a Yiddish word meaning a tedious journey or to carry slowly or awkwardly. Secondary data archives were small; if a student was lucky, his or her major professor would provide access to his or her funded data set for a thesis or dissertation.

Requests for data from organizations might result in receiving a reel of computer tape that must be mounted on a large mainframe computer, and the available software might or might not be compatible with the data. On the other hand, such requests might mean the researcher must spend months transferring information from paper forms to computer-readable formats. Analysis meant weeks and months of feeding batch programs to the mainframe, examining results, correcting errors, resubmitting jobs, and submitting new ones. Turnaround time of 20 to 30 minutes from submission to printout was considered rapid progress. All of this was in addition to the time needed to review research literature, develop research designs, construct indicators, interpret data, and report the results.

In a short 1963 article in the *American Behavioral Scientist*, Barney Glaser discussed how the independent researcher, someone who decides to do basic research with little or no resources, benefits from secondary data. With the emergence of inexpensive and accessible data sources, Glaser's suggestions are even more relevant today because the largest cost of doing research is data collection, not data analysis. Glaser discussed four types of independent researchers: team members, students, teachers, and people in administrative positions; here, students are briefly discussed.

Undergraduate and graduate students who want to engage in original research and/or are required to do a thesis or dissertation typically have few or no funds to support data collection and are unlikely, by themselves, to obtain any external funding in large amounts. Ideally, students can participate in the data-gathering efforts of well-funded research that might result in their access to primary data. More commonly, self-funding means making use of existing resources within a university that includes free use of computers for data processing, access to libraries, and being able to consult with faculty. The ready availability of a large number of data sets solves the expensive problem of data collection.

An opposing argument is that students need the learning experience of collecting their own data. It is difficult to see, however, what useful knowledge is gained by learning how to collect data with no funds and limited time. Students are sufficiently familiar with how poverty limits opportunities without imposing formal requirements. In addition, graduate students are increasingly expected to graduate with one or more publications to their credit. Being able to publish a thesis or dissertation is much more likely if higher quality data available from other research projects is used.

Difficult-to-Observe Events

Rare Events

Many phenomena are so statistically rare that secondary data are the only practical source of information. As a rule, the more serious the crime, the less frequently it occurs and the less frequently it can be observed directly. For example, in 2000, there were 891 murders in an Illinois population of almost 12.5 million people. Given the rarity and generally unannounced nature of that crime, information on murders must be gathered as a by-product of police investigation and apprehension.

Events Occurring in Settings Not Subject to Surveillance

Many events of interest to researchers occur in settings that are not routinely subject to surveillance. For example, crimes such as assaults, burglaries, robberies, and rapes occur in settings and ways that make identifying and apprehending offenders difficult. They only become known if the victim reports the crime to the police or if he or she happens to be a respondent in a crime victimization survey.

Of course, while settings are subject to routine surveillance is increasingly becoming an open question. For example in September, 2002, Madelyne Toogood turned herself in to the police because she was observed beating her child by a surveillance camera in a store parking lot. The fact that the video was carried on national television contributed to her turning herself in.

There are also events that occur in protected settings such as homes. For example, for decades women and children were physically assaulted and otherwise victimized in their homes without outside attention. Changes in legislation required reporting of child abuse and more careful accounting of spousal violence. Additionally, abused and battered women now have alternatives to remaining in an abusive relationships such as hotlines and women's shelters. Such changes led to the creation and storage of records that can be used for research.

Private Behavior with Public Consequences

People may engage in a variety of secret or routine behavior that comes to the attention of medical personnel, among others, who attribute very different interpretations to it and are frequently legally required to report it. Such information results in secondary data sources. Examples include wounds from weapons, repetitive patterns of injuries from automobile or industrial accidents, increases in certain types of infections or diseases, and the use of controlled substances. For example, the federal government supports a program called the Drug Abuse Warning Network (DAWN), which has two crucial drug indicators. The first is emergency department episodes in which persons are brought to a hospital emergency room with a drug-related reaction. The second source of information is obtained from medical examiners or coroners who report that one or more drugs caused or contributed to the death of persons.

Costly Data Collection

A major advantage of secondary data is that it makes information accessible that is too costly to collect under any other circumstances. There are several instances of secondary data sources that are costly to collect because of the scope of the information collected, because their utility stems from periodic repetition, or both. Perhaps the best example of secondary data of a repetitive extremely large-scale data collection that requires the resources of a national government is the U.S. Census. While the census is constitutionally mandated, it is used to do more than count people.

There are numerous costly national surveys of social indicators. The National Crime Victimization Survey, completed every six months by the Census Bureau and the Bureau of Justice Statistics, uses a nationally representative sample to provide details about crime victimization that exceed what is available from law enforcement sources. The General Social Surveys have been carried out annually (except for 1979, 1981, and 1992) by the National Opinion Research Center. The primary topics surveyed in national samples include socioeconomic status, social mobility, family, race relations, social control, sex relations, civil liberties, and morals.

Finally, the National Health Interview Surveys have been conducted since 1969 by the National Center for Health Statistics. By means of national sampling, it obtains information about the amount and distribution of illness, its effects in terms of disability and chronic impairments, and the kinds of health service people receive. Supplemental surveys collect data on such topics as AIDS knowledge and attitudes, child health care and immunization, dental care, and hospitalization.

Evaluation of the Functioning of Agencies

With respect to evaluating agencies, secondary data is used in two ways. The first views statistics and records as objective indicators of organizational effectiveness. Number of units sold, patients treated, cases resolved, and persons arrested are examples of how information from organizations is used to evaluate their performance.

Second, statistics and records can be used as an indicator of organizational processes. The records of organizations are viewed as representations of individual and institutional polices and practices. Arrests for illegal gambling, for example, represent police responses to public pressures to do something about crime more than they represent an indication of the actual amounts of what is defined as that crime. Similarly, a record of prosecutions for environmental pollution may show differential enforcement that reflects the extent of political contributions to the party in power.

Cross-Cultural or Transnational Research

Secondary data is essential to cross-cultural or transnational research not only because of the cost of collecting data, but because of the challenging organizational tasks of getting together a group of cooperating researchers and agreeing on a data collection instrument. ICPSR maintains a large collection of data sets comparing different countries. For example, *Political Participation and Equality in Seven Nations, 1966–1971* is a cross-national data set on political participation from Austria, India, Japan, the Netherlands, Nigeria, Yugoslavia, and the United States.

Comparisons of Different Times and Places

Secondary data can be used to compare changes in different places at the same time. Studies can be done comparing the amount of crime in different cities for the same time period. A study of trends illustrates how secondary data can be used to compare changes in the same place at different times. For example, the ongoing Consumer Expenditure Survey (CES) by the Bureau of Labor provides a continuous flow of information on the buying habits of U.S. consumers and also furnishes data to support periodic revisions of the consumer price index.

Limitations of Secondary Data

Indicators Not Available

The major disadvantage of secondary data is that indicators needed for the proposed concepts are not available in secondary data sets. An advantage of data collected by the investigator is that he or she specifies the concept of interest and is able to construct an indicator; the secondary data user has to use indicators that are available in the data.

There is no simple solution to the problem. In some instances, weak indicators can be found. For example, median income of a census tract has been used as an indicator of individual social class. While this has obvious weaknesses, it can be combined with other correlates of social class, such as years of education, and compared to the dependent variable. Where it is not possible to find an indicator that represents a good fit with the concept, it is possible to use several weak indicators and explore their adequacy as measures by additional analyses.

Unacceptable Levels of Aggregation

Data sets can be made available by cases or higher levels of aggregation. Where the data is available at the level of cases, it contains characteristics of the unit of analysis. For example, data on attitude surveys would be available at the level of respondents.

Data is sometimes aggregated by time intervals or by respondent characteristics. For example, the mean support for an issue is given for males in comparison to females. Where comparisons over time occur, there may be monthly or annual counts of the number of people applying for welfare, for example.

The data can be used as long as the unit of analysis in the present research is the same as the secondary data. Problems arise when the researcher wants to analyze data at a level lower than what is available. The higher level aggregation precludes creating composite variables at the level of individuals. For example, a data source may provide the monthly number of males and females, whites and African-Americans applying for unemployment. But it is impossible to examine white males, white females, African-American males or African-American females in relation to previous years of employment. Once cases are aggregated, they are "pulled apart" so that individual level comparisons are very limited.

Some analyses can be performed if there is information about the relationship between aggregated units. If one event tended to precede another event by a month, then it may be possible to compare months of occurrence to subsequent events one month later. For example, if comparisons are made between a criminal event and when the offender is arrested and only monthly data are available, it is possible to lag month of occurrence behind month of arrest in the analysis. Hence, the assumption is that most arrests occurred one month later than the month the crime occurred. While this is a reasonable use of aggregated data, it is no substitute for information that provides date of crime occurrence and date arrested for each offender.

Complex Data Structures

Secondary data is sometimes available only as complex data structures. One distinction is between rectangular, or flat, and hierarchal files. The simplest type is rectangular files, in which cases are the rows and variables are the columns, as seen in Table I. Hierarchal files can be illustrated by considering homicides as an event in which there may be any number of offenses, victims, and offenders. An incident record is created with administrative information and links to offense, victim, and offender records, however many of each there may be. The disadvantage is that it is more difficult to analyze hierarchal data sets because until recently most statistical packages assumed the use of flat files.

Inadequate Documentation

Clearly written and specific documentation is essential to using secondary data. But the clarity and specificity is a consequence of the amount of control over the data collection. When a national agency is acting as a clearinghouse in compiling data from local agencies, the national agency has little control over what they receive and relatively little quality control over data collection. On the other hand, when the agency has control over the data collection process, there may be initial detailed documentation, and it is revised and refined on the basis of the continuing data collection process. Thus, the U.S. Census has higher quality data than FBI national reports on crime, which are compiled from local police agencies.

A related problem is whether changes in the reporting system are adequately documented. It is important not only to know what changes occurred, but also to know how continuity in the data series is maintained. For example, the World Health Organization compiles mortality data from a large number of countries. Approximately every decade, representatives from participating countries gather to determine what changes need to be made in their publication the *International Classification of Diseases*. The question then becomes how the newly implemented changes in data collection procedures and definitions are related to previous decades.

The National Center of Health Statistics (NCHS) collects data for the United States according to the *International Classification of Diseases*. To determine the effect of classification revisions, NCHS calculates comparability ratios based on dual codings of the same data using previous and recent classifications. This provides a quantitative indication of the comparability between revisions.

Table I Data Matrix

	Variables						
Cases	Y	X_1	X_2	X_3	X_4	X_5	X_6
1	0	1	1	1	1	1	1
2	1	0	1	1	1	1	1
3	1	1	0	1	1	1	1
4	1	1	1	0	1	1	1
5	1	1	1	1	0	1	1
6	1	1	1	1	1	0	1
7	1	1	1	1	1	1	0

Y = dependent variable; X = independent variable; 1=reported value; and 0=missing value. Taken from Riedel (2000, p. 114) with permission of Sage Publications.

Missing Data

Missing data consists of unit nonresponses and item nonresponses. For an attitude survey; unit nonresponses exist when no respondents are available to provide any information. Item nonresponses occur when there is information about the unit but no information about variables: for example, when information is absent about whether respondents are males or females.

The issue about how much missing data can exist in a data set without biasing the results is an unsettled one. Some experts suggest that 5% or less missing values for a variable will not seriously bias the results. However, large data sets can absorb the loss of information better than small ones. In addition, there are techniques available to determine the effect of missing information.

Table I is useful for understanding the effect of missing data; it is a hypothetical data matrix of seven cases with six independent variables (X_k) and one dependent variable (Y). A general strategy of researchers is to ignore missing data. To do so, the researcher employs either listwise deletion or pairwise deletion. Suppose the researcher decides to analyze this data using a multivariate statistical technique, that is, a statistic that uses all the independent variables (X_1 through X_6) to determine their relative importance in explaining the dependent variable (Y). A general requirement of these techniques is that values for each variable and each unit be completely reported. If one or more values are missing, the entire unit is dropped from the analysis. Listwise deletion occurs in the latter instance, and inspection of Table I indicates the researcher would have no cases to analyze; every case would have one value missing.

Suppose, on the other hand, the researcher decides to use a bivariate statistical technique. Bivariate techniques would compare Y to X_1, then compare Y to X_2, and so on. This would eliminate the problem associated with listwise deletion because only two cases would be lost in each comparison.

But pairwise deletion presents a different sort of problem. Examination of Table I indicates that a comparison of Y and X_1 would use a different subset of data from Y and X_2. In the first comparison, cases 1 and 2 would be

excluded, while in the second comparison, cases 1 and 3 would be excluded. If researchers assume the data are drawn from the same population and the results of bivariate tests can be compared to one another, they would be in error. In fact, comparisons are made from samples drawn from overlapping populations.

One solution to the problem is missing data imputation. Some secondary data sources routinely impute missing data while others do not, and it is not always clear from the documentation whether and what type of imputation has been used. The difficulty with imputed data sets is that the secondary data user does not have access to the original, or nonimputed data. Unless and until the secondary data user understands how the imputation or weighting technique was used to compensate for missing data, a serious bias may be introduced. While imputation is not an improvement over thorough and careful data collection procedures, it represents a important attempt to deal with the problem of missing data.

Research Issues

Designing Back to Front

Research with information gathered for another purpose is unlike research in which researchers gather their own observations. Using secondary data means the approach to research design has to be "back to front." Instead of designing a study and collecting data in accordance with it, the researcher needs to have a detailed knowledge of the characteristics of the data set, then consider that in relation to hypotheses that he or she wants to test.

For research with official records, the first step is to determine the nature and extent of data. One strategy for doing so is to arrange for an interview with the person who manages the records. Using blank documents, the strengths and limitations of agency records can be reviewed with that person. In addition to help with the research design, such a preliminary step allows the researcher to determine the quality of the data before going through procedures necessary to gain access.

Learn the Social and Legal Background

In assessing the quality of the data, it is important to learn the goals of the organizations that collect the data. This provides clues as to the kind of data available, because data collection supports the major activities and mission of agencies. Knowing something about the goals of organizations helps to understand what they define as a "case." For example, the U.S. Department of Education funds a National Public Education Financial Survey in which a state is the unit of analysis.

Organization of the Records

How are the records organized? Are they ordered alphabetically, by the type of event, or by initial action taken? How records are organized is important if the researcher wants to draw a representative sample. If the records are ordered alphabetically, then a simple random sample is sufficient; more complex samples are needed for other types of data organization.

Documentation

How adequate is the documentation? Archival data typically provide more adequate documentation than official statistics taken directly from agencies. The most problematic are official records in which abbreviations or shorthand is used in the records. In the latter instance, it is necessary to discuss with records managers what each of the symbols mean.

A major documentation problem is indications of missing data. Conventionally, missing values is a statement of ignorance: we do not know what the value is. Frequently, blanks are used to indicate missing data, but the meaning of the blank is unclear. For example, if information is missing about an offender's previous criminal history, does that mean he or she had no previous criminal history or does it mean the information was lost or never collected?

Changes in the Record-Keeping System

When a study covers several years, the data has to be evaluated for changes in record keeping. Periodic shifts include elimination or introduction of a new form or revisions in existing forms. In addition, when a new procedure or law has been implemented, what is the effective date that information began to be collected?

Changes in record keeping pose major issues of comparability. Other than NCHS, few organizations perform comparability studies to assess the effect of changes in record keeping. Coping with the changes may mean a simplified analysis. For example, suppose in earlier versions of the data, race is classified as "white" and "nonwhite," and a revision classifies race in several race and ethnic groups. Unless the researcher is satisfied with data only from the revision, he or she has to divide the variable into "white" and "nonwhite."

Selection Bias

James J. Heckman
The University of Chicago, Chicago, Illinois, USA

Glossary

generalized Roy model A model of sectoral choice with a more general sectoral selection criterion than that of the Roy model.
population distribution A mathematical description of the probability of the outcomes that random variables can assume.
Roy model A model of sectoral choice in which agents choose their sector of employment on the basis of where they get the highest income.
selection bias A bias arising, in general, from nonrandom sampling.
weighted distribution A distribution derived from a population probability distribution by weighting the sampling at some values of the population distribution differently than simple random sampling.

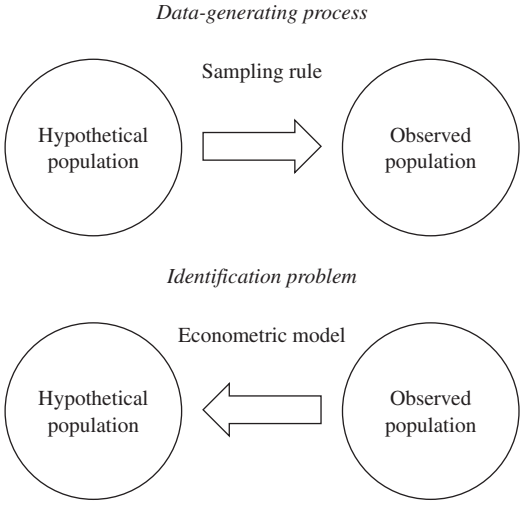

Figure 1 Relationship between hypothetical (counterfactual) populations and observed data.

A random sample of a population produces a description of the population distribution of characteristics. A sample selected by any rule not equivalent to random sampling produces an inaccurate description of the population distribution of characteristics, no matter how big the sample size. The problem of selection bias arises when a rule other than simple random sampling is used to sample the underlying population of interest. The resultant distorted representation of a true population in a sample as a consequence of a sampling rule is the essential source of the selection problem. The identification problem is the problem of recovering features of a hypothetical population from an observed sample. The hypothetical population can refer, for example, to the potential wages of all persons (whether or not they work and have observed wages) or to the potential outcomes of any choice problem when only outcomes from choices made. Selection rule distortions may arise from decisions of sample survey statisticians, or as a consequence of self-selection, so only a subset of possible outcomes is observed. There are two important characterizations of the selection problem. The first, which originates in statistics, involves characterizing the sampling rule depicted in Fig. 1 as applying a weighting to hypothetical population distributions to produce observed distributions. The second, which originates in econometrics, explicitly treats the selection problem as a missing-data problem and uses observables to impute the relevant unobservables.

Weighted Distributions

Any selection bias model can be described in terms of weighted distributions. Let Y be a vector of outcomes of interest and let X be a vector of "control" or "explanatory"

variables. The population distribution of (Y, X) is $F(y, x)$. To simplify the exposition, assume that the density is well defined and write it as $f(y, x)$. Any sampling rule is equivalent to a nonnegative weighting function $\omega(y, x)$ that alters the population density. People are selected into the sampled population by a rule that differs, in general, from random sampling. Let (Y^*, X^*) denote the random variables produced from sampling. The density of the sampled data $g(y^*, x^*)$ may be written as

$$g(y^*, x^*) = \frac{\omega(y^*, x^*) f(y^*, x^*)}{\int \omega(y^*, x^*) f(y^*, x^*)\, dy^*\, dx^*}, \qquad (1)$$

where the denominator of the expression is introduced to make the density $g(y^*, x^*)$ integrate to one as is required for proper densities. Simple random sampling corresponds to the case where $\omega(y, x) = 1$. Sampling schemes for which $\omega(y, x) = 0$ for some values of (Y, X) create special problems because not all values of (Y, X) are sampled. For samples in which $\omega(y, x) = 0$ for a nonnegligible proportion of the population, it is useful to consider two cases. A truncated sample is one for which the probability of observing the sample from the larger random sample is not known. For such a sample, Eq. (1) is the density of all the sampled Y and X values. A censored sample is one for which the probability is known or can be consistently estimated.

In many problems in economics, attention focuses on $f(y \mid x)$, the conditional density of Y given $X = x$. If samples are selected solely on the x variables (selection on the exogenous variables), $\omega(y, x) = \omega(x)$ and there is no problem about using selected samples to make valid inferences about the population conditional density. Sampling on both y and x is termed "general stratified sampling," and a variety of different sampling schemes can be characterized by the structure they place on the weights.

From a sample of data, it is not possible to recover the true density $f(y, x)$ without knowledge of the weighting rule. On the other hand, if the weight $\omega(y^*, x^*)$ is known and the support of (y, x) is known and $\omega(y, x)$ is nonzero, then $f(y, x)$ can always be recovered because

$$\frac{g(y^*, x^*)}{\omega(y^*, x^*)} = \frac{f(y^*, x^*)}{\int \omega(y^*, x^*) f(y^*, x^*)\, dy^*\, dx^*}, \qquad (2)$$

and by hypothesis both the numerator and denominator of the left-hand side are known, and $\int f(y^*, x^*)\, dy^*\, dx^* = 1$, so it is possible to determine $\int \omega(y^*, x^*) f(y^*, x^*)\, dy^*\, dx^*$. It is fundamentally easier to correct for sampling plans with known nonnegative weights or weights that can be estimated separately from the full model than it is to correct for selection when the weights are not known and must be estimated jointly with the model. Choice-based sampling, length-biased sampling, and size-biased sampling are examples of the former. Sampling arising from more general selection models cannot be put in this form because the weights require that the model be known in advance of any analysis of the data. Selection with known weights has been studied under the rubric of the Horvitz–Thompson estimates since the mid-1950s. Contributions to the choice-based sampling literature in economics were made by Manski and McFadden in 1981. Length-biased sampling is analytically equivalent to choice-based sampling and has been studied since the late 19th century by Danish actuaries. Heckman and Singer extended the classical analysis of length-biased sampling in duration analysis to consider models with unobservables dependent across spells and time-varying variables. In their more general case, simple weighting methods with weights determined independently from the model are not available.

The requirements that the support of (y, x) is known and $\omega(y, x)$ is nonzero are not innocuous. In many important problems in economics, the second requirement is not satisfied: the sampling rule excludes observations for certain values of (y, x) and hence it is impossible without invoking further assumptions to determine the population distribution of (Y, X) at those values. If neither the support nor the weight is known, it is impossible, without invoking strong assumptions, to determine whether the fact that data are missing at certain (y, x) values is due to the sampling plan or that the population density has no support at those values. Using this framework, a variety of sampling plans of interest in economics have been analyzed, showing what assumptions they make about the weights and the model to solve the inferential problem of going from the observed population to the hypothetical population.

A Regression Representation of the Selection Problem when there is Selection on Unobservables

A regression version of the selection problem when the weights $\omega(y, x)$ cannot be estimated independently of the model has been devised. Let there be two outcomes, Y_1 and Y_0, corresponding to outcomes in sector 1 and outcomes in sector 0. The outcomes are written as follows:

$$Y_1 = \mu_1(X) + U_1, \qquad (3a)$$

$$Y_0 = \mu_0(X) + U_0. \qquad (3b)$$

The decision rule that characterizes the sector of choice is based on I, a net utility, and

$$I = \mu_I(Z) + U_I, \qquad (3c)$$

$$D = \mathbf{1}[I \geq 0]. \qquad (3d)$$

The special case where $\mu_I(Z) = \mu_1(X) - \mu_0(X)$ and $U_I = U_1 - U_0$ so $I = Y_1 - Y_0$ is the Roy model. In this model, selection only occurs on outcomes; (Y_1, Y_0) are potential outcomes. For simplicity, assume that (U_1, U_0, U_I) are statistically independent of (X, Z) and that (U_1, U_0, U_I) have mean zero. Then $Y = DY_1 + (1-D)Y_0$ and Y_1 (or Y_0, but not both) are observed. In some applications, Y_0 (or Y_1) is never observed. In general,

$$E(Y_1 \mid X, D = 1) \neq \mu_1(X),$$
$$E(Y_0 \mid X, D = 0) \neq \mu_0(X).$$

The observed outcomes are a nonrandom sample of potential outcomes,

$$E(Y \mid X, Z, D = 1) = E(Y_1 \mid X, Z, D = 1) = \mu_1(X) + E(U_1 \mid X, Z, D = 1) \quad (4a)$$

and

$$E(Y \mid X, Z, D = 0) = E(Y_0 \mid X, Z, D = 0) = \mu_0(X) + E(U_0 \mid X, Z, D = 0). \quad (4b)$$

In some cases, only Eq. (4a) or (4b) can be constructed because only Y_1 or Y_0 is observed. The conditional means of U_0 and U_1 are the "control functions," or bias functions. The mean observed outcomes (the left-hand variables) are generated by the means of the potential outcomes plus a bias term. The control function is the bias term.

Define $P(z) = \Pr(D = 1 \mid Z = z)$. As a consequence of the decision rule, Eq. (3d), it has been demonstrated that under general conditions these expressions may always be written as

$$E(Y \mid X, Z, D = 1) = \mu_1(X) + K_1[P(Z)] \quad (5a)$$

and

$$E(Y \mid X, Z, D = 0) = \mu_0(X) + K_0[P(Z)], \quad (5b)$$

where $K_1[P(Z)]$ and $K_0[P(Z)]$ are control functions and depend on Z only through P. The functional forms of the K depend on specific distributional assumptions. The value of P is related to the magnitude of the selection bias. As samples become more representative, $P(Z) \to 1$, $K_1(P) \to 0$. Figure 2 shows a plot of control function $K_1(P)$ versus P. As $P \to 1$, the sample becomes increasingly representative because the probability of any type of person being included in the sample is the same (and $P = 1$). The bias function declines with P. The population mean of Y_1 in samples can be computed with little selection (high P). In general, regressions on selected samples are biased for $\mu_1(X)$. The selection bias term is conflated with the function of interest. If there are variables in Z not in X, regressions on selected samples would indicate that they "belong" in the regression. Equations (5a) and (5b) are the basis for an entire econometric literature on selection bias in regression

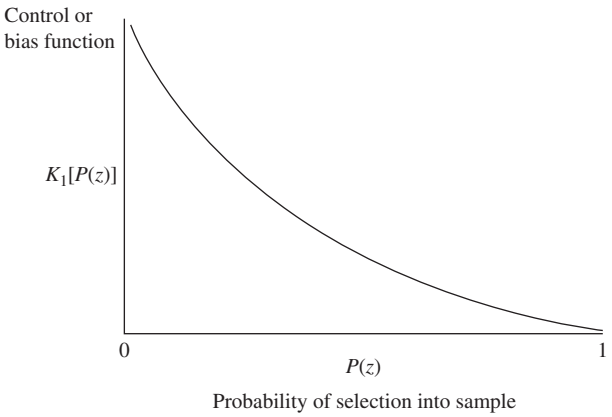

Figure 2 Control function or selection bias as a function of $P(Z)$.

functions. The key idea in all this literature is to control for the effect of P on fitted relationships.

The control functions relate the missing data (the U_0 and U_1) to observables. Under a variety of assumptions, it is possible to form these functions up to unknown parameters and identify the $\mu_0(X)$, $\mu_1(X)$ and the unknown parameters from regression analysis, and control for selection bias. In the early literature, specific functional forms for Eqs. (4) and (5) were derived assuming that the U were joint normally distributed:

Assumption 1 $\quad (U_0, U_1, U_2) \sim N(0, \Sigma)$.

Assumption 2 $\quad (U_0, U_1, U_2) \perp\!\!\!\perp (X, Z)$.

Assumption 1 coupled with Assumption 2 produces precise functional forms for K_1 and K_0. There is a two-step estimation procedure for censored samples: (1) Estimate $P(Z)$ from data on the decision to work and (2) using an estimated $P(Z)$, form $K_1[P(Z)]$ and $K_0[P(Z)]$ up to unknown parameters. Then Eqs. (5a) and (5b) can be estimated using regression. This produces a convenient expression linear in the parameters when $\mu_1(X) = X\beta_1$ and $\mu_0(X) = X\beta_0$. A direct one-step regression procedure has been developed for truncated samples. Equations (5a) and (5b) are the basis for an entire literature that generalizes and extends the early models, and remains active to this day.

Identification

Much of the econometric literature on the selection problem combines discussions of identification (going from populations generated by selection rules back to the source population) with discussions of estimation in solving the inferential problem of going from observed samples to hypothetical populations. It is analytically useful to distinguish the conditions required to identify the

selection model from ideal data from the numerous practical and important problems of estimating the model. Understanding the sources of identification of a model is essential to understanding how much of what is being obtained from an empirical model is a consequence of what is put into it.

Paul Holland used the law of iterated expectations to write the conditional distribution of an outcome, say Y_1 on X, in the following form:

$$F(Y_1 \mid X) = F(Y_1 \mid X, D = 1)\ \Pr(D = 1 \mid X) + F(Y_1 \mid X, D = 0)\ \Pr(D = 0 \mid X). \quad (6)$$

It is possible to observe Y_1 only if $D = 1$. In a censored sample, it is possible to identify $F(Y_1 \mid \mathrm{X},\ D = 1)$, $\Pr(D = 1 \mid X)$ and hence $\Pr(D = 0 \mid X)$; Y_1 is not observed when $D = 0$. Hence, $F(Y_1 \mid \mathrm{X})$ is not identified. Independent work of James Smith and Finis Welch made a similar decomposition of conditional means (replacing F with E).

Holland questioned how $F(Y_1 \mid X)$ could be identified and compared selection models with other approaches. Smith and Welch discussed how to bound $F(Y_1 \mid X)$ or $E(Y_1 \mid X)$ by placing bounds on the missing components, $F(Y_1 \mid X, D = 0)$ and $E(Y_1 \mid X, D = 0)$, respectively. (Smith and Welch use their analysis to bound the effects of dropping out on the black–white wage gap.) A clear precedent for this idea was the work of Peterson, who developed nonparametric bounds for the competing risk model of duration analysis, which is mathematically identical to the Roy model, which is the model of Eqs. (3a)–(3d) when $I = Y_1 - Y_0$. The competing risks model replaces $\max(Y_0, Y_1)$ with $\min(Y_0, Y_1)$ for selecting outcomes. In this model, $D = 1$ if $I = Y_0 - Y_1 > 0$.

The normality assumption widely made in the early literature has been called into question. Arabmazar and Schmidt presented Monte Carlo analyses of models showing substantial bias for models with continuous outcomes when normality was assumed but the true model was nonnormal. The empirical evidence is more mixed. Normality is not a bad assumption for analyzing models of self-selection for log wage outcomes once allowance is made for truncation and self selection. Normality of latent variables turns out to be an acceptable assumption for discrete-choice models except under extreme conditions.

Heckman and Honoré have considered identification of the Roy model ($I = Y_1 - Y_0$ in the notation of Eqs. (3a)–(3d)) under a variety of conditions. They establish that under normality, the model is identified even if there are no regressors, so there are no exclusion restrictions. They further establish that the model is identified (up to subscripts) even if only Y is observed, but analysts do not know if it is Y_1 or Y_0. The original normality assumption used in selection models was based on powerful functional form assumptions. They develop a nonparametric Roy model and establish conditions under which variation in regressors over time or across people can identify the model nonparametrically. The distributional assumptions can be replaced with different types of variation in the data to identify the Roy version of the selection model. Heckman and Smith and Carneiro, Hansen and Heckman extend this line of analysis to the generalized Roy model where the decision is based on a more general I. It turns out that the decision rule with $I = Y_1 - Y_0$ plays a crucial role in securing identification of the selection model. In a more general case, when I may depend on $Y_1 - Y_0$ but on other unobservables as well, even with substantial variation in regressors across persons or over time, only partial identification of the full selection model is possible. When the models are not identified, it is still possible to bound crucial parameters, and an entire literature has grown up elaborating this idea.

Bounding and Sensitivity Analysis

Starting from Eq. (6) or its version for conditional means, the work of Smith and Welch, Holland, and Glynn, Laird, and Rubin characterized the selection problem more generally without the structure of Eqs. (3a)–(3d), offering Bayesian and classical methods for performing sensitivity analyses for the effects of different identifying assumptions on inferences about population mean.

Selection on observables solves the problem of selection by assuming that Y_1 is independent of D given X, so $F(Y_1 \mid \mathrm{X},\ D = 1) = F(Y_1 \mid X)$. This is the assumption that drives matching models. It is inconsistent with the Roy model of self-selection. Various approaches to bounding this distribution, or moments of the distribution, have been proposed in the literature, all building on insights by Holland and by Peterson. To illustrate these ideas in the simplest possible setting, let $g(Y_1 \mid X,\ D = 1)$ be the density of outcomes (e.g., wages) for persons who work ($D = 1$ corresponds to work). Assume censored samples. Missing is $g(Y \mid X,\ D = 0)$ (e.g., the density of the wages of nonworkers).

In order to estimate $E(Y_1 \mid X)$, Smith and Welch used the law of iterated expectations to obtain

$$E(Y_1 \mid X) = E(Y_1 \mid X, D = 1)\ \Pr(D = 1 \mid X) + E(Y_1 \mid X, D = 0)\ \Pr(D = 0 \mid X).$$

To estimate the left-hand side of this expression, it is necessary to obtain information on the missing component $E(Y_1 \mid X,\ D = 0)$. Smith and Welch proposed and implemented bounds on $E(Y_1 \mid X,\ D = 0)$; for example,

$$Y_{\mathrm{L}} \leq E(Y_1 \mid X, D = 0, Z) \leq Y^{\mathrm{U}},$$

where Y^{U} is an upper bound and Y_{L} is a lower bound. (In their problem, there are plausible ranges of wages

that dropouts can earn.) Using this information, the following bounds were constructed:

$$E(Y_1 \mid X, D = 1)\ \Pr(D = 1 \mid X) + Y_{\mathrm{L}}\ \Pr(D = 0 \mid X) \leq E(Y_1 \mid X) \leq E(Y_1 \mid X, D = 1)\ \Pr(D = 1 \mid X) + Y^{\mathrm{U}}\ \Pr(D = 0 \mid X).$$

A sensitivity analysis produces a range of values for $E(Y \mid X)$ that are explicitly dependent on the range of values assumed for $E(Y \mid X, D = 0)$. Later work has developed this type of analysis more systematically for a variety of models.

Glynn, Laird, and Rubin present a sensitivity analysis for distributions using Bayesian methods under a variety of different assumptions about $F(Y_1 \mid X, D = 0)$ to determine a range of values of $F(Y \mid X)$. Holland proposes a more classical sensitivity analysis that varies the ranges of parameters of models. The objective of these analyses of bounds and the Bayesian and classical sensitivity analyses is to clearly separate what is known from what is conjectured about the data, and to explore the sensitivity of reported estimates to the assumptions used to secure them. Others have demonstrated the extra restrictions that come from using the structure of Eqs. (3a)–(3d) to produce bounds on outcomes.

Much of the theoretical analysis presented in the recent literature is nonparametric, although in practice, much practical experience in statistics and econometrics demonstrates that high-dimensional nonparametric estimation is not feasible for most sample sizes available in cross-sectional econometrics. Some form of structure must be imposed to get any reliable nonparametric estimates. However, feasible parametric versions of these methods run the risk of imposing false parametric structure. The methods used in the bounding literature depend critically on the choice of conditioning variables X. In principle, all possible choices of the conditioning variables should be explored, especially in computing bounds for all possible models, although, in practice, this is never done. If it were, the range of estimates produced by the bounds would be substantially larger than the wide bounds already reported.
